XIX BACTERIAL INFECTIONS OF THE UPPER RESPIRATORY TRACT

Harvey B. Simon, m.d.

Overview of Upper Respiratory Tract Infections

Upper respiratory tract infections range from common, benign processes, such as nasopharyngitis, to uncommon, potentially lethal processes, such as epiglottitis. Pathogens range from pyogenic bacteria [*see 7:I Infections Due to Gram-Positive Cocci and 7:II Infections Due to Mycobacteria*] to *Chlamydia* [*see 7:XIII Diseases Due to Chlamydia*], mycoplasmas [*see 7:XII Infections Due to Mycoplasmas*], respiratory viruses [*see 7:XXV Respiratory Viral Infections*], and, on occasion, fungi [*see 7:XXXVII Mycotic Infections*]. Despite this heterogeneity, some general anatomic and physiologic principles apply.

pathophysiology

The upper respiratory tract is composed of two distinct types of epithelial surface. A stratified squamous epithelium lines the oropharynx and nasopharynx [*see Figure 1*]. These regions are normally teeming with a variety of microbial flora, and many potential pathogens can temporarily colonize these epithelial surfaces without causing true infection [*see Table 1*]. Bacteriologic cultures are easily obtained from these areas. As a result, the microbiology laboratory faces the challenge of isolating potential pathogens from the normal mouth flora, and the clinician faces the challenge of distinguishing between the carrier state and active infection. A respiratory epithelium, composed of ciliated columnar cells, goblet cells, and mucous and serous glands, lines the paranasal sinuses, the middle ear, and the airway below the epiglottis. These regions, in contrast to the oropharynx and nasopharynx, are normally sterile. Because these areas are inaccessible for routine culture, it is often necessary to diagnose and treat infections on the basis of clinical findings and statistical probabilities [*see Table 1*] rather than on the basis of bacteriologic data derived from an individual patient.

Many host defense mechanisms protect the upper airway from infection. Mechanical defenses tend to prevent penetration by organisms from the nasopharynx and oral cavity into more vulnerable areas. These defenses are the cough, gag, and sneeze reflexes; the viscous mucous secretions, which entrap particulate material; and ciliary action, which propels entrapped particles outward. In addition, local immunologic defenses attempt to deal with organisms that have breached the mechanical barriers; such defenses include abundant lymphoid tissue, secretory IgA antibodies in respiratory secretions, and a rich vasculature that can rapidly deliver phagocytic leukocytes.

etiology

Upper respiratory tract infections typically occur after insults to host defenses—such as allergic rhinitis, chemical irritation, trauma, and, especially, viral respiratory tract infections—that impair ciliary function and produce increased volumes of thin secretions and mucosal edema that block the narrow channels draining the sinuses and middle ear. Barotrauma, which results from a rapid change in atmospheric pressure, can intensify upper respiratory tract problems, particularly in patients with rhinitis, otitis, or sinusitis.

Many upper respiratory tract infections are caused by viruses, and many of the bacterial infections in this region will resolve without antibiotic therapy.[1] Unfortunately, antibiotics are overprescribed for upper respiratory tract infections; in the United States, antibiotics are prescribed for 50% to 75% of ambulatory patients seen for viral upper respiratory tract infections.[2]

complications

The complications of upper airway infections stem from several factors. The proximity of upper airway structures to the central nervous system and the presence of abundant vascular channels connecting the two account for some of the most severe complications. In addition, the numerous fascial planes of the head and neck provide potential spaces where infection can become sequestered. Furthermore, because the upper airway is narrow, infection in the neck may compromise the patency of the airway itself. Finally, immunosuppression renders persons vulnerable to unusual pathogens and unusual complications.

Sinusitis

Although infections of the paranasal sinuses are common, they are greatly overdiagnosed by patient and physician. Acute sinusitis is characterized by nasal congestion, purulent nasal discharge, fetid breath, facial pain that typically increases when the patient stoops forward, and, often, fever and other systemic symptoms. In most patients, acute sinusitis responds well to medical therapy; in a few persons, however, chronic sinusitis may result. Chronic sinusitis is characterized by purulent discharge, usually without fever, that persists for weeks or months.

etiology

Viral, allergic, or vasomotor rhinitis is frequently an antecedent to sinusitis. Nose blowing propels nasal fluid into the sinuses, potentially introducing viscid fluid and bacteria that can lead to sinusitis.[3] Nasal polyps, deviation of the nasal septum, or hypertrophied adenoids may predispose to purulent sinusitis by obstructing sinus drainage. Cigarette smoke and overuse of topical decongestants impair ciliary action and alter the mucous blanket, predisposing to sinusitis. Contributing factors may include rapid changes in altitude, trauma, intranasal foreign bodies or tumors, cocaine abuse, and such systemic processes as cystic fibrosis and Kartagener syndrome (situs inversus, bronchiectasis, and sinusitis). Factors that predispose to chronic sinusitis include inadequately treated bacterial infections, long-term impairment of mucociliary clearance, obstruction of sinus drainage, and allergies and asthma.

Nosocomial sinusitis occurs as a complication of nasotracheal intubation or, less often, the use of nasoenteric feeding tubes.[4] Unexplained fever may be the presenting symptom, and computed tomography scanning is often required for diagnosis if the patient cannot localize the pain.

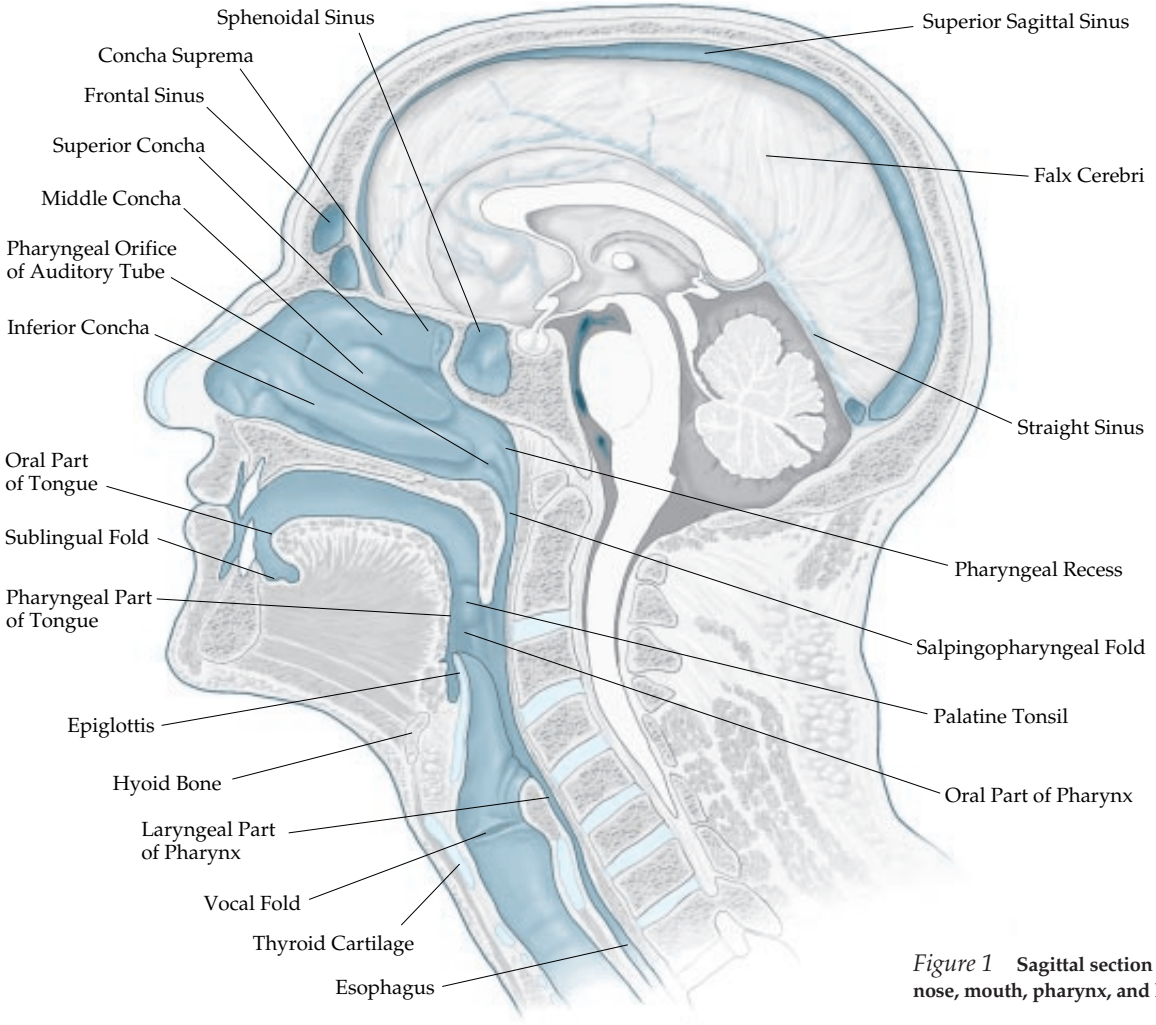

Figure 1 **Sagittal section through the nose, mouth, pharynx, and larynx.**

Immunosuppression increases the frequency and severity of sinusitis. Sinusitis is common in patients with AIDS and is often severe and refractory to treatment.

CLINICAL VARIANTS

The sinuses may be involved singly or, more often, in combination [*see Figure 2*]. Frontal sinusitis and maxillary sinusitis are most common in adults; ethmoiditis is most common in children.

Frontal sinusitis produces pain and tenderness over the lower forehead and purulent drainage from the middle meatus of the nasal turbinates. Maxillary sinusitis produces pain and tenderness over the cheeks. Pain is often referred to the teeth, and the hard palate may be edematous in severe cases. Purulent drainage is present in the middle meatus. Patients with ethmoidal sinusitis complain of retro-orbital pain and may have pain, tenderness, and even erythema over the upper lateral aspect of the nose. The anterior ethmoidal cells drain through the middle meatus, whereas the posterior cells drain through the superior meatus. Isolated sphenoid sinusitis, which occurs in only 3% of patients with sinusitis, is often misdiagnosed. This disorder has traditionally been considered to cause pain at the occiput or vertex; in fact, frontotemporal, retro-orbital, or facial pain is more common. Photophobia and tearing may be present. Purulent drainage is present in the superior meatus.

DIAGNOSIS

Clinical Features and Imaging Studies

Acute sinusitis The diagnosis of acute sinusitis can usually be established on clinical grounds. Useful criteria are a poor response to decongestants; maxillary, facial, or tooth pain; and a duration of more than 7 days.[5] Purulent nasal discharge is not specific for sinusitis and may occur in viral nasopharyngitis.[6] The diagnosis of sinusitis can be confirmed by the finding of opacity when the frontal or maxillary sinuses are transilluminated or by radiographic findings such as mucosal thickening, sinus opacification, or air-fluid levels.[7]

Chronic sinusitis The symptoms of chronic sinusitis are nasal congestion and discharge. Pain and headache are usually mild or absent, and fever is uncommon. Bone erosion may be present in chronic sinusitis. CT scans provide much more information than the traditional sinus x-ray series. Radiologic studies are essential in the diagnosis of severe, refractory, nosocomial, or complicated cases of sinusitis but are not necessary in routine cases.

Bacteriology

Because of technical difficulties in obtaining valid cultures, the bacteriology of sinusitis has been incompletely defined. Nasal

cultures are unreliable because they correlate poorly with actual sinus fluid. Sinus punctures reveal that the most common pathogens in acute sinusitis are *Haemophilus influenzae*, pneumococci, streptococci, and *Moraxella catarrhalis*.[5,7] *Staphylococcus aureus* has been isolated in nasal cultures from some patients with acute sinusitis, but the organisms are probably contaminants rather than the true causative agents. Nosocomial sinusitis is typically polymicrobial; *S. aureus* and gram-negative bacilli are often present.[8]

Table 1 Major Microbial Flora of the Upper Respiratory Tract

Organism	*Oral Cavity*	*Nasopharynx, Tonsils*	*Epiglottis, Larynx*	*Paranasal Sinuses, Middle Ear*

Respiratory syncytial virus		CP	CP	

*Anaerobic bacteria predominate in the normal flora of the upper respiratory tract. They are uncommon pathogens in acute infections but are common pathogens in chronic sinusitis and otitis, as well as in abscesses, soft tissue infections, and periodontal infections; aerobic pathogens participate synergistically in most of these processes.
CC—Common colonizer: organism present in many individuals, often transiently, without causing disease; CP—Common pathogen: organism frequently causes disease in this location; NF—Normal flora: organism present in most healthy individuals; UC—Uncommon colonizer: organism present without causing disease but relatively uncommon; UP—Uncommon pathogen: organism infrequently causes disease in this location.

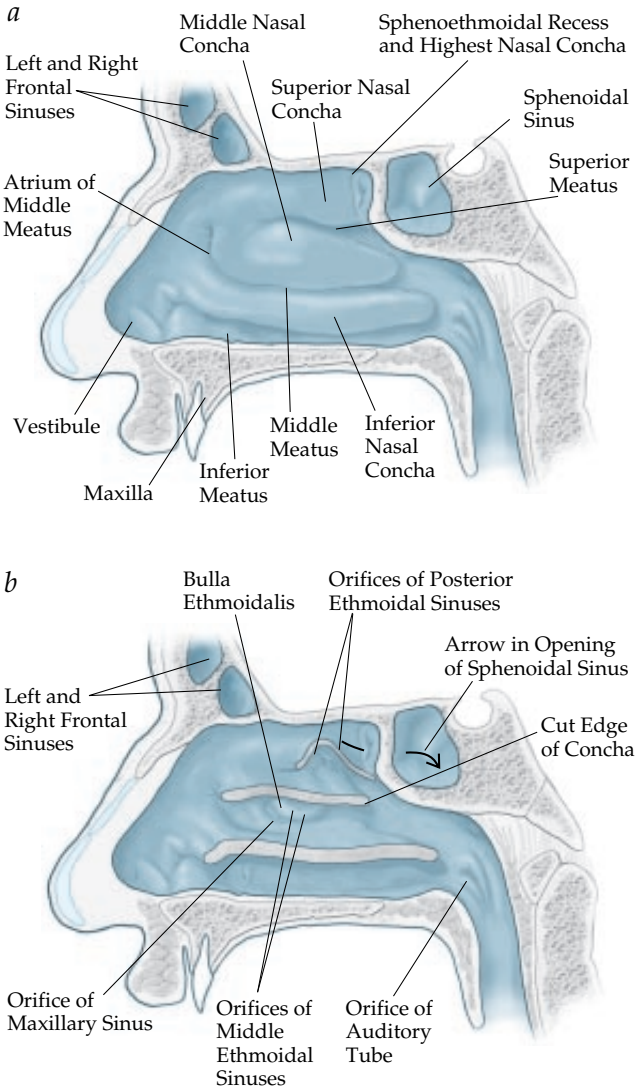

Figure 2 **(*a*) The lateral wall of the right half of the nasal cavity: internal aspect. (*b*) The three nasal conchae have been partially removed.**

Chronic sinusitis is usually a polymicrobial infection. Anaerobic organisms have been isolated in as many as 51% of patients with chronic sinusitis; anaerobic streptococci and *Prevotella* species predominate.[9] Anaerobes are also important in chronic sinusitis because they predominate in brain abscesses associated with sinus infections. *S. aureus* has been recovered from cultures in as many as 33% of patients with chronic sinusitis; enteric gram-negative bacilli may also be present.

Viruses seldom cause clinical sinusitis. Such fungi as *Aspergillus, Mucor,* and *Rhizopus* species produce invasive sinusitis in patients with leukemia or poorly controlled diabetes[10,11] and, occasionally, in normal hosts.[10] In immunocompromised patients, sinusitis may also be caused by *Candida, Alternaria, Pseudomonas, Nocardia, Legionella,* atypical mycobacteria, and certain parasites.[12]

DIFFERENTIAL DIAGNOSIS

Noninfectious processes must be considered in the differential diagnosis of sinusitis. Allergic or vasomotor rhinitis is by far the most common noninfectious cause of sinus symptoms. However, polyps, tumors, cysts, foreign bodies, and vasculitis (such as Wegener granulomatosis) occasionally produce symptoms of sinusitis.

TREATMENT

Medical therapy Acute sinusitis is treated with analgesics and topical heat for patient comfort. Decongestants are of paramount importance. Pseudoephedrine can be administered orally or by nasal spray. The danger of rebound after short-term use of nasal spray has probably been exaggerated. Patients should spray each nostril once and then wait a minute to allow the anterior nasal mucosa to shrink; a repeat spray will reach the upper and posterior mucosa, including the nasal turbinates and sinus ostia. This procedure can be repeated every 4 hours for several days when needed. Antihistamines are not indicated, because they thicken secretions and impair drainage.[5] Intranasal steroids are not necessary in most patients but may accelerate symptomatic improvements in some individuals[13]; however, they may be harmful. Nasal inhalation of warm, humidified vapor may relieve symptoms. Sleeping supine or with the head of the bed elevated 45° promotes sinus drainage; patients with unilateral sinusitis should be encouraged to sleep with the unaffected side on the pillow. Other ancillary measures that may be helpful are nasal saline irrigations and aerobic exercise, which promotes mucous flow. Mucoregulating agents are often recommended but have not been adequately studied.

Many patients with uncomplicated acute sinusitis respond well to decongestants and steam inhalations and do not need antibiotics.[5,14,15] Antibiotics should be used in moderately to seriously ill patients, in patients whose symptoms fail to respond to decongestants, and in patients who have complications. Older agents such as amoxicillin, doxycycline, and trimethoprim-sulfamethoxazole have produced good results.[5] Second-line agents that are often prescribed include amoxicillin–clavulanic acid, cefuroxime, clarithromycin, azithromycin, and levofloxacin; they are no more effective than the less expensive first-line drugs.[16,17] Because both *H. influenzae* and *M. catarrhalis* can produce β-lactamase, the use of antibiotics that resist these enzymes has attracted interest. However, antibiotics that are resistant to β-lactamase have not proved to be superior to those that are susceptible, possibly because comparative studies have been small and because many patients recover without antibiotic therapy. The optimal duration of antimicrobial therapy is no more certain than are the indications for therapy or the choice of agents[18]; 7- to 14-day courses of antibiotics are traditional, but one trial found 3 days of trimethoprim-sulfamethoxazole to be as effective as 10 days of therapy.[19] Clinical guidelines for the diagnosis and treatment of sinusitis are available.[20]

Surgical therapy Surgical intervention should be avoided in acute sinusitis unless the patient fails to respond to medical therapy and unless complications are present. Surgical drainage may be necessary in cases of chronic sinusitis or nosocomial sinusitis[8] and is mandatory in invasive fungal sinusitis.[10,11]

Functional endoscopic sinus surgery has provided an important advance in the surgical management of sinusitis. Patients with recurrent or chronic sinusitis who fail to respond to vigorous medical management may be candidates for this procedure. The patient should undergo a detailed preoperative evaluation, which usually includes a sinus CT scan. Surgery is performed using either local anesthesia with sedation or general anesthesia. A fiberoptic nasal endoscope is used to visualize the sinus ostia;

when obstruction is present, it can be relieved. This technique restores patency and allows normal ciliary action to transport mucus to the natural ostium. Complications are uncommon when the procedure is performed by a skilled surgeon. Nasal endoscopy can also be used as an alternative to sinus puncture when it is necessary to obtain specimens for culture.[21]

COMPLICATIONS

The potentially life-threatening complications of sinusitis have become uncommon in the antibiotic era. However, frontal sinusitis can lead to osteomyelitis of the frontal bones, especially in children. Patients have headache, fever, and a characteristic doughy edema, termed Pott puffy tumor, over the affected bone. The organisms involved are those responsible for the underlying sinusitis, although *S. aureus* is more common in osteomyelitis than in sinusitis. Treatment should include decongestants for the sinusitis, high-dose intravenous antibiotics for the osteomyelitis, and surgical debridement when bone destruction is substantial. It is important to rule out coexisting brain abscess of the frontal lobe, which may be clinically occult.

Because the orbit is bordered on three sides by the paranasal sinuses, orbital infection can result from sinusitis. This disorder is most frequently a complication of ethmoidal sinusitis; it is caused by direct extension of infection through the lamina papyracea. Orbital cellulitis usually begins with edema of the eyelids and rapidly progresses to ptosis, proptosis, chemosis, and diminished extraocular movements. Patients are usually febrile and acutely ill. Pressure on the optic nerve may lead to vision loss, which can be permanent; retrograde spread can lead to intracranial infection. Therapy with high-dose intravenous antibiotics is mandatory. Unless a specific pathogen can be isolated from the blood or from purulent drainage, antibiotics should cover both staphylococci and gram-negative rods. When an orbital abscess is present, surgical drainage may be necessary; CT and ultrasound studies aid this evaluation.

Retrograde spread along venous channels from the sinuses, the orbit, or the nose can produce septic cavernous sinus thrombophlebitis. Patients have high fever and appear toxic. Lid edema, proptosis, and chemosis are present. In cavernous sinus thrombophlebitis (but not in uncomplicated orbital cellulitis), third, fourth, and sixth cranial nerve palsies are prominent; the pupil may be fixed and dilated, and ophthalmoscopic examination may reveal venous engorgement and papilledema. Although at first the process is usually unilateral, spread across the anterior and posterior intercavernous sinuses makes it bilateral. Patients may exhibit alterations of consciousness, and lumbar puncture may reveal inflammatory changes in the cerebrospinal fluid. CT with a contrast agent or venography may help confirm the diagnosis. High-dose intravenous antibiotics, including antistaphylococcal drugs, are mandatory. Anticoagulants are not of established benefit and may even be harmful.

Sinusitis can lead to intracranial suppuration either by direct spread through bone or by spread through venous channels. Various syndromes, such as epidural abscess, subdural empyema, meningitis, and brain abscess, can result. Clinical findings, which vary greatly, range from the subtle personality changes associated with frontal lobe abscesses to headache, symptoms of elevated intracranial pressure, alterations of consciousness, visual symptoms, focal neurologic deficits, seizures, and, ultimately, coma and death. These are true medical emergencies requiring high-dose antibiotics and, except for meningitis, neurosurgical intervention [*see 7:XXXVI Bacterial Infections of the Central Nervous System*].

Otitis

ACUTE OTITIS MEDIA

Acute otitis media is one of the most common childhood infections; in the United States alone, the annual costs of the infection are estimated to be $3 billion to $5 billion.[22] However, the incidence of otitis media declines with age, and it is uncommon in adults. Purulent otitis media results when bacteria ascend from the nasopharynx to the normally sterile middle ear. Abnormal eustachian tube function or obstruction caused by viral or allergic nasopharyngitis is considered important in the pathogenesis[23]; heredity may also play a role.

Etiology

The most common causes of purulent otitis media are the pneumococcus, nontypable strains of *H. influenzae*, and *M. cartarrhalis*[24]; the previously important group A streptococci are now uncommon.[25] Other organisms that can cause acute otitis media are coagulase-negative staphylococci and anaerobic bacteria. Gram-negative bacilli and *S. aureus* can cause acute otitis media in neonates. Viruses and mycoplasmas are uncommon as the primary pathogens in acute otitis media, but in 41% of children with acute bacterial otitis, respiratory tract viruses are also present; respiratory syncytial virus is the most common causal organism, followed by parainfluenza and influenza viruses.[26] Purulent nosocomial otitis is uncommon and occurs in only 4% of patients who have undergone endotracheal intubation; gram-negative bacilli are the responsible agents in this setting.

Diagnosis

Pain and hearing loss are the classic presenting complaints of acute otitis media; fever is present in some cases**,** especially when pneumococci are responsible.[25] The cornerstone of the clinical diagnosis is a bulging tympanic membrane, with impaired mobility and obscuration of the bony landmarks. Tympanic membrane perforation and otorrhea may occur. Concurrent conjunctivitis suggests the presence of *H. influenzae*.[25]

Needle aspiration of the middle ear can be used to confirm the diagnosis of purulent otitis media and to identify the causative organism; however, it is seldom necessary, because the bacteriology of otitis media is well defined and the clinical course is easy to monitor. Routine nose or throat cultures are not diagnostically reliable.

Differential Diagnosis

The major disorder considered in the differential diagnosis of acute otitis media is serous otitis media. Fever and pain are absent in serous otitis media; although fluid is present in the middle ear, the tympanic membrane is usually retracted and the bony landmarks are preserved.

Treatment

Acute otitis media may be treated with analgesics, decongestants, and antibiotics. Except in the Netherlands, where only about 30% of patients with otitis media take antibiotics, nearly all affected patients in developed countries are treated with antibiotics. In the United States, 20% of all prescriptions for oral antibiotics are issued for the treatment of otitis media; the average child consumes 3 months' worth of antibiotics in the first 2 years of life.[27] As a result, *H. influenzae*, *M. catarrhalis*, and *Streptococcus pneumoniae*—the organisms most frequently

responsible for acute otitis media—are manifesting dramatically increased resistance to antibiotics.

The utility of antibiotics is being reappraised.[22,24,28,29] Their benefits appear to be modest; a meta-analysis concluded that to prevent one child from experiencing pain by 2 to 7 days after infection, 17 children must be treated with antibiotics.[30] Further studies are required to determine which patients are most likely to benefit from antibiotics,[31] which drugs are best, and how long therapy should be continued. A new approach that merits study is a delayed-therapy strategy, in which an antibiotic is prescribed when otitis media is diagnosed, but the parents of the child are encouraged to fill the prescription only if the child's condition has not improved after 72 hours.[32] Until more data are available, clinicians in the United States are likely to continue their traditional use of such drugs as ampicillin, amoxicillin, amoxicillin–clavulanic acid, trimethoprim-sulfamethoxazole, and the newer oral cephalosporins and macrolides. As in the case of sinusitis, drugs active against β-lactamase–producing bacteria have not proved to be superior to amoxicillin in the treatment of acute otitis media, perhaps because antibiotics are only slightly more effective than placebos[33]; 81% of patients with acute otitis media recover without any antibiotic therapy.[34] Although antibiotics are generally administered for 10 days, 5 days of treatment may be equally effective in uncomplicated cases.[35,36] A single intramuscular dose of ceftriaxone is also as efficacious as 10 days of oral therapy.[37] Myringotomy does not hasten recovery but is indicated for patients with intractable pain, progressive deafness, or early mastoiditis or for those who respond poorly to medical therapy.

Complications

The prognosis for acute otitis media is excellent. Chronic serous otitis media, hearing loss, and recurrent purulent otitis media are the most common complications. Recurrences are usually caused by reinfection rather than relapse or persistent infection; antibiotics may be used for chemoprophylaxis of recurrent otitis in children.[24] Tympanostomy tubes may be helpful in children with numerous recurrences.

Acute mastoiditis, which is now rare, develops in patients with inadequately treated otitis media. Presenting symptoms consist of fever, otalgia, and postauricular edema and tenderness. The tympanic membrane is abnormal in all cases; perforations and otorrhea are present in about half of cases. Mastoid x-rays are usually abnormal. The species of bacteria responsible for mastoiditis are the same as those that cause acute otitis media. Patients who fail to respond to antibiotic therapy within 48 hours and those with CNS complications should be considered for early mastoidectomy.

Other rare suppurative complications of acute otitis media include purulent labyrinthitis, meningitis, lateral sinus thrombosis, and brain abscess. Bacteremia can be documented in 3% of young febrile children with otitis media, but it does not appear to alter the prognosis or to warrant parenteral antibiotic therapy.

CHRONIC OTITIS MEDIA

Chronic otitis media, which can occur at any age, results from neglected or recurrent acute otitis media. Pain and fever are usually absent but can occur during sporadic flare-ups.[38] Diminished hearing and foul otorrhea are major symptoms.

Physical examination discloses perforation of the tympanic membrane. Central perforations of the pars tensa are associated with benign disease, but peripheral perforations may occur with invasive cholesteatomas. X-rays reveal sclerosis of the mastoid air cells and bone destruction. Various organisms can be cultured from middle-ear drainage, including *P. aeruginosa*, staphylococci, streptococci, and enteric gram-negative bacilli. Anaerobes are present in 16% of cases, almost always in mixed infections with aerobes. Systemic antibiotics are generally of little benefit, but antibiotic eardrops may be helpful; quinolones appear to be more effective and safer than aminoglycosides.[39] Surgery is required in advanced cases. Without therapy, chronic otitis media can cause the same intracranial suppurative complications seen in acute otitis media.

OTITIS EXTERNA

Otitis externa is a common, generally benign inflammatory disorder that is usually precipitated by excessive moisture in or trauma to the external auditory canal. Patients have pruritus or pain, or both, that may be severe. Crusting, inflammation, and discharge in the canal are typical findings. Pain resulting from movement of the external ear helps distinguish otitis externa from otitis media. A broad range of organisms, including gram-positive cocci, gram-negative bacilli, and fungi, can cause otitis externa. Excellent results are produced by topical therapy with eardrops containing polymyxin B, neomycin, and corticosteroids or eardrops containing acetic acid and corticosteroids.[40] Patients occasionally acquire true cellulitis of the external ear; such patients require systemic antibiotics and even debridement of infected cartilage.

Malignant otitis externa, an infection with *P. aeruginosa* that progressively invades the cartilage, soft tissue, and skull, is a rare condition that occurs in diabetic patients. Neurologic complications can be lethal. Prolonged, maximal parenteral therapy with combinations of antipseudomonal agents, such as tobramycin and piperacillin, is generally recommended. Monotherapy with intravenous ceftazidime and prolonged therapy with oral ciprofloxacin have been successful. Other antibiotics that may prove useful alone or in combination are aztreonam, cefepime, imipenem, and meropenem. Aggressive surgical debridement has been a mainstay of treatment but may be required less often in patients who are treated early and aggressively with antibiotics. CT scans are superior to magnetic resonance imaging for early diagnosis, but either technique can be used to monitor patients for bone destruction and neurologic complications; should these sequelae occur, debridement is required. Mortality is high but has decreased since 1990. *Aspergillus* is a rare cause of malignant otitis externa.

Pharyngitis

Although pharyngitis is one of the most common problems in clinical practice, a surprising number of practical questions remain unanswered.[41] Group A streptococci are the most therapeutically important cause of pharyngitis, although in terms of frequency, they cause as few as 5% of the cases of pharyngitis and as many as 38% of the cases of tonsillitis.

STREPTOCOCCAL PHARYNGITIS

Diagnosis

Four clinical criteria have been proposed as suggestive of group A streptococcal pharyngitis: tonsillar exudates, tender anterior adenopathy, absence of cough, and history of fever. Unfortunately, however, there is considerable overlap between streptococcal and viral pharyngitis.

Because streptococcal and viral pharyngitis cannot be distinguished reliably on clinical grounds,[42] laboratory studies are necessary to make a diagnosis of streptococcal pharyngitis. Throat cultures remain the standard method for identifying group A streptococci in the pharynx. In addition, rapid diagnostic tests suitable for office use are available. These procedures entail the extraction of streptococcal antigens from throat swabs and the rapid identification of the antigens through immunologic tests such as latex agglutination or enzyme-linked immunosorbent assay (ELISA). The sensitivity of these tests ranges from 77% to 95%; specificity ranges from 86% to 100%. Thus, these tests are acceptable for clinical practice, and the Infectious Disease Society of America no longer recommends throat cultures to confirm the results of rapid antigen tests.[43]

The diagnosis of streptococcal pharyngitis is suspected on clinical and epidemiologic grounds and confirmed by a rapid antigen test or throat culture. Although the laboratory recognition of group A streptococci is straightforward [*see 7:I Infections Due to Gram-Positive Cocci*], it is difficult to determine whether the organisms are responsible for a patient's symptoms. The carrier rate of group A streptococci in healthy persons approaches 20%, and even among patients with symptomatic pharyngitis, only 50% of those with positive throat cultures demonstrate a serologic response to streptococci. Except for a serologic determination, there is no proven method for distinguishing between the carrier state and active infection. Similarly, controversy exists about the need for obtaining cultures from asymptomatic family contacts of patients with streptococcal pharyngitis, for treating asymptomatic persons with small numbers of group A streptococci in their throat cultures, and for performing follow-up cultures after therapy. On balance, all of these procedures are probably unnecessary unless the patient is highly susceptible to rheumatic carditis because of previous acute rheumatic fever.[44,45]

Treatment

Fortunately, no uncertainty exists about the therapy for streptococcal pharyngitis in symptomatic patients. The disease is ordinarily self-limited, but early antibiotic therapy can alleviate symptoms,[46] as can simple analgesic antipyretics. Antibiotics prevent rheumatic fever and local suppurative complications and limit droplet spread. Because rheumatic fever is now rare in the United States and can be prevented even when therapy is delayed as long as 9 days after the onset of symptoms, treatment need not be started until rapid-antigen assay or throat culture results are available.[47] The goal of therapy is the eradication of group A streptococci from the nasopharynx. In more than 80% of patients, this result can be achieved with oral penicillin V, 250 mg four times a day for 10 days. Twice-a-day dosing is also effective in children and may improve compliance.[48] When patient compliance is in doubt, a single injection of 600,000 to 1.2 million units of benzathine penicillin G will be at least as effective. In patients who are allergic to penicillin, oral erythromycin is an excellent alternative, but it must be continued for 10 days. Tonsillectomy was once widely performed on children to prevent recurrent pharyngitis, but it has largely been abandoned.

Although only a minority of sore throats are caused by group A streptococci, 73% of adults who consult physicians for pharyngitis receive antibiotics; 68% of these prescriptions are for nonrecommended agents.[49] Five-day regimens of newer macrolides or cephalosporins are being studied in Europe, but these drugs are expensive, and the regimens are not currently recommended in the United States.[45]

OTHER FORMS OF BACTERIAL PHARYNGITIS

Other bacterial causes of pharyngitis are uncommon. Groups C and G streptococci can cause pharyngitis, but complications are rare. Gonococci transmitted by oral sex can produce sore throat, erythema, exudates, and lymphadenopathy; asymptomatic colonization of the pharynx may occur. Meningococci sometimes cause symptomatic pharyngitis but are more commonly found in throat cultures of asymptomatic persons. *H. influenzae* pharyngitis can be extremely painful but is rare in adults; epiglottitis is a life-threatening complication of this type of pharyngitis. In patients who have not been immunized, *Corynebacterium diphtheriae* can cause painful membranous pharyngitis, often characterized by dysphagia and prominent edema of the neck. *Arcanobacterium haemolyticum*, formerly known as *Corynebacterium haemolyticum*, can cause pharyngitis and scarlatiniform rash, particularly in teenagers and young adults; administration of penicillin or erythromycin produces rapid relief of symptoms. *Yersinia enterocolitica* is an uncommon cause of pharyngitis; the pharyngitis may be present without enteritis, particularly in adults.

Many other bacterial species can be cultured from the pharynges of both symptomatic and asymptomatic patients [*see Table 1*], but they almost never cause pharyngitis. In particular, although pneumococci and staphylococci commonly reside in the nasopharynx and can cause severe disease in other parts of the respiratory tract, they do not cause pharyngitis. *Mycoplasma pneumoniae* causes pharyngitis in children and adults, but this diagnosis is seldom made in the absence of pneumonitis. *Chlamydophila pneumoniae* (formerly *Chlamydia pneumoniae)* can also cause pharyngitis, which may be protracted.[50]

Treponema pallidum, a spirochete that is not part of the normal flora, can cause pharyngitis in patients with primary or secondary syphilis. Among the other causes of pharyngitis, *Mycobacterium tuberculosis* is very rare. *Candida albicans*, which is part of the normal mouth flora, can produce painful oropharyngeal moniliasis, or thrush, if antibiotics or debilitating illnesses (particularly HIV infection) upset microbial interactions and host defenses. This disease is characterized by a white, cheesy exudate that can be scraped off to demonstrate yeast forms by smear and culture. Nystatin oral suspension is therapeutically effective, but frequent, large doses may be required. Clotrimazole troches are also effective. Patients with HIV infection may require systemic therapy with fluconazole. Other forms of fungal pharyngitis are rare.

Deep Tissue Infections

Infections originating in the pharynx may extend by contiguous spread to the deep tissues of the pharynx and neck. In the neck, numerous fascial planes create a variety of potential spaces where infection can become loculated to form a phlegmon or a full-fledged abscess. Although these processes are now uncommon, prompt recognition is mandatory because antibiotics and surgical drainage are required to control infection and to prevent obstruction of the airway, invasion of vital neurologic and vascular structures, and spread of infection to the mediastinum and bloodstream.

PERITONSILLAR ABSCESS

Peritonsillar abscess, also called quinsy throat, is a complication of streptococcal tonsillitis most often seen in adolescents and young adults. Group A streptococci are the primary cause

of the condition, although most peritonsillar abscesses also harbor mixed oral bacteria, with a predominance of anaerobes. Patients have fever and sore throat, often with pain referred to the ear. Dysphagia prevents the patient from swallowing saliva, commonly causing drooling; edema and pain produce a characteristic muffled, so-called hot-potato voice. The affected tonsil is visibly displaced forward, downward, and toward the midline; the soft palate may be edematous. Trismus occurs in some patients. CT scans are helpful in diagnosis and management. Treatment consists of parenteral penicillin and surgery. The traditional approach consists of immediate incision and drainage, followed by tonsillectomy 4 to 6 weeks later; early tonsillectomy has also produced excellent results. Treatment with needle aspiration and oral antibiotics has also been successful; 80% to 92% of patients with peritonsillar abscess can be cured with this approach, thereby obviating hospitalization and surgery.

RETROPHARYNGEAL AND PARAPHARYNGEAL INFECTIONS

Retropharyngeal infections are most common in childhood because the lymph nodes in this region atrophy during adult life. Patients have fever and systemic toxicity, as well as neck pain, dysphagia, muffled voice, and respiratory stridor. Physical findings include erythema and bulging of the posterior wall of the pharynx. CT scans and lateral-view x-rays of the neck are extremely useful, invariably demonstrating soft tissue swelling and forward displacement of the larynx [*see Figure 3*]. Although the bacterial agent of retropharyngeal infections is not determined in many patients, streptococci and other mouth flora predominate. Penicillin is the traditional antibiotic of choice, but agents that provide a broader spectrum of antibacterial coverage may be justified until culture data are available. Surgical drainage is vital to prevent asphyxiation and extension of infection to the mediastinum. Infections of the retropharyngeal space must be distinguished from infections of the prevertebral space.

The prevertebral space lies posterior to the retropharyngeal space and is separated from it by the prevertebral fascia. Infection of the prevertebral space often originates from osteomyelitis of the cervical vertebrae. This infection is frequently caused by staphylococci and may lead to spinal cord damage unless treated through an approach that combines immobilization, antistaphylococcal antibiotics, and external drainage.

The parapharyngeal space is demarcated by the parotid gland and the internal pterygoid muscle laterally and by the superior constrictor muscle medially. The internal jugular vein, carotid artery, and cranial nerves IX, X, and XII pass through the parapharyngeal space. Infection can reach the parapharyngeal space from the pharynx or from parotid or dental foci. Patients have severe trismus, externally visible inflammation behind the angle of the jaw, and inflammation in the lateral wall of the pharynx, with medial displacement of the tonsil. Treatment consists of intravenous penicillin and drainage; CT-guided needle aspiration may be effective in some patients, but surgical drainage from behind the angle of the jaw is required in others.

Infections of the parapharyngeal space occasionally spread to the jugular vein and cause the syndrome of postanginal sepsis (Lemierre syndrome), which is characterized by the presence of septic phlebitis, septic pulmonary emboli, and anaerobic bacteremia. Pharyngitis and dental infections may also lead to postanginal sepsis. Facial swelling is an early diagnostic clue to this syndrome. CT is important for detecting abscesses, and ultrasonography is helpful for identifying jugular vein throm-

c

Figure 3 **(*a*) An oblique-view x-ray of the skull of a 16-year-old boy with fever, headache, and doughy edema of the forehead shows soft tissue swelling and a small area of underlying cortical irregularity indicative of osteomyelitis. (*b*) Sinus film reveals severe pansinusitis. (*c*) Because of subtle personality changes, a CT scan was taken; it revealed a large frontal lobe abscess. At surgery, 45 ml of pus was evacuated. Anaerobic streptococci were isolated from the subperiosteal collection and the brain abscess. Prolonged penicillin therapy and surgical management led to recovery.**

bosis. Anaerobic gram-negative bacilli, such as *Fusobacterium* species, are typically responsible for the condition. Management requires intravenous administration of penicillin; metronidazole and clindamycin are useful alternatives. Heparin, venous ligation, and surgical thrombectomy have also been advocated, but data do not allow firm guidelines to be established for these interventions.

LUDWIG ANGINA

Ludwig angina is a cellulitis of the submandibular, sublingual, and submental regions. In 86% of patients, the infection originates from a dental focus. Clinical features include fever, marked toxicity, and a rapidly progressive brawny edema in the floor of the mouth and the anterior neck. Elevation of the tongue impedes swallowing, and airway obstruction may be lethal. Streptococci and mouth flora are the most common etiologic agents, but *H. influenzae*, staphylococci, and gram-negative bacilli have also been implicated; broad antibiotic coverage may be necessary initially. Because endotracheal intubation can provoke laryngeal spasm, tracheostomy may be necessary to preserve the airway. Surgical decompression may be required.

Acute Epiglottitis (Supraglottitis)

No infection of the upper respiratory tract is more rapidly progressive or more lethal than acute epiglottitis, also known as supraglottitis. Acute epiglottitis occurs most commonly in children between 2 and 8 years of age and is more frequent in boys. The incidence of epiglottitis in childhood is declining rapidly in populations that have received *H. influenzae* type b vaccinations. Cases in adults appear to be increasing, however, perhaps because of improved diagnosis.

ETIOLOGY

The major cause of acute epiglottitis in children and adults is *H. influenzae* type b. Other pathogens, including pneumococci, streptococci, staphylococci, and *Klebsiella pneumoniae*, can produce an identical syndrome. Although viral epiglottitis is rare, this syndrome can occur secondary to infection with herpes simplex virus type 1.[51] In the immunocompromised host, additional organisms may be responsible, including *Candida* and *Kingella kingae*; fortunately, such cases are rare.

DIAGNOSIS

Epiglottitis begins with startling rapidity; severe sore throat and fever progress rapidly to dysphagia, with retention of secretions and drooling. Systemic toxicity is marked; if the illness is not treated, dyspnea and progressive respiratory obstruction occur in a matter of hours.

Although uncommon, acute epiglottitis in adults often extends to the supraglottic structures, and edema may be more prominent than acute inflammation. Whereas children with acute epiglottitis usually present with respiratory distress, adults may first complain of pharyngeal symptoms (severe pain and odynophagia) before developing respiratory symptoms.[52] The course of the disease in adults is slower than it is in children, often extending over several days because of the larger diameter of the adult airway.

Acute epiglottitis is a medical emergency. The key to the diagnosis is a swollen, edematous, cherry-red epiglottis. Simple inspection of the pharynx is usually unrewarding. Furthermore, any instrumentation, even a tongue blade, can provoke spasm and total airway obstruction, although adults are at lower risk for this complication. Therefore, unless acute respiratory distress is present, a lateral-view x-ray of the neck should be taken immediately. If the film does not demonstrate epiglottal edema, indirect laryngoscopy can be undertaken; if edema is present, however, the diagnosis is confirmed, and instrumentation is unnecessary. In all cases, patients must be monitored continuously for signs of respiratory obstruction.

DIFFERENTIAL DIAGNOSIS

In the differential diagnosis in children, it is important to distinguish between epiglottitis and croup caused by viral laryngitis with laryngeal and subglottal edema and airway obstruction. Croup usually affects younger patients and progresses more slowly than epiglottitis, and patients with croup present with hoarseness and a characteristic cough. In addition, in croup, the epiglottis is normal or only minimally inflamed on physical or radiographic examination. Cold, humidified oxygen is the mainstay of treatment of croup, and close observation is vital because emergency intubation or tracheostomy may be necessary. In children, bacterial tracheitis or membranous croup may present as severe laryngotracheitis, requiring antibiotic therapy and respiratory support. In patients of all ages, angioneurotic edema of the larynx, foreign bodies lodged in the upper airway, or impingement on the airway by various mass lesions may initially be confused with epiglottitis, but these conditions should be readily recognizable on physical examination and radiography.

TREATMENT

Although tracheostomy is the traditional means of securing a patent airway in patients with epiglottitis, nasotracheal intubation is safe and effective. As a result, direct laryngoscopy by an experienced observer who is prepared to proceed with intubation (or, if necessary, tracheostomy) can be relied on for diagnosis when taking x-rays would produce excessive delay.

Because there is no margin for error, initial therapy with high-dose intravenous antibiotics effective against *H. influenzae* (including penicillinase-producing strains), other gram-negative bacilli, and staphylococci is warranted. Many regimens are available, including cefuroxime or cefamandole, ampicillin-sulbactam, meropenem, imipenem-cilastatin, and a third-generation cephalosporin combined with a penicillinase-resistant penicillin. The choice of drugs depends on the results of throat and blood cultures and on ampicillin-sensitivity testing of *H. influenzae* isolates. A mist tent may be helpful. Steroids are sometimes advocated to reduce the edema, but their effectiveness has not been tested in controlled clinical trials. Above all, preservation of the airway is critical; nasotracheal intubation or tracheostomy is required in about half of all cases. If the airway can be protected while antibiotics take effect, most patients can be saved.

Miscellaneous Upper Respiratory Tract Infections

Many other infectious processes can invade the upper respiratory tract and adjacent regions of the head and neck. Common viral infections of the oropharynx are primary herpes simplex gingivostomatitis and adenovirus and coxsackievirus infections. Spirochetes play a role in ulcerative gingivitis and periodontitis. *Actinomyces israelii* can produce chronic burrowing infections of the gums and jaw, occasionally with secondary involvement of the respiratory tract. Although rare in the United States, rhinoscleroma, believed to be caused by *Klebsiella rhinoscleromatis*, can

occur in immigrants from developing countries or in HIV-infected persons. *S. aureus* may produce acute bacterial sialadenitis or suppurative parotitis; less commonly, gram-negative bacilli or even anaerobes produce parotitis in hospitalized patients.

Many bacterial species have been implicated in a variety of dental infections. Mixed infections with normal mouth flora can occur in debilitated patients. Fusobacteria and spirochetes can cause gingivitis (trench mouth) or necrotic tonsillar ulcers (Vincent angina); patients have foul breath, pain, and dirty-gray membranous inflammation that bleeds easily. Oral irrigations and penicillin are effective therapy. A similar combination of spirochetes and other bacteria can produce a rare but extremely serious invasive gangrene of the mouth, cancrum oris, which occurs only in malnourished infants or in patients with advanced malignant disease or immunosuppression. Anaerobes may play a role in chronic or recurrent tonsillitis.[38] Dental infection is the leading cause of necrotizing cervical fasciitis.

Many noninfectious processes in these regions can produce symptoms that mimic bacterial infection. Aphthous stomatitis may be the most common example. Drug reactions and primary dermatologic diseases cause oral and pharyngeal ulcerations. Vasculitis, carcinomas, lymphomas, and sarcoidosis of the upper airway can also mimic bacterial infection. Even subacute thyroiditis, which may produce fever and referred pain, may be mistaken for pharyngitis or otitis.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XX PNEUMONIA AND OTHER PULMONARY INFECTIONS

HARVEY B. SIMON, M.D., F.A.C.P.

Pulmonary infections span a wide spectrum, ranging from self-limited to life-threatening and from acute to chronic. This chapter details the pathophysiology, epidemiology, general features, and treatment of pulmonary infections, particularly bacterial pneumonia [*see Table 1*].

Pneumonia

Although overall hospitalization rates are declining, hospitalizations for acute lower respiratory tract infections have increased steadily since 1980.[1] Taken together, pneumonia and influenza rank as the sixth leading cause of death in the United States and lead all other infectious diseases in this respect. Antibiotics have greatly modified the natural history of pneumonia and have sharply reduced the overall case-fatality rate. At the same time, the widespread use of antimicrobial agents has led to the emergence of drug-resistant strains, thereby altering and expanding the range of pathogens responsible for pneumonia, especially in hospitalized patients. The growing population of patients with chronic obstructive pulmonary disease (COPD) and other debilitating illnesses and the use of respiratory therapy and immunosuppressive drugs have contributed to the increasing incidence of nosocomial and opportunistic pneumonias, which have a very high mortality.

PATHOPHYSIOLOGY

Host Defense Mechanisms

The lung is normally sterile. In healthy people, an intricate series of defense mechanisms maintain that sterility in the face of heavy bacterial colonization of the upper respiratory tract, inhalation of thousands of bacteria in droplet nuclei each day, and nearly universal aspiration of upper airway secretions during normal sleep each night.[2,3] Defects in host defense mechanisms account for most cases of pneumonia [*see Table 2*].

Transmission of Organisms to Lungs

Inhalation of aerosolized droplets accounts for the transmission of respiratory viruses, such as influenza virus, which cause highly contagious infections that often occur in epidemics.[4] Other nonviral agents produce pneumonia through similar means of spread. Such agents include mycoplasmas, which are transmitted from person to person and cause primary atypical pneumonia; *Coxiella burnetii*, which is transmitted from livestock and causes Q fever; and *Chlamydophila* (formerly *Chlamydia*), which is transmitted from birds (*C. psittaci*) or humans (*C. pneumoniae*). *Mycobacterium tuberculosis* is spread from person to person by aerosolized droplets. The organisms that are responsible for causing the systemic mycoses are probably inhaled from sources in nature. Of bacteria that cause pneumonia, *Legionella pneumophila* is the species most likely to be spread by inhalation of aerosolized organisms that originate in contaminated fresh water.

Pneumococci are spread from person to person by aerosolized droplets, but pneumococcal pneumonia is not highly contagious and is caused in many cases by aspiration of nasopharyngeal organisms, the second major mechanism of infection.[4] Aspiration of nasopharyngeal organisms occurs in nearly all persons during sleep and is probably responsible for most bacterial pneumonias, including staphylococcal and gram-negative bacillary pneumonias; it certainly accounts for the necrotizing pneumonitis that results from the aspiration of mixed mouth flora.

Hematogenous seeding, the third and least common mechanism for pneumonia, accounts for occasional cases of staphylococcal pneumonia that complicate tricuspid valve endocarditis or septic thrombophlebitis. This mechanism is also responsible for various gram-negative bacillary pneumonias in patients with bacteremia.

Tissue Responses

Once organisms succeed in bypassing host defense mechanisms to arrive at the alveoli, a variety of tissue responses may ensue, depending on the nature of the pathogen and on the integrity of the host inflammatory response. Although the inflammatory response is essential for the control of infection, it can produce tissue damage, impair ciliary action, and impede phagocytosis.[3]

The inflammatory response to *Streptococcus pneumoniae* or *Haemophilus influenzae* often produces lobar consolidation, but these infections rarely result in tissue necrosis. In contrast, staphylococci and many gram-negative bacilli often produce necrosis, which can lead to cavitation and even frank abscess formation; a peribronchial distribution is characteristic, but lobar consolidation may occur. Viruses generally produce interstitial inflammation rather than air-space exudates. The infection is usually bilateral and causes diffuse alveolar damage and interstitial edema. Similar tissue responses may be initiated by *My-*

Table 1 Major Causes of Pulmonary Infection

Gram-positive cocci: *Streptococcus pneumoniae*, *S. pyogenes*, other streptococci, staphylococci
Gram-positive bacilli: *Bacillus anthracis*
Gram-negative cocci: *Neisseria meningitidis*, *Moraxella catarrhalis*
Gram-negative coccobacilli: *Haemophilus influenzae*
Gram-negative bacilli: *Klebsiella pneumoniae, Pseudomonas* species, *Escherichia coli, Proteus, Serratia* species, *Acinetobacter, Yersinia pestis, Francisella tularensis*, *Enterobacter* species, *Prevotella*, *Legionella* species
Mixed flora (aspiration pneumonia)
Mycobacteria: *Mycobacterium tuberculosis, M. avium* complex
Fungi: *Histoplasma, Coccidioides, Blastomyces*, *Cryptococcus, Candida, Aspergillus,* Mucoraceae
Parasites: *Pneumocystis carinii*, *Toxoplasma gondii*
Mycoplasmas: *Mycoplasma pneumoniae*
Chlamydophila (chlamydiae): *C. pneumoniae, C. psittaci, C. trachomatis*
Rickettsia-like organisms: *Coxiella burnetii*
Viruses: influenza virus, parainfluenza virus, adenovirus, respiratory syncytial virus, rhinovirus, measles virus, varicella-zoster virus, cytomegalovirus

Table 2 Host Defense Mechanisms against Pulmonary Infection

Mechanism	*Modifying Factors*
Normal flora of upper respiratory tract	Antibiotic therapy, respiratory therapy, hospitalization
Aerodynamic properties of upper respiratory tract	Tracheal intubation
Protective reflexes (e.g., cough, sneeze, gag, bronchoconstrictor)	Sedatives and hypnotics, alcohol and drug abuse, neurologic disorders, age and debility, tracheal intubation (gastrointestinal disorders)
Mucous carpet that entraps particles	Viral infections, smoking, chemical irritants, dehydration
Ciliary action, mucociliary transport	Smoking, viral infections, advanced age, aspirin (?)
Antibacterial substances in respiratory secretions (e.g., lysozyme, lactoferrin, α_1-antitrypsin, IgA)	None
Fibronectin in respiratory secretions (competitively inhibits adherence of gram-negative bacilli)	Decreased fibronectin levels in seriously ill patients
Free drainage of tracheobronchial tree	Foreign bodies, obstructing tumors, bronchostenosis
Rich blood supply	Vascular obstruction (e.g., emboli)
Alveolar macrophages	Viral infections, smoking (both increase macrophage numbers but impair function)
Lymphatic tissue	Cytotoxic therapy
Humoral immunity (B cells, IgG and IgA antibodies, complement, polymorphonuclear neutrophils)	Immunosuppressive disorders and therapy
Cellular immunity (T cells, lymphokines, mononuclear phagocytes)	Immunosuppressive disorders and therapy

coplasma, *Chlamydophila*, and *Legionella* species; by gram-negative bacteremia (shock lung); and by other causes of the acute respiratory distress syndrome. Mycobacteria and fungi typically evoke a slow granulomatous response.

EPIDEMIOLOGY AND ETIOLOGY

Community-Acquired Pneumonia

Like other respiratory tract illnesses, pneumonia is most common in the winter because of the seasonal increase in viral infections and the close contact of persons confined indoors. Community-acquired pneumonias are a major problem in the United States, with an estimated four million cases occurring annually.[5] About one million cases require hospitalization,[5] and at least 60,000 result in death.[6] The mortality of community-acquired pneumonia ranges from less than 1% in patients who are not ill enough to require hospitalization to 13.7% for hospitalized patients, 19.6% for bacteremic patients, and 36.5% for patients admitted to intensive care units.[7] Clinical and laboratory data can be used to determine which patients are at greatest risk for death and thus require hospitalization and aggressive therapy. Comorbidity is the strongest risk factor, with neoplastic disease, neurologic disease, and alcoholism being particularly worrisome.[8] Advanced age is another strong predictor of risk,[6] in part because older patients often underreport symptoms.[7-10] Physical findings of high fever, tachypnea, confusion, hypoxia, and hypotension also portend an adverse result.[11] The presence of extensive radiographic abnormalities, especially bilateral pleural effusions, is associated with higher risk, as are laboratory abnormalities such as hypoxia, azotemia, acidosis, hyponatremia, and hypophosphatemia. Postobstructive, aspiration, gram-negative, and staphylococcal pneumonias produce a high mortality. Patients lacking these adverse prognostic indicators have a low risk of death and can usually be treated successfully as outpatients. Patients hospitalized for pneumonia have a greater than fivefold likelihood of requiring subsequent hospitalization for pneumonia than patients with other serious illnesses. They also have substantially higher long-term mortality than age-matched control subjects.[12,13]

In the preantibiotic era, pneumonia was nearly synonymous with *S. pneumoniae* infection. Pneumococci still account for 30% to 60% of all community-acquired pneumonias for which an etiology can be determined.[14] Pneumococci are particularly likely to be responsible for community-acquired pneumonias severe enough to require hospitalization and for pneumonia in persons older than 60 years.[15]

The second most common bacterial cause of community-acquired pneumonia is *H. influenzae,* which accounts for about 10% of cases[14]; patients with COPD are particularly vulnerable. Although infection with *Moraxella catarrhalis* is much less common than infection with *H. influenzae,* it is being recognized increasingly as a cause of community-acquired pneumonia. Like *H. influenzae, M. catarrhalis* has a predilection for patients with cardiopulmonary disease. In rare cases, *M. catarrhalis* causes fulminant pneumonia, bacteremia, or both.

Staphylococci and gram-negative bacilli are much less common but more serious causes of community-acquired respiratory infections. Significant predisposing conditions are required for these organisms to produce pneumonia. In the community setting, staphylococcal pneumonia usually follows influenza. Gram-negative pneumonias in the community setting are most common in patients who have recently been hospitalized and treated with antibiotics, in smokers and others with chronic lung disease, and in immunosuppressed patients.[2,16] Exposure to aerosols of contaminated water is an additional risk factor for infection with *Pseudomonas aeruginosa,*[17] and alcoholism predisposes to *Klebsiella* pneumonia. Meningococcal pneumonia is rare.[18] A variety of other bacteria, including *L. pneumophila,* can cause pneumonia in the community setting.[15] Aspiration of mixed mouth flora is responsible for infection in some patients.

In about half the patients with community-acquired pneumonia, the etiologic agent cannot be identified.[19] Especially in younger patients, many of these infections result from so-called atypical agents, which lack the cell wall structure that characterizes ordinary bacteria. In a study of patients with a mean age of 41 years, for example, *M. pneumoniae* accounted for 22.8% of community-acquired pneumonias, and *C. pneumoniae* for 10.7%; in addition, influenza A accounted for 2.7% .[19] *C. pneumoniae* is also increasingly being recognized as a cause of community-acquired pneumonia in adults with COPD [*see 14:III Chronic Ob-*

structive Diseases of the Lung]. Respiratory tract viruses, including respiratory syncytial virus, adenoviruses, and influenza or parainfluenza viruses,[20] can also cause community-acquired pneumonias in persons of all ages.[1,15]

Hospital-Acquired Pneumonia

Pneumonia is the second most common nosocomial infection in the United States[21]; about 200,000 cases occur annually, accounting for 17.8% of all hospital-acquired infections and 40,000 to 70,000 deaths. Risk factors for nosocomial infections include aspiration, COPD or other chronic severe illnesses, thoracic and upper abdominal surgery, and treatment in an ICU. Patients who require mechanical ventilation are particularly at risk; pneumonia develops in 9% to 24% of patients who require intubation for more than 48 hours.[22] Ventilated patients who acquire nosocomial pneumonia have a much higher mortality (54%) than comparably ill ventilated patients who do not acquire pneumonia (27%).

The bacterial etiologies of hospital-acquired pneumonias are very different from those of community-acquired pneumonias. Many nosocomial pneumonias are polymicrobial; gram-negative bacilli are isolated in 47% of patients, anaerobes in 35%, and *Staphylococcus aureus* in 26%. In contrast, pneumococci account for no more than 10% of hospital-acquired pneumonias. Other organisms that are associated with community-acquired infections can occasionally cause pneumonia in the hospital setting; such organisms include *Legionella* species, *M. pneumoniae,* and *C. pneumoniae*.[23]

Pseudomonas, Klebsiella, and *Escherichia coli* are the most commonly implicated causes of gram-negative pneumonias. Nosocomial gram-negative pneumonias often occur in patients with serious underlying diseases; as a result, mortality is as high as 30% to 50%. Previous antibiotic administration, respiratory therapy, chronic illness, and confinement to bed predispose to oropharyngeal colonization with gram-negative bacilli, which occurs in up to 45% of ICU patients and precedes pneumonia in most cases. Upper intestinal colonization has also been implicated, but its importance is uncertain. Although most nursing home residents are elderly and chronically ill, only 14% of them become colonized with gram-negative bacilli; oropharyngeal colonization in this population is transient and does not appear to predispose to gram-negative pneumonia. Hence, pneumonia in these patients can be approached as a community-acquired infection rather than a hospital-acquired infection.[24,25]

Pneumonia in Immunosuppressed Patients

Immunosuppressed patients, particularly those with AIDS,[26,27] are vulnerable to a broad range of pulmonary pathogens. In addition to being susceptible to the many organisms that produce community- and hospital-acquired pneumonias, these patients are susceptible to many opportunistic microbes that are unlikely to cause pneumonia in immunologically competent hosts.[28] Such organisms include bacteria (e.g., *Pseudomonas, Nocardia,* and *Legionella* species), mycobacteria (e.g., *M. avium* complex), viruses (e.g., cytomegalovirus and herpesvirus), fungi (e.g., *Candida, Aspergillus*, and *Mucor* species), and protozoa (e.g., *Pneumocystis carinii* and *Toxoplasma gondii*). As a result, immunosuppressed patients require an aggressive approach to diagnosis and therapy [*see 7:X Infections Due to Haemophilus, Moraxella, Legionella, Bordetella, and Pseudomonas, 7:XI Infections Due to Brucella, Francisella, Yersinia pestis, and Bartonella, and 7:XXXVIII Mycotic Infections in the Compromised Host*].

DIAGNOSIS

Clinical Features

Classic signs and symptoms of pneumonia include cough, sputum production, chest pain, fever, chills, hypoxia, and dyspnea. Although the results of physical examination in patients with typical pneumonias are often nonspecific, the examination may reveal rales, rhonchi, or bronchial breath sounds, as well as percussion dullness over the involved segments of the lung. Pleural effusions may accompany pneumonia. The chest x-ray shows infiltrates.

Nonbacterial and bacterial pneumonias have differing clinical presentations. Although both types of pneumonia can affect persons of all ages, nonbacterial pneumonias are most common in older children and young adults. Patients with viral, mycoplasmal, or chlamydial pneumonias will often complain of a severe hacking cough, but substantial sputum production is unusual. Sputum production is also minimal in Legionnaires disease, but these patients are usually sicker than those with nonbacterial pneumonias [*see 7:X Infections Due to Haemophilus, Moraxella, Legionella, Bordetella, and Pseudomonas*].

Patients with bacterial pneumonias are more likely to have copious sputum production—as well as an abrupt onset of illness, high temperatures, chills, and development of significant pleural effusions—than are patients with nonbacterial pneumonias.

On physical examination, a patient with bacterial pneumonia generally looks sicker than a patient with nonbacterial pneumonia, and chest examination of patients with bacterial pneumonia usually reveals signs of consolidation or at least localized rales and rhonchi. In contrast, the chest examination of patients with nonbacterial pneumonias typically shows only fine rales, and often, the physical findings are less extensive than the radiologic abnormalities.

Laboratory Studies

Patients with bacterial pneumonias are more likely to have polymorphonuclear leukocytosis. If the chest x-ray reveals lobar or segmental consolidation, abscess formation, or significant pleural effusion, bacterial pneumonia is more likely. A patchy infiltrate can occur in either process, but a true interstitial infiltrate suggests a nonbacterial etiology. Computed tomography is extremely helpful in patients with complex infections.

The sputum examination is central to the etiologic diagnosis of pneumonia.[29] The sputum of patients with bacterial pneumonia is typically thick and either green or brownish and is sometimes blood tinged. A good sputum specimen for microscopic examination and culture is crucial.[30] If the patient cannot expectorate spontaneously, pulmonary physiotherapy, intermittent positive pressure ventilation with humidified air, or nasotracheal suction may be used to obtain the specimen. The Gram stain of sputum from patients with bacterial pneumonia usually reveals abundant polymorphonuclear leukocytes and will often disclose the primary pathogens. Patients with nonbacterial pneumonias or Legionnaires disease generally produce only scant quantities of thin sputum. In influenzal pneumonia, the sputum may be bloody. The Gram stain of sputum from patients with pneumonia from atypical agents reveals an absence of bacteria and a scant cellular response; in patients with mycoplasmal pneumonia, mononuclear cells may predominate.[31] It can be difficult to determine the etiology in patients with nosocomial pneumonias; prolonged hospitalization, antibiotic ad-

ministration, and ventilatory therapy predispose to colonization with organisms that contaminate sputum specimens but can also cause pneumonia. Bronchoalveolar lavage is effective in identifying the responsible pathogen.[32]

Kits for the detection of nucleic acids from *Legionella, Mycoplasma,* and mycobacterial species in sputum are currently available, and similar tests may soon be available for the detection of other pathogens.[33] Urinary antigen assays may assist in the diagnosis of *Legionella*[34] and pneumococcal[35] pneumonias. Blood cultures are of limited value in the management of patients with community-acquired pneumonias.[36]

Invasive Studies

In immunocompromised patients, numerous opportunistic agents can cause pneumonia, and aggressive techniques may be required to obtain a satisfactory specimen. Although invasive procedures rarely are necessary in immunocompetent patients, they may be required in patients who present with unusual features, are critically ill, or fail to respond to conventional therapy. Procedures such as transtracheal aspiration, bronchoscopy (sometimes including transbronchial biopsies), bronchial brushing, or percutaneous lung taps[37] may be necessary; bronchoalveolar lavage is a particularly useful technique and is generally well tolerated. If these less invasive techniques fail to produce a diagnosis, open lung biopsy should be considered.

Diagnosis of Ventilator-Associated Pneumonia

The diagnosis of ventilator-associated pneumonias may be based on clinical criteria, Gram stains and cultures of tracheal aspirates, and pulmonary infection scores or invasive techniques.[38,39] Even with bronchoscopy and lavage, the diagnosis can be difficult; the detection of a marker called soluble triggering receptor expressed on myeloid cells (sTREM-1) in lavage fluid may be an indication of ventilator-associated pneumonia.[40]

DIFFERENTIAL DIAGNOSIS

Noninfectious diseases can be mistaken for infections of the respiratory tract. Asthmatic bronchitis and hypersensitivity pneumonitis are common examples. COPD, including emphysema and bronchiectasis, may be misleading if previous x-rays are not available. Atelectasis, pulmonary infarction, pulmonary edema, and lung tumors may also be confused with pneumonia. Hypersensitivity reactions and toxins—in the form of aerosols, systemic drugs, or chemicals—produce clinical illnesses and pulmonary infiltrates simulating those of infectious pneumonia. Radiation pneumonitis, sarcoidosis, vasculitis, uremic pneumonitis, pulmonary hemorrhage, eosinophilic pneumonia, organizing pneumonia, and lipoid pneumonitis are included in the differential diagnosis [*see 14:V Chronic Diffuse Infiltrative Lung Disease*].

One of the primary considerations in patients with a lower respiratory tract infection is to distinguish between acute bronchitis and pneumonia. The distinction is anatomic rather than etiologic because the same basic range of organisms can cause the two syndromes. As a result, these conditions often overlap clinically, but bronchitis requires less intensive therapy [*see* Acute Bronchitis, *below*].

TREATMENT

Certain general principles are useful in the care of all patients with pneumonia. Adequate hydration is important to help clear secretions; hydration can be achieved by systemic administration of fluids and local airway humidification. Expectorants such as guaifenesin may be helpful in loosening the sputum. Although clinical trials have demonstrated that chest physiotherapy does not hasten the resolution of pneumonia, this traditional therapeutic modality may provide symptomatic benefit to patients with copious airway secretions. In general, the cough reflex should not be suppressed in patients with bacterial infections, because coughing is an important mechanism for clearing secretions. If severe paroxysms of coughing produce respiratory fatigue or harsh pain, however, temporary relief may be obtained with small doses of codeine. Chest pain should be treated with analgesics that do not suppress cough. If hypoxia is present, oxygen should be administered. Persons who have COPD and retain carbon dioxide must be monitored very closely because oxygen therapy can lead to respiratory depression.

Specific antimicrobial therapy depends on the etiologic agent. Whereas culture and sensitivity testing require at least 24 to 48 hours to provide definitive information, the clinical setting,

Table 3 Initial Antibiotic Therapy for Community-Acquired Pneumonia in Outpatients*

Drug	*Typical Dose*†	*Cost/Mo ($)*‡	*Comments*
Fluoroquinolones			Excellent first-line drugs
Levofloxacin	500 mg p.o., q. 24 hr for 10 days, or 750 mg p.o., q. 24 hr for 5 days	279	
Gatifloxacin	400 mg p.o., q. 24 hr	252	
Moxifloxacin	400 mg p.o., q. 24 hr	265	
Gemifloxacin	320 mg p.o., q. 24 hr	NA	
Macrolides			
Erythromycin	250–500 mg p.o., q. 6 hr	34	Cost-effective alternative, but GI intolerance is common
Clarithromycin	250–500 mg p.o., q. 12 hr	235	Better GI tolerability and activity against *Haemophilus* and *Moraxella*; good first-line drug
Azithromycin	500 mg p.o. day 1, then 250 mg p.o. days 2–5	NA	Better GI tolerance and activity against *Haemophilus* and *Moraxella*
Doxycycline	100 mg p.o., q. 12 hr	92	Cost-effective alternative

*See text for details.
†For details, see *7:XIV Chemotherapy of Infection* (especially Tables 3 and 4).

GI—gastrointestinal

Table 4 Initial Antibiotic Therapy for Community-Acquired Pneumonia in Patients Who Require Hospitalization*

Regimen	*Typical Dose*†	*Cost/Mo ($)*‡	*Comments*
Cephalosporins Cefotaxime or ceftriaxone + a macrolide† or a fluoroquinolone†	Cefotaxime, 1–2 g I.V. q. 4 hr; ceftriaxone, 1–2 g I.V. q. 12–24 hr	—	First-line treatment of choice for severely ill patients
Fluoroquinolones			
Levofloxacin	500 mg p.o. or I.V. q. 24 hr	279	First-line treatment, either alone or with a third-generation cephalosporin
Moxifloxacin	400 mg p.o. or I.V. q. 24 hr	265	
Gatifloxacin	400 mg p.o. or I.V. q. 24 hr	252	
Vancomycin + a macrolide§ or a fluoroquinolone†	Vancomycin, 1 g I.V. q. 12 hr	—	Alternative for severely ill patients who are allergic to β-lactams
Linezolid + a macrolide‡ or a fluoroquinolone†	Linezolid, 600 mg p.o. or I.V. q. 12 hr	3,308	For severely ill patients who cannot tolerate β-lactams or vancomycin

*See text for details.
†For details, see *7:XIV Chemotherapy of Infection* (especially Tables 3 and 4).
§For macrolide doses, see Table 3; azithromycin may be administered intravenously.
‡Costs are derived from online pharmaceutical sources and are intended to indicate relative costs of available therapies.

chest x-ray, and sputum Gram stain usually enable the physician to make a reasonable presumptive diagnosis and to initiate therapy at once. Treatment can then be modified as necessary on the basis of culture results. Because antibiotics penetrate sputum by passive diffusion, it is important to maintain adequate blood levels of these drugs. The administration of antibiotics by aerosol is not indicated for most cases of pneumonia but may help patients with cystic fibrosis and endobronchial *Pseudomonas* infections.[41]

It is best to choose an antibiotic regimen directed specifically at organisms seen on Gram stain and, after 24 to 48 hours, identified from sputum or blood cultures. Even if these data are lacking, however, a reasonable choice of initial antimicrobial therapy can be made on the basis of the epidemiologic setting and clinical features.

Community-Acquired Pneumonia

Several factors are responsible for rapid changes in the empirical treatment of community-acquired pneumonias: the emergence of drug-resistant pneumococci; the increasing population of elderly or chronically ill patients who are vulnerable to infections caused by *H. influenzae* and *M. catarrhalis;* the increased importance of atypical pathogens such as *M. pneumoniae, C. pneumoniae,* and *L. pneumophila;* and the availability of new fluoroquinolones with enhanced activity against gram-positive cocci (including penicillin-nonsensitive pneumococci) and anaerobes (including mouth flora). For patients who do not require hospitalization, several options are available [*see Table 3*].[42] Erythromycin is cost-effective, but the so-called advanced macrolides clarithromycin and azithromycin may be preferable because of their better gastrointestinal tolerability and their activity against *Haemophilus* and *Moraxella* species.[43-45] Doxycycline is an effective and inexpensive alternative.[46] However, because of the increasing prevalence of drug-resistant pneumococci, use of one of the so-called respiratory fluoroquinolones (i.e., levofloxacin, gatifloxacin, moxifloxacin, or gemifloxacin) is recommended.[47] These agents have excellent activity against the major causes of community-acquired pneumonia, and prospective trials have been very favorable.[47,48] They are a particularly good choice for patients who have recently received antibiotic therapy.[49] The use of high-dose levofloxacin (750 mg a day) may enable short-course (5-day) therapy, potentially improving compliance and reducing costs.[50] The respiratory fluoroquinolones may also emerge as drugs of choice for patients with community-acquired pneumonia who require hospitalization; levofloxacin, moxifloxacin, and gatifloxacin are available in preparations for intravenous administration [*see Table 4*]. Levofloxacin-resistant pneumococci are still uncommon, but their emergence is a concern.[51,52] In addition, dual therapy may be preferable for patients with severe pneumococcal pneumonia.[53,54] For that reason, patients with moderate to severe community-acquired pneumonia may benefit from cefotaxime or ceftriaxone in combination with a macrolide or a fluoroquinolone.[42] Because vancomycin is active against virtually all pneumococci, it can be substituted for the third-generation cephalosporin in patients allergic to β-lactams; linezolid is another alternative.[55] When aspiration is suspected, penicillin, clindamycin, or metronidazole is useful; amoxicillin-clavulanate, imipenem, meropenem, and respiratory fluoroquinolones are also active against oral anaerobes [*see Table 5*].

In all cases, antibiotic therapy should be tailored to the results of culture and sensitivity, the clinical response, and the occurrence of side effects. Many patients who require intravenous antibiotics initially can be switched to oral therapy within 3 days,[56] facilitating early hospital discharge.[57] In most patients with uncomplicated pneumococcal pneumonia, antibiotics can be discontinued after 3 afebrile days; most patients with other bacterial pneumonias are treated for 7 to 14 days, and most with atypical pneumonias are treated for 10 to 21 days.

Immunizations may help prevent community-acquired pneumonia. Each fall, influenza vaccine should be offered to patients 50 years of age and older and to other vulnerable persons [*see 7:XXV Respiratory Viral Infections*]. Pneumococcal polysaccharide vaccine should be offered to persons 65 years of age and older and to others who are at increased risk[58] [*see 7:I Infections Due to Gram-Positive Cocci*]. Patients who have recovered from one bout of pneumonia may benefit from both vaccines.

Table 5 Antibiotic Choices for Aspiration Pneumonia*

Drug	*Typical Dose*†	*Cost/mo ($)*‡	*Comments*
Penicillin	500 mg p.o., q. 6 hr, to 1–2 million units I.V. q. 4 hr, depending on severity of infection	22	Traditional drug of choice
Clindamycin	150–300 mg p.o., q. 6 hr, to 600 mg I.V. q. 8 hr, depending on severity of infection	318	May be superior to penicillin
Metronidazole	500 mg p.o., q. 8 hr, to 500 mg I.V. q. 6 hr, depending on severity of infection	28	Excellent alternative
Ampicillin-sulbactam	1–2 g ampicillin + 0.5–1 g sulbactam I.V. q. 6 hr		Alternative useful in hospitalized patients
Imipenem	0.5–1 g I.V. q. 6–8 hr		Alternative useful in hospitalized patients
Meropenem	1 g I.V. q. 8 hr		Alternative useful in hospitalized patients
Fluoroquinolones			
Gatifloxacin	400 mg p.o. or I.V. q. 24 hr	252	Excellent for community-acquired pneumonias but less active against oral anaerobes than penicillin, clindamycin, and metronidazole
Moxifloxacin	400 mg p.o. or I.V. q. 24 hr	265	
Levofloxacin	500 mg p.o. or I.V. q. 24 hr	279	

*See text for details.

Hospital-Acquired Pneumonia

Because gram-negative bacilli and *S. aureus* cause many nosocomial pneumonias, patients with hospital-acquired pneumonias require broad antimicrobial coverage until the results of Gram stains, cultures, and sensitivity tests permit focused therapy. Options for the initial treatment of hospital-acquired pneumonia include ticarcillin–clavulanate or piperacillin-tazobactam; meropenem or imipenem-cilastatin; a third-generation cephalosporin plus nafcillin or vancomycin; a first-generation cephalosporin plus an aminoglycoside; or vancomycin plus an aminoglycoside. The prevalence of resistant bacteria in a particular hospital or patient care unit should help guide the initial therapy; for example, if methicillin-resistant staphylococci are common, vancomycin is a desirable component of the initial therapy, and when multidrug-resistant *Klebsiella* organisms are common, meropenem or imipenem-cilastatin should be considered. Linezolid is an effective alternative to vancomycin for the treatment of nosocomial pneumonia caused by methicillin-resistant gram-positive cocci. Patients with ventilator-associated nosocomial pneumonia may respond as well to 8 days of antibiotics as to 15 days of therapy.[59] Because of the high mortality associated with pneumonias in the ICU, strategies to prevent them have been studied,[60] and comprehensive guidelines are available.[61]

Infections Caused by *Legionella* Species

LEGIONNAIRES DISEASE

Epidemiology and Etiology

Since it was first identified in 1976, Legionnaires disease has become recognized as a common cause of both community-acquired and hospital-acquired pneumonias. Worldwide, it accounts for between 2% and 15% of all community-acquired pneumonias severe enough to require hospitalization.[62] It is estimated that 10,000 to 25,000 cases occur in the United States each year, but only 1,200 to 1,500 are reported annually.[63] Legionnaires disease is caused by *L. pneumophila*, a fastidious, filamentous, flagellated, aerobic gram-negative bacillus. The organism can be grown on charcoal–yeast extract agar; optimal growth occurs at 35° C in 5% carbon dioxide, but growth is slow, and a period of 3 to 6 days is required for colonies to form.

At least nine serogroups of *L. pneumophila* exist; most clinical isolates belong to serogroup 1. By special staining techniques, large numbers of the organism can be identified in tissue sections of alveoli, both within macrophages and extracellularly. Virulence factors of *L. pneumophila* and various extracellular enzymes that the organism secretes have been identified. *L. pneumophila* is able to survive intracellularly in host leukocytes. Antibody is not protective, but cell-mediated immunity does promote recovery and prevent reinfection.

In nature, *L. pneumophila* survives principally in water and, to a lesser extent, in soil. Human disease is acquired primarily by inhalation of aerosols contaminated with organisms; person-to-person transmission has not been documented. Contaminated water systems have been responsible for both community-acquired and hospital-acquired outbreaks [*see 7:X Infections Due to Haemophilus, Moraxella, Legionella, Bordetella, and Pseudomonas*].

The attack rate for Legionnaires disease appears to be higher in elderly persons and persons with underlying conditions such as COPD, neoplastic disease, organ transplants, and renal failure. Although *L. pneumophila* is a relatively uncommon pathogen in persons infected with HIV, it can cause severe disease in them.

Diagnosis

Clinical features Legionnaires disease is characterized by a 1-day prodrome of myalgias, malaise, and slight headache after an incubation period of 2 to 10 days. Acute onset of high fever, shaking chills, nonproductive cough, tachypnea, and, often, pleuritic pain ensues. The cough may subsequently become slightly productive, but the sputum is not purulent. Obtundation or toxic encephalopathy is common, but frank meningitis is not a feature. Abdominal pain, vomiting, and, especially, diarrhea may be present. Signs of consolidation on lung examination are present infrequently, but rales are commonly heard. Chest radiographs show patchy or interstitial infiltrates, which often progress to areas of nodular consolidation in a single lobe or multiple lobes; minimal effusions are present in up to one

third of cases. Abscess formation is uncommon but has been observed. Pulmonary fibrosis may occur in some survivors.

Although pneumonia is present in nearly all patients with Legionnaires disease, extrathoracic symptoms can be the presenting or predominant features. Central nervous system, GI, and renal manifestations are especially common. *L. pneumophila* has been isolated from blood cultures, and the organism can be found in many organs both in immunosuppressed patients and in previously normal patients who are afflicted with severe disease. Extrapulmonary manifestations include ocular and pericardial involvement, perirectal abscess, wound infection, peritonitis, cellulitis, rhabdomyolysis and acute renal failure, neutropenia, hemolytic anemia, and thrombotic thrombocytopenic purpura. Implanted devices such as heart valves and hemodialysis fistulas can become colonized.

A nonpneumonic form of legionellosis called Pontiac fever has a short incubation period and a low mortality. It has been responsible for at least four outbreaks of illness, including several related to whirlpools and hot tubs.

Laboratory studies The peripheral white blood cell count is mildly elevated to between 8,000 and 16,000/mm^3. Cold agglutinins are negative. Other laboratory findings may include an elevated erythrocyte sedimentation rate, hypoxia, abnormal liver function test results, and elevated creatine phosphokinase levels.[64] Proteinuria and microscopic hematuria have been observed, and acute renal failure may complicate the course on occasion.

Gram stains of the sputum or tracheal secretions will not reveal *L. pneumophila,* but the organism can be isolated from sputum and other specimens by using charcoal–yeast extract agar. The diagnosis can be established rapidly in about 20% of cases by demonstrating the organism with direct immunofluorescent staining of sputum specimens; bronchoalveolar lavage may be helpful in immunosuppressed patients. A kit that uses radiolabeled complementary DNA is commercially available, but clinical experience is still limited. A very promising polymerase chain reaction assay has been developed.[65]

Another method of rapid diagnosis involves detection of *L. pneumophila* antigen in the urine; this radioimmunoassay test is highly specific and has a sensitivity of about 80% to 90%.[65] However, the test is available only for *L. pneumophila* serogroup 1, which is the most common cause of Legionnaires disease. Most often, however, the diagnosis is established by an indirect fluorescent antibody technique involving staining of the causative bacterium. With this technique, a fourfold or greater rise in titer during the illness or a stable titer of 1:256 or greater is considered diagnostic.

The clinical picture and radiologic findings in Legionnaires disease are not specific. The diagnosis should be considered in patients with segmental, lobar, or interstitial pneumonia in which the etiologic agent is not evident on Gram stains of sputum or tracheal secretions. A mild case may resemble *Mycoplasma* pneumonia or other types of atypical pneumonia.

Treatment

On in vitro susceptibility testing, *L. pneumophila* has been shown to be susceptible to a variety of antimicrobial agents, including erythromycin, clarithromycin, azithromycin, tetracycline, rifampin, and the fluoroquinolones. Current evidence indicates that azithromycin[66] or levofloxacin is the treatment of choice.[67] Occasionally, patients may experience a relapse if antibiotics are discontinued prematurely; recovery occurs during a second, more prolonged course of treatment. A combination of rifampin and either azithromycin or levofloxacin may be considered in patients who fail to respond to monotherapy and in immunologically impaired patients with overwhelming disease. Improvements in diagnosis and therapy have produced a dramatic decline in the case-fatality rate of *L. pneumophila* infection, from 34% in 1980 to 12% in 1998.[68]

INFECTIONS CAUSED BY OTHER *LEGIONELLA* SPECIES

Since 1943, unusual, fastidious *Rickettsia*-like organisms have been identified as causes of isolated cases of pneumonia. Long considered medical curiosities, these organisms were named after their discoverers or the patients from whom they were isolated. Such obscure nomenclature (e.g., TATLOCK, OLDA, HEBA, and WIGA) reflected the absence of knowledge concerning these agents. Subsequent studies of these organisms led to their reclassification as *Legionella* species. Of the more than 30 *Legionella* species that have been identified, at least 19 have been recognized as causes of pneumonia, particularly in immunosuppressed hosts.

The clinical picture is not distinctive. Fever is the most common feature, cough is variable in severity, and sputum production is absent or scant. Pleurisy or dyspnea may develop, and chest x-rays show a patchy or nodular, progressive bronchopneumonia. *L. micdadei* is the most important of these organisms. Previously known as TATLOCK and HEBA, this organism was rediscovered as the Pittsburgh pneumonia agent that caused acute suppurative pneumonia in 13 immunosuppressed patients from two centers. *L. micdadei* can also cause pneumonia in immunologically intact hosts and extrathoracic infections in immunologically impaired hosts. It has been isolated from hospital water supplies and can cause nosocomial infections in immunosuppressed patients.[69]

In the first 13 patients with Pittsburgh pneumonia, the diagnosis was established through a lung biopsy or autopsy that revealed acute alveolar inflammation and short, weakly acid-fast, gram-negative bacilli. More recent cases have been diagnosed by culturing the agent on charcoal–yeast extract agar or by serologic means. Erythromycin has been used with success. Unlike *L. pneumophila, L. micdadei* is susceptible to penicillins and cephalosporins in vitro; however, there are no data on the use of these drugs in clinical *L. micdadei* infection.

Many other *Legionella* species have been identified as causes of pneumonia. These organisms grow on charcoal–yeast extract agar. Some cases in which *Legionella* species have been implicated share common features: patients have been exposed to infected water and have COPD or are immunosuppressed.[70] Therapy with erythromycin, alone or with rifampin, has been suggested.

CHLAMYDOPHILA (CHLAMYDIA) PNEUMONIAE

C. pneumoniae, initially known as the Taiwan acute respiratory disease (TWAR) agent, is an important pathogen, accounting for up to 10% of all pneumonias in the United States.[71] Serologic surveys suggest that a majority of adults have been infected at some point, indicating that most cases are mild or subclinical.

Unlike psittacosis, which is a true zoonosis that spreads only from animals to humans,[72] *C. pneumoniae* spreads from person to person via respiratory droplets. The incubation period of *C. pneumoniae* is long. Unlike *C. trachomatis,* which causes neonatal pneumonia, *C. pneumoniae* infects mainly older children and young adults; however, older patients (especially those with

COPD) can also be affected. Clinically, *C. pneumoniae* pneumonia in young patients resembles *M. pneumoniae* pneumonia[73]; after a prodrome of pharyngitis that lasts no more than 2 weeks, nonproductive cough and fever occur. Pulmonary infiltrates are mild. The infection is usually self-limited. In older patients with underlying COPD, *C. pneumoniae* can cause bronchitis that may be mild or very persistent. Bronchospasm may be prominent.[74] This organism can sometimes cause severe pneumonia in patients with COPD, and fatalities have been reported in debilitated patients. A macrolide, a tetracycline, or a fluoroquinolone is recommended for therapy.

Recurrent Pneumonia

Patients with recurrent pneumonia present a diagnostic and therapeutic challenge. Anatomic abnormalities should be carefully sought in all such patients and should be suspected particularly when the infections recur in one bronchopulmonary segment. Examples of anatomic abnormalities include cysts, blebs, abscess cavities, bronchiectasis, and bronchial obstruction by tumors, foreign bodies, or bronchiostenosis. If shifting locations are involved, systemic abnormalities may be present. Examples include defects of leukocyte function, immunoglobulin deficiencies, α_1-antitrypsin globulin deficiency, and cystic fibrosis. Recurrent aspiration may be responsible, in which case a carefully performed neurologic examination and a barium swallow may reveal the proper diagnosis. It is important to remember that noninfectious processes may produce recurrent pulmonary infiltrates that may be accompanied by cough and fever [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. Examples of such processes include organizing pneumonia, eosinophilic pneumonia, hypersensitivity pneumonitis, vasculitis, pulmonary hemosiderosis, and pulmonary emboli.

Chronic Pneumonia

Often, bacterial pneumonias exhibit delayed resolution, in which radiographic abnormalities persist for weeks or even months after clinical recovery. Infrequently, pyogenic infection pursues a slow but progressively destructive course despite antibiotic therapy; *K. pneumoniae* and other gram-negative bacilli have been implicated in some patients with such chronic bacterial pneumonias. Mycobacteria and *Actinomyces* are common causes of chronic pulmonary infection; fungi are particularly common in patients treated with corticosteroids. Persistent infiltration caused by neoplasia, sarcoidosis, pulmonary hemorrhage, vasculitis, fibrosing alveolitis, alveolar proteinosis, lipoid pneumonia, toxins, and other processes may mimic chronic pulmonary infection. Fiberoptic bronchoscopy is very useful for diagnosis, but lung biopsy may be needed.

Aspiration Pneumonia

EPIDEMIOLOGY AND ETIOLOGY

Although aspiration is probably the mechanism responsible for most bacterial pneumonias, the term aspiration pneumonia is best reserved for infection caused by mixed mouth flora. Seventy percent of patients with depressed consciousness have demonstrable pharyngeal aspiration, often involving much larger volumes of material than that aspirated by healthy persons. Because of the larger volumes of aspirated material, underlying diseases impairing host defenses, and alterations in oropharyngeal flora, patients with altered consciousness are most prone to aspiration pneumonia. In clinical practice, aspiration pneumonia most often results from alcoholism, drug abuse, administration of sedatives or anesthesia, head trauma, and seizures or other neurologic disorders. In addition, aspiration of GI contents is more frequent in patients with abnormalities of deglutition or esophageal motility resulting from placement of nasogastric tubes, esophageal carcinoma, bowel obstruction, or repeated vomiting from any cause. Poor oral hygiene and periodontal disease predispose to aspiration pneumonia because of the increased bacterial flora in these patients.

The clinical results of pulmonary aspiration depend in large part on the nature and volume of material aspirated. Aspiration of gastric contents is a common problem that may produce Mendelson syndrome, a fulminating illness, if a large volume of acidic gastric juice is aspirated.[75] Aspiration of particulate material can produce acute airway obstruction and death by asphyxiation; aspiration of smaller particles may produce atelectasis of a pulmonary segment or even of an entire lung, resulting in dyspnea, wheezing, and cyanosis. Characteristic pulmonary injuries and distinctive clinical syndromes are produced by aspiration of smoke, freshwater or saltwater, and fats or oils (lipoid pneumonitis).

DIAGNOSIS

Clinical Features

Patients with mixed aspiration pneumonia may present with an acute febrile illness, or the illness may follow a more indolent course, extending over many days or even weeks. Fever, cough, and sputum production are the dominant symptoms; the sputum may be copious, foul smelling, or both. Physical examination typically discloses rales and signs of pulmonary consolidation. An evaluation of dental hygiene and of the gag reflex is helpful; disordered pharyngeal sensation is a better predictor of vulnerability than is an absent gag reflex.

Laboratory Studies

Radiographically, infiltrates are most common in dependent areas of the lung, especially the apical segments of the lower lobes and the posterior segments of the upper lobes. Tissue necrosis can occur. Without treatment, aspiration pneumonia may produce multiple small cavities, which reflect a necrotizing pneumonitis. Lung abscesses or empyemas may ensue.

The sputum of patients with classic aspiration pneumonia contains abundant polymorphonuclear leukocytes and mixed mouth flora. If specimens are obtained by transtracheal aspiration or other procedures that avoid contamination of sputum by organisms from the oral cavity, aerobic and anaerobic bacteriologic techniques can reveal the specific causative bacteria. Because anaerobes are the dominant flora of the upper respiratory tract (outnumbering aerobic or facultative bacteria by 10 to 1), it is not surprising that anaerobes are the dominant organisms in aspiration pneumonia. Of particular importance are *Prevotella melaninogenica* and other *Prevotella* (formerly, oral strains of *Bacteroides*) species (slender, pleomorphic, pale gram-negative rods), *Fusobacterium nucleatum* (slender gram-negative rods with pointed ends), and anaerobic or microaerophilic streptococci and *Peptostreptococcus* (small gram-positive cocci in chains or clumps). As expected, multiple organisms are recovered from most patients.

TREATMENT

With the exception of *B. fragilis*, which can be identified along with other anaerobic species in 17% of patients with classic aspiration pneumonia, all the anaerobes found are penicillin sensitive. Penicillin is effective when *B. fragilis* is present in combination with penicillin-sensitive organisms, suggesting that aspiration pneumonias are synergistic infections that can be treated successfully by elimination of most but not necessarily all of the organisms involved. Penicillin dosages of 2.4 to 6.0 million units daily are generally effective. Parenteral therapy is advisable initially, but a 10- to 14-day course of treatment can be concluded with orally administered antibiotics if the patient responds well. Clindamycin represents an excellent alternative agent and may even be superior to penicillin for treatment of necrotizing aspiration pneumonias and lung abscesses.

Hospitalization or antibiotic therapy alters the usual oropharyngeal bacterial flora, so that staphylococci, facultative gram-negative bacilli, or both may be identified in patients. As a result, aspiration pneumonia in hospitalized patients often involves pathogens that are uncommon in community-acquired pneumonias. Gram stains and cultures of sputum are especially important for identifying gram-negative bacilli and staphylococci in the hospital setting. Broad antimicrobial coverage is required until specific pathogens have been identified by culture and sensitivity testing. Although tube feedings are often recommended to prevent aspiration pneumonia, there is no evidence that they are effective.[75]

Other Pulmonary Infections

ACUTE BRONCHITIS

Cough is the chief complaint responsible for an estimated 30 million physician office visits in the United States annually. For about 12 million of these patients, the clinical diagnosis is acute bronchitis.[76]

Acute bronchitis is commonly defined as an acute respiratory tract infection in which cough, with or without sputum production, is a prominent feature. In most cases, an etiologic diagnosis is not established. When sputum is absent or scant, the illness is often attributed to a respiratory tract virus; when purulent sputum is present, the bacteria that cause community-acquired pneumonias are considered likely causes.

Most otherwise healthy persons recover from acute bronchitis in 1 to 3 weeks, but the cough can linger for more than a month in up to 20% of patients.[77] Although 70% to 90% of patients are treated with antibiotics, published trials demonstrate little clinical benefit, even if purulent sputum is present.[77-79] Guidelines of the Infectious Disease Society of America, the American College of Physicians–American Society of Internal Medicine, and the American Academy of Family Physicians state, "Routine antibiotic treatment of uncomplicated acute bronchitis is not recommended, regardless of duration of cough."[80] Suspected cases of pertussis constitute an exception.[81] Clinicians who are confronted with demands for antibiotics may find a delayed prescription strategy useful.[82,83] This strategy involves providing patients with a prescription, but instructing them to fill it only if their symptoms fail to improve within the next few days. Patients with high fever, chills, respiratory distress, underlying pulmonary or immunosuppressive disorders, or physical signs of pulmonary parenchymal infection should be evaluated for pneumonia and treated according to the guidelines for community-acquired pneumonia (see above).

CHRONIC BRONCHITIS

Patients with chronic bronchitis characteristically produce sputum on most days for at least 3 months each year for more than 2 years. The sputum is frequently colonized by *H. influenzae* (nontypable), *S. pneumoniae*, or *M. catarrhalis*, singly or in combination. Although it is not certain whether the bacteria themselves produce additional airway damage, heavy bacterial loads correlate with increased inflammation.[84] Patients who acquire a new strain of bacteria are at increased risk for symptomatic exacerbations of their chronic bronchitis.[85] The role of long-term prophylactic antibiotic therapy in chronic bronchitis is controversial. Long-term antibiotic therapy may provide symptomatic relief in certain patients who experience multiple exacerbations of bronchitis during the winter, but it is not useful in improving or preserving pulmonary function. However, short-term antibiotic therapy is effective in treating acute exacerbations of chronic bronchitis.[86]

BRONCHIECTASIS

True saccular, or cystic, bronchiectasis involves both dilatation of the bronchi and destruction of the bronchial walls. Bronchiectasis results most often from neglected or recurrent infection, especially in childhood; therefore, bronchiectasis has become much less common since the introduction of antibiotics. Aggressive medical therapy has greatly improved the prognosis.

Symptoms include cough that may be dry or productive of copious foul sputum, recurrent lower respiratory tract infection, and hemoptysis. In rare instances, bronchiectasis can present as pleuritic chest pain. In advanced cases, fibrosis can lead to cor pulmonale and respiratory failure. The chest x-ray may show increased lung markings, honeycombing, atelectasis, or pleural changes, but high-resolution or helical chest CT is required for definitive diagnosis[87] [*see 14:III Chronic Obstructive Diseases of the Lung*].

Lung Abscess

EPIDEMIOLOGY AND ETIOLOGY

In the antibiotic era, lung abscesses have become less common and less serious. The most common variety has been termed the primary, simple, nonspecific, or putrid abscess. Primary lung abscess accounts for about 60% of all lung abscesses and originates from a necrotizing suppurative bronchopneumonia caused by the aspiration of mixed oropharyngeal bacteria. Thus, both the predisposing factors and the causative organisms are similar to those identified in aspiration pneumonia. Patients with primary lung abscesses typically have alterations of consciousness because of underlying problems such as alcoholism and neurologic disorders; periodontal disease is often present. The organisms causing the abscess are much more reliably identified by transtracheal aspirates than by sputum cultures, which are invariably contaminated with anaerobes and other mouth flora. Percutaneous lung aspiration and bronchoalveolar lavage may also be useful for bacteriologic diagnosis. Mixed anaerobic bacteria are seen in most cases; *F. nucleatum, P. melaninogenica, Peptostreptococcus,* and anaerobic or microaerophilic streptococci predominate. *B. fragilis* is recovered with other organisms in 15% of cases.

Many other conditions can lead to lung abscess. Necrotizing

bacterial pneumonias caused by *S. aureus, K. pneumoniae,* or other gram-negative bacilli can lead to abscess formation. In other patients, abscess develops as a result of bronchial obstruction caused by tumors, foreign bodies, or bronchial stenosis. Septic pulmonary embolization is a cause of abscess formation. Pulmonary tuberculosis, fungal infection, or actinomycosis often leads to cavity formation. In the immunosuppressed host, *Nocardia* and other opportunistic organisms may also produce cavitation. Lung abscesses in patients with AIDS are caused by a wide array of organisms and respond poorly to therapy.

Noninfectious processes can produce cavitary lung lesions. Primary and metastatic tumors, bullae, cysts, intralobar pulmonary sequestration, pulmonary infarcts, vasculitis (including Wegener granulomatosis), and rheumatoid lung disease must be considered in the differential diagnosis of lung abscess.

DIAGNOSIS

Clinical Features

The clinical presentation of the patient with a lung abscess depends on the type of abscess. Patients with abscesses resulting from necrotizing staphylococcal or gram-negative bacillary pneumonias are usually acutely ill and exhibit clinical features of the underlying pneumonia. Although patients with primary lung abscess may also present acutely with aspiration pneumonia, they more often experience insidiously progressive symptoms for weeks or even months before diagnosis. Cough is present in almost all patients; when the abscess drains into the bronchial tree, production of copious foul-smelling sputum is characteristic. Hemoptysis is present in approximately one third of cases and may occasionally reach life-threatening proportions. Chest pain consisting of either a dull ache or a true pleurisy is common. Most patients have fever, but frank rigors are unusual. Often, patients with a chronic course of lung abscess lasting many weeks have anorexia, weight loss, and debility.

Physical Examination and Imaging

Physical examination of a patient with a lung abscess may disclose pulmonary rales, signs of consolidation, or, rarely, clubbing of the nails. These findings are not diagnostic, however, and chest x-rays or CT scans are required to establish the presence of an abscess. Although any lung segment may be involved, abscesses are most common in the posterior segments of the upper lobes and the apical segments of the lower lobes, because these areas are dependent when a person is recumbent. Abscesses may be single or, less often, multiple. The finding of air-fluid levels signifies rupture into the bronchial tree.

Laboratory Studies

As is the case with other pulmonary infections, examination of the sputum is crucial to the diagnosis of lung abscess. In patients with primary lung abscesses, the sputum is often putrid and contains numerous polymorphonuclear leukocytes and an abundant mixed microbial flora. Sputum cultures reveal only normal mouth flora. Meaningful anaerobic bacteriology depends on obtaining, either by transtracheal aspiration or by bronchoscopy, specimens that have not traversed the oropharynx. Percutaneous needle aspiration can also be very helpful, both diagnostically and therapeutically. In a typical case of aspirational putrid lung abscess, these invasive procedures may not be necessary. They are important, however, if the diagnosis is uncertain. The indications for bronchoscopy in patients with lung abscess are debatable. Although some physicians advocate bronchoscopy in all such patients, other physicians reserve the procedure for patients in whom there is a suspicion of bronchial obstruction by a foreign body or tumor, for patients who fail to respond to medical therapy, and for patients from whom specimens are required to rule out tuberculosis, fungal infection, or carcinoma. Bronchoscopy may be helpful therapeutically by promoting bronchial drainage from cavities that incompletely communicate with the bronchial tree.

TREATMENT

If specific pathogens such as *S. aureus* or *Klebsiella* are present in reliable specimens, therapy should be directed at the causative pathogen. In primary lung abscesses caused by mixed oral flora, penicillin has been the drug of choice. Prospective studies comparing penicillin therapy with clindamycin therapy in 66 patients with lung abscess found clindamycin to be the superior agent; however, the long clinical experience with penicillin warrants retaining it as the drug of choice, with clindamycin an excellent alternative for patients who are allergic to penicillin or who respond poorly to that drug. Despite its excellent bactericidal activity against anaerobic bacteria, metronidazole appears less effective in treating lung abscess. Most centers initiate treatment with I.V. penicillin in a dosage range of 6 to 12 million units a day or with I.V. clindamycin in a dosage of 600 mg every 8 hours. After a clear-cut clinical response is observed, oral penicillin V in a dosage of 750 mg four times a day or oral clindamycin in a dosage of 300 mg every 6 hours can be substituted. Parenteral therapy is often required for 2 to 4 weeks before the occurrence of defervescence, diminished sputum production, and reduction in cavity size. The duration of therapy depends on the clinical course, but prolonged treatment for 4 to 8 weeks is usually required.

In addition to administration of antibiotics, adequate drainage is essential and can usually be achieved with intensive pulmonary physiotherapy and postural drainage. Bronchoscopy can be very useful in promoting drainage and for excluding the diagnosis of cancer. Although surgery was once the mainstay of treatment for lung abscess, antibiotics are now almost always able to control infection, and surgery is needed only when complications occur. Massive hemoptysis is an indication for lung resection. Uncontrolled sepsis may occasionally necessitate lobectomy. CT-guided percutaneous tube drainage may be very helpful in patients who are too ill to tolerate thoracotomy and may be the treatment of choice for lung abscesses that are refractory to medical management. Empyema, another complication of lung abscess, requires external drainage by thoracentesis, chest tube, or rib resection. The persistence of a thin-walled cavity after otherwise successful medical treatment, however, is not an indication for surgery. Recurrent or persistent infection, recurrent hemoptysis, or the suspicion of tumor may mandate operative intervention. Shaggy, thick-walled cavities may be suggestive of tumor. Complications of lung abscess that have become uncommon because of antibiotic therapy include bronchogenic spread of infection to other pulmonary segments, bronchiectasis, and bacteremia with metastatic infection such as brain abscess.

Whereas patients with gram-negative or staphylococcal bacillary pneumonias or serious underlying diseases have a substantial mortality, the prognosis for patients with primary lung abscess is quite good. It is important to prevent recurrent pulmonary infection by treating dental disease and by avoiding factors that predispose to pulmonary aspiration.

Empyema

ETIOLOGY

Bacteria can reach the pleural space by many routes. Most often, empyema results from the direct spread of bronchopulmonary infections, including pneumonias, lung abscesses, and bronchiectasis.[88] Less often, empyema develops as a complication of thoracotomy or, rarely, thoracentesis. Open chest trauma provides another means for the direct introduction of microorganisms. Intra-abdominal infections, especially subphrenic abscesses, can penetrate the diaphragm to cause empyemas. Uncommonly, esophageal rupture can cause spread of infection from the mediastinum to the pleural space. Finally, hematogenous seeding is an infrequent mechanism of empyema formation.

S. aureus, various species of *Streptococcus,* and gram-negative bacilli are the most common causes of empyema; among the gram-negative bacilli, *K. pneumoniae* has been linked with diabetes.[89] Many infections are mixed. Anaerobes have been recognized in 25% to 76% of empyemas and may occur in pure culture or in combination with aerobic or facultative organisms. *Fusobacterium, Prevotella,* and anaerobic gram-positive cocci are the anaerobes most often seen. *M. tuberculosis* has become a relatively rare cause of pleural space infections, and fungi are implicated uncommonly.[90] Transdiaphragmatic rupture of a liver abscess occasionally produces amebic empyema.

DIAGNOSIS

In most patients, the clinical presentation of empyemas includes fever, dyspnea, chest pain, and cough. Hemoptysis is less common than these other symptoms. If diagnosis and treatment are delayed, weight loss and debility may be prominent. The physical findings in patients with empyemas are no different from those in other patients with pleural effusions. In addition, chest wall tenderness may be present, and there may be signs of an underlying pneumonia or intra-abdominal infection. Tachypnea and respiratory distress may occur, and septic shock may complicate advanced cases. Polymorphonuclear leukocytosis is common; other laboratory findings may include anemia and hypoxia. Chest x-rays reveal pleural effusions that are free flowing in early disease but frequently loculated in late cases. Ultrasonography may be necessary to distinguish fluid from pleural fibrosis. Unless surgery or thoracentesis has been performed, air-fluid levels in the pleural space suggest a bronchopleural fistula.

DIFFERENTIAL DIAGNOSIS

In the differential diagnosis of empyema, it is important to consider the many causes of noninfected pleural effusions.[91] Most important is the distinction between sterile parapneumonic effusions and true empyemas. Thoracentesis is mandatory for the diagnosis of empyema. Several thoracenteses may be needed if the fluid is loculated; CT or ultrasound guidance is very helpful in these circumstances. Gross purulence is diagnostic for empyema, but the absence of frank pus does not rule out infection. Like other inflammatory effusions, empyema fluids have the characteristics of exudates: protein levels greater than 3 g/dl and lactic dehydrogenase values in excess of 550 units. Pleural fluid acidosis is characteristic of empyemas, but alkalosis can occur if the infection is caused by a urea-splitting organism such as *Proteus*. Pleural fluid glucose levels are depressed in empyemas, and although white cell counts are variable, counts above 5,000/mm^3 are common, with polymorphonuclear leukocytes predominating. Gram stains of the pleural fluid will often reveal the causative organisms. Both aerobic and anaerobic cultures are mandatory; a foul odor suggests anaerobic infection. Stains and cultures for mycobacteria and fungi are important in selected cases.

TREATMENT

Treatment of empyemas involves both antibiotics and drainage. Antibiotics should be selected on the basis of the causative pathogens. High-dose parenteral therapy is required, and prolonged courses of 3 weeks or more are often needed. Adequate drainage is of paramount importance. In acute empyemas, the pleural cavity is lined by acute fibrinous inflammation, and percutaneous drainage of free-flowing fluid may be possible by repeated thoracentesis or tube thoracostomy. Closed chest tube drainage is the traditional method for draining empyemas, but image-guided catheter drainage is also effective, particularly when the fluid is loculated. Resolution of fever generally signifies satisfactory drainage. If complete drainage cannot be achieved with chest tubes, video-assisted thoracoscopic surgery (VATS) can often disrupt intrapleural adhesions and achieve excellent drainage of loculated effusions[92]; although VATS requires endotracheal intubation and general anesthesia, it is less invasive than the next alternative, rib resection with thoracotomy for decortication. Enzymatic debridement with streptokinase may enable some patients to avoid surgery.

Septic Pulmonary Embolism

Although once uncommon, septic pulmonary embolism is now encountered because of I.V. drug abuse, which accounts for more than 75% of cases; tricuspid valve endocarditis and direct injection of infected material cause most of these cases. *S. aureus* and gram-negative bacilli are the predominant etiologic agents in I.V. drug abusers. Septic pulmonary embolism may also develop in patients with septic phlebitis of peripheral veins (especially phlebitis related to I.V. lines or pelvic infections), abscesses, or other bacteremic infections.

Unlike bland emboli, septic pulmonary emboli produce pulmonary infarction in most instances. Small emboli produce flame-shaped or patchy infiltrates that may shift in location; these manifestations generally resolve with antibiotic therapy. Larger emboli often cavitate and may lead to lung abscess, empyema, or bronchopleural fistula formation. In addition to antibiotics, surgical drainage may be required for such complications. Operative intervention may be needed to control the source of emboli in some patients. Heparin can be useful in patients with septic phlebitis.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XXI PERITONITIS AND INTRA-ABDOMINAL ABSCESSES

W. Conrad Liles, m.d., ph.d.
E. Patchen Dellinger, m.d.

Peritonitis

Peritonitis is a diffuse or localized inflammatory process affecting the peritoneal lining.[1,2] Peritonitis has acute and chronic forms and may have a variety of causes, including pyogenic bacteria (e.g., *Escherichia coli*), tuberculosis, fungi, parasites (such as those from ruptured hepatic amebic abscesses or hydatid cysts), carcinomatosis, chemical irritation (such as that from bile), drug-hypersensitivity reaction, foreign-body reaction (such as starch peritonitis), and certain systemic illnesses (such as familial Mediterranean fever and systemic lupus erythematosus). Only acute peritonitis caused by bacteria or fungi, including primary and secondary peritonitis, is discussed here. Primary peritonitis has no underlying intra-abdominal disorder. Secondary peritonitis has an intra-abdominal focus that initiates the infection. Tuberculous peritonitis is considered elsewhere [*see 7:II Infections Due to Mycobacteria*].

SPONTANEOUS BACTERIAL PERITONITIS

Epidemiology and Etiology

Spontaneous bacterial peritonitis (SBP) is being recognized with increasing frequency in patients with either advanced chronic liver disease and concomitant ascites or fulminant hepatic failure and ascites.[3,4] The underlying chronic liver disease is usually alcoholic cirrhosis in older patients, whereas postnecrotic cirrhosis predominates in children and young adults. SBP is both common and serious, occurring in 10% to 30% of patients with cirrhosis and ascites, with an associated mortality between 30% and 50%.[2,5-7] The risk of SBP is increased in cirrhotic individuals with low ascitic protein levels (1 g/dl or lower).[8,9] *E. coli* is the most common cause of SBP and is isolated in about half of patients. Pneumococcal and streptococcal species are each responsible for 15% to 20% of cases, *Klebsiella* species for about 10%, and anaerobic or microaerophilic organisms for about 5%. *Staphylococcus aureus* is an infrequent cause of SBP but a major cause of peritonitis in cirrhotic patients with LeVeen peritoneovenous shunts. A variety of other organisms, including *Listeria monocytogenes*, *Campylobacter coli*, and *Aeromonas* species, have been responsible for isolated cases of SBP. In most instances in which the causative organism is aerobic, a single organism is involved, and concurrent bacteremia is frequent.

Although primary peritonitis occurs most often in children, it can develop in adults; nearly all adult patients are women.[10] Although many patients have had nephrosis, most have not had preexisting ascites. The source of infection is usually occult but may involve the female genital tract. The infecting organisms are almost always pneumococci or group A β-hemolytic streptococci; gram-negative bacilli are only rarely implicated. For reasons that are unclear, the incidence of primary peritonitis has decreased strikingly in the past several decades.

Occasionally, SBP develops in patients with systemic lupus erythematosus and lupus nephritis without detectable ascites, most of whom have been receiving corticosteroid therapy. The most common etiologic agents in this form of SBP are gram-positive cocci such as *Streptococcus pneumoniae* and group B streptococci. The most likely route of infection is bacteremic seeding of ascitic fluid, which may be precipitated by portal hypertension; intrahepatic shunting; intestinal bacterial overgrowth; and impaired host defense mechanisms, including diminished bactericidal activity in ascitic fluid.[3,6] Less often, SBP results from transmural migration of enteric bacteria (possibly associated with diarrhea, a common symptom in cirrhosis). Severe liver disease, hepatocellular carcinoma, gastrointestinal bleeding, and a focus of infection in the urinary tract or elsewhere in the body increase the risk of SBP.[9,11,12] Prior paracentesis may be contributory in a few instances. Penetrating lesions of the biliary tract, peptic ulcer disease, and overt bowel inflammation (such as appendicitis or diverticulitis) do not appear to be sources of infection.

Diagnosis

Clinical features The clinical presentation of SBP is often subtle.[3,6,7] Although ascites is always present, the volume of fluid may occasionally be small enough to necessitate ultrasonography for confirmation. Fever is the most common symptom but is absent in more than 30% of cases. Abdominal pain and hepatic encephalopathy are present in most patients. However, only half of the patients with SBP have abdominal tenderness, and as many as one third may be free of signs and symptoms of infection. Hence, SBP should be suspected in any cirrhotic patient who presents with unexplained clinical deterioration or hypotension.

Laboratory tests The key to diagnosis is examination of the ascitic fluid for bacteria and white blood cells. The polymorphonuclear leukocyte (PMN) count of the ascitic fluid is the best indicator of SBP. Although counts of more than 500 cells/mm^3 are considered specific for SBP, counts of 250 cells/mm^3 or more suggest a diagnosis of SBP and are considered specific enough to mandate treatment of SBP in cirrhotic patients in whom no other evidence of infection is present. An ascitic fluid PMN count below 250 cells/mm^3 excludes the diagnosis of SBP.[6,7]

Because bacterial counts are often very low, Gram stain of ascitic fluid in SBP is typically negative. However, a Gram stain is always useful because visualization of a single bacterial type would be consistent with SBP, whereas the presence of multiple bacterial forms would suggest secondary peritonitis. Because of the low concentration of bacteria, cultures are best performed by inoculation of 10 to 20 ml of ascitic fluid into a blood culture or BACTEC bottle at the bedside.

Three variants of SBP have been recognized on the basis of ascitic fluid PMN counts and cultures. In typical SBP, the PMN count is 250 cells/mm^3 or higher and cultures are positive. When the PMN count is 500 cells/mm^3 or higher but cultures are negative, the syndrome is called culture-negative neutrophilic ascites (CNNA). When the PMN count is below 250 cells/mm^3 but cultures are positive, the syndrome is termed bacterascites (BA). The clinical features and prognosis of SBP and CNNA are indistinguishable, and the two variants should

be managed identically. In contrast, BA can be self-limited; if patients are asymptomatic, they can be managed with careful observation and repeat paracentesis after 48 hours. Antibiotic therapy can be initiated if clinical symptoms develop or if the PMN count of the ascitic fluid rises.

It is important to distinguish SBP from secondary peritonitis resulting from intra-abdominal disease, such as a perforated viscus. An ascitic-fluid white blood cell count of 10,000/mm^3 or higher suggests secondary peritonitis, as does the presence of multiple bacterial species, anaerobes, or fungi. Patients should, of course, always be evaluated clinically and radiologically to exclude an underlying intra-abdominal process that might give rise to secondary peritonitis. Peripheral blood leukocytosis and positive blood cultures are common in both SBP and secondary peritonitis.

Differential Diagnosis

Bacterial peritonitis may be closely mimicked by acute pancreatitis, particularly in a patient with cirrhosis [*see also* Pancreatic Infections, *below*]. Abdominal pain, fever, rebound tenderness, hypotension, and peripheral leukocytosis are common in both bacterial peritonitis and acute pancreatitis. In a patient with pancreatitis, a diagnostic abdominal aspiration may even reveal cloudy fluid, but the turbidity is caused by floating fat globules derived from fat necrosis. Very high serum amylase levels are present in acute pancreatitis, but elevated levels also occur in peritonitis after intestinal perforation or obstruction and in the presence of renal failure.

In a patient with cirrhosis and ascites, a number of conditions may be mistaken for peritonitis, including acute peptic ulcer, cholecystitis, mesenteric artery occlusion, and other intra-abdominal processes. Paracentesis is helpful in arriving at a diagnosis in these circumstances.

Acute bacterial peritonitis may be distinguished from tuberculous peritonitis by several features. Tuberculous peritonitis is marked by a more indolent course, the absence of a peripheral leukocytosis, radiologic evidence of pulmonary tuberculosis, and a mononuclear response in the peritoneal fluid. In the patient with tuberculous peritonitis who does not have cirrhosis and ascites, the abdomen may have the characteristic so-called doughy consistency.

Peritonitis may be superficially suggested by the abdominal pain of acute porphyria, by lead colic, by diabetic acidosis, and by tabetic crisis, but the other features of these illnesses serve to distinguish them from peritonitis. The signs and symptoms of familial Mediterranean fever—high temperature, abdominal pain, abdominal guarding, and peripheral leukocytosis—may suggest bacterial peritonitis. The periodicity of familial Mediterranean fever and its occurrence predominantly in persons of Sephardic, Armenian, and Arab ancestry are helpful in differentiating it from bacterial peritonitis.

SBP may be difficult to diagnose in a patient with systemic lupus erythematosus who experiences acute abdominal pain and fever. These symptoms may stem from a variety of independent surgical problems (e.g., perforated ulcer, intestinal obstruction, and mesenteric occlusion) that must be distinguished from abdominal problems directly related to lupus, such as vasculitis, pancreatitis secondary to vasculitis or corticosteroid therapy, and SBP. Examination of peritoneal fluid obtained by paracentesis, by culdocentesis, or during laparotomy may be the only way to determine the presence of bacterial peritonitis.

Treatment

Until culture results are available, broad coverage should be directed against enteric organisms. Nephrotoxic drugs, including aminoglycosides, should be avoided whenever possible.[13] Cefotaxime (2 g I.V. every 8 hours) has emerged as the favored agent for the empirical treatment of SBP; alternative useful agents include ceftriaxone, ceftazidime, cefonicid, ceftizoxime, ampicillin-sulbactam, meropenem, and imipenem-cilastatin, as well as fluoroquinolones (i.e., ciprofloxacin, levofloxacin, gatifloxacin, and moxifloxacin).[6,7] Traditionally, intravenous antibiotics have been administered for 10 to 14 days, but 5 days of therapy appears to be as effective, provided that the patient is doing well clinically and that the ascitic fluid is sterile, with a PMN count that is below 250 cells/mm^3 before discontinuance of antibiotics.[6,7,14]

Renal failure is a frequent complication of SBP; peripheral vasodilation and renal vasoconstriction are probably responsible.[15] Infusions of albumin (1.5 g/kg at the time of diagnosis and 1 g/kg on day 3) can substantially reduce the incidence of renal failure and mortality in patients with SBP.[16]

Prophylaxis Because patients with cirrhosis are at high risk for primary SBP and because recurrences develop in 43% of these patients within 6 months and in 69% within 1 year after an initial episode of SBP, both primary and secondary prophylaxis regimens are now recommended for certain subgroups of patients. In nonbleeding cirrhotic patients with persistent ascites after an initial episode of SBP, continuous secondary prophylaxis with oral norfloxacin (400 mg daily) is currently recommended. Alternative oral antimicrobial agents for prophylaxis include ciprofloxacin, levofloxacin, trimethoprim-sulfamethoxazole, and amoxicillin-clavulanate. In cirrhotic patients with upper gastrointestinal hemorrhage, primary prophylaxis with oral norfloxacin (400 mg every 12 hours) or alternative systemic therapy (ciprofloxacin, levofloxacin, ampicillin-sulbactam) for a minimum of 7 days is advised. Primary prophylaxis with norfloxacin or another fluoroquinolone should also be considered in cirrhotic patients with low ascitic protein levels (i.e., less than 1.5 g/L).[6,7,17-19] Appropriate prophylaxis not only reduces the incidence of SBP but also improves overall survival.[20]

SECONDARY PERITONITIS

Etiology

Secondary peritonitis occurs as a complication of intra-abdominal disease. It may result from appendicitis, diverticulitis, penetrating abdominal wounds, blunt trauma to the abdomen, perforation of the gastrointestinal tract (e.g., by a peptic ulcer or bowel neoplasm), or rupture of an intra-abdominal abscess. Secondary peritonitis can be divided into spontaneous cases caused by an underlying disease such as appendicitis or diverticulitis and cases that result from a ruptured viscus incurred from an operation, a procedure, or an episode of trauma.[21] Most of these infections are polymicrobial. The pathogens include both anaerobic species (principally *Bacteroides fragilis,* peptococci, and peptostreptococci) and aerobic species (*E. coli*, *Proteus* species, *Klebsiella* species, and various streptococci and enterococci).[22] Bacteremia—which occurs in only 20% to 30% of cases—is most commonly caused by *E. coli*, *Bacteroides* species, or both.[23-25] The prognosis of secondary peritonitis depends on the underlying cause and the patient's physiologic response to the infection. Mortality is lowest in patients with appendicitis or

perforated duodenal ulcer (10%) and highest in those with other intra-abdominal processes (50%) or postoperative peritonitis (60%). Both mortality and the likelihood of complications, including the necessity for a second operation, increase as the patient's physiologic response to the disease is more marked. This is most easily assessed using the Acute Physiology and Chronic Health Evaluation II (APACHE II) score.[23,24]

Tertiary peritonitis is a relatively new term that refers to the persistence of intra-abdominal infection after the initial surgical and medical treatment of secondary peritonitis.[26] Not all authors discussing tertiary peritonitis agree on the definition of this syndrome. In a typical case of tertiary peritonitis, operative exploration in a patient with signs and symptoms of peritonitis after prior treatment for peritonitis will reveal inflammation and bacterial growth despite the absence of a focus for continuing infection, such as a perforated viscus, gangrenous tissue, or abscess. The organisms recovered tend to be considered nonpathogens and tend not to be typical of enteric flora. Tertiary peritonitis can be considered evidence for a type of host defense failure.

Diagnosis

The clinical features of secondary peritonitis most commonly include peritoneal signs such as involuntary guarding, referred percussion tenderness, and abdominal tenderness. There may be abdominal distention. Testing for rebound tenderness is painful to the patient and unhelpful in diagnosis. The abdomen is often not silent. Fever and leukocytosis are usually present. Free air may or may not be visible on plain abdominal films. An ultrasound or CT scan showing peritoneal free fluid or gas in association with a compatible clinical picture confirms the diagnosis. If the diagnosis is clinically obvious, radiographic studies are not required.

In the absence of ascites, the peritoneum has a remarkable capacity to wall off and localize infection to a portion of the abdomen. Thus, in situations such as rupture of the appendix, a localized peritonitis develops and results in a periappendiceal or pelvic abscess [*see* Intra-abdominal Abscesses, *below*].

Treatment

Peritonitis secondary to bowel perforation, ruptured gangrenous appendix, or penetrating trauma requires prompt surgical intervention in addition to antimicrobial therapy. Surgical therapy, known as source control, should be directed at correction of the underlying disease, debridement of the surrounding tissues, and prevention of recurrent microbial soilage. In general, this requires draining, resecting, excluding, or patching the involved viscus during laparotomy or laparoscopy. Intraoperative saline lavage and radical peritoneal debridement have not proved useful; postoperative peritoneal lavage and planned repeat laparotomy have been suggested but are not of established benefit.

Approximately 20% to 30% of patients who require an operation for treatment of peritonitis or intra-abdominal abscess will require a second operative procedure to resolve the infection and establish adequate source control.[27] Surgeons' assessments of the adequacy of the source control achieved with the original operative procedure have been found to be strongly predictive of patients' subsequent need for reoperation and mortality.[28]

The choice of antimicrobial agent depends on the organisms involved in the peritonitis. Initial selection, however, is always made before culture results are available, and it must take into consideration the organisms that are predominant in the colon: *B. fragilis*, enteric gram-negative bacilli, streptococci, and enterococci. Animal studies and clinical experience have shown the importance of using antibiotics that are effective against both aerobic and anaerobic bacteria to treat patients with polymicrobial peritonitis, but clinical trials have failed to establish the superiority of any particular regimen. Newer antibiotics that provide broad-spectrum coverage of many aerobic and anaerobic species allow single antibiotic therapy in many cases. Useful single agents include ampicillin-sulbactam, ticarcillin–clavulanic acid, cefoxitin, cefotetan, piperacillin-tazobactam, ertapenem, meropenem, and imipenem-cilastatin. Effective multidrug regimens include (1) an aminoglycoside combined with either clindamycin or metronidazole, (2) aztreonam combined with clindamycin, and (3) a quinolone or a third-generation cephalosporin combined with either clindamycin or metronidazole[29,30] [*see 7:XIV Chemotherapy of Infection*]. Although multiple drugs provide broader antimicrobial coverage, they do not appear to be more effective than single-drug regimens. In all cases, the final choice of antibiotics should be determined by the results of culture and sensitivity testing and the clinical course.

Most antibiotics attain concentrations in ascitic fluid that are at least half of the simultaneous serum levels and that exceed the minimum inhibitory concentration for the infecting organism. For this reason, systemic therapy alone is generally adequate in the management of bacterial peritonitis in patients with ascites; intraperitoneal instillation of antibiotics does not appear necessary. The necessary duration of antibiotic administration has never been systematically studied. For most patients, antimicrobial agents can be stopped as soon as clinical signs of infection begin to resolve, intestinal function resumes, and temperature and white blood cell count begin to return to normal. It is unusual for patients to require more than 7 days of treatment, and many patients can be managed with less.[29,30]

PERITONITIS IN DIALYSIS PATIENTS

Epidemiology

Infection continues to be a significant problem for peritoneal dialysis patients. Peritonitis develops in as many as 60% of patients undergoing continuous ambulatory peritoneal dialysis during the first year of treatment, and the infection recurs in 20% to 30% of these patients; elderly patients are the most vulnerable.[31]

Diagnosis

Clinical features The development of fever, abdominal pain or tenderness, and leukocytosis and the isolation of a bacterial or mycotic agent from the effluent fluid in a patient on peritoneal dialysis indicate peritonitis. Isolation of bacteria from the dialysate in a patient without these findings often signals contamination rather than infection. Turbidity of the dialysate from neutrophils occurs in 2% to 3% of dialyses. Although turbidity itself does not necessarily indicate peritonitis, it should be considered an indication of infection until the results of the culture are available. Absence of bacteria on a Gram stain of the dialysate sediment does not necessarily confirm the absence of infection, however, because of the extensive dilutions required. Therefore, one cannot rely on a negative Gram stain to discriminate between infection and sterile inflammation.[31]

Bacteriology The principal organisms in peritonitis that complicate peritoneal dialysis are coagulase-negative staphylo-

cocci, *S. aureus, Pseudomonas aeruginosa, E. coli* and other enteric organisms, and *Candida* species.[31-33] Microorganisms may enter the peritoneal cavity exogenously (i.e., after colonization of the abdominal wound area or by contamination of the dialysate) or endogenously (i.e., by bacteremia or by transmural migration of bowel flora, perhaps enhanced by catheter-induced trauma). Most episodes are monomicrobial, but polymicrobial peritonitis can occur.[34,35] Failure to respond to antibiotic therapy within 96 hours often signals infection with gram-negative bacilli (typically, *P. aeruginosa*); the prognosis in these patients is worse than in those who respond rapidly. Removal of the dialysis catheter may be necessary to control infection.

Treatment

Peritonitis caused by *Candida* species occurs most often as a complication of peritoneal dialysis, gastrointestinal surgery, or perforation of an abdominal viscus. Candidal peritonitis that complicates peritoneal dialysis is treated with intravenous amphotericin B, intraperitoneal amphotericin B, or both at a final dialysate concentration of 2 to 4 μg/ml. Fluconazole may also be useful for treatment of peritonitis caused by *C. albicans,* as may caspofungin.[31,36]

Whereas the addition of peritoneal lavage, with or without antibiotics, does not appear to improve on the results achieved by intravenous antibiotics and conventional surgical therapy, intraperitoneal administration of antibiotics may be useful in patients who require peritoneal dialysis. For example, different antibiotics can be added directly to the dialysate in specific concentrations, such as ampicillin in a concentration of 50 mg/L or gentamicin in a concentration of 5 to 10 mg/L. Because bacteremia may occur, antibiotics should also be administered intravenously in these patients in a dosage appropriate to the patient's level of renal function. When peritonitis develops as a complication of peritoneal dialysis or peritoneovenous shunting, it is often necessary to remove or replace the catheter during administration of antibiotics to control the peritonitis.[31,36] In patients with a history of peritonitis caused by *S. aureus,* prophylaxis with either topical mupirocin ointment in the nares or oral rifampin may reduce the incidence of subsequent episodes of staphylococcal peritonitis and peritoneal catheter loss.[31,36,37]

Intra-abdominal Abscesses

Intra-abdominal abscesses may present as complications of an abdominal operation, intra-abdominal conditions (e.g., diverticulitis, appendicitis, biliary tract disease, pancreatitis, perforated viscus, peritonitis), or penetrating abdominal trauma; as fever of obscure origin; or as dysfunction of neighboring organs (e.g., so-called lower lobe pneumonia related to a subphrenic abscess or small bowel obstruction). Bacteremic spread of infection from a distant focus to an intra-abdominal site is a less common cause of intra-abdominal abscesses.

Intra-abdominal abscesses are conveniently classified according to the anatomic location in which they occur: intraperitoneal, retroperitoneal, or visceral. Intraperitoneal abscesses are areas of localized peritonitis in which infection has progressed but has been walled off by omentum, peritoneum, and adjacent viscera. Retroperitoneal infections include pancreatitis-associated infections, perinephric abscesses, and paravertebral abscesses. Visceral abscesses develop within abdominal viscera—predominantly, the liver and, less often, the spleen—and other organs. In general, the location of the abscess does not affect the diagnosis or treatment beyond influencing the choice of percutaneous or surgical drainage.

GENERAL APPROACH TO INTRA-ABDOMINAL ABSCESSES

Diagnosis

Although the location of the abscess determines its particular features, many intra-abdominal infections share common elements. Fever, for example, is almost invariable; it often recurs in a spiking pattern and may be accompanied by rigors. Hypotension and even septic shock may develop. Abdominal pain is a major clue to the presence of an intra-abdominal abscess: when present, it can predominate; when it is absent, the diagnosis can be very difficult. Geriatric patients, in particular, may present atypically, without abdominal pain or fever. On laboratory studies, leukocytosis and elevation of liver enzyme and serum amylase levels are common. Bacteremia, which may be polymicrobial, occurs in up to one fourth of cases.

Intra-abdominal abscesses characteristically contain multiple bacterial species. Anaerobic bacteria can be isolated from 60% to 70% of such abscesses; the bacteria most commonly isolated include *B. fragilis,* peptostreptococci and peptococci, *Clostridium* species, and facultative species such as *E. coli, Enterobacter, Klebsiella,* and enterococci. The specific organisms isolated do not generally provide clues to the nature of the underlying process. However, the presence of *Citrobacter* species strongly suggests a biliary or upper gastrointestinal source; *S. aureus,* otherwise uncommon in intra-abdominal abscesses, suggests bacteremic seeding or vertebral osteomyelitis, which can lead to retroperitoneal or perinephric abscesses.

Plain radiography (kidneys, ureters, and bladder [KUB]; upright and lateral decubitus views) may afford important clues to the diagnosis of intra-abdominal abscesses. For example, air-fluid levels may indicate an intra-abdominal collection, free air may point to perforation of a viscus as the underlying problem, displaced loops of bowel may signify an abscess, and a so-called soap-bubble appearance or loss of the normal psoas shadow may suggest a retroperitoneal collection.

Ultrasonography and computed tomographic scanning, however, are much more sensitive and specific than plain radiography and are now the standard radiologic techniques for evaluating intra-abdominal abscesses.[38] Both are excellent for diagnosis, and both can be used to guide percutaneous abscess drainage [*see* Treatment and Prevention, *below*].[39] CT scanning is the more accurate study; its specificity and sensitivity rates can exceed 90%. Compared with ultrasonography, CT scanning has the additional advantages of allowing simultaneous administration of contrast, of not requiring skin contact (hence, surgical dressings do not interfere with the study), and of producing accurate results even in the presence of ileus and abdominal gas collections. Ultrasonography, however, is less expensive, is often more readily available, can sometimes be done with portable equipment at the bedside, and does not involve exposure to radiation. Ultrasonography is most accurate for detecting abscesses in the left or right upper quadrant of the abdomen and in the true pelvis; it is also sensitive and specific for identifying ascites. In patients with acute abdominal disease, however, ultrasonography is often limited by bowel gas, which obscures any deeper findings.

Magnetic resonance imaging plays a negligible role in the evaluation of intra-abdominal infections. Nuclear medicine studies are also less helpful than CT and ultrasonography. Although early results appeared promising, gallium-67 scanning

and indium-111 scanning both have proved less helpful than CT and ultrasonographic techniques. Cholescintigraphy scans using technetium-99m–labeled hepatoiminodiacetic acid (HIDA, or lidofenin) are useful in evaluating the gallbladder and for demonstrating a bile leak after cholecystectomy or other biliary procedure [*see 4:VI Gallstones and Biliary Tract Disease*]. Arteriography and barium contrast studies are seldom used to diagnose intra-abdominal abscesses. If fistulous tracts are present, however, sinograms may occasionally be helpful.

Treatment and Prevention

The choice of antibiotics depends on the organisms isolated from cultures of blood or abscess material. Until this information is available, the choice of drugs should be guided by the same principles as those that apply to the treatment of peritonitis. Although the use of antibiotics is essential, especially because of the risk of bacteremia, such therapy alone will not eradicate intra-abdominal abscesses and is therefore secondary to prompt, effective abscess drainage.

Until the mid-1970s, surgical drainage was mandatory for the treatment of intra-abdominal abscesses. However, treatment changed dramatically within just a few years of the introduction of percutaneous abscess drainage under ultrasonographic or CT guidance. Ultrasonography may be used to guide drainage of large or superficial collections, but CT is preferable for smaller or deeper abscesses.[40] Many studies have demonstrated that percutaneous abscess drainage is safe and effective for a broad range of intra-abdominal collections; success rates range from 47% to 92%, with most studies reporting better than 80% success, similar to the success rate for surgical drainage.[41] Failure of treatment is more common in immunosuppressed patients and in those with poorly defined phlegmons, multilocular abscesses, thick hematomas or organized infections, or abscesses with associated fistulous tracts.

Radiographic features alone cannot indicate which abscesses will respond to percutaneous drainage. Hence, it seems reasonable to institute percutaneous drainage in all patients who have a safe access route, provided that skilled personnel are available and that the patient does not otherwise require surgical intervention. Surgical drainage may then be used in patients with recurrences, failures, or complications. A surgeon should be involved in the decision regarding the method of drainage, because the surgeon will be called if the initial approach is not successful. Even in the case of abscesses that usually require surgical intervention, such as periappendiceal and diverticular abscesses and peripancreatic infections (see below), percutaneous drainage can provide temporary control of sepsis, allowing the operative procedure to be delayed until conditions are optimal and sometimes allowing a single definitive procedure instead of staged procedures.

A number of effective preventive strategies are available to reduce the likelihood of both wound infections (incisional surgical site infections) and intra-abdominal abscesses (organ/space surgical site infections) after abdominal operations.[42] These include the appropriate use of prophylactic antibiotics,[43] maintenance of normothermia in the operating room,[44,45] provision of high levels of inspired oxygen,[45,46] adequate fluid resuscitation during the operation,[47] and maintenance of euglycemia in the perioperative period.[48-50]

INTRAPERITONEAL ABSCESSES

Intraperitoneal abscesses may form in either of two ways: (1) from diffuse peritonitis in which loculations of pus develop in anatomically dependent areas such as the pelvis, paracolic gutters, and subphrenic areas or (2) by spread of infection from a localized inflammatory process to contiguous peritoneum. About one third of intra-abdominal abscesses are intraperitoneal, and almost one half of intraperitoneal abscesses occur in the right lower quadrant.

Subphrenic Abscesses

About 60% of subphrenic abscesses develop after operations involving the duodenum and stomach, biliary tract, or appendix; 20% to 40% develop after rupture of a hollow viscus (such as perforated peptic ulcer or acute appendicitis), in which the infection is subsequently sealed off. A variable percentage of subphrenic abscesses develop after penetrating or blunt (closed) abdominal trauma, and less than 5% develop without predisposing circumstances. Diagnosis of subphrenic abscesses is sometimes delayed because of their location in the intrathoracic portion of the peritoneal cavity, which is not amenable to examination.

Clinical features The manifestations of a subphrenic abscess range from a severe acute illness to an insidious chronic process characterized by intermittent fever, weight loss, anemia, and nonspecific symptoms. The chronic syndrome is most often observed in patients who have previously received antibiotics; in the past, such an abscess could smolder subclinically for prolonged periods before diagnosis. This is currently uncommon. In any patient with fever of undetermined origin who has had an abdominal operation—even if the operation was performed many months earlier—a chronic intra-abdominal abscess must be suspected and a CT scan should be done.

Spiking fever, abdominal pain and tenderness (most often at the lower costal margin), and weight loss are common manifestations. Features of an intrathoracic process, such as shoulder pain, chest pain, cough, dyspnea, rales, and pleural effusion, are more commonly observed than features of an intra-abdominal condition. Leukocytosis is common. Rarely, patients will have a prolonged, obscure febrile illness complicated by the sudden development of an empyema when the subphrenic abscess ruptures through the diaphragm. Although pleural fluid is present in about 80% of patients with a subphrenic abscess, it is usually a sympathetic transudate. A pleural effusion that develops after an abdominal operation is more commonly caused by inflammation below the diaphragm than inflammation above it.

Diagnosis CT scanning and ultrasonography are the best radiologic techniques for establishing the diagnosis. The plain x-ray findings in patients with subphrenic abscess include pleural effusion, limitation of diaphragmatic movement, elevation of a hemidiaphragm, and lower-lobe pneumonia or atelectasis.

RETROPERITONEAL ABSCESSES

Pyogenic infections of the retroperitoneum present like other intra-abdominal infections. Indeed, many retroperitoneal abscesses arise from disorders of the abdominal viscera; more than two thirds of patients with retroperitoneal abscesses also have underlying debilitating conditions, including malignancies, corticosteroid use, alcoholism, and diabetes. More than 80% of these infections are polymicrobial, involving aerobic and anaerobic enteric organisms.[51] CT scanning is the key to diagnosis of retroperitoneal abscesses. The same is true for primary psoas abscesses, which are often caused by *S. aureus*,[52] and for perinephric abscesses, which usually originate in the urinary

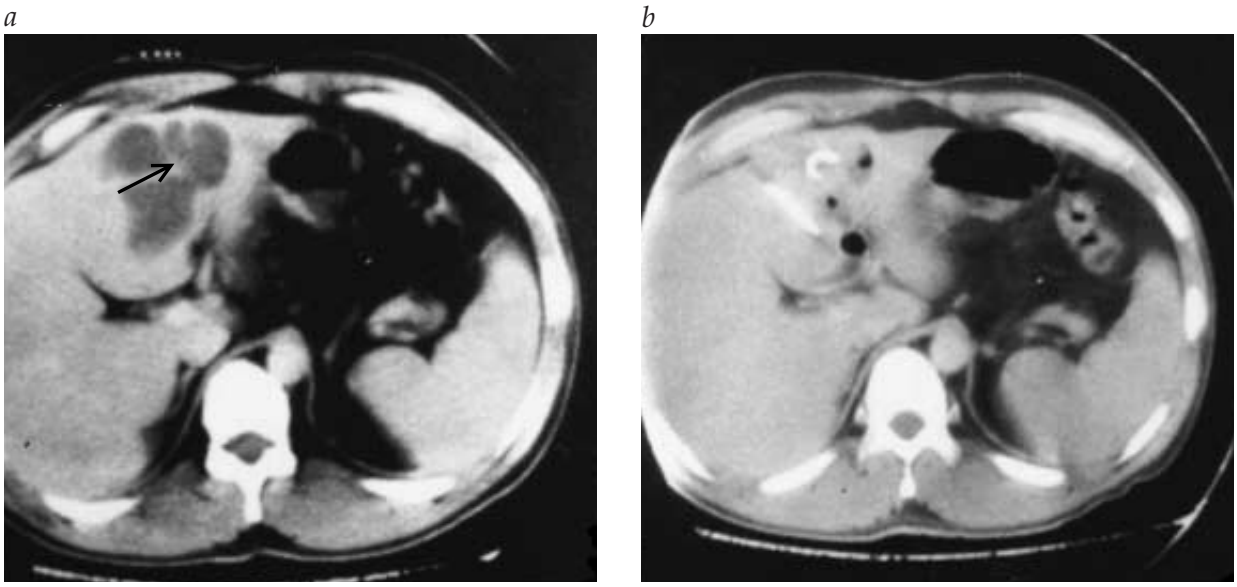

Figure 1 **CT scan (*a*) shows multilobular liver abscess (arrow). Four days after percutaneous abscess drainage, CT scan (*b*) shows resolution of the abscess cavity.**

tract.[53] As with other abscesses, successful management requires prompt percutaneous or surgical drainage and the administration of appropriate antibiotics.[53,54]

Pancreatic Infections

Most pancreatic infections occur as a complication of pancreatitis, which can result from alcoholism (38%), gallstones (11%), surgical trauma (16%), or other factors (35%). Pancreatic infections have been divided into infected pancreatic and peripancreatic necrosis and pancreatic abscesses.[55] Infected pancreatic necrosis tends to occur during the first 3 weeks after the onset of acute necrotizing pancreatitis and is poorly localized within the retroperitoneum. Source control is difficult, and morbidity and mortality can be high. Infected necrosis often requires open operative debridement, although there are promising reports of combined percutaneous drainage and laparoscopically assisted debridement. Pancreatic abscess refers to a more localized infectious process. It can occur either in or adjacent to the pancreas and tends to occur more than 3 weeks after the acute onset of disease. An infected pseudocyst is also a pancreatic abscess. Pancreatic abscesses can often be managed percutaneously but are still likely to require additional source control.[56]

Pancreatic infections are often polymicrobial, typically containing three or four species of bacteria. Most are enteric organisms, including *E. coli,* enterococci, *Klebsiella* species, and anaerobes such as *Bacteroides, Peptococcus, Fusobacterium,* and *Clostridium* species. Nonenteric organisms, including staphylococci, *P. aeruginosa,* and, less often, *Candida* species, may be involved. Bacteremia occurs in about 26% of cases. Recent reports demonstrate a shift in the usual microbial flora of infected pancreatitis, with an increase in gram-positive cocci and fungi (e.g., *Candida* species), probably secondary to the increasingly common use of prophylactic antibiotics for long periods in patients with necrotizing pancreatitis.[57,58]

Clinical features The initial presentation of noninfected acute necrotizing pancreatitis involves fever, leukocytosis, and abdominal pain and tenderness. The clinical features do not allow the differentiation between infected and uninfected patients. Most infections occur after at least 1 week of disease.

Diagnosis The most accurate method for determining whether an area of pancreatic or peripancreatic necrosis is infected is to perform CT scan–guided fine-needle aspiration for Gram stain and culture. This step is indicated if a patient's clinical condition deteriorates after initial stabilization or improvement.[59]

Treatment Source control is mandatory. It can often be accomplished by open surgical debridement, sometimes aided by percutaneous drainage, laparoscopic techniques, or both. The outcome is improved when intervention occurs later in the course of the disease. Antibiotic therapy is the same as for other intra-abdominal infections.

VISCERAL ABSCESSES

Liver Abscesses

Epidemiology and etiology Pyogenic liver abscesses occur in several settings, including biliary tract infection, direct extension from a contiguous site of infection, portal bacteremia from intra-abdominal septic foci, and nonpenetrating trauma.[60-62] Liver abscesses may occur as a result of systemic bacteremia or as complications of abdominal surgery or penetrating abdominal trauma. They may also occur as complications of hepatocellular carcinoma,[63] chronic granulomatous disease,[64,65] or percutaneous transhepatic biliary drainage procedures in patients with cancer and obstructive jaundice. Pyogenic abscesses may be single or multiple.

Like other intra-abdominal abscesses, pyogenic liver abscesses principally involve enteric bacteria; two thirds of these abscesses have polymicrobial origins, and at least one third involve anaerobes. *S. aureus* may be the causative organism in patients with bacteremia and in children. *Klebsiella* species are often responsible for gas-forming liver abscesses, which typically occur in patients with diabetes.[66] Blood cultures are positive

in about half of patients with a pyogenic liver abscess, and metastatic infections may occur.

Clinical features Fever is the most common symptom and is present in nearly 90% of patients. Chills and weight loss occur in about half of cases. Because abdominal pain, abdominal tenderness, or hepatomegaly is present in only half of cases, many of these patients present with fever of undetermined origin. Leukocytosis is present in most cases. Jaundice is infrequent, but the serum alkaline phosphatase level is elevated in almost all patients. Rupture of a liver abscess, although uncommon, is often accompanied by diffuse abdominal pain and septic shock.[67]

Diagnosis CT scanning is the most accurate diagnostic technique [*see Figure 1*], yielding positive results in up to 95% of confirmed cases; ultrasonography is also helpful, yielding positive results in up to 80% of confirmed cases. The initial clue to the diagnosis may come from plain x-rays, which may show an elevated right hemidiaphragm, a right pleural effusion, or an air-fluid level.

The major differential diagnosis is amebic liver abscess [*see 7:XXXIV Protozoan Infections*]. Amebic abscesses are more likely to be solitary and confined to the right lobe of the liver; a history of travel or diarrhea may suggest the diagnosis. Stool ova and parasite examination revealing *Entamoeba histolytica* is highly suggestive, but results are often negative in patients with hepatic amebiasis. However, most patients with amebic liver abscesses have positive amebic serologies. It is important to note that *E. histolytica* has been reclassified into two morphologically similar but genetically distinct species: *E. histolytica,* the pathogenic protozoan that causes amebic dysentery and hepatic abscess, and *E. dispar*, a nonpathogenic commensal protozoan of humans. Specific enzyme-linked immunosorbent assay–based serologic testing to distinguish *E. dispar* colonization from *E. histolytica* infection is recommended before treating amebiasis.[68,69] Less often, hepatic cysts or neoplasms may be confused with liver abscesses.

Treatment Whereas surgery was formerly the mainstay of therapy, percutaneous drainage should now be the initial drainage procedure in most patients with pyogenic liver abscesses. Antibiotics with broad coverage of enteric organisms and staphylococci should be administered intravenously until specific pathogens have been isolated from the abscess or the bloodstream.[70] Mortality depends largely on the underlying disease and is highest in patients with cancer.[71] Surgical therapy is required for ruptured abscesses, but the mortality is high, approaching 44%.[67]

Splenic Abscesses

Splenic abscesses are uncommon.[72] Unlike other intra-abdominal abscesses, they are often bacteremic in origin, especially in patients with endocarditis. In other patients, hemoglobinopathy, vasculitis with splenic infarction, trauma, and immunosuppression may be predisposing factors. Fever and chills and left upper quadrant pain are common. If the upper pole of the spleen is affected, diaphragmatic and pleural and pulmonary symptoms may predominate, but peritoneal symptoms are more common if the lower pole is the site of infection. Responsible organisms include *S. aureus,* streptococci, *Salmonella* species, and enteric bacteria; fungi are important causes in immunocompromised patients. CT scans and ultrasonography are the most useful radiographic studies. Appropriate antimicrobial therapy is essential. Although splenectomy has often been required for effective management in the past, evidence now indicates that percutaneous drainage or even antibiotics alone may suffice in selected cases.[73] More experience is needed before the optimal management of these uncommon infections can be determined.[74]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XXII VAGINITIS AND SEXUALLY TRANSMITTED DISEASES

MATTHEW R. GOLDEN, M.D., M.P.H.

Sexually transmitted diseases (STDs) are among the most common causes of infectious illness in the world. The United States leads industrialized nations in the occurrence of STDs, with an estimated 12 million new cases annually, three million of them in teenagers.[1] In many developing nations, STDs (excluding HIV infection) are the second greatest cause of disability-adjusted years of life lost,[2] and highly prevalent bacterial and viral STDs may facilitate HIV transmission.[3]

Of the more than 30 sexually transmitted pathogens that are currently recognized, eight have been identified since 1980, and it seems likely that the full spectrum of STD remains undefined.[4] Antimicrobial resistance has made treatment of some well-established infections (e.g., gonorrhea) more difficult. Finally, decreasing age of menarche, declining median age of populations in developing countries, delayed marriage, increased global travel and trade, urbanization, migration, war and associated social upheaval, and the dissolution of socially restrictive political systems in the former Soviet Union and, to a lesser extent, China all ensure that STDs will remain a major and probably increasing health problem in coming decades.[5]

For the clinician, the increasing recognition of viral STDs and the emergence of screening for chlamydial infections as a population-based STD control strategy has heightened the importance of familiarity with the management of these common infections. This chapter presents general concepts in the epidemiology and approach to patients with STD and reviews important STD syndromes, including urethritis, vulvovaginitis, mucopurulent cervicitis, pelvic inflammatory disease, and genital ulcer disease. Finally, the approach to STD in men who have sex with men and to sexually transmitted enteric infections will be presented. Specific pathogens, including *Chlamydia*, *Neisseria gonorrhoeae,* herpes viruses, and *Treponema pallidum,* are discussed in other chapters. The Centers for Disease Control and Prevention (CDC) issues guidelines for STD/HIV testing and counseling, as well as STD treatment (http://www.cdc.gov/hiv/dhap.htm). Clinicians are advised to refer to these guidelines for updated recommendations.[6-8]

Epidemiology and Transmission Dynamics

The transmission of an STD through a population can be conceptualized mathematically with the formula $R_0 = \beta cD$, in which R_0 is the average number of secondary cases generated by each primary infection in a population (i.e., the reproductive number); β is the average probability of transmission with each sexual partnership, c is the average number of sexual partnerships formed per unit of time; and D is the mean duration of infection.[9] For diseases in which each case generates an average of one additional case, R_0 equals 1 and the prevalence remains stable; values less than 1 and greater than 1 are associated with a declining or rising prevalence, respectively.

Although each of the terms in this equation is complex, the simplification that the equation offers can explain a great deal about the distribution of different STDs in a population and provides a framework for conceptualizing STD epidemiology. For example, gonorrhea is thought to be efficiently transmitted (β = 0.5), but it has a relatively short duration of infection, especially in settings in which medical care and therapy are readily available.[9,10] Consequently, for the reproductive number to remain 1 or greater, c must be relatively high. Thus, infection tends to concentrate in a population of highly sexually active persons, sometimes referred to as a core group.[11] In part because young people tend to be more sexually active than older people, the incidence of gonorrhea, like that of chlamydial infection, is highest among teenagers and persons in their early 20s. (This is less true of men who have sex with men, in whom gonorrhea incidence is less concentrated in the young.) In contrast, herpes simplex virus type 2 (HSV-2) has a very long duration of infection, and R_0 may exceed 1 even in populations with very low rates of partnership change. As a result, the prevalence of genital herpes rises with age, peak incidence likely occurs at a somewhat older age than with *Chlamydia* infection or gonorrhea, and the infection is widely disseminated throughout the population.[12]

This simple model of STD transmission dynamics focuses on average behavior in a population and the host-parasite relationship as determinants of STD epidemiology. However, it neglects the critical role played by variance in sexual behavior and patterns of sexual mixing (i.e., sexual networks) in defining transmission dynamics. The prevalence of STD in a population is in part a function of the extent to which persons who are more sexually active mix primarily with one another (assortative mixing) versus mixing more randomly with others, including persons who are less sexually active.[13] The frequency of concurrent partnerships in a population also exerts a profound influence on STD prevalence; such partnerships allow infections to spread in two directions, connecting groups of people and facilitating rapid transmission of infection.[14,15]

In eliciting a sexual history, clinicians have traditionally focused on the patient's behavior, asking about the number of sexual partners the patient has had and about the use of condoms. In many cases, however, self-reported behavior is not associated with risk of STD; sexual network factors may be more important in defining risk. For example, virtually all studies of selective screening for chlamydial infection have found that self-reported behavior is an insensitive predictor of infection,[16-18] whereas demographic factors such as age, race, socioeconomic status, source of clinical care, and geography are strongly associated with a variety of STDs.[19-21] These factors, which reflect the organization of human society and dictate sexual mixing patterns, play a critical role in defining an individual's risk of infection.[22] STDs exist within a social context; therefore, clinicians should base their assessment of risk on their practice setting and the patient's social milieu. Persons whose behavior would suggest a low risk of STD can in fact be at elevated risk simply by virtue of their sexual network, a population that is often socially determined rather than individually chosen. This knowledge should temper any tendency to entertain stigmatizing stereotypes related to sexual behavior and STD.

STD Prevention

SEXUAL HISTORY AND COUNSELING

What is the best way to elicit a sexual history? Although relatively little research has been done on this question, some general principles can be articulated. In eliciting a sexual history, the clinician must balance the need to collect specific information with the desire to engage the patient in a conversation about sexual risk. Whenever possible, questions should be open ended, allowing the patient to define factors that may have placed him or her at risk for STD (e.g., "What are you doing now, or what have you done in the past, that you think may have put you at risk for a sexually transmitted disease?"). Subsequent questions may be more specific, but the questions should be clear, direct, and phrased nonjudgmentally (e.g., "Do you have sex with men, women, or both men and women?"). Typically, a sexual history should include questions about sexual orientation, the number of sexual partners, the use of condoms, any history of STD, and the sexual repertoire (oral, insertive or receptive anal, and vaginal sex). Persons with HIV or those at high risk for HIV should be asked if they know the HIV status of their sexual partners. Persons with HIV should be asked whether they have informed their partners of their own HIV status.

Clinicians should seek to integrate elicitation of the sexual history with STD prevention counseling. The CDC recommends a client-centered approach to counseling. This approach involves an effort to help patients assess the circumstances and behaviors that place them at risk for STD and then help them commit to a single, defined plan for reducing their risk. Risk-reduction plans should be specific rather than general. For example, a specific goal might be to carry condoms when going out on a date or to ask a specific partner about his or her HIV status, rather than the general goals of using condoms all the time or having safe sex all the time.[23] Client-centered counseling has been shown (in a randomized trial of heterosexual STD clinic patients) to reduce the risk of STDs.[6,24]

Table 1 Recommended STD Screening[8]

Population	*Screening Measures*
All men and women	Retest all patients diagnosed with gonorrhea or *Chlamydia* infection 10–18 wk after initial treatment
Women Sexually active, age ≤ 24 yr Age > 24 yr with a new sexual partner or multiple sexual partners	Annual chlamydial screening
Pregnant women	Test for *Chlamydia trachomatis*, *Neisseria gonorrhoea*, hepatitis B virus infection, and syphilis; offer HIV testing and counseling Test for bacterial vaginosis in women at high risk (e.g., those with history of preterm delivery) Perform Pap smear if none was performed in the past year
Men who have sex with men (MSM)*	Perform the following at least annually: Serologic testing for HIV and syphilis Rectal culture for gonorrhea and chlamydial infection Pharyngeal culture for gonorrhea Consider serologic testing for HSV-2, particularly in HIV-negative MSM Serologic testing for hepatitis A and B antibodies†

*Screening guidelines apply to both HIV-positive and HIV-negative MSM. HIV and hepatitis testing should be performed only for susceptible patients. Current data are insufficient for a recommendation of technologies other than culture to test for rectal gonorrhea or chlamydial infection or pharyngeal gonorrhea. Because herpes simplex virus type 2 (HSV-2) increases the risk of HIV acquisition, HSV-2 screening should be considered to aid in HIV risk assessment and counseling. More frequent screening should be considered for those at highest risk of STD.
†Vaccinate for hepatitis A and B if negative.

STD REPORTING AND SEXUAL PARTNER MANAGEMENT

By law, gonorrhea, syphilis, chancroid, lymphogranuloma venereum (LGV), donovanosis (granuloma inguinale), and, in most parts of the United States, chlamydial infections must be reported to local health departments. In general, health departments in the United States routinely attempt to ensure the treatment of sexual partners of persons with syphilis; they only sometimes attempt to contact persons reported to have HIV to offer them assistance in notifying their sexual and needle-sharing partners; and they seldom make any routine effort to notify the partners of persons with gonorrhea or chlamydial infection. Some health departments will provide such services if specifically asked to do so by a clinician or a person diagnosed with an STD. Although clinicians should make their patients aware that they may be contacted by public health authorities regarding partner notification, in most instances, it is the responsibility of the diagnosing clinician and the patient to ensure that sexual partners are evaluated and treated. Several recent studies have suggested that giving patients medication to give to their sexual partners is feasible and may reduce chlamydial reinfection rates.[25-27] However, at present, there are no guidelines that define the circumstances in which this approach to partner management should be employed.

STD SCREENING

Because STDs are often asymptomatic, screening is a critical component of prevention. Recommendations for screening vary according to population [*see Table 1*].[8] Data in support of STD screening are strongest for chlamydial infection; a randomized trial has demonstrated that chlamydial screening reduces the rate of PID.[28]

Urethritis in Men

EPIDEMIOLOGY

Urethritis is one of the most common STD syndromes in men, resulting in an estimated 200,000 initial physician visits in the United States in 2000.[28] The syndrome is typically divided into urethritis resulting from infection with *N. gonorrhoeae* and nongonococcal urethritis (NGU). Rates of gonococcal urethritis in most developed nations have declined dramatically over the past 20 years, although rates in the United States and Europe now appear to be rising again, particularly among men who have sex with men.[29,30]

ETIOLOGY AND MICROBIOLOGY

Since the mid-1970s, *Chlamydia trachomatis* has been recognized as the most common cause of NGU; *C. trachomatis* has typically been isolated in 30% to 40% of cases of NGU, although the prevalence of *C. trachomatis* in men with NGU may now be declining,[31] and chlamydial infection is less common in older

men with NGU than in younger ones. In areas of the United States where the prevalence of *C. trachomatis* has declined in recent years, most patients with symptomatic urethritis have no evidence of either gonorrhea or chlamydial infection.[32] Other established causes of NGU include *Trichomonas vaginalis*, HSV-2, and, in men who engage in insertive anal intercourse, enteric pathogens. Approximately one third of men with primary genital herpes have dysuria and a urethral discharge. *T. vaginalis* is a more common cause of NGU in older men. However, HSV and *Trichomonas* combined are probably responsible for fewer than 10% of all cases of NGU. *Ureaplasma urealyticum* and *Mycoplasma genitalium* have been associated with NGU in case-control studies, but at present no tests for these organisms are commercially available.[33-35]

DIAGNOSIS

Clinical Manifestations

Clinical manifestations of urethritis include urethral discharge, dysuria, and itching at the distal urethra. Inguinal adenopathy is unusual. Likewise, fever, chills, perineal pain, scrotal mass, genital pain, and other urinary symptoms (e.g., hematuria, frequency, hesitancy, nocturia, or urgency) are unusual and should prompt consideration of alternative diagnoses, such as urinary tract infection (UTI), epididymitis, orchitis, or prostatitis. Although gonorrhea is generally associated with a more abrupt onset of symptoms and a more copious and purulent discharge than NGU, these distinctions are not reliable.

Asymptomatic and subclinical gonoccocal and chlamydial urethral infections probably play an important role in sustaining endemic levels of these STDs, but their incidence is uncertain. A prospective study of gonococcal urethritis found that only 2% of infections remained asymptomatic in the 14 days after acquisition.[36] However, cross-sectional studies have demonstrated that asymptomatic infection is common among the sexual partners of infected women[37] and, at least in some parts of the United States that have a high prevalence of gonorrhea, in the general population of young adults.[38] Prospective data on the frequency of asymptomatic chlamydial urethritis are not available, but as with gonorrhea, cross-sectional studies have demonstrated that asymptomatic or subclinical chlamydial urethritis is common.[38,39]

Physical Examination

Objective evidence of urethral inflammation should be sought in men presenting with dysuria or urethral discharge. Physical examination should include a genital examination, preferably conducted several hours after the patient last urinated; the examination should include a search for purulent or mucopurulent discharge. If no discharge is observed, the examiner should strip the urethra from the base of the penis to the urethral meatus to elicit a discharge.

Laboratory Tests

A urethral Gram stain should be performed on all men with symptoms of urethritis, even those with no discharge evident on physical examination. Urethral specimens for Gram stain are obtained by inserting a thin calcium-alginate–tipped swab 3 to 4 cm into the urethra, then rolling the swab over a glass slide. A diagnosis of urethritis is established by the presence of five or more polymorphonuclear neutrophils (PMNs) per 1,000× oil-immersion field. Alternatively, the diagnosis can be made through use of a centrifuged 10 to 15 ml first-void urine specimen; the diagnosis is established by the finding of 10 or more PMNs per 400× field on at least one of five randomly selected fields. A positive urine leukocyte esterase test is also sufficient for establishing the diagnosis. Among experienced microscopists, the finding of gram-negative intracellular diplococci (GND) is 90% to 95% sensitive and over 95% specific in detecting urethral gonorrhea in symptomatic men,[40,41] and the presence of GND establishes the diagnosis of gonorrhea [*see Figure 1*]. The Gram stain should be considered equivocal if only extracellular organisms are seen. Regardless of Gram stain findings, specific microbiologic testing should be performed for *N. gonorrhoeae* and *C. trachomatis*.

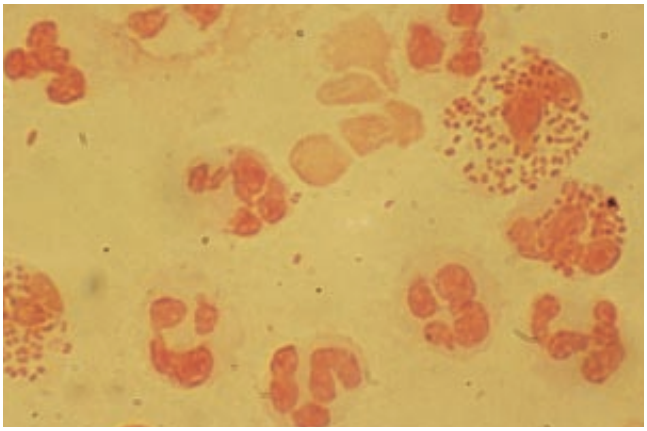

Figure 1 **This figure shows a Gram stain of a urethral discharge from a man with gonorrhea. The gram-negative intracellular diplococci are *Neisseria gonorrhoeae* organisms.**

Because it provides data on antimicrobial susceptibility, culture remains the preferred microbiologic test for gonorrhea. Nonamplified DNA probes offer the advantage of simplified specimen handling and the ability to perform both gonococcal and chlamydial testing on a single specimen. These tests have a specificity of approximately 99%, and their sensitivity is comparable to that of culture for gonorrhea.[42]

Nucleic acid amplification tests (NAATs) of urethral specimens or urine (e.g., ligase chain reaction [LCR], polymerase chain reaction [PCR], transcription-mediated amplification [TMA], and strand displacement amplification [SDA]) have sensitivities comparable or superior to that of culture; although typically more costly, these assays offer the advantage of testing without urethral swabs. In low-prevalence populations, positive NAAT results may require confirmatory testing. The sensitivities of tests for *C. trachomatis* vary widely. Although test performance varies, depending on organism burden and anatomic site of collection, culture has a sensitivity of between 50% and 90%; enzyme immunoassays and nonamplified genetic probes have a sensitivity of 40% to 75%; and NAATs have a sensitivity of more than 90%.[43,44] For that reason, NAATs are preferred, when available.

TREATMENT

Initial Management

Patients with evidence of gonococcal infection on urethral Gram stain should be treated for gonorrhea. Recommended regimens include single doses of the following agents: (1) cefixime, 400 mg orally; (2) ceftriaxone, 125 mg intramuscularly; (3) ciprofloxacin, 500 mg orally; (4) ofloxacin, 400 mg orally; and (5)

levofloxacin, 250 mg orally. Quinolone-resistant *N. gonorrhoeae* has recently emerged as a problem in Asia, the Pacific Islands, and, most recently, California. Consequently, quinolones are no longer recommended for the empirical treatment of gonorrhea in persons in these areas or in their contacts. Because of the high chlamydial coinfection rate, all patients with gonorrhea should also be treated for *Chlamydia,* unless that diagnosis has been microbiologically excluded. Treatment for presumptive chlamydial infection in men with NGU is with azithromycin in a single 1 g oral dose or doxycycline, 100 mg orally twice a day for 7 days.

Treatment of Recurrent or Persistent Urethritis

Although recognition of the pathogenic role of *C. trachomatis* has reduced a major cause of persistent or recurrent urethral symptoms after treatment for gonococcal urethritis, such symptoms continue to affect a minority of patients. Management should include questions regarding adherence to medical therapy and partner treatment, a urethral Gram stain to document evidence of urethral inflammation, and repeat testing for gonorrhea and chlamydial infection. Consideration should be given to possible trichomonal or herpes infection. Erythromycin, 500 mg four times a day for 7 days, with or without a single 2 g dose of metronidazole, is the recommended empirical treatment in patients who are believed to have adhered to their initial regimen and who have not been reexposed to gonorrhea or chlamydial infection.[8]

Lower Genital Tract Infections in Women

Women with STDs involving the lower genital tract may present with dysuria, urethritis or vulvovaginitis, and abnormal or altered vaginal discharge. The initial evaluation of women with these complaints seeks to differentiate urethritis, cystitis, vulvovaginitis, and cervicitis and to identify women with upper genitourinary tract infections (e.g., pyelonephritis or salpingitis). Subsequent microbiologic testing and treatment are guided by this evaluation.

Syndromes Causing Dysuria and Urethritis

STDs that can cause dysuria in women include vulvitis resulting from candidal infection and genital herpes and urethritis caused by *C. trachomatis* or *N. gonorrhoeae*. Dysuria and sterile pyuria (the presence of leukocytes and the absence of more than 10^2 organisms/ml of conventional urinary pathogens in a midstream urine specimen) in a woman are consistent with a diagnosis of urethral infection.[45] Other factors suggesting urethral infection include the absence of other symptoms and signs typical of UTI; risk factors or risk markers for chlamydial infection (young age, new or multiple sexual partners, failure to consistently use condoms, African-American race); symptoms lasting 7 days or longer; purulent vaginal discharge; pelvic pain or tenderness; and evidence of mucopurulent cervicitis.

Women presenting with a syndrome of dysuria and sterile pyuria should be tested for gonorrhea and chlamydial infection. Because HSV-2 can cause urethritis in women, particularly in women with primary HSV infection, the possibility of genital herpes should also be considered. HSV or candidal vulvitis typically causes external, as opposed to internal, dysuria, which occurs when urine comes in contact with the introitus or labia. Women with these infections typically have vulvar irritation or lesions; vaginal discharge; or a history of either HSV or candidal vaginitis.

In the differential diagnosis of dysuria in women, particular attention should be given to bacterial UTI, which is the most common cause of dysuria. Symptoms, signs, and laboratory findings that support the diagnosis of bacterial cystitis include urinary frequency or urgency, a history of UTI, duration of symptoms of less than 4 days, gross or microscopic hematuria, the patient's belief that she has a UTI, suprapubic tenderness, a positive urine nitrite test, and evidence of typical urinary tract pathogens on Gram stain or urine culture.[46-48] Fever or flank pain in a woman with dysuria and other findings consistent with UTI suggests pyelonephritis. Vaginal discharge or irritation is not typical of UTI.

Diagnostic testing for gonococcal and chlamydial urethritis in women should be based on specific tests [*see* Laboratory Tests, *above*]. In women with no evidence of pelvic inflammatory disease (PID), treatment is identical to that for men [*see* Treatment, *above*].

Syndromes Causing Vulvovaginitis and Vaginal Discharge

Abnormal vaginal discharge is one of the most common reasons for women to seek medical attention. Since the 1960s, the number of women receiving care for vulvovaginal infections increased approximately threefold. In 2000, an estimated three million initial physician office visits in the United States were prompted by vulvovaginal infections.[28]

The most common causes of an abnormal vaginal discharge are bacterial vaginosis (BV), vulvovaginal candidiasis (VVC), and trichomonal vaginitis (TV) [*see Table 2*]. Both BV and trichomoniasis have been associated with preterm labor.[49,50] However, to date, treatment of these infections has not definitively been shown to decrease preterm delivery.[51-54] BV has been identified as a risk factor for PID, and both BV and trichomoniasis may increase the risk of HIV acquisition and transmission.[55-59] Consequently, these diagnoses have assumed new importance in HIV prevention.

Evaluation of women with vaginal complaints should include a pelvic examination and a directed laboratory evaluation. Although these infections tend to have different clinical features, a study of patients triaged and selectively treated after a telephone assessment found poor agreement between the diagnosis made by nurses and other providers and the diagnoses obtained after examination and testing.[60] Similarly, a study of women purchasing over-the-counter antifungal therapies found that only one third had vaginal candidiasis, and 53% had a diagnosis other than vulvovaginal candidiasis.[61] These findings emphasize the need for a complete evaluation in women complaining of vaginal discharge or discomfort. Less frequent causes of vaginitis include atrophic vaginitis with secondary bacterial infection, vaginitis associated with foreign bodies or toxins, *Staphylococcus aureus* vaginitis associated with toxic-shock syndrome, group A *Streptococcus*–associated vaginitis, desquamative vaginitis (clindamycin responsive), erosive lichen planus, allergic vaginitis, vaginitis associated with autoimmune disease, and idiopathic vaginitis.[62]

Bacterial Vaginosis

BV is the most common cause of vaginal discharge in women of reproductive age. Prevalence studies have found BV in 10% to 40% of women tested, with higher rates of infection in women tested in STD clinics and in African Americans. Douching and use of intrauterine devices (IUDs) have also been associated with BV.[63]

Table 2 Clinical Features and Management of Vulvovaginitis

Feature	*Normal Vaginal Examination*	*Vulvovaginal Candidiasis*	*Trichomonal Vaginitis*	*Bacterial Vaginosis*
Etiology	Uninfected; lactobacilli predominate	*Candida albicans* most common; candidiasis caused by species other than C. *albicans* may be increasing	*Trichomonas vaginalis*	Loss of normal vaginal lactobacilli; associated with *Gardnerella vaginalis*; increased anaerobic bacteria and mycoplasmas
Symptoms	None	Abnormal vaginal discharge, external dysuria, vulvar itching, pain and/or irritation	Yellow vaginal discharge, external dysuria, vulvar itching	Increased, abnormal, or malodorous vaginal discharge
Discharge Amount Color Consistency	 Variable Clear or white Nonhomogeneous, patchy (floccular)	 Scant White Clumped; adherent plaques	 Profuse Yellow Homogeneous or frothy	 Moderate White or gray Adherent, homogeneous discharge that uniformly coats vagina
Inflammatory findings	None	Vulvar erythema, edema, or fissure; erythema of vaginal epithelium; introitus	Erythema of vaginal and vulvar epithelium; colpitis macularis	None
pH of vaginal fluid*	Usually ≤ 4.5	Usually ≤ 4.5	Usually > 4.5	Usually > 4.5
Amine (fishy) odor with 10% KOH	None	None	May be present	May be present
Microscopy	Normal epithelial cells; lactobacilli predominate	Leukocytes, epithelial cells; mycelia or pseudomycelia† (50%–85% of cases)	Leukocytes; trichomonads seen in 50%–70% of culture-positive cases	Clue cells (81%–94% of cases); few leukocytes; lactobacilli outnumbered by mixed flora
Recommended treatment	—	Intravaginal imidazole (butoconazole, clotrimazole, miconazole, terconazole, tioconazole) for 3–7 days; fluconazole, 150 mg p.o. (single dose)	Metronidazole, 2 g p.o. (single dose); metronidazole, 500 mg p.o., b.i.d., for 7 days	Metronidazole, 500 mg p.o., b.i.d., for 7 days; metronidazole gel, 0.75%, 5 g intravaginally each night for 5 nights; clindamycin cream 2%, 5 g intravaginally each night for 7 days
Sexual partner treatment	—	None if asymptomatic; topical treatment if candidal dermatitis of the penis or balanitis is detected	Metronidazole, 2 g orally (single dose)	None

*pH determination is not useful if blood is present.

†To detect fungal elements, vaginal fluid is digested with 10% KOH before microscopic examination; to examine for other features, fluid is mixed (1:1) with normal saline. Culture may be necessary if microscopy results are negative and the suspicion of *Candida* is high.

Pathophysiology and transmission The etiology of BV is unknown. The syndrome constitutes a disturbance in normal vaginal bacterial flora characterized by a reduction in the concentration of hydrogen peroxide–producing lactobacilli[64] and increased growth of mixed bacterial flora that include *Gardnerella vaginalis,* anaerobes, and *Mycoplasma hominis*. There is evidence that BV can be transmitted sexually. This evidence includes the following: studies have demonstrated that the inoculation of women with vaginal fluid from another woman with BV can induce the syndrome[65,66]; there is a high prevalence of BV in patients being treated at STD clinics; there are high rates of concordant BV among lesbian sexual partners[67]; longitudinal studies have associated BV with having higher numbers of sexual partners and with having new sexual partners[68-70]; and most studies have found that BV is absent in virgins.[71] Evidence against sexual transmission includes the lack of benefit from treating sexual partners[72-74] and inconsistent associations with levels of sexual activity.

Diagnosis Physical examination of women with BV typically reveals a homogeneous, white, uniformly adherent vaginal discharge.[63] The Amsel criteria for diagnosis of BV include the following: (1) presence of a homogeneous, thin vaginal discharge; (2) vaginal pH greater than 4.5; (3) clue cells (bacteria attached to vaginal epithelial cells on wet mount); and (4) presence of an amine (fishy) odor when vaginal fluid is mixed with 10% potassium hydroxide (KOH).[71,75-77] The presence of three of the four criteria establishes the diagnosis [*see Table 3*].

Treatment BV is treated with metronidazole. A meta-analysis found higher cure rates with a dosage of 1 g a day for 7 days than with a single 2 g dose (82% versus 73%).[63] Intravaginal metronidazole and intravaginal clindamycin offer efficacy comparable to 7-day courses of metronidazole, with fewer side effects, but are not effective in the treatment of trichomoniasis and are typically more costly. Recurrence of BV is common, occurring in 50% to 70% of cases. Multiple randomized trials have failed to demonstrate any benefit from treating male partners.[72-74]

Trichomoniasis

T. vaginalis is a sexually transmitted protozoan. In the United States, the number of women seeking care for trichomonal vaginitis declined by over 50% from 1966 to the mid-1980s; in 2000, physicians in the United States saw an estimated 200,000 patients with TV.[28] A cross-sectional study of 13,816 pregnant women in the United States found TV in 13%; the vast majority of those infections were subclinical or asymptomatic. Risk fac-

Table 3 Amsel Criteria for the Diagnosis of Bacterial Vaginosis[71,75,77]

Criterion	*Sensitivity (%)*	*Specificity (%)*
Homogeneous, thin vaginal discharge	52–65	71–97
Vaginal pH > 4.5	92–97	53–62
Clue cells on vaginal wet mount	81–94	94–98
Amine odor when vaginal fluid is mixed with 10% potassium hydroxide (KOH)	43–84	98—99

Note: the presence of three of these four criteria establishes the diagnosis of bacterial vaginosis.

tors for TV included African-American ethnicity, cigarette smoking, unmarried status, and lower educational level.[77] Untreated infections in women are thought to persist for a median of 3 to 5 years.[78]

Diagnosis Clinical manifestations of trichomonal infection include yellow vaginal discharge and vulvar itching. Neither is highly sensitive or specific. On physical examination, signs associated with *Trichomonas* infection include frothy or purulent vaginal discharge, which is sometimes profuse; vulvar or vaginal erythema; and cervical mucopus.[79,80] All of these signs have far greater specificity than sensitivity. The finding of colpitis macularis—punctate cervical hemorrhages and ulcers, sometimes referred to as strawberry cervix—has a specificity of 99% for TV but is seen in fewer than 5% of patients on unaided physical examination; colpitis macularis is much more readily visible on colposcopy.[79] In expert hands, a finding of motile *Trichomonas* on wet-mount examination has a sensitivity of 50% to 70%, although in clinical practice, wet-mount examination is usually considerably less sensitive. Culture on Diamond medium is the traditional diagnostic gold standard, but this technique is not available in most practice settings. Recently, InPouch, a relatively simple and inexpensive culture method, became available. The sensitivity of InPouch is comparable to that of Diamond medium and superior to that of wet mount.[81] PCR has been successfully used in research settings, but no NAAT is commercially available at present. Antigen detection tests are also under investigation.

Treatment A single 2 g dose of metronidazole is the treatment of choice for TV. Reported cure rates are 82% to 88%.[80] Sexual partners should be treated concurrently, and couples should be advised to abstain from sex for 1 week after treatment. Topical metronidazole is not effective.[82] Resistance to metronidazole occurs infrequently, and most cases respond to prolonged courses of metronidazole therapy. Some authors have reported successful treatment of metronidazole-resistant cases using either tinidazole or paromomycin cream.[83]

Vulvovaginal Candidiasis

Because VVC is not a reportable infection, only limited epidemiologic data are available. In the United States, a study of female university students found that over half experienced at least one episode of VVC by 25 years of age,[84] and 6.5% of women who participated in a national random-digit–dialing survey reported that a health care provider had told them they had candidal vaginitis at least once in the preceding 2 months.[85] Higher rates of VVC have been observed in African Americans and in users of oral contraceptives, vaginal sponges, or IUDs.[86] Although VVC is not clearly identified as an STD, it has been associated with the onset of sexual activity in young women and with cunnilingus.[84,86] Other predisposing factors include recent use of antibiotics; diabetes mellitus; pregnancy; and immunodeficiency, including that from HIV infection.

Diagnosis Vulvovaginal pruritus is generally the most common symptom of VVC.[87] Other findings sometimes associated with VVC include a cottage-cheese–like discharge; external dysuria; external genital burning or pain; perineal edema or erythema; and vulvar erythema, edema, and fissures.[87,88] However, several studies have reported the absence of any signs or symptoms significantly associated with VVC.[4,89] As a result, the diagnosis requires microscopic and, at times, microbiologic assessment. A 10% KOH preparation of fluid taken from the vagina has a sensitivity of 50% to 85% in the diagnosis of VVC[90,91]; if this test is negative but the clinical picture is consistent with VVC and there is no alternative diagnosis, culture for yeast should be performed.

Treatment Topical azoles (e.g., butoconazole, clotrimazole, miconazole, econazole, tioconazole, and terconazole) are 80% to 90% effective in treating VCC [*see Table 2*]. Most of these agents are available over the counter. No clear advantage favors one azole over another. Oral azoles (fluconazole or itraconazole) are comparably or slightly more effective and may be more convenient, but these agents also pose a small risk of systemic reactions. Because there are no compelling data favoring any one agent or route of administration, patient preference should guide the choice of treatment. Immunosuppressed patients and those with candidal infections caused by a species other than *Candida albicans* may require more prolonged therapy (e.g., 14 days).

Long-term therapy is indicated for patients with recurrent VVC, which is defined as four or more episodes of VCC in a year. Approximately 5% of women with VVC experience recurrences. Treatment may require 14 days of induction therapy followed by once-weekly maintenance therapy. Patients with *C. glabrata* VVC who do not respond to prolonged courses of azole therapy may benefit from topical boric acid (600 mg once a day for 2 weeks) or topical flucytosine.[92]

Mucopurulent Cervicitis

Mucopurulent cervicitis (MPC) is an inflammatory process affecting the columnar epithelium and subepithelium of the endocervix and adjacent exocervix. As with NGU in men, MPC is common and has most frequently been associated with *N. gonorrhoeae* or *C. trachomatis* and, less frequently, with HSV or *T. vaginalis*. Unlike NGU, MPC typically produces no symptoms; or it may produce nonspecific symptoms, such as a yellow vaginal discharge, that often do not prompt women to seek treatment. In recent years, as the prevalence of gonorrhea and chlamydial infections have decreased in some settings, MPC with no defined microbiologic etiology has come to constitute the majority of cases.[4] MPC is important because of its association with known infections and because patients with MPC have an elevated risk of PID and adverse pregnancy outcome.

Diagnosis Different diagnostic criteria have been used for MPC. According to current CDC guidelines, the diagnosis of

MPC is made on the basis of a finding of a visible purulent or mucopurulent exudate on cervical examination or on endocervical swab. The finding of cervical mucopus is 28% to 52% sensitive and 82% to 94% specific for the presence of either *C. trachomatis* or *N. gonorrhoeae.*[88,93,94] Some investigators use additional criteria for MPC, including a finding of from 20 to 30 PMNs per high-power field (hpf) on cervical Gram stain or easily induced cervical bleeding.[4,94] These factors have been associated with the likelihood of *C. trachomatis* or *N. gonorrhoeae* infection, but they have not consistently been included as diagnostic criteria of MPC; with regard to the use of cervical Gram stain, these findings have not consistently been useful in defining a population in need of empirical therapy.

Treatment The decision to treat MPC is based largely on the local prevalence of *C. trachomatis* or *N. gonorrhoeae* and on the patient's risk. In areas where both gonorrhea and chlamydial infection are common, empirical therapy should be directed at both pathogens. In areas where gonorrhea rates are low, treating for *Chlamydia* infection alone is reasonable. Recent evidence suggests that in areas where the prevalence of both infections is low, older patients (i.e., those older than 30 years) suspected of having MPC need not be treated until microbiologic test results are available, provided follow-up care is ensured.[94]

Pelvic Inflammatory Disease

PID is an inflammatory process involving a variable combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. PID can be blood-borne (e.g., tuberculosis) or result from extension of an intra-abdominal process. At present, however, PID most often develops when bacteria ascend from the vagina or cervix into the endometrium, fallopian tubes, and pelvic peritoneum. Although the number of women seeking care for PID has declined by over 25% since the 1980s, 8% of participants in the 1995 National Survey of Family Growth, a national representative sample of United States women, reported a history of PID.[95] Identified risk factors for PID include a previous history of PID, higher numbers of lifetime sex partners, douching, and a history of bacterial STD. In the past, IUD use was identified as a risk factor, but its importance beyond the first 30 days after insertion is now controversial; a recent case-control study found no association between the use of currently available copper IUDs and the occurrence of PID.[96] Gynecologic procedures that disrupt the protective cervical barrier (e.g., pregnancy termination, IUD insertion, dilatation and curettage, and hysterosalpingography) elevate the risk of PID and may lead to PID in the absence of classic sexually transmitted pathogens.

MICROBIOLOGY

Studies of PID conducted in the United States and Europe in the 1980s typically implicated *C. trachomatis, N. gonorrhoeae,* or both as a cause of PID in approximately half of cases.[97] Frequently, these bacteria were part of a polymicrobial infection involving diverse normal vaginal flora, including anaerobic bacteria, facultative anaerobes, and genital mycoplasmas. *M. genitalium* has been associated with endometritis and PID.[98] *Actinomyces israelii* is a cause of PID in women with IUDs.

DIAGNOSIS

The diagnosis of PID is difficult. To date, studies have been unable to identify any single clinical finding or constellation of findings that allow accurate identification of women with PID.[99,100] Moreover, PID studies have typically enrolled only women with overt disease and, consequently, have not provided an accurate picture of the full spectrum of the clinical entity. Indeed, most cases of PID probably go undiagnosed. Approximately two thirds of women with postinfectious fallopian tube occlusion report no history of PID, although many have sought care for abdominal pain.[101] When the diagnosis is made clinically, it may not be supported by surgical findings. Only 60% to 70% of women with clinically diagnosed PID typically have laparoscopic evidence of PID.[102]

In clinically detected cases, the cardinal symptom of PID is pelvic or abdominal pain. The pain is typically dull or aching. Onset can be acute or subacute and frequently occurs at the beginning of menses. Typically, patients present after having symptoms for less than 2 weeks. In a Swedish study of 623 patients with PID, all had pelvic or abdominal pain, cervical motion tenderness, and increased inflammatory cells in vaginal or cervical secretions. Other symptoms and laboratory findings included an erythrocyte sedimentation rate (ESR) of 15 mm/hr or higher (75%), leukocytosis greater than 10,000/ml (60%), abnormal vaginal discharge (55%), fever higher than 38° C (100.4° F) (41%), abnormal vaginal bleeding (36%), dysuria (19%), vomiting (10%), and anorectal symptoms (anorectal pain, tenesmus, or rectal bleeding or discharge) (7%).[103] A large study showed that only temperatures higher than 38° C (100.4° F) had a specificity of more than 90% for the diagnosis of PID, although its sensitivity was only 11%.[103]

The differential diagnosis of PID includes other causes of abdominal or pelvic pain. Depending on the clinical circumstances, the physician may need to consider such disorders as appendicitis, endometriosis, bleeding corpus luteum, pelvic adhesions, gastroenteritis, and ectopic pregnancy.

Although laparoscopy has been the traditional gold standard for diagnosing PID, many women with abnormal fimbrial biopsies have normal results on laparoscopy. Moreover, some women have histologic evidence of endometritis without salpingitis,[104] which suggests that laparoscopy may be insensitive for the detection of milder cases or of PID that is restricted to the uterus.

Transvaginal ultrasound (TVUS) should be performed when symptoms are severe, when the physical examination reveals a pelvic mass, or when the diagnosis of PID is uncertain. Studies assessing the performance of different imaging modalities in the diagnosis of PID have been small, with no single study enrolling more than 50 patients with the diagnosis.[102] Small studies of TVUS have reported sensitivities of 81% to 93%, but specificities have been highly variable, ranging from 5% to 100%, with the test performing best in patients with more severe infection.[102] A case-control study of power Doppler TVUS reported a sensitivity of 100% and a specificity of 80%,[105] suggesting it may offer advantages over conventional TVUS. In women with tubo-ovarian abscess, repeat TVUS is often indicated to assess response to therapy. Small studies of CT and pelvic MRI have also reported high sensitivity and specificity. Laparoscopy should be performed if appendicitis, ectopic pregnancy, or ruptured abscess is suspected; laparoscopy should also be considered in women who do not respond to antibiotics.

TREATMENT

Because the diagnosis of PID can be challenging, the sequelae of PID can be severe, and treatment is safe and inexpensive, all

Table 4 Treatment Regimens for Pelvic Inflammatory Disease

Route	*Regimen*
Parenteral	Cefotetan, 2 g I.V. q. 12 hr *or* Cefoxitin, 2 g I.V. q. 6 hr *plus* Doxycycline, 100 mg p.o. or I.V. q. 12 hr
	Clindamycin, 900 mg I.V. q. 8 hr *plus* Gentamicin, 2 mg/kg I.V. or I.M. once, then 1.5 mg/kg I.V. q. 8 hr (single daily dose may be used)
	Ofloxacin, 400 mg I.V. q. 12 hr *or* Levofloxacin, 500 mg I.V. q.d. *plus* Doxycycline, 100 mg p.o. or I.V. q. 12 hr *with or without* Metronidazole, 500 mg I.V. q. 8 hr *or* Ampicillin-sulbactam, 3 g I.V. q. 6 hr
Oral	Ofloxacin, 400 mg p.o., b.i.d. *or* Levofloxacin, 500 mg I.V. q.d. for 14 days *with or without* Metronidazole, 500 mg p.o., b.i.d., for 14 days
	Ceftriaxone, 250 mg I.M. once *or* Cefoxitin, 2 g I.M. once with probenecid, 1 g p.o. *plus* Doxycycline, 100 mg b.i.d. for 14 days *with or without* Metronidazole, 500 mg p.o., b.i.d., for 14 days

*Parenteral therapy can be discontinued after the patient improves clinically, but doxycycline should be continued for 14 days.

patients suspected of having PID should undergo treatment for PID. The CDC recommends initiating treatment of PID in all sexually active young women with adenexal tenderness or cervical motion tenderness.[8] These criteria are likely to be sensitive, but they are also quite nonspecific.[100]

Treatment for PID is directed against *C. trachomatis*, *N. gonorrhoeae*, gram-negative facultative anaerobes, vaginal anaerobes, and streptococci. Numerous regimens have been found acceptable [*see Table 4*]. A recent randomized trial in women with mild to moderate PID found no advantage of inpatient therapy with intravenous cefoxitin and doxycycline over outpatient therapy with a single intramuscular dose of cefoxitin and probenecid followed by oral doxycycline.[106] Indications for hospitalization include the following: (1) inability to exclude a possible surgical emergency (e.g., appendicitis), (2) pregnancy, (3) failure to respond to oral antibiotics, (4) inability to tolerate or adhere to outpatient oral therapy, (5) tubo-ovarian abscess, and (6) inability to reliably ensure follow-up. Patients should show significant improvement within 3 days after starting therapy. Those receiving oral therapy should be reevaluated within 72 hours. Treatment should include efforts to ensure that sexual partners also receive therapy. In addition, patients with *Chlamydia* or *N. gonorrhoeae* infections should be rescreened for those infections 10 to 18 weeks after treatment.

COMPLICATIONS

Although the vast majority of women with PID in developed nations recover fully, long-term sequelae are common; these sequelae include tubal infertility, ectopic pregnancy, and chronic pelvic pain. In the largest study of PID sequelae performed to date, Swedish investigators performed laparoscopy on 1,730 women with suspected PID and then followed them for a mean of 6.9 years. After a single episode of PID, 8% of patients suffered tubal infertility, compared with 1% of control subjects in whom there was no laparoscopic evidence of PID. Of PID patients who subsequently became pregnant, 10% had an ectopic pregnancy, compared with 1% of women without PID. Similarly, pelvic pain lasting longer than 6 months occurred in 17% of women with PID but in only 2% of control subjects.[107] Recurrent episodes of PID multiplied the risk of sequelae [*see Figure 2*], as did more severe PID and longer duration of symptoms before treatment.

Genital Ulcer Disease

Genital ulcers are a frequent presentation of STDs. Epidemiologic studies, as well as studies measuring HIV shedding, suggest that genital ulcer disease (GUD) increases the risk of both HIV acquisition and HIV transmission.[3,108] As a result, the prevention and treatment of GUD is a high public health priority.

ETIOLOGY

Herpes, syphilis, and chancroid are the major causes of genital ulcer disease. Less common causes of GUD include lymphogranuloma venereum (infection with L-serotypes of *C. trachomatis*), donovanosis (infection with *Calymmatobacterium granulomatis*), superinfection of ectoparasitic infections, trauma, neoplasm, Behçet syndrome, Reiter syndrome, and fixed drug eruptions (e.g., from doxycycline or sulfonamides).

Herpes is the most common cause of GUD in developed nations. In the United States in 2000, over two million people sought care for genital herpes. In contrast, a total of 5,979 cases of primary and secondary syphilis and 82 cases of chancroid were reported to the CDC.[28] A 1996 study of 516 STD clinic patients

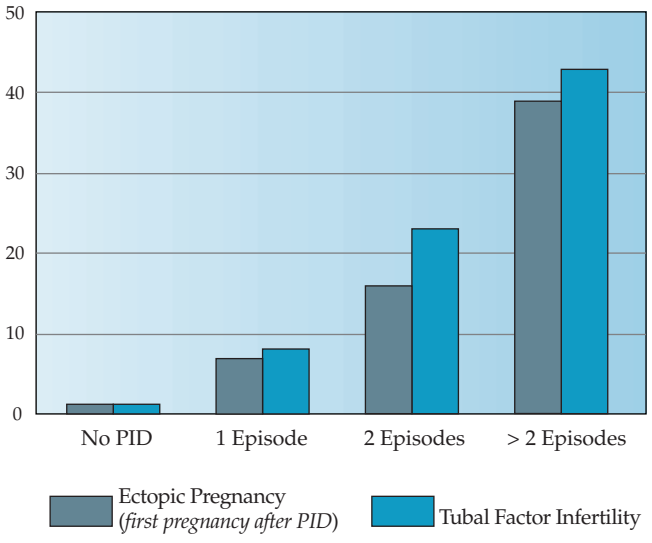

Figure 2 **Proportion of women experiencing an ectopic pregnancy or tubal infertility by number of episodes of pelvic inflammatory disease (PID) among 1,282 patients with PID and 448 control subjects.[97,107]**

Table 5 Clinical Features and Laboratory Diagnosis of Genital Ulcers

Disease	*Etiology*	*Incubation Period*	*Number of Lesions*	*Primary Lesion Type*	*Ulcer Diameter*	*Ulcer Characteristics*	*Pain or Tenderness*	*Lymphadenopathy*	*Laboratory Diagnosis*
Syphilis	*Treponema pallidum*	9–90 days	Usually one	Papule	5–15 mm	Superficial or deep; sharply demarcated; indurated; nonvascular, purulent base	Uncommon	Firm, nontender, bilateral	Darkfield microscopy, RPR/VDRL and FTA, MHA-TP
Herpes	HSV-1 or -2	2–7 days	Multiple, may coalesce	Vesicle	1–2 mm	Superficial; erythematous edges, no induration	Frequently tender	Firm, tender, small; often bilateral with first episode	DFA, culture, serology
Chancroid	*Haemophilus ducreyi*	1–14 days	Multiple, may coalesce	Pustule	Variable	Deep; irregular, undermined edges; purulent base bleeds easily	Usually tender	Tender, may be fluctuant, loculated; usually unilateral	Culture of ulcer base,* NAAT (e.g., PCR, LCR, TMA, SDA)
LGV	L-serotypes of *Chlamydia trachomatis*	3 days to 6 wk	Usually one	Papule, pustule, or vesicle	2–10 cm	Very rarely seen, because of rapid healing; can be superficial, deep, elevated, round, or oval	Variable	Tender, may suppurate or form sinus tracts; loculated, usually unilateral; more common in men than women	Culture, PCR, microimmunofluorescent antibody
Donovanosis	*Calymmatobacterium granulomatis*	1–4 wk (up to 6 mo)	Variable	Papule	Variable	Extensive, indolent ulcer with granulation tissue; elevated, rolled irregular edges on raised ulcer; beefy-red vascular base bleeds easily†	Uncommon	None; pseudobuboes	Giemsa or Wright stain of tissue smear

*Culture of material from bubo seldom positive.

†Less common variants can be hypertrophic, necrotic, or sclerotic.

DFA—direct fluorescent antibody HSV—herpes simplex virus LGV—lymphogranuloma venereum LCR—ligase chain reaction MHA-TP—microhemagglutination assay–*T. pallidum* NAAT—nucleic acid amplification test PCR—polymerase chain reaction RPR—rapid plasma reagin SDA—strand displacement amplification TMA—transcription-mediated amplification VDRL—Venereal Disease Research Laboratory

with genital ulcers found that 62% had HSV, 10% had syphilis, 3% had both syphilis and herpes, 3% had chancroid, and 22% had no identified pathogen.[109]

Traditionally, chancroid and syphilis have been the most common cause of genital ulcers in most developing nations. However, recent studies undertaken in sub-Saharan Africa have documented the increasing importance of herpes as a cause of GUD, particularly in areas where HIV is highly prevalent.[110]

DIAGNOSIS

Clinical Manifestations

When examining patients with genital ulcers, clinicians should note the number and depth of lesions; the presence of vesicles, induration, necrotic material on the ulcer bed, or an undermined ulcer border (i.e., the ulcer invades beneath the superficial edges); the presence or absence of pain; and any associated adenopathy [*see Table 5*]. Although physical findings can be helpful, different GUD etiologies cannot be reliably distinguished by physical examination alone.[111]

Laboratory Tests

Because physical findings are unreliable, clinical assessment should be supported by laboratory evaluation. The laboratory evaluation of GUD typically concentrates on herpes and syphilis. Chancroid, donovanosis, or LGV should be considered if the patient lives in or has traveled to an area where one of those infections is common or if the physical findings are highly suggestive of one of those infections.

When possible, laboratory evaluation should include dark-field microscopy, serologic testing for syphilis (e.g., rapid plasma reagin [RPR] or venereal disease research laboratory (VDRL); and fluorescent treponemal antibody [FTA] or microhemagglutination assay for antibody to *T. pallidum*), and culture for herpes. If available, RPR should be performed. Dark-field microscopy is 70% to 95% sensitive in detecting treponemes, but sensitivity is highly dependent on the expertise of the technician. Culture should seek to distinguish between HSV-1 and HSV-2, because the former typically produces a less severe infection with fewer recurrences. This is particularly important in light of recent data that suggest that HSV-1 is an increasingly common cause of genital herpes.[112] If initial evaluation does not establish a cause of genital ulcers and the clinician's suspicion for chancroid, LGV, or donovanosis remains low, further diagnostic efforts should focus on ruling out genital herpes. Several type-specific serologic tests that target the HSV glycoprotein G-2 (gG-2) are now available.[113] Patients who have no serologic evidence of HSV-2 may have primary infections. Only limited data are available on how soon seroconversion can be detected by commercially available type-specific tests, but the median time from exposure to seroconversion appears to be 2 to 3 weeks. Patients with a clinical syndrome consistent with genital herpes who test negative for HSV-2 should be retested after 6 to 12 weeks if an intervening recurrence of genital ulcers does not establish the diagnosis of HSV infection and the clinical suspicion for genital herpes is high. Older HSV serologic tests are neither sensitive nor specific and should not be used. Clinicians should be aware that type-specific serologic tests have not been studied extensively for HSV-2 screening. Given the

imperfect specificity of these tests, it is likely that widespread testing in populations in which the prevalence of HSV-2 is low will result in large numbers of false positive test results. Because of poor specificity, a positive HSV-2 serologic test result in a patient without signs or symptoms of genital herpes or definite exposure to HSV-2 should be interpreted with caution.

TREATMENT

Treatment of patients with genital ulcers is usually empirical [*see Table 6*]. If patients have physical findings suggestive of syphilis, are residents of or recent travelers to areas where syphilis remains common, or are members of groups at high risk for syphilis (e.g., men who have sex with men, as well as commercial sex workers or their clients), treatment should include benzathine penicillin G, 2.4 million units intramuscularly, and a regimen for genital herpes [*see Table 7*]. If the suspicion for syphilis is low and follow-up can be ensured, initial empirical treatment can focus on genital herpes alone. The treatment and follow-up of patients with genital herpes and syphilis are discussed in other subsections.

Patients with genital herpes should be counseled about the recurrent nature of the infection and advised that subclinical viral shedding is common. The median recurrence rate in the first year after HSV-2 acquisition is 0.33 recurrences monthly.[114] During the first 6 months after HSV-2 acquisition, virus can be isolated by culture on 6% of days and by PCR on 20% to 35% of days.[115] It is not known to what extent HSV can be transmitted by patients whose cultures are negative and whose PCR results are positive. The American Social Health Association Web site (http://www.ashastd.org) is an excellent source of information on STD in general and genital herpes in particular, and it has information on support services for persons with genital herpes.

STDs in Men Who Have Sex with Men and Anorectal STDs in Women

Although surveillance data on STDs in men who have sex with men (MSM) are limited, cases of gonorrhea and syphilis in MSM in selected cities in the United States declined by more than 10-fold in the decade following the first recognition of AIDS.[116] More recently, numerous cities in the United States and Europe have reported rising rates of STDs in MSM.[30,117] Limited data suggest that HIV transmission may also be increasing.[118] Because STDs can enhance HIV transmission, the control of STDs in MSM is a public health priority. Moreover, an STD can be a sentinel event, alerting the clinician to a patient's risk of acquiring HIV infection or transmitting it to others.

GENERAL CONSIDERATIONS IN MSM

Several aspects of the care of MSM merit consideration. First, it is imperative that clinicians adopt a nonjudgmental, direct approach when discussing sexual behavior. In addition to the questions typically included in a sexual history, clinicians should ask patients about the HIV status of their sexual partners and about their anal sexual exposure. The latter can be determined by asking, "Are you a top, a bottom, or both a top and a bottom?" The term top refers to a man who practices insertive anal sex; a bottom practices receptive anal sex.

Second, the spectrum of STD is wider in MSM than in heterosexuals. Several pathogens that are rarely sexually transmitted among heterosexuals are relatively common causes of STD in MSM. These include hepatitis A virus, *Shigella* species, *Salmonella* species, *Campylobacter* species, *Giardia lamblia*, and *Entamoeba histolytica*. *Strongyloides stercoralis* and *Enterobius vermicularis* are occasionally transmitted sexually in MSM.

Third, the anus is a more common sexual organ for MSM than it is for heterosexuals. Consequently, STD should figure prominently in the differential diagnosis of MSM who present with anorectal symptoms, and rectal screening should be part of standard STD screening in MSM.[24] Finally, although there are no guidelines for regular STD screening of heterosexual men, the CDC currently recommends annual STD screening for MSM [*see Table 1*].[8]

PROCTITIS, PROCTOCOLITIS, AND ENTERITIS

Although anorectal STD occurs in both men and heterosexual women, anal STD syndromes are more common in MSM. The symptoms of anorectal infection vary, depending on the level

Table 6 Treatment of Genital Ulcers

Disease	*Regimen*
Syphilis	Benzathine penicillin G, 2.4 million U I.M.*
Chancroid	Azithromycin, 1 g p.o. once *or* Ceftriaxone, 250 mg I.M. once *or* Ciprofloxacin, 500 mg p.o., b.i.d., for 3 days *or* Erythromycin, 500 mg p.o., t.i.d., for 7 days
Lymphogranuloma venereum	Doxycycline, 100 mg p.o., b.i.d., for 21 days
Donovanosis	Doxycycline, 100 mg p.o. for at least 3 wk or until lesion is healed *or* Trimethoprim-sulfamethoxazole, double strength (800 mg/160 mg), one tablet p.o., b.i.d., for at least 3 wk or until lesion is healed
Herpes	See Table 7

Note: treatment should always include evaluation and treatment of sexual partners.
*For primary or secondary syphilis.

Table 7 Treatment of Genital Herpes in Immunocompetent Patients

Primary herpes	Acyclovir, 400 mg p.o., t.i.d., for 7–10 days *or* Valacyclovir, 1 g p.o., b.i.d., for 7–10 days *or* Famciclovir, 250 mg p.o., t.i.d., for 7–10 days
Recurrent herpes	Acyclovir, 800 mg p.o., b.i.d., for 5 days *or* Acyclovir, 800 mg p.o., t.i.d., for 2 days *or* Valacyclovir, 1g p.o., q.d., for 5 days *or* Valacyclovir, 500 mg p.o., b.i.d., for 3–5 days *or* Famciclovir, 125 mg p.o., t.i.d., for 5 days

and extent of anatomic involvement and on the microbiologic etiology.[119] Proctitis is limited to the rectum. It results from direct inoculation of pathogens through anal sex and presents as some combination of rectal pain, constipation, hematochezia, tenesmus, and mucopurulent rectal discharge. Sexually transmitted proctitis is caused by gonorrhea, chlamydial infection (non-LGV), syphilis, or HSV. In proctocolitis, the inflammatory process extends to the colon. As a result, in addition to the symptoms of proctitis, patients may complain of diarrhea, abdominal pain, and bloating or nausea. Most cases of proctocolitis result from oral-genital or oral-anal sex (anilingus, or so-called rimming) and are caused by *Shigella*, *Salmonella*, or *Campylobacter* species; *E. histolytica*; or LGV serovars of *C. trachomatis*. *G. lamblia* infection involves the small bowel alone (enteritis) and typically presents as diarrhea, abdominal pain, and bloating or nausea in the absence of rectal symptoms. The differential diagnosis in patients presenting with symptoms of colitis or proctocolitis should include *Clostridium difficile* infection and inflammatory bowel disease. In persons with HIV infection and $CD4^+$ T cell counts less than $50/mm^3$, cytomegalovirus infection is also a possibility. Depending on their level of immunosuppression, HIV-infected patients presenting with enteritis should also be evaluated for *Mycobacterium avium* complex, cryptosporidium, *Isospora belli, Cyclospora cayetanensis,* and *Microsporidia* organisms.

DIAGNOSIS

History and Physical Examination

Evaluation of a patient with anorectal symptoms should include questions about anal, oral-genital, and oral-anal sex and condom use. In the evaluation, an attempt should be made to differentiate symptoms of proctitis, proctocolitis, and enteritis. Physical examination should include a careful anal examination, digital rectal examination, and anoscopy directed toward finding ulcers consistent with HSV or syphilis, condylomata lata, or rectal discharge or bleeding.

Laboratory Tests

If a rectal exudate is present, a Gram stain should be performed to look for gonorrhea. The reported sensitivity of Gram stain is highly variable (30% to 79%).[120] In one study, rectal Gram stain specimens obtained by anoscopy were more sensitive in detecting gonorrhea than were those obtained blindly (53% versus 79%).[120] In men without rectal symptoms, however, anoscopically obtained rectal cultures do not appear to be more sensitive in detecting gonorrhea than those obtained by blindly inserting a swab 2 to 3 cm into the rectum.[121]

Laboratory evaluation in patients with suspected proctitis or proctocolitis should include cultures for gonorrhea and chlamydial infection, a serologic test for syphilis, and a rapid syphilis test. Rectal ulcers or lesions should be cultured for HSV; when possible, a specimen should be obtained for dark-field evaluation. If symptoms suggest proctocolitis, stool specimens should be obtained for enteric pathogens and *E. histolytica*. Patients with recent antibiotic exposures should also be tested for *C. difficile*. Stool *Giardia* antigen testing should be performed if enteritis is suspected.

TREATMENT

In general, treatment should be directed by laboratory findings. If patients with proctitis have severe symptoms or if follow-up cannot be ensured, empirical therapy should be directed against gonorrhea and chlamydial infection. The CDC recommends treatment with ceftriaxone, 250 mg intramuscularly, and doxycycline, 100 mg a day orally for 7 days. Alternative therapies for gonorrhea (cefixime, 400 mg orally or ciprofloxacin, 500 mg orally once) and chlamydial infection (azithromycin, 1 g orally once) are probably effective but have not been studied. Clinicians should have a low threshold for adding empirical therapy for herpes to this regimen.

The author has received research support from Roche Diagnostics and Gen-Probe.

XXIII URINARY TRACT INFECTIONS

Kalpana Gupta, m.d., m.p.h
Walter E. Stamm, m.d., f.a.c.p.

Definitions

Urinary tract infection (UTI) is the most common of all bacterial infections; it affects persons throughout their life span. The term UTI encompasses a variety of clinical entities, ranging from asymptomatic bacteriuria to cystitis, prostatitis, and pyelonephritis. UTIs may be further characterized as uncomplicated (occurring without an anatomic or other predisposing reason) or complicated (associated with structural or functional abnormalities of the urinary tract and kidney) and as community acquired or nosocomial (generally, catheter associated).

Epidemiology and Risk Factors

UTI occurs far more commonly in females than in males, except at the extremes of age [*see Table 1*]. During the neonatal period, the incidence of UTI is slightly higher in males than in females because of the greater frequency of congenital anomalies of the urinary tract in male infants. After 50 years of age, the incidence of UTI is almost as high in men as in women, presumably because of obstruction from prostatic hypertrophy. In persons between 1 and about 50 years of age, UTI is predominantly a disease of females.

WOMEN

As many as 50% to 80% of women in the general population acquire at least one UTI during their lifetime; most of these infections are uncomplicated cystitis.[1] In a prospective cohort study of sexually active healthy women, the incidence of acute cystitis was 50 to 70 episodes per 100 person-years.[2] Recent use of a diaphragm with spermicide, frequency of sexual intercourse, and a history of UTI were identified as independent risk factors for cystitis in this study.[2] Cystitis has also been temporally related to recent sexual intercourse.

The incidence of acute uncomplicated pyelonephritis is difficult to ascertain because this infection is less common than cystitis and because most episodes are treated in the outpatient setting. In a population-based case-control study of young healthy women, the annual incidence of pyelonephritis was approximately 28 per 10,000 women. Factors independently associated with pyelonephritis in this study included frequency of sexual intercourse, having a new sexual partner, UTI in the past 12 months, maternal history of UTI, diabetes, and incontinence.[3]

Table 1 Incidence of Urinary Tract Infection According to Age and Sex

Age Group	*Incidence (%)*	*Approximate Sex Ratio (Male:Female)*
Neonatal	1.0	1.5:1.0
Preschool age	1.5–3.0	1:10
School age	1.2	1:30
Reproductive age	3–5	1:50
Geriatric	10–30	1:1.5

Thus, many of the factors predisposing women to cystitis also increase the risk of pyelonephritis.

YOUNG MEN

UTI is rare in young men and has traditionally been attributed to the presence of urologic abnormalities. However, it is apparent that uncomplicated UTI can occur in men who acquire uropathogens through direct sexual contact, in the form of unprotected anal intercourse with a man or a woman, or unprotected vaginal intercourse with a woman whose vagina is colonized with uropathogens.[4] Lack of circumcision is also associated with an increased risk of UTI, because of an increased incidence of *Escherichia coli* colonization of the glans and prepuce and the subsequent migration of *E. coli* to the urinary tract.[5,6]

RECURRENT UTI

About 20% to 30% of women who have had one episode of UTI will have recurrent episodes.[4] Recurrence may result from relapse or reinfection. Relapse in either sex is caused by the reappearance of an organism from a sequestered focus, usually within the kidney or prostate, shortly after completion of therapy. Sequestration of infecting organisms in the bladder epithelium has been demonstrated in animals, but the importance of this phenomenon in humans is not yet clear.[7] In reinfection, the course of therapy has successfully eradicated the infection and there is no sequestered focus, but organisms are reintroduced from the fecal reservoir. The majority of recurrences are thought to be reinfections.[4] Studies of the natural history of recurrent UTI in women have found that the rate of recurrence ranges from 0.3 to 7.6 infections per patient per year, with an average rate of 2.6 infections per year.[8] Clustering of episodes occurs; it is not uncommon for multiple recurrences to follow an initial infection. The likelihood of a recurrence decreases with increasing time since the last infection. A case-control study of women with recurrent UTI identified frequency of sexual intercourse, use of spermicide, having a new sexual partner, a history of first UTI occurring before 15 years of age, and a maternal history of UTI as independent risk factors for recurrent UTI.[9]

PREGNANCY

The incidence of asymptomatic bacteriuria in pregnant women is approximately 4% to 10%, which is similar to the rate reported in sexually active nonpregnant women of childbearing age.[10-12] If not treated, 20% to 40% of pregnant women with bacteriuria in the first trimester will acquire acute pyelonephritis later in pregnancy. A recent meta-analysis estimated that treatment of asymptomatic bacteriuria would lead to approximately a 75% reduction in the incidence of pyelonephritis.[12] Premature births and perinatal mortality are increased in pregnancies complicated by UTI.[11,12] There is little evidence that the infections that develop during pregnancy have long-term effects.

DIABETES

The rates of asymptomatic bacteriuria and UTI in diabetic women are twofold to threefold higher than those in nondiabetic women; these differences have not been observed in men.[13] In hospitalized diabetic patients, particularly those with multiple-

organ complications, the incidence of infection and true pyelonephritis also appears to be increased, partly because of poor bladder function and urinary catheterization. Other clinical conditions causing obstruction in urinary flow or incomplete voiding also predispose diabetic patients to infection. In addition, impaired cytokine secretion may contribute to asymptomatic bacteriuria in diabetic women.[14]

Etiology

The spectrum of organisms causing UTI varies by clinical syndrome. In acute uncomplicated cystitis, the etiologic agents are highly predictable: *E. coli* accounts for 75% to 90% of isolates; *Staphylococcus saprophyticus* accounts for 5% to 15% of isolates (particularly in younger women); and *Klebsiella* species, *Proteus* species, enterococci, and other organisms account for 5% to 10% of isolates. The spectrum of agents that cause uncomplicated pyelonephritis is less well studied than, but is similar to, that which causes acute cystitis. In complicated UTIs, *E. coli* remains the predominant organism, but other aerobic gram-negative rods, such as *Klebsiella* species, *Proteus* species, *Citrobacter* species, *Acinetobacter* species, *Morganella* species, and *Pseudomonas aeruginosa* are also frequently isolated. Gram-positive bacteria, such as enterococci, *S. aureus,* and *S. epidermidis,* as well as yeast, are also important pathogens in complicated UTI.

Pathogenesis

Bacteria can establish infection in the urinary tract by traveling from the urethra to the bladder and then up the ureter to the kidney. However, introduction of bacteria into the bladder does not inevitably lead to sustained infection. For example, bacteria often enter the bladder after sexual intercourse, but normal micturition and innate host defense mechanisms in the bladder eliminate these organisms. The bladder mucosal surface has antibacterial properties that eliminate some organisms, presumably through mucus trapping and a polymorphonuclear leukocyte response. In addition, urine that has a low pH, high or very low osmolarity, high urea concentration, or high organic acid content inhibits bacterial growth. Abnormal micturition, a significant residual urine volume, or both will promote true infection. There are also acquired and intrinsic host factors, as well as bacterial virulence factors, which increase the likelihood of development of UTI (see below).

Bacteria can also gain access to the urinary tract through the bloodstream. However, hematogenous spread accounts for fewer than 2% of documented UTIs and usually results from bacteremia caused by relatively virulent organisms, such as *Salmonella* and *S. aureus.* Hematogenous infections may produce focal abscesses or areas of pyelonephritis within a kidney and result in positive urine cultures.

VAGINAL ECOLOGY AND UTI

In women, colonization of the vaginal introitus with organisms from the fecal flora, usually *E. coli,* is the critical initial step in the pathogenesis of UTI. Sexual intercourse and the use of a diaphragm with spermicide or of spermicide alone are strongly associated with an increased risk of *E. coli* vaginal colonization and bacteriuria, probably because of alterations in the normal vaginal microflora.[15]

In postmenopausal women, there is an increased incidence of gram-negative vaginal colonization and bacteriuria. These trends correlate with the changes in the vaginal environment that occur with menopause: disappearance of the previously predominant lactobacilli from the vaginal microflora and a rise in pH. A case-control study of community-dwelling postmenopausal women found significantly lower rates of vaginal colonization with lactobacilli in those women who were not taking hormone replacement therapy than in those who were using systemic or topical estrogen.[16] In a randomized, placebo-controlled trial in postmenopausal women with a history of recurrent UTI, topical estrogen therapy resulted in restoration of the premenopausal vaginal flora and a decrease in both the prevalence of vaginal *E. coli* colonization and the incidence of UTI.[17]

GENETIC FACTORS

There is increasing evidence that genetically determined factors may influence susceptibility to recurrent UTI. Women with recurrent UTI demonstrate a propensity for persistent vaginal colonization with *E. coli,* even during asymptomatic periods. Vaginal and periurethral mucosal cells from women with recurrent UTI bind threefold more uropathogenic bacteria than do mucosal cells from women without recurrent infection. These observations suggest that epithelial cells from susceptible women may possess specific types or greater numbers of receptors to which *E. coli* can bind, thereby facilitating colonization. This increased susceptibility is determined in part by Lewis blood group type and whether the woman secretes blood group antigens into bodily fluids. Vaginal epithelial cells from nonsecretors of blood group antigens bind significantly greater numbers of bacteria, and nonsecretors are particularly at risk for recurrent UTI.[18,19] Mutations in host-response genes (e.g., those coding for Toll receptors and the interleukin-8 receptor) have been linked to severity of UTIs in animals, although they have not yet been linked in humans.[20]

BACTERIAL VIRULENCE

Certain strains of *E. coli* possess chromosomally encoded virulence determinants that confer the ability to infect the anatomically normal urinary tract and produce acute inflammatory disease (e.g., cystitis and pyelonephritis). Characteristics that have been associated with uropathogenicity are the presence of certain O and K surface antigens (the O antigen is the outer polysaccharide portion of the bacterial envelope, and the K antigen is the antiphagocytic capsular antigen), the presence of the siderophore aerobactin, resistance to the bactericidal activity of serum, the ability to produce toxins such as hemolysin and cytotoxic necrotizing factor, and certain intracellular metabolic capabilities.[21]

Also important is the presence of adhesins on the surface of uropathogenic bacteria that mediate binding to specific receptors on the surface of uroepithelial cells. The best-studied adhesion structure is the P fimbriae, which are hairlike protein structures found on the surface of certain pathogenic strains of *E. coli.* P fimbriae interact with a specific receptor on epithelial cells. This epithelial cell receptor contains the carbohydrate moiety α-D-galactopyranosyl-(1→4)-β-D-galactopyranoside, which is found in the P blood group antigens. The prevalence of P-fimbriated *E. coli* correlates with severity of disease the strain is likely to cause: there is a low prevalence (10% to 20%) in *E. coli* strains from the fecal flora of asymptomatic persons; there is a higher prevalence (50% to 60%) in strains that cause cystitis; and the highest prevalence (70% to 100%) is found in strains that cause pyelonephritis.[21,22] P fimbriae also appear to be important

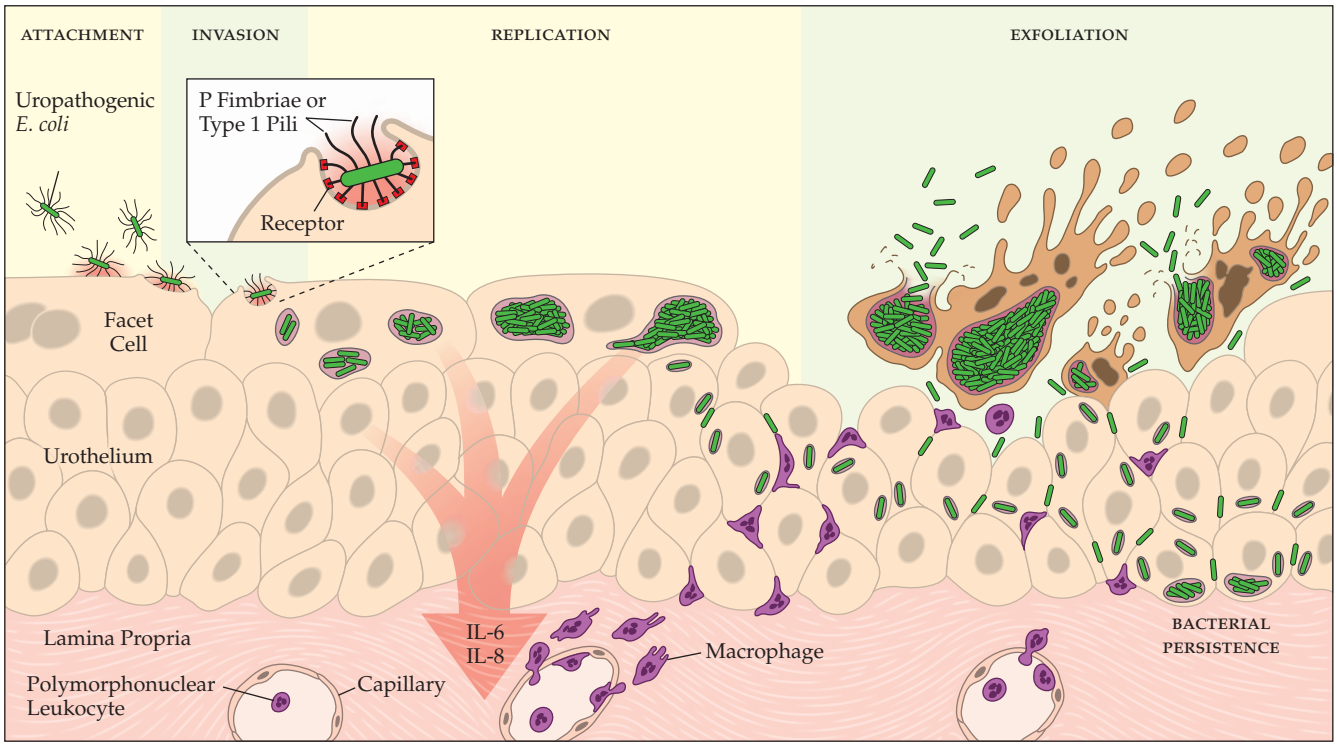

Figure 1 **The pathophysiology of infection by uropathogenic *Escherichia coli* in bladder epithelial cells.[20] Uropathogenic *E. coli* organisms attach to receptors on superficial bladder cells with P fimbriae or type 1 pili. Once contact is established, the bacteria are internalized into the cells, where they can replicate to high levels. However, attachment or invasion can result in the activation of apoptotic pathways within the cells, leading to the eventual exfoliation and clearance of infected host cells. Interactions between *E. coli* and the cells can also result in the induction of inflammatory cytokines, leading to the influx of polymorphonuclear leukocytes into the bladder epithelium. *E. coli* can escape from dying cells, thereby avoiding clearance by exfoliation, and infect surrounding and underlying epithelial cells. Within the bladder epithelium, *E. coli* can escape immune surveillance and persist at subclinical levels. (IL-6 — interleukin-6; IL-8 — interleukin-8)**

in the pathogenesis of bloodstream invasion from the kidney. From 75% to 100% of *E. coli* strains isolated from the blood of otherwise healthy patients with pyelonephritis express P fimbriae. In contrast, *E. coli* strains that cause urosepsis in persons with compromising medical conditions are much less likely to have P fimbriae.[22]

Another adhesion structure is the type 1 pilus (fimbria), which all *E. coli* strains possess. Type 1 pili are also thought to play a key role in initiating *E. coli* bladder infection; they mediate binding to uroplakins, which are mannosylated glycoproteins on the surface of bladder uroepithelial cells.[21] In addition to P fimbriae and type 1 pili, other adhesins may play a role in mediating attachment of uropathogenic strains of *E. coli* to the uroepithelium in selected circumstances.

The binding of uropathogenic *E. coli* to receptors on uroepithelial cells initiates a complex series of intracellular signaling events that alters epithelial cell function [*see Figure 1*].[8] Chemokines and cytokines are synthesized and secreted, inflammatory cells are attracted into the bladder epithelium, and epithelial cells undergo apoptosis and exfoliation, carrying attached *E. coli* away in the urine.

ANATOMIC AND FUNCTIONAL ABNORMALITIES

Persons who have major anatomic and functional abnormalities of the urinary tract, including vesicoureteral reflux, ureteral obstruction, or a foreign body (e.g., a stone, a catheter, or a tumor), are markedly predisposed to UTI, particularly infections involving the kidney. In such persons, UTI can develop as a result of infection with bacteria, including *E. coli* strains, that are not normally uropathogenic.[21] Not surprisingly, infection with nonuropathogenic strains of bacteria is also common in hospitalized patients, presumably because they have anatomic and functional abnormalities. Bacterial invasion of the prostate and incomplete bladder emptying caused by bladder outlet obstruction are the primary predisposing factors in men with UTI. Instrumentation and incomplete bladder emptying are important predisposing factors for UTI in patients with spinal cord injury or diabetes. Inhibition of ureteral peristalsis leading to vesicoureteral reflux is important in the pathogenesis of pyelonephritis in pregnant women.

Vesicoureteral reflux plays a key role in the pathogenesis of renal infection and, more important, in the evolution of chronic renal damage. It is commonly associated with UTI in children but also occurs because of anatomic abnormalities in children without UTI. Reflux provides a direct route for infection to reach the pelvicalyceal system of the kidney; severe reflux may occur intrarenally. Renal scars caused by chronic pyelonephritis are often associated with such reflux. Most reflux-associated renal damage occurs in infancy, because with growth there is a tendency for self-correction of at least mild degrees of reflux. The long-term effects of reflux on kidney structure and function are a major justification for an aggressive radiologic approach in infants and young children with UTI [*see* Management, *below*].[23]

Diagnosis

CLINICAL PRESENTATIONS AND LABORATORY FINDINGS

The clinical presentation of UTI is quite variable, ranging from asymptomatic bacteriuria to typical symptomatic cystitis to acute pyelonephritis. In addition, clinical symptoms do not always correlate with the site of infection (bladder versus kidney) or with the degree of bacteriuria. Approximately 30% of patients with lower urinary tract symptoms also have silent infection of the kidney.[4] Despite considerable effort, researchers have been unable to develop a noninvasive technique for differentiating renal infections from bladder infections. The best noninvasive test to delineate the anatomic site of infection appears to be the response to short-course antibiotic therapy [*see* Management, *below*].

Cystitis

The typical symptoms of cystitis are dysuria, urinary frequency, and urgency. Nocturia and suprapubic or back discomfort are also often present. In addition, the urine may be cloudy, malodorous, or bloody.

A meta-analysis evaluating the probability of UTI on the basis of history and physical findings concluded that the probability of UTI was at least 50% in a woman presenting with one or more symptoms of UTI. If vaginal discharge and complicating factors are absent and risk factors for UTI are present, then the probability of UTI is close to 90% and no laboratory evaluation is needed. Similarly, a combination of dysuria and frequency—the most common symptoms—in the absence of vaginal discharge increases the probability of UTI to 96%. Further laboratory evaluation with dipstick or urine culture can be omitted in such patients, and empirical therapy can be considered. If the history is not clear, then a urine dipstick should be performed. A positive nitrite or leukocyte esterase result makes the probability of UTI about 80%, and empirical treatment can be considered without further testing. In this setting, a negative dipstick result does not rule out UTI, and a urine culture and close clinical follow-up are recommended. Interestingly, the only physical examination finding that increased the probability of UTI was costovertebral angle tenderness (suggesting pyelonephritis), and the authors recommended that the physical examination could be omitted in patients with typical symptoms of acute uncomplicated cystitis.[24]

On dipstick testing, the presence of leukocyte esterase, nitrite, or both has about 75% to 90% sensitivity and 70% to 82% specificity.[4] The pH is typically elevated, and blood may be present. Depending on the clinical circumstances, it may be appropriate to follow dipstick testing with urine culture and antimicrobial-sensitivity testing [*see* Management, *below*].

Urine microscopy reveals pyuria in nearly all cases of cystitis and hematuria in about 30% of cases. Bacteriuria is demonstrable on Gram stain of unspun urine in over 90% of cases with 10^5 bacteria/ml or higher. Approximately two thirds of women presenting with clinical cystitis will have urinary colony counts of 10^5 bacteria/ml or higher. Studies in women with symptoms of cystitis have found that a colony count threshold of greater than 10^2 bacteria/ml has greater sensitivity (95%) and specificity (85%) than a threshold of 10^5 bacteria/ml for the diagnosis of acute cystitis in women[4] [*see* Bacterial Count on Urine Culture, *below*].

Pyelonephritis

Patients with pyelonephritis can present with clinical manifestations that range from mild to relatively severe—from low-grade fever with lower back or costovertebral angle pain to fever, shaking chills, nausea, vomiting, and loin pain. Symptoms are generally acute in onset and may or may not be associated with symptoms of cystitis.[4,25] The primary finding on physical examination is costovertebral angle tenderness on deep palpation. Tachycardia may accompany fever. Pyuria and bacteriuria are usually demonstrable on urine microscopy and Gram stain. Bacteremia may complicate the course of pyelonephritis; but in patients with pyelonephritis, bacteremia is seldom associated with the more serious sequelae of gram-negative infection (i.e., triggering of the complement, clotting, and kinin systems), which may lead to septic shock, disseminated intravascular coagulation, or both. When shock or disseminated intravascular coagulation occurs, the possibility of obstruction must be considered. In a particularly serious form of obstructive uropathy associated with acute papillary necrosis, the sloughed papillae may obstruct the ureter. This should be suspected in diabetic patients who have severe pyelonephritis and persistent bacteremia despite antibiotic therapy. Papillary necrosis may also be evident in some cases of pyelonephritis complicated by obstruction, sickle cell disease, analgesic nephropathy, or combinations of these conditions. Emphysematous pyelonephritis, which is a particularly severe form of pyelonephritis associated with production of gas in renal and perinephric tissues, occurs almost entirely in diabetic patients.

Renal and Perirenal Abscesses

Two unusual forms of UTI are macroscopic renal and perirenal abscesses. In the past, most of these abscesses were secondary to hematogenous infection with *S. aureus.* Currently, most of them are secondary to ascending UTI with the usual Enterobacteriaceae organisms. Such infections are often complicated by renal calculi and obstruction of urinary flow from either the kidney or the ureter. Less commonly, preexisting renal cysts become infected and develop into abscesses. In rare instances, there is contiguous spread from a neighboring site of suppuration, such as the colon or overlying rib. The usual presentation of such infections is insidious, with chronic fever, weight loss, night sweats, and anorexia, and is often associated with flank or back pain. When the abscess is under pressure, usually because of obstruction, a more acute presentation with associated bacteremia may occur. Symptoms specific to the urinary tract, such as dysuria, hematuria, and urinary retention, are sometimes noted but are often absent. On physical examination, costovertebral angle tenderness or even a palpable mass may be found; in 30% to 50% of patients, however, this finding is absent.

Routine laboratory tests are of variable value in patients with renal or perirenal abscesses: leukocytosis may be present, anemia is not unusual, and signs of inflammation (e.g., pyuria or proteinuria) may be evident on urinalysis. In more than half of patients with renal or perirenal abscesses, the organism in the abscess may be isolated on urine culture. Definitive diagnosis, however, depends on radiographic detection of a mass lesion. Gallium and ultrasound scans may be helpful, but a computed tomographic or magnetic resonance imaging scan is considered the diagnostic test of choice.[26] If prompt drainage and antibiotic therapy are not provided, renal or perirenal abscesses may extend to the peritoneal cavity, chest, or skin.

Prostatitis

A common complication of UTI in men is prostatitis. Bacterial prostatitis is usually caused by the same gram-negative bacilli

that cause UTI in females; 80% or more of such infections are caused by *E. coli.* The pathogenesis of this condition is poorly understood. Antibacterial substances in prostatic secretions probably protect against such infections.

A National Institutes of Health expert consensus panel has recommended classifying prostatitis into three syndromes: acute bacterial prostatitis, chronic bacterial prostatitis, and chronic pelvic pain syndrome (CPPS). Acute bacterial prostatitis is a febrile illness characterized by chills; dysuria; urinary frequency and urgency; and perineal, back, or pelvic pain. Bladder outlet obstruction may occur. On physical examination, the prostate is found to be enlarged, tender, and indurated. Pyuria is present, and urine cultures generally grow *E. coli* or another typical uropathogen.

Chronic bacterial prostatitis is a clinically more occult disease and may be manifested only as recurrent bacteriuria or variable low-grade fever with back or pelvic discomfort. Urinary symptoms usually relate to the reintroduction of infection into the bladder, with both pyuria and bacteriuria being present; a chronic prostatic focus is the most common cause of recurrent UTI in men.

CPPS describes the large group of men who present with minimal signs on physical examination but have a variety of irritative or obstructive voiding symptoms; perineal, pelvic, or back pain; and sexual dysfunction. These men can be divided into those with and those without inflammation (defined as > 10 white blood cells per high-power field in expressed prostatic secretions). The etiology and appropriate management in these patients, regardless of inflammatory status, is unknown.[27,28]

INTERPRETATION OF URINE CULTURES

The correlation between clinical symptoms and the presence of infection is imprecise. In addition, it is frequently difficult to obtain a urine specimen that is uncontaminated by the normal microbial flora of the distal urethra, vagina, or skin. When evaluating urine cultures, therefore, the physician should consider both the species and the number of bacteria found.[4]

Species Found on Urine Culture

More than 95% of UTIs result from a single bacterial species. Thus, in most instances, a culture that grows out mixed bacterial species is contaminated and needs to be repeated. Polymicrobial infection may occur in certain settings, however, including long-term catheterization, incomplete bladder emptying because of neurologic dysfunction, and the presence of a fistula between the urinary tract and the GI or genital tract. Organisms that are commonly found in the vaginal introitus and distal urethra, such as *S. epidermidis,* diphtheroids, and lactobacilli, seldom cause UTI except in complicated settings. Another marker of contamination is the presence of squamous epithelial cells in a urine specimen. On the other hand, pyuria is highly associated with inflammation of the urinary tract, which is most commonly caused by infection.

Bacterial Count on Urine Culture

The number of organisms per milliliter of a clean-voided urine specimen is a useful indicator.[4] The growth of 10^5 or more colonies of a single bacterial species per milliliter of urine in two consecutive urine cultures is the diagnostic criterion for asymptomatic bacteriuria in women. In women with acute dysuria, the presence of at least 10^2 organisms/ml of a single coliform species appears to be a more accurate criterion for infection than a threshold of 10^5 organisms/ml. Women with dysuria and pyuria who have less than 10^2 bacteria/ml may have urethritis caused by *Chlamydia trachomatis, Neisseria gonorrhoeae,* or herpes simplex virus or vulvovaginitis caused by *Trichomonas vaginalis* or *Candida* species. Clinical and laboratory criteria can help differentiate these conditions [*see Table 2*]. In men, the minimal level indicating infection appears to be 10^3 organisms/ml. In general, probably 70% of persons with true bacterial UTI will have more than 10^5 organisms/ml; 30% will have lower concentrations of bacteria.

The presence of organisms on a Gram stain of unspun urine is highly suggestive of significant bacteriuria; however, a negative Gram stain does not rule out infection. The Gram stain has excellent sensitivity for demonstrating bacteriuria when the urine colony count exceeds 10^5 organisms/ml but has poor sensitivity at lower colony counts.

Management

ANTIMICROBIAL THERAPY

In general, antimicrobial therapy is warranted for any symptomatic infection of the urinary tract. The choice of antimicrobial agent, dose, and duration of therapy depends on the site of infection and the presence or absence of complicating conditions. Therefore, each category of UTI merits a different approach on the basis of the particular clinical syndrome that is present.

Table 2 Common Causes of Acute Dysuria in Women[68]

Condition	*Pathogen*	*Laboratory Findings*			*Symptoms, Onset, and Factors*
		Pyuria	*Hematuria*	*Urine Culture (cfu/ml)*	
Cystitis	*Escherichia coli* (most common), *Staphylococcus saprophyticus, Proteus* species, *Klebsiella* species	Usual	Often	10^2 to ≥ 10^5	Abrupt onset, multiple symptoms (dysuria, increased frequency, and urgency), suprapubic or low back pain, suprapubic tenderness on examination
Urethritis	*Chlamydia trachomatis, Neisseria gonorrhoeae,* herpes simplex virus	Usual	Rare	< 10^2	Gradual onset, mild symptoms, vaginal discharge or bleeding (caused by concomitant cervicitis), lower abdominal pain, new sexual partner, cervicitis or vulvovaginal herpetic lesions on examination
Vaginitis	*Candida* species, *Trichomonas vaginalis*	Rare	Rare	< 10^2	Vaginal discharge or odor, pruritus, dyspareunia, external dysuria, no increased frequency or urgency, vulvovaginitis on examination

Treatment of Women with Acute Uncomplicated Cystitis

Antimicrobial therapy for healthy reproductive-age women with uncomplicated UTI should have the dual objective of eradicating the infection and eliminating uropathogenic clones of bacteria from the vaginal and GI reservoirs to prevent early recurrences. In general, the species and antimicrobial susceptibilities of the bacteria that cause acute uncomplicated cystitis are highly predictable. Thus, in otherwise healthy women presenting with typical symptoms of acute cystitis (dysuria and frequency without signs or symptoms of vaginitis), it is safe and cost-effective to omit the urine culture and use empirical short-course therapy. Three-day therapy seems to be optimal; single-dose therapy results in higher relapse rates (probably because of failure to eradicate the uropathogen from the vaginal reservoir), and 7-day therapy offers no additional benefit but costs more and causes more side effects. Therapy for 7 days, however, should be considered in women with a history of recent UTI, symptoms of more than 7 days' duration, or diabetes.[29]

Several effective therapeutic regimens for acute uncomplicated cystitis in women are available [*see Table 3*]. Traditionally, trimethoprim-sulfamethoxazole (TMP-SMX) has been recommended as first-line treatment.[30,31] However, resistance of uropathogens to TMP-SMX is increasing and now approaches 15% to 20% in some communities.[32,33] Because in vitro TMP-SMX resistance has been correlated with clinical and bacteriologic failure of TMP-SMX therapy, factors other than the expected prevalence of TMP-SMX resistance should also be considered. These include a history of recent use of TMP-SMX or another antimicrobial and recent travel to an area with high TMP-SMX–resistance rates.[33]

In such settings, an alternative first-line agent should be considered for empirical therapy.[29,32,33] Many strains of *E. coli* that are resistant to TMP-SMX are also resistant to amoxicillin and cephalexin; thus, these drugs should be used only in patients infected with susceptible strains. Other β-lactams, such as amoxicillin-clavulanate or cefpodoxime, can be used but are expensive and may be associated with higher relapse rates, probably because they fail to eradicate the uropathogen from the vaginal reservoir. Nitrofurantoin remains highly active against *E. coli* and most non–*E. coli* isolates (except for *Proteus* species, which are intrinsically resistant to the drug); however, 7 days of therapy may be required to achieve reasonable cure rates with this drug. Most fluoroquinolones are effective for short-course therapy of cystitis. In a randomized trial, 3-day regimens of ciprofloxacin (100 mg twice daily), double-strength TMP-SMX (160/800 mg twice daily), or ofloxacin (200 mg twice daily) were equally effective in the treatment of acute uncomplicated cystitis in women.[34] In separate studies, 3-day regimens of TMP-SMX and ofloxacin were found to be equally cost-effective.[35,36] Higher costs were associated with 3-day regimens of ampicillin, cefadroxil, and nitrofurantoin because of lower efficacy and higher rates of side effects.[35,36] However, increasing fluoroquinolone use has been correlated with increased rates of fluoroquinolone resistance, which suggests that patients with uncomplicated cystitis should be treated with an agent other than a fluoroquinolone, if possible.[37]

If a patient is still symptomatic after therapy, both urinalysis and urine culture are necessary [*see Figure 2*]. If the urinalysis and culture are negative, a 2-day course of the urinary tract analgesic phenazopyridine, 200 mg three times daily after meals, can be prescribed.[38] A pelvic exam for evaluation of alternative diagnoses such as chlamydial, gonococcal, or herpetic infection should be considered, and close clinical follow-up is recommended.[24] If testing shows pyuria but not bacteriuria, pelvic examination for alternative diagnoses should be performed. If the patient has both pyuria and bacteriuria, the antimicrobial susceptibility of the infecting strain should be assessed for resistance and an alternative agent should be given. Finally, a patient who is symptomatic after a short-course regimen and has persistent infection with a uropathogen that is sensitive to the antibiotic used should be regarded as having covert renal infection. In this circumstance, a 14-day course of a fluoroquinolone or TMP-SMX is indicated.[4]

Table 3 Treatment Regimens for Acute Uncomplicated Cystitis[4*]

Host Considerations	*Empirical Treatment Regimens*
Otherwise healthy woman	*Three-Day Regimens* TMP-SMX , 160/800 mg q. 12 hr Trimethoprim, 100 mg q. 12 hr Fluoroquinolones: Ciprofloxacin, 100–250 mg q. 12 hr Ciprofloxacin XR, 500 mg q.d. Gatifloxacin, 200 mg q.d. Levofloxacin, 250 mg q.d. *Five- to Seven-Day Regimens* Nitrofurantoin monohydrate/macrocrystals, 100 mg q. 12 hr Nitrofurantoin macrocrystals, 50–100 mg q.i.d. Amoxicillin, 250 mg q. 8 hr or 500 mg q. 12 hr Cephalexin, 250 mg q. 6 hr, or other cephalosporin
Male sex, diabetes, symptoms for 7 days, recent antimicrobial use, age > 65 yr	*Consider Seven-Day Regimen* TMP-SMX , 160/800 mg q. 12 hr Fluoroquinolones, as per 3-day regimen Cephalexin, 250 mg q. 6 hr, or other cephalosporin
Pregnancy	*Consider Seven-Day Regimen* Amoxicillin, 250 mg q. 8 hr or 500 mg q. 12 hr Nitrofurantoin monohydrate/macrocrystals, 100 mg q. 12 hr Nitrofurantoin macrocrystals, 50–100 mg q.i.d. Cephalexin, 250 mg q. 6 hr, or other cephalosporin TMP-SMX , 160/800 mg q. 12 hr‡

* Characteristic pathogens are *Escherichia coli* (85% to 90%) and *Staphylococcus saprophyticus* (5% to 15%); other organisms, which account for < 5% of cases, are *Proteus mirabilis*, *Klebsiella pneumoniae*, and *Enterococcus* species.

† Treatments listed are those to be prescribed before the etiologic agent is known (Gram stain can be helpful); regimens can be modified once the agent has been identified. The recommendations are limited to drugs currently approved by the Food and Drug Administration, although not all the regimens listed are approved for these indications. Optimal empirical regimens may differ among settings because of differences in the antimicrobial susceptibility profiles of uropathogens. Fluoroquinolones should not be used in pregnancy.

‡ Although TMP-SMX is classified as pregnancy category C, it is widely used; however, avoid use of this drug in the first and third trimesters of pregnancy.

TMP-SMX—trimethoprim-sulfamethoxazole

Treatment of postmenopausal women The antimicrobial approach for postmenopausal women with symptomatic cystitis is similar to that for younger women—namely, short-course therapy with TMP-SMX or a fluoroquinolone initially; longer courses of therapy should be reserved for patients who do not

respond to short-course therapy. In a randomized clinical trial of the treatment of acute cystitis in postmenopausal women, 3-day therapy with ofloxacin was more cost-effective than 7-day therapy with cephalexin.[39] In another randomized trial, 3 days of ciprofloxacin for treatment of cystitis in women 65 years of age and older was equivalent to 7 days of ciprofloxacin and associated with fewer adverse effects.[40] The major difference in the management of older women with UTI is the recognition that topical estrogen replacement, in the form of vaginal estriol cream, may decrease the incidence of recurrent UTI in postmenopausal women.[17] Some studies of postmenopausal women have not found a protective effect with topical estrogen, particularly when it is delivered by pessary. The effects of systemic estrogen replacement on risk of UTI have not been studied in a randomized, controlled trial, but in general, a protective effect has not been demonstrated with this intervention.[41,42]

Treatment of recurrent UTI Recurrence of uncomplicated cystitis in reproductive-age women is common, and some form of preventive strategy is indicated if three or more symptomatic episodes occur in 1 year. A variety of antimicrobial strategies are available, but before embarking on one of them, the patient should try such simple interventions as voiding immediately after sexual intercourse and using a contraceptive method other than a diaphragm and spermicide. There is little evidence to support the former approach, but it is still often recommended, given the difficulty in adequately studying this behavior and the low morbidity associated with implementing it. Ingestion of cranberry juice has been shown to be effective in decreasing bacteriuria with pyuria, but not bacteriuria alone or symptomatic UTI, in an elderly population.[43] Cranberry juice was demonstrated to reduce the rate of recurrent UTI in younger women when combined with lingonberry.[44] A more recent randomized trial comparing placebo, cranberry juice, and cranberry tablets also demonstrated a reduction in the UTI rate in young women from 32% in the placebo group to 20% with juice and 18% with tablets.[45] Thus, although the efficacy of cranberry juice for prevention of UTI needs further evaluation, there is mounting evidence that it may be effective in young otherwise healthy women.[46] This effect appears to be independent of any urinary acidification; rather, it is postulated that cranberry juice contains substances that inhibit the attachment of bacterial adhesins to the uroepithelium.[47]

If simple nondrug measures are ineffective, continuous or postcoital—if the infections are temporally related to intercourse—low-dose antimicrobial prophylaxis with one of several regimens should be considered. A single dose of TMP-SMX (one half of a single-strength tablet, which amounts to 40 mg of trimethoprim and 200 mg of sulfamethoxazole), a fluoroquinolone (one tablet), or nitrofurantoin (50 mg; or 100 mg of nitrofurantoin macrocrystals) can safely and effectively decrease the rate of recurrent infections.[18] Typically, a prophylactic regimen is initially prescribed for 6 months and then discontinued. If the infections recur, the prophylactic program can be instituted for a longer period. Antimicrobial prophylaxis has been effectively used for as long as 5 years in preventing recurrence of infection.[8]

An alternative approach to antimicrobial prophylaxis for women with less frequent recurrences (fewer than four a year) is to supply the patient with TMP-SMX or a fluoroquinolone and allow her to self-medicate with short-course therapy at the first symptoms of infection. The patient is directed to keep track of the number of such episodes and to contact the physician if more than four episodes occur over a 12-month period or if symptoms persist on such therapy. This approach has been shown to be safe and effective in two separate studies of women with recurrent UTI.[48,49]

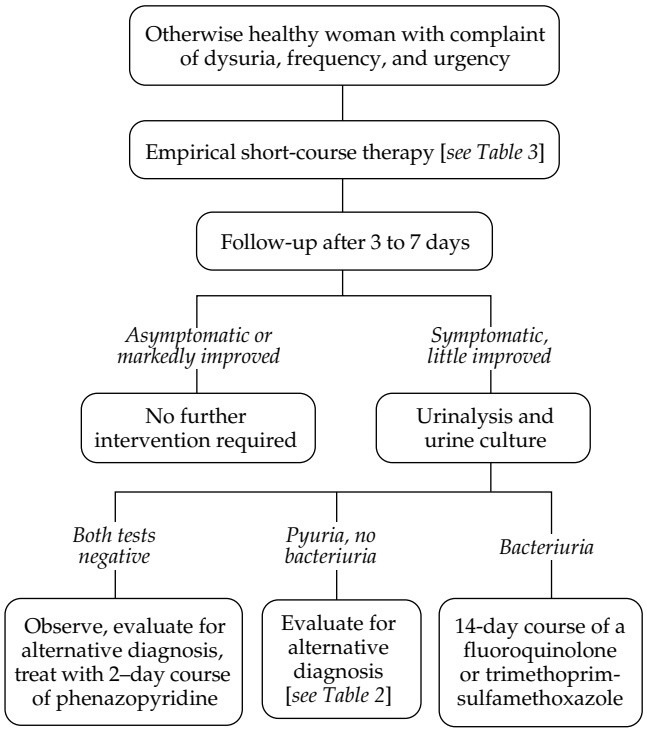

Figure 2 **Clinical approach to acute uncomplicated cystitis in a woman.**

Treatment of relapsing infection The approach to the minority of patients with relapsing infection, as evidenced by finding the same bacterial strain in a UTI that occurs within 2 weeks after completion of antimicrobial therapy, is very different from the management of reinfection. Two factors may contribute to the pathogenesis of relapsing infection in women: deep-tissue infection of the kidney that is suppressed but not eradicated by a 14-day course of antibiotics, and structural abnormality of the urinary tract, particularly calculi. Patients with true relapsing UTIs should undergo radiologic or urologic evaluation and should be considered for longer-term therapy.

Acute Uncomplicated Pyelonephritis

Patients with clear-cut symptomatic pyelonephritis have deep-tissue infection, have (or are at risk for) bacteremia, and merit antimicrobial therapy. Two requirements guide the initial choice of antimicrobial regimens for pyelonephritis: the probability that the infecting organism is sensitive to the regimen should be at least 99%, and therapeutic blood levels should be quickly achievable. Depending on the severity of illness and the presence of comorbid conditions, pyelonephritis can be initially managed with oral outpatient therapy or with parenteral inpatient therapy. Patients with mild disease (low-grade fever and no signs of sepsis) who are otherwise healthy and do not have significant nausea or vomiting can be managed as outpatients with an oral fluoroquinolone or TMP-SMX [*see Figure 3 and Table 4*].[4,29,50] A randomized clinical trial demonstrated that 7 days of therapy with oral ciprofloxacin (with or without an initial intra-

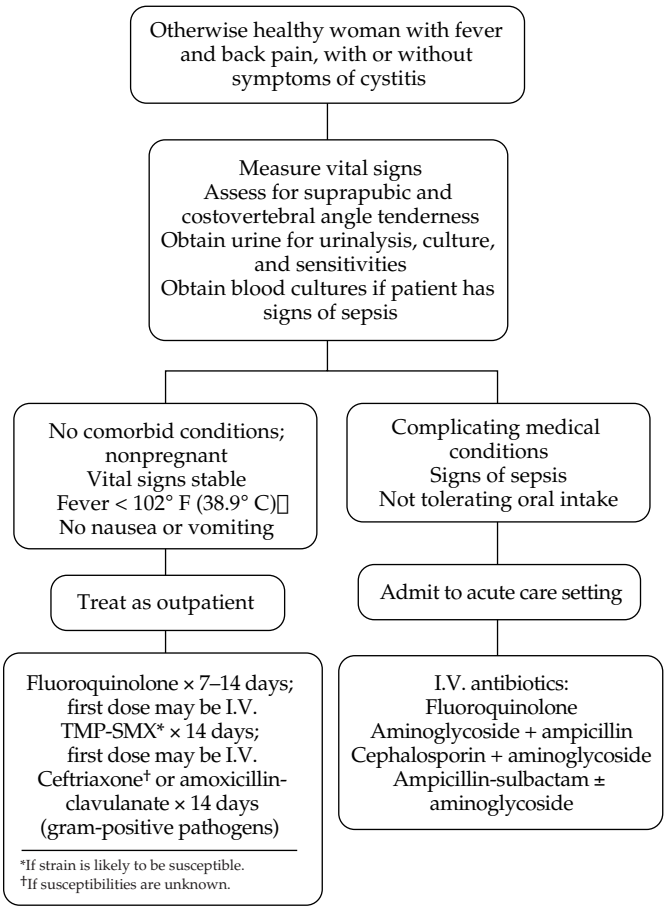

Figure 3 **Clinical approach to acute uncomplicated pyelonephritis in a woman.**

venous dose of the drug) was highly effective for the initial management of pyelonephritis in the outpatient setting.[50] Oral TMP-SMX is also very effective but should not be used unless the prevalence of TMP-SMX resistance in the area is very low or the strain is known to be susceptible.[29] An initial I.V. dose of ceftriaxone should be considered when oral TMP-SMX is being used, because in one study, patients receiving this combination regimen had high success rates even when the infecting strain was resistant to TMP-SMX.[51] Amoxicillin-clavulanate should be considered if the Gram stain suggests enterococci. Regardless of which outpatient oral regimen is chosen, an initial I.V. dose of a fluoroquinolone or a third-generation cephalosporin in an observed setting may be of benefit.[33]

Patients who are severely ill, cannot tolerate oral medication, or have complicating medical conditions should be hospitalized for parenteral therapy. Various regimens can be used, such as ampicillin plus gentamicin; fluoroquinolones; the third-generation cephalosporins (e.g., ceftriaxone); or, for susceptible strains, TMP-SMX. Combinations of a β-lactam and a β-lactamase inhibitor (e.g., ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam) or imipenem-cilastatin can be used in patients with more complicated histories, previous episodes of pyelonephritis, or recent urinary tract manipulations. After the patient has been afebrile for 24 hours (usually within 72 hours of initiating therapy), there is no benefit in maintaining parenteral therapy. Currently, prescription of oral TMP-SMX or a fluoroquinolone to complete a 14-day course of outpatient therapy appears to be the most effective means of eradicating both tissue infection and residual clones of uropathogens present in the GI tract that could cause early recurrence if allowed to remain.[29]

UTI during Pregnancy

There are three major differences between the approach to UTI in pregnant women and that in nonpregnant women. First, in pregnant women, asymptomatic bacteriuria is actively sought and is as aggressively treated and followed as symptomatic infection; this is clearly not the case in nonpregnant women, for whom screening for asymptomatic bacteriuria is not recommended. Second, although short-course therapy is also the cornerstone of treatment during pregnancy for patients with uncomplicated cystitis (as well as those with asymptomatic bacteriuria), the drugs that can be safely used are far more limited for pregnant women. Third, follow-up of patients with bacteriuria during pregnancy is more intense, with a more rapid deployment of prophylactic strategies in pregnant women with recurrent bacteriuria.[11]

Nitrofurantoin, ampicillin, and the cephalosporins have been considered relatively safe in early pregnancy. Sulfonamides should be avoided in the first trimester because of possible teratogenic effects and avoided near term because of a possible role in the development of kernicterus. Trimethoprim is usually avoided because of evidence of fetal toxicity at high doses in animals, although it has been used successfully in humans during pregnancy without evidence of toxicity or teratogenicity. Fluoroquinolones are avoided because of possible adverse effects on fetal cartilage development. Nitrofurantoin, ampicillin, and the cephalosporins have been used most extensively in pregnancy and are the regimens of choice for the treatment of asymptomatic or minimally symptomatic UTI [*see Table 3*]. For pregnant women with overt pyelonephritis, admission to the hospital for parenteral therapy should be the standard of care; β-lactams with or without aminoglycosides are the cornerstone of therapy.[11,51]

Prevention of UTI, including pyelonephritis, can be accomplished during pregnancy with nitrofurantoin or cephalexin taken prophylactically after coitus or at bedtime without relation to coitus. Such prophylaxis should be considered for patients who have had acute pyelonephritis during pregnancy, patients with bacteriuria during pregnancy who have had a recurrence after a course of treatment, and patients who had recurrent UTI before pregnancy that required prophylaxis.[11,52]

Treatment of Men with UTI

It is uncommon for men to have UTI that is analogous to acute uncomplicated cystitis in women. Even when seemingly uncomplicated UTI does occur, men should never be treated with short-course therapy, because of a high rate of early relapse. Instead, 7- to 14-day regimens of a fluoroquinolone should be prescribed. TMP-SMX is the best alternative drug, assuming susceptibility of the strain.[53]

In men older than 50 years with UTI, bacterial invasion of the prostate and possibly the kidneys should be considered, even in the absence of overt signs of infection at these sites. Acute bacterial prostatitis should be treated with a fluoroquinolone for 2 weeks or with TMP-SMX for at least 4 weeks. Recurrence is common and usually connotes a sustained focus in the prostate that has not been eradicated. Several factors make eradication of prostatic foci difficult. Many antimicrobial agents do not diffuse well across the prostatic epithelium into the prostatic fluid,

where the infection lies. The prostate may harbor calculi, which can block drainage of portions of the prostate gland or act as foreign bodies in which persistent infection can reside. An enlarged (and inflamed) prostate gland can cause bladder outlet obstruction, resulting in pools of stagnant urine in the bladder that are difficult to sterilize.[28]

In view of these factors, intensive therapy for at least 4 to 6 weeks is recommended for chronic bacterial prostatitis. The drugs of choice for this purpose, assuming the organisms are susceptible, are the fluoroquinolones. The best alternative agent is TMP-SMX. Prolonged treatment with any of these drugs has a greater than 60% probability of eradicating infection. Most therapeutic failures result from either anatomic factors or infection by *Enterococcus faecalis* or *P. aeruginosa;* these two organisms are particularly likely to cause relapse after treatment with the antimicrobial agents currently recommended. Relapses should be treated for 12 weeks. If this therapy fails, long-term antimicrobial suppression or repeated treatment courses for each relapse are often needed.[28]

Complicated UTI

Complicated UTI occurs in a heterogeneous group of patients with a wide variety of structural and functional abnormalities of the urinary tract and kidneys. The range of antimicrobial species and their susceptibility to antimicrobial agents are likewise heterogeneous. As a consequence, therapy for patients with complicated UTI requires individualization, although the following guidelines appear to be useful[54]:

- As a rule, only symptomatic UTI requires therapy.
- If symptoms of UTI are present, a urine culture and susceptibilities should always be obtained.
- If the antimicrobial susceptibilities of the infecting organism are not known and symptomatic infection requires immediate therapy, consideration of previous microbiology or recent antimicrobial exposures can help guide initial empirical therapy.
- In patients with mild disease [*see* Pyelonephritis, *above*]), an oral regimen with a fluoroquinolone, or possibly TMP-SMX, is appropriate and can be given in the outpatient or inpatient setting depending on other patient factors.
- In patients who cannot take oral regimens or who have more severe disease, intravenous therapy with fluoroquinolones or broad-spectrum agents such as ampicillin plus gentamicin, imipenem-cilastatin, or piperacillin-tazobactam should be considered until the susceptibilities of the invading organism are identified [*see Table 4*].
- Whenever possible, every effort should be made to correct the underlying complicating factor in conjunction with the antimicrobial therapy.

Asymptomatic Bacteriuria

Bacteriuria detected in the absence of symptoms referable to the urinary tract does not warrant antimicrobial therapy except in specific settings. These include during pregnancy, before surgery or instrumentation of the urinary tract, and after renal transplantation. Treatment of asymptomatic bacteriuria in patients who are immunosuppressed because of transplantation other than renal (i.e., other solid organ or bone marrow) or because of neutropenia has not been well studied and is not currently recommended as standard practice.

In women with diabetes and asymptomatic bacteriuria, a large randomized trial of antimicrobial treatment versus no antimicrobials found no difference in the time to first symptomatic UTI between the groups. The authors conclude that there is no benefit to screening for asymptomatic bacteriuria or treating it in women with diabetes.[55]

RADIOLOGIC EVALUATION TO RULE OUT FUNCTIONAL ABNORMALITIES

A final consideration in the management of UTI is the role of

Table 4 Treatment Regimens for Acute Pyelonephritis[4]

Patient Status	*Regimen*	*Comment*
Outpatient	Fluoroquinolones × 7–14 days*	Fluoroquinolones can be given orally throughout the entire course, if patient can tolerate oral intake
	Ciprofloxacin, 250–500 mg q. 12 hr	
	Ciprofloxacin XR, 1,000 mg q.d.	
	Gatifloxacin, 400 mg q.d.	
	Levofloxacin, 250–500 mg q.d.	
	TMP-SMX, 160/800 mg q. 12 hr × 14 days	If strain is likely to be susceptible
	Amoxicillin, 500 mg q. 8 hr or 875 mg q. 12 hr	
	Amoxicillin-clavulanate, 875/125 mg q. 12 hr × 14 days	If *Enterococcus* is suspected
Inpatient	I.V. fluoroquinolones × 14 days	Patients can be switched to oral therapy after they have been afebrile for 24 hr
	Ciprofloxacin, 200–400 mg q. 12 hr	Particularly useful if enterococcal infection is suspected
	Gatifloxacin, 400 mg q.d.	
	Levofloxacin, 250–500 mg q.d.	
	Ceftriaxone,* 1–2 g I.V. q. 24 hr, or other third- or fourth-generation cephalosporin	
	Ampicillin, 1 g I.V q. 6 hr *plus* gentamicin, 1 mg/kg I.V. q. 8 hr or 3–5 mg/kg I.V. q. 24 hr	
	Ampicillin-sulbactam	
	Ticarcillin-clavulanate	
	Piperacillin-tazobactam	Useful in complicated cases
	Imipenem-cilastatin	

*First dose of a fluoroquinolone or ceftriaxone may be given intravenously.
TMP-SMX—trimethoprim-sulfamethoxazole

radiologic evaluation. Intravenous pyelography, ultrasonography, or CT should be carried out expeditiously to rule out obstruction in any patient with acute pyelonephritis who does not respond to an effective antimicrobial agent and in any patient in whom a persistent bacteremia has been demonstrated. Contrast-enhanced helical CT is the radiologic study of choice for imaging and evaluation of renal infections. The study should be performed without contrast when renal calculi are suspected.[26]

For ambulatory patients who have UTI, guidelines are less clear. Radiographic evaluation, usually with intravenous pyelography and voiding cystourethrography, is carried out for delineation of surgically correctable lesions that might predispose patients to recurrent infection or progressive renal disease. Because congenital anatomic anomalies are particularly prevalent in young children who have a first or second UTI, such studies are obligatory for patients in this age group. In addition, careful prostatic examination and assessment of postvoiding residual urine volume should be considered in males with UTI at any stage of life because such infection is highly unlikely in this population unless anatomic anomalies or specific risk factors are present[55] [*see* Young Men, *above*]. In women with uncomplicated UTI, the incidence of correctable anatomic lesions is so low that radiologic and urologic evaluation should be restricted to patients who have rapid recurrence of infection or recurrent pyelonephritis despite adequate therapy.[26]

Catheter-Associated UTI

UTIs are the most common nosocomial infections, representing 40% of all such infections. Most nosocomial UTIs are related to bladder catheterization. Catheter-associated UTIs are associated with increased mortality and costs.[56,57] Multiple risk factors for catheter-associated UTIs have been identified, including the duration of catheterization, lack of systemic antibiotic therapy, female sex, age older than 50 years, and azotemia.[57] Risk factors for bacteremia related to catheter-associated UTI are not well established.

Several guidelines can be followed to minimize the occurrence of catheter-related infection [*see Table 5*]. Most important, the catheter should be inserted with strict aseptic technique by trained persons. In addition, a closed system should be used at all times. Even with optimal care, however, catheter use for 1 month or longer will eventually result in bladder infection. Apparently, little additional protection is provided by antibiotic rinses for the bladder, antibiotic ointments applied to the urethral meatus, and instillation of disinfectants such as hydrogen peroxide into the urinary collection bag. Although systemic antibiotics are of no value when the closed system is to be in place for an extended period, antibiotics may be protective when the catheter is in place for only a few days.[56] However, this advantage should be balanced against the risk of selecting for resistant flora if catheterization must be prolonged unexpectedly. In patients who require urethral catheterization for 2 to 10 days, use of a silver alloy–coated urinary catheter may offer some protection against infection.[58-60] In one randomized study of hospitalized patients, the use of a silver alloy–coated urinary catheter resulted in a lower rate of UTIs and a significant cost savings.[59] A nitrofurazone-impregnated catheter also has been shown to decrease the incidence of UTIs caused by gram-negative organisms.[60]

Treatment of catheter-associated UTI depends on the clinical circumstances. Symptomatic patients (e.g., those with fever, chills, dyspnea, and hypotension) require immediate antibiotic therapy [*see* Complicated UTI, *above*]. In addition, it may be useful to remove and replace the urinary catheter if it has been in place for a week or longer. This eliminates difficult-to-eradicate organisms in the biofilm on the catheter. In an asymptomatic patient, therapy should be postponed until the catheter can be removed. Patients with persistent asymptomatic bacteriuria and those with lower urinary tract symptoms who have had the catheter removed respond well to short-course therapy.[61]

Patients with long-term indwelling catheters seldom become symptomatic unless the catheter is obstructed or is eroding through the bladder mucosa. In patients who do become symptomatic, appropriate antibiotics should be administered, and the catheter should be changed. Therapy for asymptomatic catheterized patients leads to the selection of increasingly antibiotic-resistant bacteria.[56,57,60] Thus, although long-term bladder catheterization carries a significant risk of chronic pyelonephritis (10% or more if the catheter is in place for more than 90 days), there is no way to avoid this event other than by catheter removal.[62]

The appearance of *Candida* in the urine is an increasingly common complication of indwelling catheterization, particularly for patients in the intensive care unit, on broad-spectrum antimicrobials, or with underlying diabetes mellitus.[63] *C. albicans* is still the most common isolate, although *C. glabrata* and other non-*albicans* species are also frequently isolated. The clinical presentation can vary from an asymptomatic laboratory finding to sepsis. In asymptomatic patients, removal of the urethral catheter results in resolution of the candiduria in as many as one third of cases. For patients with symptomatic candiduria (fever with or without cystitis symptoms), oral fluconazole, 200 mg/day for 7 to 14 days, has been shown to be highly effective. This regimen was even effective for non-*albicans* species of *Candida* that had reduced susceptibility to fluconazole, possibly because of the high concentrations achieved in the urine. For more severely ill patients, the possibility of pyelonephritis and candidemia should be evaluated, and systemic antifungal therapy with fluconazole, 6 mg/kg/day, or amphotericin, 0.6 mg/kg or more a day, should be instituted.

Table 5 Guidelines for Bladder Catheter Care

Use catheters only when absolutely necessary; remove as soon as possible.
Insert catheters aseptically and maintain by trained personnel only.
A sterile closed drainage system is mandatory. The catheter and drainage tube must never be disconnected except when irrigation is necessary to relieve obstruction. Strict aseptic technique is employed under these circumstances.
Obtain urine for culture by aspirating the catheter with a 21-gauge needle after the catheter is prepared with povidone-iodine.
Maintain downhill, nonobstructed flow, with the collection bag always below the level of the bladder and emptied at frequent intervals.
Replace indwelling catheters when obstruction or concretions are demonstrated.
Strict hand-washing precautions should be observed by staff caring for these patients.
Administer prophylactic antibiotics during catheter insertion and removal to patients with cardiac disease (particularly prosthetic valves) that predisposes to bacterial endocarditis.

Prognosis

Although earlier epidemiologic studies suggested that bacteriuria, whether symptomatic or asymptomatic, was associated with increased mortality, more recent findings suggest that bacteriuria does not itself cause an increase in mortality.[64] Rather, bacteriuria appears to be a marker for poor health, particularly in elderly patients. Not surprisingly, then, antimicrobial therapy for asymptomatic bacteriuria in the elderly is of no demonstrable clinical benefit.[65,66]

The relationships between recurrent UTI, chronic pyelonephritis, and renal insufficiency have been widely studied. In the absence of anatomic abnormalities, recurrent infection in children and adults does not lead to chronic pyelonephritis or to renal failure. Also, infection does not play a primary role in chronic interstitial nephritis; the primary etiologic factors in this condition are analgesic abuse, obstruction, reflux, and toxin exposure. In the presence of underlying renal abnormalities, however, infection as a secondary factor can accelerate renal parenchymal damage. In children, the common combination of reflux, congenital anomalies, and infection appears to lead to significant renal parenchymal damage; moreover, kidneys in children appear to be more susceptible to damage than kidneys in adults.[23]

A retrospective questionnaire study has found that men and women newly diagnosed with renal cell carcinoma were more likely to have a history of cystitis or pyelonephritis sometime in their lifetime and to be smokers than persons without renal cell carcinoma.[67] The risk was greater for males than females. Although the study shows a possible association between UTI and renal cell cancer, data on causality, temporal relatedness, dose effect, and putative mechanisms are lacking.

XXIV HYPERTHERMIA, FEVER, AND FEVER OF UNDETERMINED ORIGIN

Harvey B. Simon, m.d., f.a.c.p.

Thermoregulation and Abnormal Elevation of Body Temperature

REGULATION OF BODY TEMPERATURE

Like so many biologic functions, human body temperature normally displays circadian rhythmicity, often rising from values of 36.1° C (97.0° F) or lower in the predawn hours to 37.4° C (99.3° F) or higher in the afternoon. This diurnal flux has two important practical consequences. First, fever associated with disease states is superimposed on the normal cycle and tends to peak in the evening; hence, a patient cannot be considered afebrile until his or her temperature has been monitored for at least 24 hours. Second, temperatures exceeding what is mistakenly regarded as the normal value of 37.0° C (98.6° F) are often recorded in perfectly healthy individuals.[1] Unfortunately, many patients with temperature elevations that are entirely physiologic have been subjected to potentially hazardous tests and treatments because their elevated temperatures were incorrectly regarded as pathologic.

Within the limits of the circadian rhythm, however, body temperature is closely regulated by homeostatic mechanisms that strike a balance between heat production and heat dissipation.[2] Heat is a by-product of all metabolic processes. At rest, metabolic activity in the liver and heart produces much of the body's heat; metabolic activity in skeletal muscle accounts for the greatly enhanced thermal load of exercise. Heat is dissipated at the body's surfaces; the skin accounts for about 90% of heat loss, with the lungs contributing most of the remaining 10%. In the basal state, about 70% of the body's thermal load is dissipated by conduction; 30% is removed by the evaporation of insensible perspiration. Radiation and convection are less important mechanisms of heat removal. When the ambient temperature rises or metabolic heat production increases, evaporation accounts for the major share of heat dissipation.

The preoptic nucleus of the anterior hypothalamus functions as the thermal control center and acts to maintain the body temperature at a set value—the so-called hypothalamic thermal set point.[3] In response to elevations in core body temperature (i.e., the temperature of the blood perfusing the internal organs), the hypothalamus stimulates the autonomic nervous system to produce cutaneous vasodilatation and sweating, both of which dissipate heat. In response to either a falling core temperature or a falling skin temperature, the hypothalamus conserves heat by causing cutaneous vasoconstriction. When cold stress is severe, the hypothalamus acts to increase heat production by stimulating muscular activity in the form of shivering; shivering is mediated by the action of somatic nerves, but it is an automatic and involuntary process.

MEASUREMENT OF BODY TEMPERATURE

Body temperature can be measured in several ways. In most clinical circumstances, rectal temperature is an accurate reflection of central (core) temperature. Sublingual (oral) temperature measurements are also useful; they are typically 0.4° C (0.7° F) lower than rectal temperatures[4] and are subject to more technical variation, especially when patients are unable to fully cooperate. Tympanic membrane temperatures are typically 0.4° C (0.7° F) below sublingual readings and have even greater variability.[4,5] Axillary temperature measurements are unreliable[6] but are often used in acutely ill patients.

HYPERTHERMIA AND FEVER

Abnormal elevation of body temperature, or pyrexia, can occur in one of two ways: hyperthermia[7] or fever [*see Figure 1*]. In hyperthermia, thermal control mechanisms fail, so that heat production exceeds heat dissipation. In contrast, in fever, the hypothalamic thermal set point rises, and intact thermal control mechanisms are brought into play to bring body temperature up to the new set point. The distinction between fever and

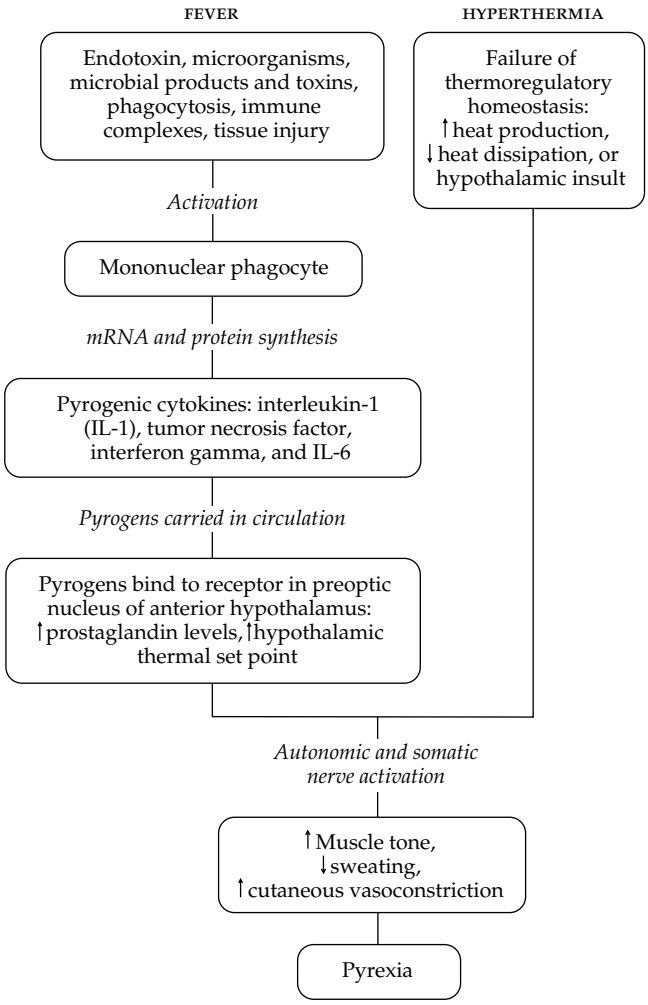

Figure 1 **Body temperature can rise to abnormal levels in one of two ways: hyperthermia or fever. In hyperthermia, thermal control mechanisms fail. In fever, by contrast, the hypothalamic thermal set point rises.**

hyperthermia is more than academic: hyperthermia is best treated with physical cooling methods that promote heat dissipation, whereas fever is best treated with drugs that lower the thermal set point, such as aspirin, other cyclooxygenase inhibitors,[8] or acetaminophen.

Hyperthermia

Hyperthermia is caused by the failure of thermoregulation; the pyrexia associated with it can be mild or severe. The most important causes of severe hyperthermia are heatstroke, neuroleptic syndrome, and malignant hyperthermia of anesthesia.

ETIOLOGY

Numerous clinical disorders can disrupt thermoregulatory homeostasis by causing increased heat production, decreased heat dissipation, or hypothalamic insult, thereby inducing hyperthermia [*see Table 1*]. Mild forms of hyperthermia are common. In dehydration, for example, cutaneous vasoconstriction and cessation of sweating occur in response to the decrease in intravascular volume as a means of conserving further loss of fluid and of minimizing the consequences of fluid loss. As a result, heat dissipation is impaired and body temperature may rise. The hyperthermia of dehydration is usually mild and is readily corrected by fluid replacement. In some cases, however, thermoregulatory disorders cause extreme pyrexia, in which body temperatures rise to 41.1° C (106.0° F) or higher[9]; examples of these thermoregulatory disorders are heatstroke, malignant hyperthermia of anesthesia, thyroid storm, and hypothalamic insult caused by infection, tumor, or drugs [*see 8:I Management of Poisoning and Drug Overdose*].

Numerous exogenous agents, including cocaine[10] and amphetamine, may cause severe hyperthermia. Because salicylates uncouple oxidative phosphorylation in skeletal muscle, excessive heat production is probably responsible for the hyperthermia seen in some children with severe aspirin toxicity.

The hyperthermia that may accompany thyroid storm and pheochromocytoma crisis also results from increased heat production, triggered in these cases by the calorigenic properties of thyroid hormones[11] and catecholamines.[12] Anticholinergic drugs may impair heat dissipation by reducing sweat production.

Hypothalamic disorders are uncommon causes of hyperthermia. Cerebrovascular accidents, however, may be responsible for sustained hyperthermia; this so-called central fever is easily confused with true fever caused by infection or drug hypersensitivity in patients who are hospitalized for major cerebrovascular accidents.

Because infectious and inflammatory diseases can also cause extreme fever, the magnitude of elevation of a patient's temperature cannot be used to distinguish between hyperthermia and fever.[9]

In most cases, hyperthermia is an acute rather than a recurrent problem, and the underlying disorder can be readily diagnosed by careful clinical examination. Exceptions occur in patients with endocrinologic[12] or hypothalamic disorders who present as diagnostic puzzles in the category of fever of undetermined origin (FUO) [*see* Fever of Undetermined Origin, *below*].

HEATSTROKE

Heatstroke is a life-threatening emergency characterized by a body temperature of 40° C (104° F) or higher and neurologic dysfunction that may include delirium, seizures, or coma.[13] Heatstroke occurs in warm, humid conditions: the high ambient temperature impairs heat loss by conduction, and the high ambient humidity limits heat dissipation by the evaporation of sweat. Sustained daily elevations in ambient temperature increase risk.[14] In one form of the syndrome, exertional heatstroke, exercise imposes the additional thermal burden of increased heat production.[15] In classic heatstroke, which is more common than the exertional form, increased heat production does not occur, but heat dissipation is often impaired as a result of a failure of sweating (anhidrosis), as well as of more subtle thermoregulatory problems imposed by underlying diseases and the medications used to treat them.

Table 1 Causes of Hyperthermia

Cause	*Example*
Excessive heat production	Delirium tremens Drug abuse (amphetamines) Exertional hyperthermia Generalized tetanus Heatstroke (exertional)* Lethal catatonia Malignant hyperthermia of anesthesia Neuroleptic malignant syndrome* Pheochromocytoma Salicylate intoxication Serotonin syndrome Status epilepticus Thyrotoxicosis
Diminished heat dissipation	Anticholinergic drugs Autonomic dysfunction Dehydration Heatstroke (classic)* Neuroleptic malignant syndrome* Occlusive dressings Drug abuse (cocaine)
Hypothalamic dysfunction	Cerebrovascular accidents Encephalitis Idiopathic hypothalamic dysfunction Neuroleptic malignant syndrome* Sarcoidosis and granulomatous infections Trauma Tumors

*Pathogenesis of these disorders is mixed.

Epidemiology

Heatstroke is far from rare. Between 1979 and 2002, more than 4,780 deaths in the United States were attributed to excessive heat exposure[16]; it seems likely that many cases of heatstroke go unrecognized or unreported and that hyperthermia also contributes to the morbidity and mortality attributed to underlying diseases.[17]

Classic heatstroke is the most common hyperthermic emergency.[7] Occurring principally during summer heat waves, classic heatstroke is most likely to affect the elderly and patients with serious underlying diseases. The urban poor are particularly vulnerable to classic heatstroke. Women are affected more often than men, and infants are also at risk.

Whereas classic heatstroke occurs in outbreaks, exertional heatstroke occurs sporadically and typically affects young, healthy individuals who engage in strenuous exercise. Exertional

heatstroke is much more common in men than in women. In the United States, military recruits, industrial workers, and athletes such as runners and football players are at greatest risk; in Saudi Arabia, both forms of heatstroke are particularly common during the annual hajj, the pilgrimage to Mecca.

Prevention

Hot, humid conditions are predisposing factors for both classic and exertional heatstroke. In addition to ambient weather conditions and muscular exertion, predisposing factors for exertional heatstroke include inappropriately heavy clothing, exposure to direct sunlight, dehydration,[18] lack of cardiovascular conditioning, lack of acclimatization to heat, and the use of performance-enhancing supplements such as Ma-huang (ephedrine) and creatine.[19] Because all of these factors can be anticipated and corrected, exertional heatstroke is preventable.

Classic heatstroke can be prevented[16] by publicizing community heat-wave alerts; providing cool environments for people at risk; encouraging the use of fans if air conditioners are not available; instructing those at risk to limit physical activity and sun exposure indoors and outdoors, to avoid cooking, to wear lightweight clothing, and to maintain adequate hydration; and promoting judicious use of diuretics, tranquilizers, antidepressants, and anticholinergic medications.

Pathophysiology

The crucial pathophysiologic events causing classic heatstroke are excessive ambient heat and humidity and impaired heat dissipation caused by anhidrosis. The typical victim of classic heatstroke is an elderly or debilitated person who is confined to a poorly ventilated room without benefit of an air conditioner or fan during a summer heat wave. Dehydration, which limits heat dissipation, is an important predisposing condition. Other factors that increase risk include neurologic and cardiovascular diseases, obesity, the use of diuretics, and the use of neuroleptics and other medications with anticholinergic properties; alcohol consumption also contributes to some cases.

The second form of heatstroke is triggered by exercising in a warm, humid environment. The major pathophysiologic mechanism responsible for exertional heatstroke is increased heat production from exercising skeletal muscles. Working at maximal intensity, muscle can increase its energy consumption to levels 20 times its basal rate; because the body's efficiency is only about 25%, much of this energy is converted into heat, which is transferred from muscle to blood, raising the core temperature. Patients who suffer exertional heatstroke do not appear to have intrinsic abnormalities of their thermoregulatory mechanisms, but they may have a high proportion of type II skeletal muscle fibers and lower work efficiency.[20]

Diagnosis

Early diagnosis is critical to prevent life-threatening complications. People who experience weakness or undue fatigue, lack of concentration or confusion, light-headedness or dizziness, headaches, nausea, or muscle cramps in the heat should cease exercise, get to a cool environment, and drink cool fluids to avert more serious heat injury. They should also be sure that medical help is available if symptoms progress.

Clinical features Despite differences in pathophysiology and epidemiology, the major manifestations of the classic and exertional heatstroke syndromes are similar. An abrupt rise in body temperature is universal; most patients with heatstroke have core temperatures in excess of 40.5° C (105° F). Disordered mentation is no less common and may span a spectrum ranging from confusion and lethargy to delirium, stupor, coma, and seizures. Virtually all patients with heatstroke also exhibit cardiovascular abnormalities. Tachycardia is present in most patients, and hypotension is present in many; shock, arrhythmias, myocardial ischemia, and pulmonary edema are most likely to occur early in elderly or debilitated patients with classic heatstroke but are also frequent preterminal events in patients with exertional heatstroke. Most heatstroke victims present with hyperventilation and respiratory alkalosis; pulmonary abnormalities may also include pulmonary edema, acute respiratory distress syndrome, and aspiration pneumonia. Other common clinical manifestations of heatstroke include oliguria, vomiting, and diarrhea; hematuria and gastrointestinal bleeding may reflect disseminated intravascular coagulation (DIC). Cutaneous manifestations of heatstroke may include hemorrhagic lesions; the skin is hot and dry in many patients with classic heatstroke but is often moist and clammy in patients with exertional heatstroke.

Laboratory findings Laboratory abnormalities in patients with heatstroke reflect widespread damage to a number of organ systems. Leukocytosis is common, and hemoconcentration may raise the hematocrit in patients who are volume depleted. Thrombocytopenia is frequently present and may be severe; prolonged prothrombin times, depressed fibrinogen levels, and elevated levels of fibrin split products indicate DIC, which is more common in exertional heatstroke than in classic heatstroke. DIC in heatstroke has been attributed to direct thermal injury to vascular endothelium; clinically significant bleeding may result from the coagulopathy, which can persist for 36 hours after the onset of heatstroke.

Renal abnormalities are common in heatstroke. The urine may sometimes be dilute despite hypotension and oliguria; hematuria, myoglobinuria, proteinuria, and casts are frequently observed. The blood urea nitrogen (BUN) and creatinine levels are usually elevated; acute renal failure occurs in about one third of patients with exertional heatstroke but is less common in patients with classic heatstroke.

Elevated bilirubin levels in patients with heatstroke may reflect hepatic injury, hemolysis, or both. Elevated transaminase levels are the rule, reflecting damage to both liver and muscle cells. Elevated creatine phosphokinase (CPK) and aldolase levels indicate muscle injury; severe rhabdomyolysis with myoglobinuria and renal failure is much more common in exertional than in classic heatstroke.

Heatstroke causes numerous metabolic abnormalities. Respiratory alkalosis is common early in the syndrome, particularly in classic heatstroke; lactic acidosis may supervene, particularly in exertional heatstroke. Potassium levels are variable, sometimes being low early and high later in the course of heatstroke. Hypophosphatemia is the rule; hypokalemia may occur, particularly in exertional heatstroke. Hypoglycemia, perhaps reflecting depletion of glycogen stores, has been reported in many patients with exertional heatstroke. Electrocardiographic abnormalities include conduction disturbances and ST-T segment changes. Elevated levels of pyrogenic cytokines have been reported in heatstroke patients,[21] but it is unclear whether the cytokines participate in the pathogenesis of heatstroke or simply reflect a subsequent host response to tissue injury.[13]

Differential Diagnosis

The differential diagnosis of elevated body temperature with numerous clinical and laboratory abnormalities is broad and includes sepsis, the systemic inflammatory response syndrome, and the other causes of hyperthermia. In practical terms, the major challenge is to distinguish classic heatstroke from sepsis and to distinguish exertional heatstroke from less severe exercise-induced abnormalities, such as exertional hyperthermia and heat exhaustion.[15]

Treatment

Heatstroke necessitates prompt and aggressive therapy. Lowering body temperature is the crucial element in management; because the pathogenesis of heatstroke involves thermoregulatory failure rather than an elevated hypothalamic set point, physical cooling is essential, but antipyretic medications are ineffective.

Field management includes removing the patient's clothing, fanning the patient, and bathing the patient's skin with cool water; ice packs should be applied if they are available. First-aid measures to maintain the patient's airway and prevent injury are important. The patient should be protected from sunlight and should be moved to a cool environment and evacuated to an emergency ward as soon as possible. Hypothermic mattresses or, in urgent circumstances, ice-water immersion may be employed. These treatments are very uncomfortable and should be used only when the hyperthermia is truly deleterious. Cool intravenous fluids should be administered as soon as parenteral therapy becomes available, but oral hydration is inadvisable because of the risk of aspiration.

Physical cooling must continue after the patient arrives in the emergency ward; many techniques are available, but choosing among them is difficult. Immersion in ice water has been a standard approach. Another traditional technique is the application of ice packs to the body surface. Both techniques have the disadvantage of producing cutaneous vasoconstriction, which could impede the transfer of heat from the body's surface; ice-water baths may also pose logistic difficulties in heatstroke patients who are combative and in those with seizures, vomiting, or diarrhea. Despite these drawbacks, ice-water baths are effective; there were no fatalities in a series of 252 marine recruits whose therapy for exertional heatstroke included ice-water immersion.[22] A newer technique for cooling relies on evaporation rather than conduction to dissipate heat: the patient is sprayed with water at a temperature of 15° C; then warm air at a temperature of 30° to 35° C is blown on the patient. A special body-cooling unit that facilitates evaporative cooling has been used with good results in Saudi Arabia.[23] Although alcohol is more volatile than water, it should not be used for evaporative cooling because of the risk of alcohol intoxication, especially in children. Many other cooling techniques, ranging from ice-water enemas and gastric lavage to the use of the downdraft from helicopter blades, have been used to treat heatstroke but are of secondary importance. In general, hospitals in the United States should choose a cooling technique on the basis of their experience and facilities.

Body temperature should be monitored continuously during cooling; in most cases, body temperature will decline significantly in 10 to 40 minutes, at which time cooling should be reduced to avoid hypothermic overshoot with associated shivering and rigors.

The administration of room-temperature intravenous fluids is an important aspect of therapy, helping to lower core temperature and to correct dehydration; meticulous cardiovascular monitoring is essential to prevent fluid overload while ensuring adequate volume replacement. In addition to needing cardiovascular support, patients with heatstroke require careful respiratory monitoring and support, along with fluid and electrolyte monitoring and therapy. Complications such as rhabdomyolysis, renal failure, aspiration pneumonia, DIC, and seizures necessitate additional therapeutic interventions. Despite its efficacy in malignant hyperthermia of anesthesia (see below), dantrolene sodium is ineffective in heatstroke.[21]

Even with aggressive therapy, heatstroke has an appreciable mortality. Most patients who recover have normal thermoregulatory mechanisms and heat tolerance, but all should be instructed on ways to reduce the risk of recurrences.

NEUROLEPTIC MALIGNANT SYNDROME

Etiology

First described in 1960, the neuroleptic malignant syndrome (NMS) is uncommon, occurring in fewer than 1% of patients receiving neuroleptic agents [*see 8:I Management of Poisoning and Drug Overdose and 13:VIII Anxiety Disorders*]. NMS usually occurs within the first 30 days of therapy; haloperidol is most often implicated, but other butyrophenones (e.g., droperidol), various phenothiazines, thioxanthenes, atypical antipsychotics (e.g., resperidone and clozapine), tricyclic antidepressants, and monoamine oxidase (MAO) inhibitors may also be responsible.[24-26] Nonpsychiatric drugs such as metoclopramide have occasionally been linked to NMS.[25] NMS may also be precipitated by the withdrawal of amantadine, levodopa, or other dopaminergic drugs used to treat Parkinson disease.[27] In some cases, dehydration and agitation are contributing factors.

Pathophysiology

NMS is primarily a disorder of excessive heat production. It is probably precipitated by the blockade of dopaminergic receptors in the nigrostriatal tracts, leading to uncontrolled contractions of skeletal muscle, which, in turn, produce excessive body heat. There is no genetic predisposition for NMS, nor does it occur as a result of a drug overdose. Physical exhaustion, dehydration, and underlying organic brain syndromes have been cited as predisposing factors. Some patients who have recovered from NMS have subsequently received neuroleptic agents without suffering recurrences of NMS, but recurrent NMS does develop in 30% of patients who are rechallenged with neuroleptics.

Diagnosis

The clinical features of NMS evolve progressively, usually over a period of 1 to 3 days. Hyperthermia is universal. Other symptoms include bradykinesia, severe muscular rigidity (sometimes described as lead-pipe rigidity); altered sensorium; autonomic dysfunction that produces tachycardia, labile blood pressure, and diaphoresis; and extrapyramidal abnormalities. Laboratory abnormalities include hypernatremia and other electrolyte abnormalities, acidosis, hemoconcentration and leukocytosis, rhabdomyolysis, and abnormal findings on renal and hepatic function tests.

Differential Diagnosis

The differential diagnosis of NMS includes infections, lethal catatonia,[28] an uncommon psychiatric disorder in which agita-

tion progresses to muscular rigidity and hyperthermia, and the serotonin syndrome (see below).

Treatment

The offending neuroleptic agent must be withdrawn in all cases of NMS. Physical cooling as treatment of NMS has not been evaluated in clinical trials but should prove useful in the acute phase of the disorder. Meticulous fluid and electrolyte therapy and careful cardiovascular support are mandatory. Dantrolene sodium, a muscle relaxant, and bromocriptine, a dopamine agonist, have each been reported to reduce the duration of hyperthermia, but these agents have not been evaluated in controlled trials.[29] Aggressive therapy has allowed the mortality associated with NMS to decline to about 10%; patients who recover face a 30% risk of recurrence.[25]

SEROTONIN SYNDROME

The serotonin syndrome[30] has become more prevalent with the increasing use of selective serotonin reuptake inhibitors (SSRIs) and other serotoninergic agents. Because of its broad range of clinical manifestations and the large number of prescription, over-the-counter, and herbal products that have been implicated, the serotonin syndrome is often unrecognized. The actual prevalence is not known, but it occurs in 14% to 16% of patients who take overdoses of SSRIs. The syndrome results from excessive agonism of serotoninergic receptors in the central and peripheral nervous systems.

Diagnosis

The syndrome begins abruptly within 5 weeks of using serotoninergic agents, either singly or in combination. In mild cases, patients exhibit hyperkinesia, intermittent tremors, hyperreflexia and clonus, hyperactive bowel sounds, diarrhea, mydriasis, and tachycardia. Patients with mild cases of the syndrome may exhibit shivering and diaphoresis, but body temperature is normal. In moderate to severe cases, however, hyperthermia is the rule and may be severe. Muscular rigidity, agitation, and ocular clonus or inducible clonus are characteristic features of the severe serotonin syndrome.

Differential Diagnosis

The differential diagnosis includes infection, anticholinergic poisoning, which can be distinguished on the basis of its normal reflexes and absent bowel sounds, and malignant hyperthermia of anesthesia (see below). NMS is the major mimic of the serotonin syndrome, but the symptoms of NMS evolve more slowly, and patients typically display bradykinesia or akinesia and so-called lead-pipe muscular rigidity rather than hyperkinesia, tremors, hyperreflexia, and clonus.

Treatment

Management of the serotonin syndrome requires removal of the responsible drug or drugs and metabolic and hemodynamic support. In mild cases, agitation and tremors can often be controlled with benzodiazepines; however, severely ill patients require sedation, neuromuscular paralysis, and ventilator support. Antipyretics, beta blockers, bromocriptine, and dantrolene are not effective. Cyproheptadine, olanzapine, and chlorpromazine have been useful in isolated cases but have not been studied fully.[30]

MALIGNANT HYPERTHERMIA OF ANESTHESIA

Like NMS, malignant hyperthermia of anesthesia (MHA) is a high-mortality disorder of involuntary skeletal muscle hyperactivity and excessive heat production triggered by a pharmacologic agent. Unlike NMS and the serotonin syndrome, however, MHA is a genetically determined disorder precipitated by anesthetic agents such as halogenated inhalation agents and depolarizing muscle relaxants. Mutations in the gene encoding the skeletal muscle ryanodine receptor type I (*RYRI*) are often responsible for the disorder.[30] Persons who are susceptible to MHA may be identified by a family history of the disorder and by performance of a muscle biopsy and a caffeine-halothane contracture test; mutation analysis and other noninvasive tests to identify susceptible individuals are being developed.[31]

Diagnosis

MHA usually begins shortly after the anesthetic is administered, but it may be delayed for hours. Muscular rigidity and severe hyperthermia are typical; other findings include tachycardia, hypotension, arrhythmias, hyperpnea, hypoxia, hypercapnia, hyperkalemia, lactic acidosis, rhabdomyolysis, and DIC.

Treatment

MHA is an anesthetic emergency. Early detection of hypercapnia during general anesthesia and prompt treatment using intravenously administered dantrolene sodium have markedly improved the prognosis of patients with MHA. Discontinuance of anesthesia is mandatory; physical cooling is therapeutically important, as are cardiopulmonary support and correction of the metabolic abnormalities.

Fever

Fever has been recognized as a cardinal feature of disease since antiquity, but only recently has the pathophysiology of fever come to be understood. Beginning with the work of Dr. Paul Beeson in 1948, it became clear that the ultimate cause of fever is not a bacterial product (a so-called exogenous pyrogen) but a product of host inflammatory cells (i.e., an endogenous pyrogen). For years, the endogenous pyrogen was thought to be a product of polymorphonuclear leukocytes and was referred to as leukocytic pyrogen. Exciting studies, however, have demonstrated that mononuclear phagocytes are the principal source of endogenous pyrogen and that a variety of mononuclear cell products—cytokines—can mediate the febrile response.[32,33] Cytokines are also important as mediators of the acute-phase response to infection and inflammation.

PATHOPHYSIOLOGY

The cytokines interleukin-1 (IL-1), IL-6, interferon gamma, and tumor necrosis factor (TNF) function as pyrogens by acting directly on the hypothalamus to elevate the thermal set point. A variety of stimuli, such as microorganisms, exposure to endotoxin and other bacterial toxins or microbial products, phagocytosis, antigen-antibody immune complexes, and various forms of tissue injury, can initiate IL-1 production by mononuclear phagocytes and many other cells. In the pathogenesis of fever, IL-1 acts as a hormone in that it is carried by the circulation from the local inflammatory site of production to the CNS, where it acts directly on the hypothalamic thermal control center. Its mechanism of action appears to involve induction of phospholipases, which in turn cause the release of arachidonic acids from membrane phospholipids. As a result, prostaglandin levels rise, particularly levels of prostaglandin E. Elevated levels of prostaglandins ap-

pear to be important in raising the hypothalamic thermal set point; this mechanism accounts for why prostaglandin inhibitors such as aspirin are effective antipyretic agents.[8]

Although this classic model of pathogenesis has been validated by numerous studies of fever, further research suggests that several additional pathways may be involved. For example, pyrogenic cytokines may be produced locally in the CNS as well as systemically,[34] and cytokines may signal the thermal control center by neural as well as hormonal mechanisms.[35]

Once the hypothalamic thermal set point has been elevated, thermoregulatory mechanisms are brought into play to raise the body temperature to the level of the new set point. Autonomic efferents lead to heat conversion through cutaneous vasoconstriction and cessation of sweating. Somatic nerves are responsible for increasing heat production via increased skeletal muscle tone or shivering. The myalgias that accompany many febrile states may in part be caused by this increased muscle tone. Rigor, which is a dramatic precursor of some fever spikes, is nothing more than an exaggerated form of shivering that rapidly elevates body temperature in response to an increased hypothalamic thermal set point.

CONSEQUENCES OF ELEVATED BODY TEMPERATURE

Possible Benefits of Fever

Although fever is a common response to infection in many species, there is no direct evidence that it is beneficial to host defense mechanisms in humans. However, insights into the immunostimulatory properties of IL-1 and TNF have led to speculation that fever itself may promote recovery from infection.[36] IL-1 and TNF appear to act across species, order, and class barriers and probably evolved 300 million years ago; this evolutionary stability further suggests that fever plays a role in host defense mechanisms.

In humans, fever appears to decrease serum iron levels. Many microbes need iron for growth, and it has been suggested that fever-induced hypoferremia is a helpful host defense mechanism. Fever is also marked by a metabolic shift away from glucose, an excellent substrate for bacteria, to fat and protein as energy sources. In addition, some microbes, including gonococci and *Treponema pallidum,* are quite heat sensitive and can be killed in experimental animals by artificially induced fevers. However, natural infection never produces body temperatures that are high enough to have this effect.

Extreme pyrexia may be surprisingly well tolerated. It seems likely that the widespread tissue damage, multiple laboratory abnormalities, and high mortality observed in disorders such as heatstroke, MHA, thyroid storm, the serotonin syndrome, and NMS are caused by the underlying disorder rather than the elevated temperature itself. Indeed, in the preantibiotic era, fever therapy was well tolerated, with little evidence of tissue damage, despite the fact that temperatures as high as 41.7° C (107.1° F) were induced.

Therapeutic hyperthermia is being used to treat noninfectious diseases. Regional hyperthermia is a traditional therapy for many musculoskeletal disorders. Heating pads, whirlpools, and ultrasonography have all been used to increase the temperature of injured tissues. Despite widespread endorsements by patients and practitioners, however, heat treatments for musculoskeletal injuries have not been subjected to controlled clinical trials. Hyperthermia is also being investigated for a possible role in treating malignancies. Adjunctive regional hyperthermia often improves the rate of response when compared with radiotherapy or chemotherapy alone; superficial tumors respond most favorably, but better responses may be obtained with internal malignancies as techniques for deep heating are improved.

Complications of Fever

Pyrexia can have deleterious consequences, but complications depend more on the underlying cause of the temperature elevation and the patient's overall condition than on the level of the temperature. Elevated body temperatures are most harmful to the very young and the very old. Because pyrexia increases oxygen consumption, it imposes circulatory demands that may precipitate ischemia, arrhythmias, or congestive heart failure in patients with cardiovascular disease. Fever during pregnancy does not appear to cause fetal death,[37] but during the first trimester, fever may increase the risk of congenital heart disease.[38] Febrile seizures are a risk in children between 6 months and 6 years of age. The patient's age and the degree of fever are the major risk factors; genetics may also influence vulnerability.[39] Although febrile convulsions are generally benign, they are alarming, and it is always necessary to exclude underlying neurologic illnesses, including meningitis.[40] Both intravenous diazepam and intranasal midazolam are effective in controlling febrile convulsions.[41] In the absence of unprovoked seizures, long-term anticonvulsant therapy is usually unnecessary in children with febrile seizures and may even be deleterious; diazepam, administered orally only when fever occurs, safely and effectively reduces the risk of recurrent febrile seizures.[42] The long-term prognosis is excellent.[43]

Febrile seizures do not occur in adults, but fever often results in decreased concentration and sleepiness; high temperatures commonly produce an altered sensorium, including stupor and delirium. Patients with strokes are at risk for additional brain injury from fever; the result is a marked increase in morbidity and mortality,[44] especially when the pyrexia occurs soon after the stroke.[45] Because of this, even modest elevations in temperature should be suppressed in patients with acute strokes.[46] In addition, moderate induced hypothermia may improve the outcome of strokes, even in patients who are afebrile on presentation.[47] Hypothermia may also improve outcome after traumatic brain injury[48] in neonates with hypoxic-ischemic encephalopathy,[49] and in patients receiving cardiopulmonary resuscitation.[50]

DIAGNOSIS

The diagnostic process involves determining whether the patient is febrile, which requires (1) accurate measurements of body temperature and comparisons of body temperature with the diurnal range of normal body temperature and (2) a determination of whether the elevation in temperature is the result of inflammation or infection (fever) rather than thermoregulative failure (hyperthermia).

TREATMENT

The approach to the febrile patient involves three elements: diagnosis and management of the underlying disorder; cardiac, respiratory, and metabolic support; and, when indicated, lowering of body temperature. Infection is the leading cause of elevated body temperature; all febrile patients should be systematically evaluated for infection, and antibiotics should be administered whenever appropriate.

In patients with extreme pyrexia, additional laboratory studies are important both to screen for hyperthermia caused by thermoregulatory defects and to assess tissue damage. Elec-

trolytes, coagulation parameters, muscle enzymes, and arterial blood gases should all be measured, and renal and liver function should be assessed. Studies of thyroid and adrenal function may be indicated. Cardiac function, blood pressure, urine output, and neurologic status should be monitored closely. Adequate hydration is mandatory, and circulatory or respiratory support may be necessary.

Proper management of the elevated temperature itself depends on the clinical circumstances. Although clinicians usually choose to suppress fever, it is unclear whether elevated body temperatures promote or impede recovery from infection; similarly, the risks and benefits of antipyretic therapy have not yet been defined.[8,51,52] Because many patients tolerate high body temperatures very well, antipyretic therapy may actually produce more discomfort than the pyrexia itself. In other patients, myalgias, flushing, fatigue, loss of concentration, shivering, or chills can be very uncomfortable, and antipyretic therapy should be used for symptomatic relief. Significant pyrexia should always be treated in patients with strokes, in young children, in elderly or debilitated patients, and in persons with cardiopulmonary disease, because these patient groups are most likely to suffer adverse consequences. Hyperthermia should be treated in all patients with MHA, heatstroke, NMS, the serotonin syndrome, or thyroid storm. Finally, it may be prudent to treat any patient whose temperature exceeds 40° C (104° F), even a healthy young adult.

The choice of cooling technique depends on the pathogenesis of the temperature elevation [*see Figure 1*]. In patients with fever caused by infection or other inflammatory states, an elevated hypothalamic thermal set point is responsible for the pyrexia. Aspirin or acetaminophen should be used to lower the set point; the drugs seem equally effective as antipyretics, but acetaminophen is preferred in pediatric patients because aspirin may precipitate Reye syndrome in children with influenza or varicella. A broad range of nonsteroidal anti-inflammatory drugs (NSAIDs) and other cyclooxygenase-2 (COX-2) inhibitors can also lower the set point.[8,53] Acetaminophen may act by inhibiting COX-3, a COX-1 variant.[54] If physical cooling methods are used before antipyretic drugs are fully effective, homeostatic mechanisms will continue to operate in an attempt to raise body temperature, resulting in intense vasoconstriction and shivering,[55] which produce adverse cardiovascular and metabolic effects, as well as intense patient discomfort. To avoid these problems, febrile patients who require physical cooling to rapidly lower body temperature should be heavily sedated and ventilated to prevent shivering in conjunction with physical cooling.[56] In contrast, physical cooling is the treatment of choice for patients with hyperthermia. In all patients, careful attention is required to prevent hypothermic overshoot on the one hand and recurrent fever on the other.[57] Although pyrexia may be the most spectacular symptom, meticulous attention to the underlying disorder is of primary importance in all cases.

Fever of Undetermined Origin

FUO presents one of the most challenging and perplexing problems in clinical medicine. Such fevers may persist for weeks or months in the absence of characteristic clinical findings or clues. Ultimately, most such obscure fevers prove to be caused by common diseases presenting in an atypical fashion rather than by rare and exotic illnesses.

Petersdorf and Beeson, in their classic monograph,[58] specified three criteria to define FUO:

1. Duration: at least 3 weeks. This requirement eliminates from consideration most short-lived fevers of indeterminate or viral origin and most postoperative fevers.
2. Magnitude: a temperature higher than 38.3° C (100.9° F) on at least several occasions. This criterion eliminates from consideration persons with unusually prominent circadian fluctuations in body temperature with daily readings on the order of 38.0° C (100.4° F). If such persons are not clinically ill, their elevated temperature should not cause too much concern.
3. Obscure nature: perplexing enough to defy diagnosis after 1 week of study. In the past, inpatient study was required to evaluate FUO, but with changing admission practices, intelligent and thorough study encompassing at least three outpatient visits or 3 days in the hospital is now considered sufficient.[59]

ETIOLOGIC CLASSIFICATION

Although geographic factors are relevant, the leading causes of FUO are reasonably uniform throughout the United States. The relative frequency of the etiologic categories responsible for FUO have been relatively stable over the past 5 decades [*see Table 2*]. In a community hospital study,[60] noninvasive testing provided the diagnosis in 42% of patients, with serologies and lysis centrifugation blood cultures being the most useful noninvasive techniques. Computed tomography–guided percutaneous biopsies were the most useful invasive procedures. Only 9% of patients remained undiagnosed. With an increasing population of

Table 2 Causes of Fever of Undetermined Origin Over 5 Decades

Cause	*Study*				
	New Haven, 1961[58] *(% of 100 Patients)*	*Boston, 1973*[104] *(% of 128 Patients)*	*Seattle, 1982*[105] *(% of 105 Patients)*	*Rhode Island, 1992*[60] *(% of 89 Patients)*	*Leuven, Belgium, 2003*[106] *(% of 290 Patients*)*

Table 3 Causes of Fever of Undetermined Origin

Systemic Infections
- Tuberculosis (miliary)
- Infective endocarditis (primarily bacterial endocarditis but also endocarditis with a fungal, Q fever, or chlamydial etiology)
- Bacteremia from an inapparent primary focus
- Chronic meningococcemia
- Brucellosis
- Listeriosis, vibriosis, leptospirosis, relapsing fever (caused by *Borrelia recurrentis*), rat-bite fever (caused by either *Streptobacillus moniliformis* or *Spirillum minus*)
- Miscellaneous
- Psittacosis, toxoplasmosis (disseminated acquired form), Q fever, disseminated deep mycotic infections (e.g., histoplasmosis, blastomycosis, cryptococcosis), cytomegalovirus infection, Whipple disease

Localized Infections and Abscesses
- Hepatic infections
- Liver abscess
- Cholangitis
- Intraperitoneal infections
- Upper abdomen: empyema of gallbladder, pericholecystic and subhepatic abscesses, right or left subphrenic abscesses, lesser sac abscess
- Lower abdomen: periappendiceal and peridiverticular abscesses
- Other intra-abdominal abscesses
- Tubo-ovarian abscess, pelvic inflammatory disease, pelvic abscess
- Retroperitoneal abscess, pancreatic abscess
- Urinary tract infections
- Perinephric abscess
- Renal carbuncle
- Pyelonephritis with ureteral obstruction and pyonephrosis
- Prostatic abscess

Neoplasms
- Hematopoietic malignancies: Hodgkin disease and other lymphomas, leukemias, myeloid metaplasia, malignant histiocytosis
- Other malignancies: renal cell cancer, colon cancer, hepatoma
- Benign neoplasms: left atrial myxoma, pheochromocytoma

Collagen Vascular Diseases
- Temporal arteritis, adult-onset juvenile rheumatoid arthritis, Wegener granulomatosis, polyarteritis, systemic lupus erythematosus, relapsing polychondritis

Granulomatous Diseases
- Sarcoidosis, idiopathic granulomatous hepatitis

Metabolic and Hereditary Disorders
- Familial Mediterranean fever, Fabry disease

Endocrine Disorders
- Adrenal insufficiency, thyrotoxicosis, hyperparathyroidism

Thermoregulatory Disorders
- Hypothalamic dysfunction (e.g., caused by strokes or tumors), encephalitis

Drug Fever
- Antimicrobial agents (β-lactam antibiotics, sulfonamides, nitrofurantoin, isoniazid), antihypertensives (hydralazine), anticonvulsants (phenytoin), allopurinol, and many others

Miscellaneous Conditions
- Pulmonary emboli, alcoholic hepatitis and cirrhosis, inflammatory bowel disease, thrombophlebitis, factitious fever

immunosuppressed and chronically ill patients, the relative importance of the disorders that cause FUO may change. As a result, it may be prudent to consider so-called classic FUO separately from FUO in patients with HIV infection, neutropenia, or nosocomial fevers.[59,61-63] Despite changes in host factors and diagnostic techniques, the basic categorization of the causes of FUO remains valid.

Infections

In the initial evaluation of FUO, the possibility of infection should be carefully considered.

Systemic infections The two major systemic infections to consider in the evaluation of FUO are tuberculosis (usually disseminated but sometimes confined predominantly to the liver and spleen) and infective endocarditis [*see Table 3*]. Most FUO cases caused by miliary tuberculosis arise in elderly patients in whom dissemination has followed activation of quiescent foci. Often, in cases caused by miliary tuberculosis, the intermediate-strength (5 tuberculin units) purified protein derivative skin test is negative, and miliary pulmonary lesions are not present on the chest x-ray. Anemia, leukopenia, or, rarely, a leukemoid reaction caused by bone marrow involvement may be evident; bone marrow biopsy is a very helpful diagnostic test in patients in whom miliary tuberculosis is suspected. An isolated elevation of the serum alkaline phosphatase level may indicate miliary involvement of the liver by tuberculosis, other infection, or neoplasm. The histologic findings on liver biopsy often suggest the diagnosis, and a portion of the specimen should always be cultured for the presence of tubercle bacilli.

Infective endocarditis, usually subacute, is also an important diagnostic consideration. Most patients with subacute bacterial endocarditis have a heart murmur. In about 5% of cases, however, particularly in the elderly, the murmur may be absent or may be considered functional. Blood cultures would be expected to provide the diagnosis in a patient with subacute bacterial endocarditis, particularly because only 5% of patients with endocarditis have negative blood cultures. The leading cause of negative blood cultures in patients with endocarditis is the prior administration of antibiotics. It is therefore very important that a number of blood cultures be obtained, including some as long as 5 to 10 days after antibiotics have been withdrawn. Other causes of culture-negative endocarditis that should be considered in patients with FUO include infection with fastidious bacteria, chlamydial infection, and Q fever. Careful scrutiny for the peripheral stigmas of endocarditis is essential in the evaluation of any patient with FUO. Echocardiography may reveal valvular vegetations in patients with endocarditis; transesophageal studies are more sensitive but more invasive than transthoracic echocardiography. Left atrial myxomas mimic culture-negative endocarditis but may be detected with echocardiography.

Other systemic infections, including bacteremias that occur in the absence of any obvious primary site of involvement, only rarely cause FUO [*see Table 3*]. Viral infections are usually self-limited and do not produce fevers that last longer than 3 weeks. Important exceptions to this generalization are Epstein-Barr virus (EBV)[64] and cytomegalovirus (CMV) infections, which may occasionally present as FUO (often with some mononucleosis-like features) in otherwise healthy individuals. More frequently, CMV infection develops in patients who have received multiple blood transfusions or who have undergone organ transplantation; CMV is the cause of 50% of all febrile episodes in renal transplant recipients.

Localized infections The more common types of localized infection that present as FUO include hepatic abscess, subphrenic abscess, and subhepatic and pericholecystic abscess [*see Table 3*]. Liver abscesses are often occult; the physician should look for a history that includes symptoms of biliary tract disease, recent blunt abdominal trauma, or travel, which might suggest

the diagnosis of amebiasis. Hepatomegaly may be absent initially. The serum alkaline phosphatase level is usually elevated even when the abscess is solitary. Serologic tests for amebiasis are positive in patients with amebic liver abscess. Elevation of the diaphragm, particularly when accompanied by overlying pulmonary atelectasis or a pleural effusion, should raise suspicion of a subphrenic abscess. Ultrasonography and CT are valuable in identifying such collections; gallium scans are less useful for this purpose.

Localized infection in the urinary tract is an important consideration in a patient with FUO; perinephric abscess and renal carbuncle are best diagnosed by ultrasonography or CT. Many other localized infections occasionally present as FUO; occult dental infections are one such example and illustrate the need for thoroughness in the evaluation of patients with obscure fevers.

Neoplasms

Lymphoma, particularly Hodgkin disease, is the most common neoplastic cause of obscure fever. Lymphoma may be difficult to diagnose when the principal site of involvement is the retroperitoneal nodes, but abdominal CT scans greatly facilitate this diagnosis; a skin biopsy may help identify intravascular lymphoma as the cause of an FUO.[65] Although so-called Pel-Ebstein recurrent fevers suggest Hodgkin disease, they are observed in only a minority of patients with this disorder. The development of fever in a patient who has myeloma or chronic lymphocytic leukemia is usually caused by superimposed infection and not by the neoplastic process; in some patients, however, the febrile course appears to be caused by the malignancy itself.[66] Occasionally, a patient with the preleukemia syndrome will present with fever and atypical blood and bone marrow changes, suggesting myeloid metaplasia or a leukemoid response. Only after some months can the hematologic picture be established as leukemia.

Solid tumors can also be associated with fever; hypernephroma is the leading example. As many as 10% of patients with colorectal carcinoma present with fever; either extension of the tumor through the bowel wall, producing a paracolonic abscess, or necrosis and abscess formation in a polypoid intraluminal lesion may be the underlying mechanism. Metastatic cancer may be responsible for continuing fever; hepatic involvement is not necessary for fever to occur. Occasionally, a neuroblastoma involving bone or soft tissues or a pheochromocytoma may have a febrile course. Fevers caused by malignant disease often respond to therapy with NSAIDs; fevers caused by infections may be less likely to respond completely to these agents,[67] but this distinction is not sufficient as a diagnostic test.[68] Hospitalization for FUO often reflects a poor prognosis in patients with malignancies.[69]

Collagen Vascular Disease

A variety of connective tissue disorders and vasculitides may produce prolonged fevers before the development of articular or other characteristic manifestations. In the elderly, polymyalgia rheumatica and the closely related disorder giant cell arteritis (temporal arteritis) are the most common connective tissue disorders presenting as FUO. Malaise, weight loss, muscle weakness, mild arthralgias without overt arthritis, and a markedly elevated erythrocyte sedimentation rate (often > 100 mm/hr) are usual features. Jaw claudication, visual symptoms, and a tender or thickened temporal artery suggest the diagnosis of giant cell arteritis. As many as 15% of cases of giant cell arteritis present as FUO, and in some patients, the vasculitis itself remains occult. Similarly, virtually all patients with adult-onset Still disease are febrile,[70] and systemic symptoms such as fever and weakness may antedate by weeks or months the evolution of the more characteristic clinical manifestations of adult juvenile rheumatoid arthritis. In other patients, involvement of the paranasal sinuses and mastoid or the rapid excavation of a pulmonary lesion suggests Wegener granulomatosis. Many other connective tissue diseases, ranging from classic vasculitides such as systemic lupus erythematosus to uncommon disorders such as relapsing polychondritis, can also present as FUO.

Less Common Etiologic Categories

Granulomatous disease Granulomatous diseases of noninfectious origin may be responsible for FUO. Prolonged fever is uncommon in sarcoidosis, but when it does occur, prominent hilar adenopathy, ocular involvement, erythema nodosum, and hepatic granulomas are usually also present. Biopsy of involved lymph nodes, muscle, or liver usually shows noncaseating granulomas. In addition to sarcoidosis, there are about 40 diseases that may be associated with hepatic granulomas. Treatable infectious granulomatous diseases (e.g., tuberculosis, brucellosis, histoplasmosis, and cat-scratch disease) must be ruled out by cultures, skin tests, serologic tests, and special stains of tissue biopsy specimens. In rare instances, despite extensive investigation and therapeutic trials with antituberculous drugs, an etiologic diagnosis cannot be made in patients with noncaseating hepatic granulomas who have a febrile illness of many months' duration.[71] Beneficial results have been achieved in such cases by giving corticosteroids after excluding the other specific granulomatous diseases; methotrexate also appears to be helpful.[72] Corticosteroids have been beneficial for other patients with idiopathic granulomatosis and FUO.[73] Starch peritonitis represents a febrile granulomatous response to starch introduced on surgical gloves. The nature of the process may not be appreciated for weeks; initially, findings of a doughy abdominal mass and fever are thought to be the result of a postoperative abscess.

Inflammatory bowel disease Bowel symptoms are prominent in almost all patients with idiopathic ulcerative colitis, granulomatous colitis, or regional enteritis, and the diagnosis is obvious in such febrile patients. Occasionally, however, bowel symptoms may not be marked or may be of such long duration that they become accepted as the norm. In this setting, FUO may be the presenting complaint in a patient with inflammatory bowel disease.

Alcoholic hepatitis and cirrhosis Fever is occasionally observed in cases of cirrhosis.[74] Attention should first be directed to possible complicating infections—such as spontaneous bacterial peritonitis, enterogenous bacteremias, or tuberculosis—or to an unrelated process. Active hepatocellular necrosis may occur in the course of alcoholic hepatitis and may account for low-grade fever.

Pulmonary emboli In rare instances, a patient may have multiple small pulmonary emboli, but no significant changes in arterial blood gases or on the chest film will be apparent; the patient will present primarily with a problem of unexplained fever. The fever may exceed 39.0° C (102.2° F), but high-grade fevers caused by pulmonary emboli seldom persist longer than 1 week. Thrombophlebitis itself may be a source of protracted fever, even in the absence of pulmonary emboli.

Drug fever Drug fever frequently occurs in the absence of other manifestations of hypersensitivity, such as rash and eosinophilia. Antimicrobial agents (e.g., β-lactams, sulfonamides, nitrofurantoin, and isoniazid), antihypertensives (e.g., hydralazine and methyldopa), anticonvulsants (e.g., phenytoin), and allopurinol are among the most common offenders, but many other drugs have been implicated. In most instances, the diagnosis of drug fever is considered within the first several weeks of onset of FUO, and any recently administered drugs are discontinued. Several drugs, however, such as phenytoin, methyldopa, and isoniazid, may not produce drug fever until weeks or months after their initial use. Drugs such as these may be overlooked just because they have been administered for some time without producing side effects. Intramuscular injections of analgesics can produce FUO, which may or may not be accompanied by the presence of a sterile abscess or other gross evidence of tissue injury.

Factitious fever In rare instances, a patient may simulate illness by deliberately producing false elevations in temperature.[75] Factitious fever is one of the most challenging etiologic categories of FUO. The patients are usually female and are often paramedical personnel. The underlying problem may be malingering or a more complicated emotional disorder. Discordance between the marked temperature elevations and the pulse rate, distortion of the usual diurnal temperature curve, and absence of diaphoresis when the fever abates suggest the diagnosis.

Miscellaneous causes The hereditary periodic fevers can present as FUOs.[76] The diagnosis of familial Mediterranean fever is suggested by ethnic background, episodic occurrence of fever in association with abdominal pain or other signs of polyserositis, and well-being between attacks [*see 15:VIII Systemic Vasculitis Syndromes*]. The diagnosis can be difficult when recurrent fever is the only symptom[77]; molecular techniques can facilitate the diagnosis of various hereditary periodic fever syndromes.[78]

Whipple disease is a multisystem infection caused by the gram-positive actinomycete *Tropheryma whippelii*.[79] Patients may present with a prolonged febrile illness in association with weight loss, arthralgias, and weakness.[80] The use of special tissue culture and immunodiagnostic tests in diagnosis are being studied[80]; a polymerase chain reaction test for the causative organism is highly sensitive and specific,[81] but false positive reactions have been reported.[82] Inflammatory pseudotumor of intra-abdominal lymph nodes may present as FUO[83]; the clinical features of this disorder may resemble those of Whipple disease, but the pathologic findings are distinctive, and surgical excision of the involved nodes may induce prolonged remissions. Kikuchi-Fujimoto disease is another rare cause of fever and lymphadenopathy.[84]

CNS lesions are decidedly uncommon causes of FUO, except in very obtunded patients with extensive brain damage. Endocrinologic abnormalities, such as subacute thyroiditis, or metabolic disorders, such as hypertriglyceridemia, hypercholesterolemia, or glycosphingolipid storage disease (Fabry disease), may occasionally present as FUO. Many other disorders as diverse as pernicious anemia[85] and xanthogranulomatous pyelonephritis[86] have been identified as rare causes of FUO.

FUO in the Elderly

Advanced age appears to blunt the febrile response to many illnesses ("the older, the colder").[87] Because of this, an elderly patient with a persistent rectal temperature as low as 37.5° C (99.5° F) may qualify for an FUO evaluation.[88] The causes of FUO in the elderly are similar to those in younger patients; however, in elderly patients, tuberculosis is a more common infectious cause and temporal arteritis the most common vasculitic cause.[88,89] The presence of multiple comorbidities may complicate the diagnosis of FUO in the elderly and may temper the use of invasive diagnostic studies.

FUO in Patients with AIDS

Fever is extremely common in patients infected with HIV; typically, the diagnostic challenge is not in determining the source of fever but in deciding which of several potentially pyrogenic processes is most important. However, patients infected with HIV can also present with prolonged, diagnostically obscure fevers. Most often, such patients have advanced AIDS, with $CD4^+$ T cell counts of less than $100/mm^3$.[90] Infections account for more than 75% of FUO cases in such patients[91]; in one series, the more common diagnoses were disseminated *Mycobacterium avium* complex (31%), *Pneumocystis carinii* pneumonia (13%), CMV infection (11%), disseminated histoplasmosis (7%), and lymphoma (7%).[92] Other infectious etiologies are toxoplasmosis, cryptococcosis, salmonellosis, and varicella-zoster virus infections. In Europe, leishmaniasis is also an important cause of FUO in patients with AIDS.[93] Among noninfectious etiologies, lymphoma and drug fever are most prominent. HIV itself is an uncommon cause of FUO.

Blood cultures are the most useful diagnostic tests. Although more invasive than blood cultures, biopsies of bone marrow,[93] liver,[94] or lymph nodes may provide more rapid diagnosis by allowing direct visualization of organisms. Other useful tests include CT of the chest and abdomen and a serum cryptococcal antigen determination.

DIAGNOSIS

History and Physical Examination

With rare exceptions, neither the temperature nor the pattern of fever permits discrimination between the causes of FUO. Detailed review of the history is essential, particularly regarding travel,[95] animal exposure, occupational risks, and other epidemiologic factors; previous trauma or surgery; or features relevant to each of the diagnoses outlined. When physical findings are being evaluated, particular attention should be paid to structures that may be inapparent sources of obscure fever, such as the cardiovascular system, the abdominal viscera, and the genitourinary tract. Lymph nodes should be examined not only in the usual distribution but also in the epitrochlear areas and along the medial aspect of the upper arm. A search of the skin, nail beds, and mucous membranes for petechiae and vasculitic lesions may provide important clues to the diagnosis of endocarditis or of collagen vascular diseases. Funduscopic examination may reveal choroidal tubercles or signs of vasculitis or endocarditis. Rectal examination is particularly important in elderly or obtunded patients, in whom a perirectal or prostatic abscess may be overlooked.

Common Laboratory Studies

Blood cultures Blood cultures should include aerobic (5% to 10% CO_2 tension) and anaerobic cultures that have been incubated for at least 2 weeks. Newer blood culture techniques, including the use of lysis centrifugation and the BACTEC radiometric mycobacterial culture system, may be helpful, particularly in HIV-positive patients.

Serologic tests Serologic tests often employed in cases of FUO include *Brucella* and *Salmonella* agglutinations (usually not very helpful), antistreptolysin O (ASO) titer if acute rheumatic fever is suspected, the Venereal Disease Research Laboratories (VDRL) test for syphilis, serologic tests for less common infections (e.g., psittacosis, toxoplasmosis, and CMV), the test for rheumatoid factor, and antinuclear antibody tests. A serum specimen obtained during an acute-phase host response can be frozen for subsequent comparison with a late-phase or convalescent-phase specimen to look for an increase in titers to specific pathogens. HIV testing should be performed to evaluate host factors that may predispose to FUO.

Sedimentation rate In cases of FUO, a sedimentation rate greater than 100 mm/hr suggests vasculitis but does not differentiate between this disorder and neoplasms, tuberculosis, or pyogenic infections.

Serum enzymes and chemistries The results of liver function tests may indicate primary involvement (e.g., hepatitis or a liver abscess) or secondary infiltration (e.g., miliary tuberculosis) of the liver.

Skin tests Skin testing may aid in diagnosis if other positive results are obtained or if anergy, a characteristic finding in sarcoidosis, Whipple disease, and Hodgkin disease, is demonstrated.

Spinal fluid examination Examination of the spinal fluid is usually unrewarding unless the patient has CNS signs or symptoms, such as a headache or a stiff neck.

Radiologic Studies

In patients with FUO, various radiologic studies in addition to chest films may assist in making the diagnosis:

1. Ultrasonography and CT scans are valuable for detecting intra-abdominal and pelvic abscesses and retroperitoneal adenopathy. The use of CT scans has led to a decrease in the number of biopsies of normal tissues performed in patients with FUO.[96]
2. Radionuclide scans may also be helpful.[97] Bone scans are considerably more sensitive than bone x-rays in the detection of osseous metastases or foci of osteomyelitis. Gallium scans are occasionally useful in detecting occult abscesses, but gallium scanning has had mixed results in patients with FUO.[98] A limited number of studies have examined the usefulness of scans utilizing indium-111–labeled leukocytes in the diagnosis of FUO; the specificity of this test, although not high, appears adequate as a second-line investigative tool.[99] Scans employing indium-111–labeled human immunoglobulin G[100] and technetium-99m–labeled ciprofloxacin are also being investigated.[101] Positron emission tomography may also prove helpful in selected cases.[63,102]
3. Intravenous pyelograms may indicate intrarenal or perirenal abscesses or renal tumors. Some parenchymal lesions can be demonstrated only with the use of a renal angiogram.
4. Upper and lower GI tract x-rays may indicate regional enteritis, ulcerative colitis, or large-bowel neoplasms.
5. Bone x-rays generally are not helpful in the absence of skeletal symptoms.
6. Other radiographic examinations, such as cholangiograms, angiograms, and lymphangiograms, may occasionally be useful but should be performed only when clinical clues suggest specific diagnoses.

Biopsies

All biopsy specimens should be cultured for bacteria, mycobacteria, and fungi and examined histologically. Biopsies that may help determine the diagnosis in patients with FUO include the following:

1. Percutaneous liver biopsy. Neoplastic or granulomatous diseases can generally be detected more easily by percutaneous liver biopsy than by bone marrow biopsy, particularly if hepatomegaly, abnormalities of hepatic function, or both are present.
2. Bone marrow biopsy. This technique may also be used to detect granulomatous diseases or metastatic tumor; it may be rewarding in patients in whom hematologic abnormalities are evident.
3. Lymph node biopsy. Enlarged, matted, or unusually situated nodes are the most favorable for biopsy. Because of the frequent occurrence of chronic inflammation in inguinal lymph nodes, biopsy of these nodes is less satisfactory.
4. Skin and muscle biopsy. Biopsy of skin and muscle may prove useful in diagnosing collagen vascular disease (e.g., polyarteritis or dermatomyositis); biopsy may also be useful in diagnosing sarcoidosis.
5. Temporal artery biopsy. Biopsy of the temporal artery may be the only way to establish the diagnosis of giant cell arteritis in an elderly patient who has FUO, an elevated erythrocyte sedimentation rate, and some thickening of the temporal artery.

Exploratory Laparotomy

In the past, laparotomy was advocated and employed successfully in the diagnosis of FUO. However, noninvasive radiologic techniques, especially when combined with percutaneous needle biopsies (see above), have supplanted laparotomy for the diagnosis of FUO. Laparotomy should be reserved for patients in whom the clinical and laboratory findings point to an intra-abdominal or retroperitoneal source for the fever, particularly when the fever has followed a prolonged and debilitating course.

TREATMENT

Fever is a symptom, not an illness, and treatment of patients with FUO is directed at the underlying illness. Chemotherapeutic trials have generally proved more misleading than helpful when applied to the patient with prolonged FUO. Coincidental temporary defervescence can suggest a specific therapeutic response, thus delaying measures that may provide the correct diagnosis. Occasionally, a therapeutic trial may be reasonable when directed at a specific diagnosis. Thus, a 1- to 2-week trial of a penicillin or vancomycin and an aminoglycoside may be employed when endocarditis is a realistic possibility. Aspirin may be tried in patients who may have adult-type juvenile rheumatoid arthritis. Patients with disseminated tuberculosis presenting as FUO often show a clinical response within 2 weeks after appropriate chemotherapy.

UNDIAGNOSED FUO

In 10% to 15% of patients with FUO, a detailed workup fails to reveal the diagnosis.[103] In about half these cases, the fever resolves spontaneously. Reevaluation of the patient some weeks or

even months later may provide the diagnosis. The prognosis of patients with undiagnosed FUO is surprisingly good[103]; few require empirical corticosteroid therapy, and many can be managed symptomatically with NSAIDs.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XXV RESPIRATORY VIRAL INFECTIONS

Frederick G. Hayden, m.d.
Michael G. Ison, m.d., m.sc.

The respiratory tract can be infected by a diverse group of viruses that produce syndromes ranging in severity from mild colds to fulminant pneumonias. Respiratory viral infections are a leading cause of morbidity, hospitalization, and mortality throughout the world; influenza and pneumonia were the most prevalent infectious causes of death during the 20th century in the United States.[1] Respiratory viral infections are also the single most common cause of acute illness and physician visits in the United States and, ironically, a leading cause of prescriptions for antibiotics.[2]

Epidemiology

The high prevalence of respiratory viral infections results from the large number of infectious agents and serotypes and their efficiency of transmission from person to person; from incomplete immunity, with frequent reinfections by some respiratory viruses; and, in the instance of influenza viruses, from frequent changes in viral antigenicity. The frequency of viral respiratory illness is highest in children up to 4 years of age, gradually declines in teenagers, rises again in parents exposed to children, and is generally lowest in the elderly.[3] In families, the average adult contracts two to four acute respiratory illnesses annually, about one quarter of which lead to physician contact. This age-related pattern reflects the gradual acquisition of immunity to some agents and the important role that children play in the transmission of infection. The major reservoir for most respiratory viruses is schoolchildren, who acquire infection in the classroom and introduce it into their homes.

Respiratory viral infections have strong seasonal patterns [*see Table 1*], but sporadic cases or nosocomial outbreaks can occur year-round. The presence or absence of a lipid-containing envelope affects viral survival in the environment. In temperate areas, the enveloped viruses, such as influenza virus, respiratory syncytial virus (RSV), and coronavirus, are characteristically prevalent during midwinter periods, whereas nonenveloped ones, such as rhinoviruses, are found most often in spring through fall. Although respiratory viruses spread from person to person, the relative importance of different routes depends on the virus. Large-droplet spread over short distances (< 1 m) appears common for many viruses. Viruses such as influenza virus and adenovirus spread efficiently in small-particle aerosols. Others, including rhinovirus and RSV, can spread by hand contact with contaminated skin and fomites, with subsequent inoculation onto the nasal mucosa or conjunctiva. A number of respiratory viruses, mainly RSV, influenza virus, and parainfluenza viruses (PIV), cause outbreaks of infection in closed populations, including hospitals, day care centers, and nursing homes. These outbreaks are associated with a high mortality in frail elderly or immunocompromised hosts.

Pathophysiology

Viruses that infect the respiratory tract can be divided into primary respiratory pathogens, whose transmission and replication are generally restricted to the human respiratory tract, and pathogens that affect the respiratory tract as part of a systemic or, sometimes, locally reactivated infection. The latter group includes three types of viruses: (1) those that cause pneumonia occasionally in healthy persons but more often in immunocompromised or pregnant persons, such as measles virus and varicella-zoster virus (VZV) [*see 7:XXVI Herpesvirus Infections*]; (2) those that primarily affect immunocompromised hosts, such as cytomegalovirus (CMV) [*see 7:XXVI Herpesvirus Infections*], herpes simplex virus (HSV) [*see 7:XXVI Herpesvirus Infections*], and, less frequently, human herpesvirus type 6; and (3) several viruses that cause uncommon but severe zoonotic infections, such as severe acute respiratory syndrome coronavirus (SARS-CoV), avian influenza virus, hantaviruses, and zoonotic paramyxoviruses (e.g., Hendra and Nipah viruses) [*see 7:XXXI Viral Zoonoses*]. The primary human respiratory viruses (adenovirus, coronavirus, influenza virus, PIV, human metapneumovirus [hMPV], RSV, and rhinovirus) share global distribution, mucosal sites of infection, and person-to-person transmission, but they differ in many important features, including viral composition,

Table 1 Epidemiologic Features of Principal Human Respiratory Viruses

Virus	*Incubation Period (days)*	*Principal Mode of Spread**	*Peak Seasonality*	*Nosocomial Pathogen*
Adenovirus	4–7	Aerosol, direct	Summer	Yes
Coronavirus (non-SARS)	2–5	Droplet	Winter	Minor
Human metapneumovirus	Probably 2–7	Likely hands, droplet	Early fall to spring	Yes
Influenza A and B viruses	1–4	Aerosol, droplet	Winter	Major
Parainfluenza virus	3–6	Droplet	Types 1 and 2, fall; type 3, spring and summer	Yes
Respiratory syncytial virus	2–8	Hands, droplet	Late fall to spring	Major
Rhinovirus	1–5	Hands, droplet	Early fall, late spring	Yes

*Multiple routes of transmission (i.e., direct, fomites, hand contamination–self inoculation, large droplets, and small-particle aerosols) are possible for most respiratory viruses.
SARS—severe acute respiratory syndrome

seasonality, pathogenesis of disease, and availability of vaccines and specific antiviral agents.

Pathogenesis

Although the extent of viral replication correlates well with severity of illness for most respiratory viruses, the pathogenesis of infection differs for the various groups. Rhinovirus and coronavirus infections are largely limited to the upper respiratory tract, whereas influenza virus, RSV, PIV, SARS-CoV, and adenovirus commonly also infect lower airways . With all respiratory viruses, progression to severe lower respiratory tract disease is more common in patients with impaired immune systems. Respiratory viruses may also produce intra-alveolar inflammatory exudate with hemorrhage, hyaline membrane formation, and differing amounts of epithelial damage. Tracheobronchitis and damage to the respiratory epithelium are typical of influenza virus. RSV infection in young infants is associated with epithelial damage and desquamation, bronchial edema with inflammatory cells, and plugging of small airways. In contrast, damage to the nasal mucosa is modest during rhinovirus or coronavirus colds. Disease manifestations are associated with respiratory tract damage caused by the virus and with host responses to infection, including specific immunologic responses, release of host inflammatory mediators, and neurogenic reflexes. For example, increased levels of histamine, leukotriene C_4, eosinophilic cationic protein, and virus-specific IgE occur in the respiratory secretions of children with RSV bronchiolitis. Influenza is associated with increases in the levels of interleukin-6 (IL-6), interferon gamma (IFN-γ), and tumor necrosis factor–α (TNF-α) in the nasal mucosa and the blood; correlations exist between viral replication, symptom expression, and IL-6 production.[4,5] Severe avian influenza infections in humans have been associated with elevated serum levels of TNF-α, soluble IL-2 receptor, IL-6, and IFN-γ.[6] In persons with colds from rhinoviruses, nasal secretions have higher concentrations of bradykinin, IL-1, IL-6, and IL-8. In addition, respiratory viral infections may alter bacterial colonization patterns, increase bacterial adherence to respiratory epithelium, reduce mucociliary clearance, and alter bacterial phagocytosis by host cells. The impairment of host defenses may foster bacterial infection of areas that are normally sterile, such as the paranasal sinuses, middle ear, and lower respiratory tract.

For many respiratory viruses, the presence of neutralizing antibody in serum and respiratory secretions correlates with protection against infection. Generally, immunity is longer lasting and reinfection less common with virus groups that have many serotypes (e.g., rhinovirus and adenovirus) than in those with only a few serotypes. Although reinfection is frequent with PIV and RSV, severity generally decreases with each episode. In addition to humoral responses, cell-mediated immunity appears to be important for recovery from infection by certain respiratory viruses. In patients who have undergone bone marrow or solid-organ transplantation and in other highly immunocompromised hosts (e.g., patients with acute leukemia or AIDS), many respiratory viruses can cause prolonged infection and severe pulmonary disease, graft dysfunction, and increased mortality.[7]

Diagnosis

CLINICAL MANIFESTATIONS

In general, respiratory viruses cause acute, spontaneously resolving illnesses, although involvement of the lower airways and certain complications (e.g., otitis media, sinusitis, and exacerbations of asthma or chronic obstructive pulmonary disease [COPD]) are common. Clinical diagnosis is difficult because there are a number of respiratory viruses that can cause a variety of overlapping clinical syndromes. Consequently, clinical diagnosis is accurate only under certain circumstances, such as during an influenza epidemic or outbreaks of RSV bronchiolitis. The limited correlation between virus and syndrome emphasizes the importance of rapid virologic techniques for making a specific etiologic diagnosis, particularly in hospitalized or severely affected patients [*see Table 2*]. Improvement in the accuracy of clinical diagnosis will require data from community-based surveillance programs, such as those that track which respiratory viral pathogens are circulating within a community.

LABORATORY TESTS

Most respiratory viruses can be isolated from nose and throat swabs, nasal washes or aspirates, sputum, and other lower respiratory samples. Tests done on nasopharyngeal samples taken early in illness provide the most sensitive results, although early samples in SARS may be falsely negative. However, some respiratory viruses are slow growing [*see Table 2*], and most are pres-

Table 2 Laboratory Methods for Diagnosis of Respiratory Viral Infections

Virus	*Specimen Source*	*Time to Isolation in Cell Culture (days)*	*Rapid Detection Methods and Molecular Techniques*	*Common Serologic Assays*
Adenovirus	Respiratory tract, throat, conjunctiva, urine, stool, blood	2–10	EIA, IF, RT-PCR, IC	CF, IF, NT
Coronavirus (non-SARS)	Nasopharynx	Not routine	Not routine, RT-PCR, IF	Not routine (ELISA)
Influenza A and B viruses	Nasopharynx, throat, lower respiratory tract	2–5	EIA, IF, neuraminidase assay, RT-PCR	CF, HAI, ELISA
Parainfluenza virus	Nasopharynx, lower respiratory tract	3–14	IF, RT-PCR	CF, HAI, ELISA
Respiratory syncytial virus	Nasopharynx, lower respiratory tract	3–14	EIA, IF, RT-PCR	CF, ELISA, NT
Rhinovirus	Nasopharynx	2–7	Not routine, RT-PCR	Not routine (NT)

CF—complement fixation EIA—enzyme immunoassay ELISA—enzyme-linked immunosorbent assay HAI—hemagglutination inhibition IC—immunochromatography IF—immunofluorescence NT—neutralization RT-PCR—reverse transcriptase–polymerase chain reaction SARS—severe acute respiratory syndrome

ent in lower titers in adults than in children, so samples from adults may require longer periods for isolation or have lower yields on rapid diagnostic tests. Because temperature fluctuations and freezing may cause loss of infectivity, samples should be transported at refrigerator temperatures (4° C) or on wet ice. Cell culture inoculation (shell vials) followed by antigen detection has a sensitivity of 80% or greater at 1 to 2 days for adenovirus, influenza virus, PIV, and RSV.[8]

Immunofluorescence testing of exfoliated respiratory cells and enzyme immunoassay for viral antigens are reasonably sensitive, specific, and rapid techniques for detecting some respiratory viruses, particularly RSV and influenza virus.[9] Nucleic acid amplification techniques appear to be the most sensitive direct detection methods for most viruses, including SARS-CoV. However, false negative results are possible (during the first days of infection, SARS-CoV may be undetectable even by polymerase chain reaction), and positive results must be confirmed to ensure accuracy. For simultaneous detection of respiratory viruses (influenza virus types A and B; RSV; and PIV types 1, 2, and 3), multiplex reverse transcriptase PCR (RT-PCR) has good sensitivity,[10] and a commercial assay is available. Real-time quantitative RT-PCR tests offer a sensitive means of detection of many respiratory viruses and, potentially, of monitoring responses to treatment.

Serologic diagnosis requires paired serum specimens in most instances and is intrinsically slower than direct methods. A variety of serologic techniques are used to measure antibodies, including neutralization, hemagglutination inhibition, complement fixation, and enzyme-linked immunosorbent assay (ELISA). Measurement of complement-fixation antibodies is generally less sensitive than the other methods and does not provide a serotype-specific diagnosis. Immunocompromised hosts often fail to develop diagnostic increases in antibody titers. The combined use of cultures, antigen detection, nucleic acid detection, and serology provides the most comprehensive approach for identification of important respiratory viral pathogens in hospitalized adults.

Clinical Syndromes

COMMON COLDS

Diagnosis

The common cold is generally a mild illness of the upper respiratory tract, primarily affecting the nasopharynx and paranasal sinuses. Rhinoviruses, which cause about 50% of colds, and coronaviruses, which cause 10% to 20%, are the most important pathogens. RSV, PIV, influenza virus, adenovirus, and some enteroviruses also cause colds.

Adults with rhinovirus colds typically have prominent upper respiratory tract symptoms (i.e., sneezing, nasal discharge, nasal obstruction, sore or scratchy throat, and cough) and often have headache but little fever or few systemic complaints other than malaise. Physical findings are nonspecific and include nasal discharge and mucosal erythema. Although generally absent in adults, lower respiratory tract manifestations (e.g., cough, sputum, and wheezing) do occur in about 60% of cases in elderly persons, and lower respiratory tract illness and fever are common in young children infected with rhinovirus.

The differential diagnosis of the common cold includes allergic rhinitis, bacterial nasopharyngitis in infants, and, in rare instances, nasal diphtheria or bacterial nasal infection in adults. Because nearly 50% of colds last longer than 1 week and 25% last up to 2 weeks, it is often unclear whether a complicating viral or bacterial sinusitis has occurred. More than 80% of patients with uncomplicated colds have reversible sinus abnormalities demonstrable on computed tomography,[11] and sinusitis is an inherent part of rhinovirus colds. Fever, purulent nasal drainage, cough productive of purulent sputum, increasing symptoms or malaise after 1 week, localized facial pain, or maxillary toothache suggests a bacterial sinusitis.[12] Otitis media complicates approximately 2% of colds in adults and 5% of colds in children.[13]

Treatment

Treatment of the common cold is directed toward specific symptoms. Saline nose drops may be helpful for relief from obstructing secretions, particularly in young children, and warm saline gargles reduce sore throat. Topical decongestants such as phenylephrine and the longer-acting oxymetazoline provide prompt relief of nasal obstruction but may be associated with rebound congestion and possibly throat irritation. Oral pseudoephedrine also provides partial relief of nasal obstruction but may cause anxiousness and insomnia in some patients. The oral decongestant phenylpropanolamine was removed from the market because of increased risk of hemorrhagic stroke. It is uncertain whether topical or oral vasoconstrictors alter the risk of bacterial complications. First-generation oral antihistamines, such as chlorpheniramine and clemastine, reduce sneezing and, to a lesser extent, rhinorrhea, but they are often associated with excess sedation. Nonsedating antihistamines such as loratadine and astemizole are not effective for colds in nonallergic persons. Intranasal ipratropium, a quaternary anticholinergic, reduces cold-associated rhinorrhea by about 30% and may also reduce sneezing, but excess nasal drying may result in blood-tinged mucus.[14] Cough suppressants with codeine or dextromethorphan may be used if the cough is severe or disturbs sleep, but they should be used cautiously in patients with underlying chronic obstructive disease. Specific antiviral therapy is not currently available. Two intranasal antiviral agents from different classes, the 3-C protease inhibitor ruprintrivir and the capsid inhibitor pleconaril, are being investigated. Although effective in treating rhinovirus colds, oral pleconaril was not approved by the Food and Drug Administration because of concerns about safety and drug interactions, most notably with oral contraceptives.[15] A number of other remedies (e.g., *Echinacea* preparations, zinc lozenges or nasal gels, and hot-air inhalation) are of unproven or doubtful value.[16-18]

PHARYNGITIS AND LARYNGITIS

Pharyngitis usually is associated with the same viruses that cause common colds and occurs concurrently with the common cold, but it is also often a prominent complaint of persons with adenovirus and influenza virus infections. Enteroviruses are also important causes of fever and pharyngitis during the summer and early fall.

Diagnosis

Pharyngitis may be associated with characteristic clinical findings, such as palate vesicles and ulcers caused by coxsackievirus-induced herpangina, acute ulcerative stomatitis and pharyngitis caused by HSV, or exudative pharyngitis related to Epstein-Barr virus mononucleosis. Pharyngitis occurs with primary HIV infection and may be associated with mucosal ero-

sions and lymphadenopathy. Pharyngitis caused by group A streptococci and other bacteria (anaerobes, *Corynebacterium diphtheriae, Chlamydophila pneumoniae,* and *Mycoplasma pneumoniae*) are generally not associated with acute rhinorrhea [*see 7:XIX Bacterial Infections of the Upper Respiratory Tract*].

Treatment

Treatment for most cases of viral pharyngitis is symptomatic. However, HSV stomatitis, particularly in immunocompromised patients, should be treated with specific antiviral therapy (e.g., acyclovir, famciclovir, or valacyclovir).

Hoarseness caused by laryngitis frequently occurs during acute viral infections and is more common during infections caused by viruses that invade the lower airways. Treatment is primarily voice rest.

ACUTE BRONCHITIS

Diagnosis

Acute bronchitis manifests as a severe or prolonged cough that is usually nonproductive or productive of scant mucoid sputum. Bronchitis can follow infection by any of the respiratory viruses and is a hallmark of influenza. Viral infections commonly cause exacerbation of preexisting airway disease, including chronic bronchitis, emphysema, asthma, and cystic fibrosis. Rhinoviruses are the most frequently implicated viral pathogens.[19] HSV can cause bronchospasm and sometimes ulcerative tracheobronchitis in immunocompromised persons and, less often, in immunocompetent persons.

Cough production in acute bronchitis results from direct viral damage to the respiratory mucosa, release of inflammatory mediators, stimulation of airway irritant receptors, and increased production and decreased clearance of respiratory secretions. Infection may also enhance airway hyperreactivity, characterized by increased sensitivity to cold air and pollutants such as smoke.

The differential diagnosis of acute viral bronchitis includes bacterial, mycoplasmal, chlamydial, and pertussis infections, as well as noninfectious entities such as asthma.

Treatment

Treatment of acute bronchitis in otherwise healthy persons is directed at suppression of the cough with codeine or dextromethorphan. However, these agents should be used cautiously in patients with underlying chronic obstructive disease. Antibiotics are generally not indicated.[20]

INFLUENZA SYNDROME

Diagnosis

The influenza syndrome is characterized by the rapid onset of constitutional and respiratory tract symptoms. Constitutional symptoms, which include fever, chills, prostration, muscle aches, and headache, tend to dominate during the first several days of illness. Respiratory complaints are sore throat, coryza, hoarseness, and, especially, cough. Persistent nonproductive cough, easy fatigability, and asthenia are common in the second week of illness.

Epidemic influenza A and B viruses are the principal causes of the influenza syndrome, but other respiratory viruses, including RSV, PIV, adenovirus, and, sometimes, rhinovirus can cause influenzalike illness.

Treatment

Treatment for the influenza syndrome is usually symptomatic and includes bed rest, oral hydration, antipyretics, and antitussives. Specific antiviral therapy for influenza virus infection is available [*see* Influenza Virus, *below*].[21-23] Fever should be treated in patients in whom it would contribute to disease, such as children with previous febrile convulsions or patients with preexisting cardiac disease. Aspirin should be avoided in pediatric patients because of its association with Reye syndrome.

CROUP

Diagnosis

Croup, or laryngotracheobronchitis, is a characteristic pediatric syndrome characterized by brassy or barking cough, inspiratory stridor, dyspnea, and hoarseness. Symptoms are often preceded by several days of upper respiratory tract illness and typically become worse at night. Croup is seen primarily in children younger than 5 years and is associated most closely with PIV infections and less often with RSV, hMPV, influenza viruses, adenoviruses, and rhinoviruses. Measles virus is an important cause of severe croup. Acute spasmodic croup is characterized by recurrent attacks precipitated by viral infections, allergies, and, possibly, other factors. The differential diagnosis of croup includes foreign-body aspiration or trauma, bacterial epiglottitis or tracheitis, localized abscess, and angioedema.

Inflammation of the larynx and trachea with subglottic narrowing causes localized obstruction; this obstruction is enhanced by inspiration, because of the extrathoracic location of the obstruction and the compliance of the airway walls in children. In addition, inflammatory changes occur throughout the lower respiratory tract. Symptoms usually abate in 3 to 4 days.

Treatment

Most cases of croup can be managed at home, with moist air. Correction of hypoxemia is essential for hospitalized patients. Aerosolized racemic epinephrine provides transient benefit for those with persistent stridor. Systemic glucocorticoids appear to be effective in moderating the severity of illness and shortening hospitalization; inhaled steroids are beneficial in less severe cases.

BRONCHIOLITIS

Diagnosis

Bronchiolitis is an acute inflammatory disorder of the small airways that is characterized by airway obstruction with wheezing, hyperinflation, and atelectasis. It is associated most closely with RSV infection, which is detected in about 75% of infants hospitalized with bronchiolitis, and less often with rhinoviruses, hMPV, PIV, influenza viruses, and adenoviruses. The peak incidence is in infants from 2 to 6 months of age, and over 80% of cases occur in the first year of life. Premature infants and young children with underlying pulmonary conditions are at high risk for RSV bronchiolitis or pneumonia. After several days of coryza and possibly fever, patients experience acute respiratory distress with wheezing, cough, and, often, inspiratory rales; apnea may occur in babies. Characteristic radiologic features are atelectasis and signs of hyperinflation. In mild cases, bronchiolitis symptoms resolve within several days, but prolonged or severe disease may occur in premature infants or those with underlying cardiopulmonary or immunodeficiency disorders. The

major differential diagnosis is asthma, which is uncommon in children younger than 2 years.

The bronchiolitis syndrome results from viral destruction of the respiratory epithelium and associated peribronchiolar mononuclear inflammation, which is perhaps in part immunologically mediated. In infants, because of their disproportionately narrow airways, bronchiolar obstruction causes distal collapse or air trapping and abnormal gas exchange.

Treatment

Correction of hypoxemia is the most important aspect of managing RSV bronchiolitis. Bronchodilators, glucocorticoids, and routine antibiotics are not of proven value. Aerosolized ribavirin therapy is available for selected infants hospitalized with RSV bronchiolitis or pneumonia, but it is an expensive intervention of uncertain value.[24]

REACTIVE AIRWAY DISEASE EXACERBATION

Infection with respiratory viruses, most commonly rhinoviruses,[19] can precipitate exacerbations of chronic respiratory illness. Respiratory viral infections, half of which are rhinovirus infections, can worsen asthma in patients of all ages but are associated with up to 85% of asthma exacerbations in schoolchildren.[25] Young children hospitalized with wheezing illness are in most cases infected with rhinoviruses, RSV, hMPV, or PIV. Exacerbations of COPD often result from respiratory viral infections. Approximately 25% of hospitalizations for COPD exacerbations have been associated with a documented respiratory tract viral infection; this percentage increases to 45% of COPD patients admitted between December and March.[26]

PNEUMONIA

Viral infections have been associated with at least 10% to 15% of community-acquired pneumonias in hospitalized adults and with as many as half of cases in hospitalized infants.[27] The relative importance of different viruses depends heavily on the geographic location of the outbreak, the season, and patient age and immune status. Influenza A and, less often, influenza B viruses are the most common causes of community-acquired viral pneumonia in adults and the elderly. In children younger than 3 years, RSV accounts for about 50% of all hospitalizations for pneumonia[28]; PIV type 3 is also prominent. PIV, hMPV, adenovirus, rhinovirus, and non-SARS respiratory coronavirus infections have been implicated as causes of pneumonia in children and adults.

Respiratory viruses reach the lung by contiguous spread from the upper respiratory tract or inhalation of small-particle aerosols. Depending on the agent, nonrespiratory viruses infect the lung parenchyma by hematogenous dissemination (e.g., CMV, VZV, HSV, and measles) or, less often, by contiguous spread from the tracheobronchial tree (e.g., HSV).

SARS

SARS is a unique form of viral pneumonia. In contrast to most other viral pneumonias, upper respiratory symptoms are usually absent in SARS, although cough and dyspnea occur in most patients. Typically, patients present with a nonspecific illness manifesting fever, myalgia, malaise, and chills or rigors; watery diarrhea may occur as well[29] [*see* SARS Coronavirus, *below*].

Diagnosis

The clinical and radiographic features of most viral pneumonias are not distinctive. Unless a typical exanthem of measles or varicella is present, identification of a specific pathogen requires a careful epidemiologic history and appropriate virologic studies. The clinical and radiologic appearance of viral pneumonia is often indistinguishable from that of bacterial infection, and mixed infections are common. Differentiation between pure viral pneumonias, mixed viral-bacterial pneumonias, and viral infections of the tracheobronchial tree with complicating bacterial pneumonia is usually not possible on clinical grounds.

When taking the history, the clinician should ask about risk factors for exposure, including illness in contacts, institutional residence during an outbreak of illness, travel history, and contact with animals associated with zoonotic transmission. Knowledge of local patterns of viral circulation (e.g., epidemic influenza) and of the patient's immune status are also important in diagnosis. SARS should be suspected in any patient with radiographically confirmed pneumonia who has one or more epidemiologic risk factors for the syndrome[30] [*see* SARS Coronavirus, *below*].

Treatment

Management of viral pneumonia is primarily supportive; ventilatory support has improved the prognosis for patients with extensive viral pneumonia. Specific antiviral therapy for respiratory viruses is limited, and there are no controlled data regarding the use of these agents in pneumonia. Antiviral agents are available to treat influenza[31-33] [*see* Influenza Virus, *below*]. Inhaled ribavirin is available for RSV and other viral infections but is of uncertain value; it has been used intravenously for adenovirus, hantavirus, measles, PIV, and influenza virus infections. Intravenous acyclovir is effective in HSV or VZV pneumonia.

Pneumonia in Immunocompromised Hosts

Immunocompromised hosts, particularly patients undergoing organ transplantation, experiencing chemotherapy-induced neutropenia and immunosuppression, or with HIV-related immunosuppression, are at risk for reactivation of latent viruses (e.g., HSV, CMV, or adenovirus) or acquisition of community respiratory viruses. Bronchoalveolar lavage yields viruses in up to half of immunocompromised patients with acute pneumonia.[34] CMV is the most frequently recovered, accounting for more than 80% of isolates; fewer than 10% of isolates are HSV or various respiratory viruses.[35] In immunosuppressed patients, influenza viruses, PIV, RSV, hMPV, rhinovirus, and adenoviruses can cause severe pneumonia[36] that is often nosocomially acquired and usually associated with a preceding upper respiratory tract illness.[7] It seems prudent to delay chemotherapy or transplantation in the presence of an upper respiratory tract illness.

Intravenous acyclovir is recommended for patients with HSV or VZV pneumonia. Ganciclovir with immunoglobulin appears to be effective in reducing the mortality associated with CMV pneumonia in bone marrow transplant (BMT) recipients and has been used as monotherapy in other patient groups.[37] Aerosolized ribavirin and RSV-specific antibodies (RSV immunoglobulin [RespiGam] or palivizumab), if given early, may be effective for preventing progression of RSV pneumonia or treating established disease in such patients [*see* Respiratory Syncytial Virus, *below*]. Aerosolized and intravenous ribavirin have been used for adenovirus[38] or severe measles. Intravenous cidofovir has been effective in the management of severe adenoviral infection in immunocompromised patients but may cause nephrotoxicity.[39]

Infections Caused by Specific Agents

ADENOVIRUS

Adenoviruses cause a variety of respiratory tract syndromes, ranging from pharyngoconjunctival fever (often contracted while swimming in contaminated water) to severe pneumonia in infants, immunosuppressed patients, and, uncommonly, healthy adults. Epidemics of acute respiratory disease and pneumonia caused by adenovirus have been recognized for decades in United States military recruits and are expected to continue, given the cessation of immunization programs in the military. However, a new manufacturer for adenovirus vaccine has been identified, and vaccination of military personnel is expected to resume.[40]

Classification and Pathogenesis

Adenoviruses are medium-sized (65 to 80 nm), nonenveloped, double-stranded DNA viruses, of which 49 antigenic types (divided into six subgroups) are associated with human infections. The protein coat of the virus is composed of hexagonal and pentagonal subunits (capsomers) with long fibers at each vertex, which are the sites of host cell attachment. Type-specific antigens, which give rise to neutralizing antibody, are present on the hexons and fibers of the capsid. The hexons also contain a group-specific antigen with cross-reactivity among most adenoviruses. Only about one half of serotypes cause disease. Immunity correlates with the presence of type-specific neutralizing antibody.

Epidemiology and Transmission

Adenovirus infections may be endemic or epidemic. Lower-numbered serotypes routinely infect infants and young children, although types 3, 4, and 7 are also acquired later in life and are typically associated with epidemic respiratory disease. In addition to transmission by direct contact with respiratory secretions or infectious aerosols, fecal-oral transmission occurs. Infection may be acquired by pharyngeal or conjunctival inoculation from contaminated water. Adenovirus infection occurs throughout the year but is often recognized during the summer in association with outbreaks of pharyngitis or bronchitis. Adenovirus probably accounts for about 5% of total acute respiratory infections in civilian adults. Nosocomial transmission, including clusters of pneumonia in long-term care facilities and large outbreaks of epidemic keratoconjunctivitis, is well documented.[41,42] Persistent infections occur in the tonsils and gastrointestinal (GI) tract, and prolonged viral shedding is common in immunocompromised hosts and in the GI tract of children.

Diagnosis

Clinical features The incubation period for adenovirus infection of the respiratory tract is usually 4 to 7 days. Adenovirus respiratory infection typically causes a moderate to severe pharyngitis, which is sometimes exudative, and tracheobronchitis. Fever and systemic symptoms are often prominent, and rhinitis, cervical adenitis, and follicular conjunctivitis are common. Pharyngoconjunctival fever, usually associated with serotypes 3, 4, and 7, tends not to be accompanied by lower respiratory tract symptoms. In infants and young children, infections also cause a pertussislike syndrome, croup, and bronchiolitis.

Adenovirus pneumonia is similar to other viral pneumonias; it usually begins with pharyngitis, rhinitis, fever, and cervical adenopathy—conjunctivitis may or may not be present—and then spreads to involve the lower airways and lungs. Bilateral interstitial or alveolar infiltrates are common, although focal consolidation or effusion also occurs.

Laboratory findings The presence of cells with large basophilic, intranuclear inclusions (smudge cells) in lower respiratory tract biopsy specimens may provide early histopathologic diagnosis. A variety of serotypes have been recovered from stool, urine, and lower respiratory tract specimens of immunocompromised patients.[43] Rapid methods for virus detection include enzyme immunoassay (EIA), immunofluorescence, antigen immunochromatography,[44] and RT-PCR. Quantitative PCR to measure blood adenoviral DNA levels is emerging as a useful marker for predicting the risk of progression of disease and for monitoring responses to antiviral therapy in immunocompromised patients.

Complications

Acute complications, which occur mainly in children and in immunocompromised hosts, are leukopenia, lymphocytopenia, thrombocytopenia, rhabdomyolysis, disseminated intravascular coagulation, renal failure, and bacterial infection. Survivors may acquire restrictive lung disease or bronchiectasis; children in particular are at risk for bronchiolitis obliterans. Mortality in BMT recipients with adenovirus pneumonia is as high as 60%.[45]

Adenoviruses are also associated with extrarespiratory infections, including epidemic keratoconjunctivitis; hepatitis and genitourinary infections in immunosuppressed hosts; myocarditis; arthritis; meningoencephalitis; and, especially in children, hemorrhagic cystitis, mesenteric adenitis, intussusception, and gastroenteritis. Adenovirus commonly complicates hematopoietic stem cell transplantation, especially in children, and is often associated with invasive disease, which is associated with reduced survival.[46]

Treatment

Antiviral therapy of proven value is not available, but intravenous ribavirin, ganciclovir, cidofovir, and immunoglobulin have been used to treat severe infections. In invasive adenoviral infections, including pneumonia, mortality appears lower in patients who have received cidofovir than in those who have received intravenous ribavirin, but further studies are needed.[34,47-49] Treatment is otherwise supportive.

Prevention

Live attenuated vaccines for adenovirus types 4 and 7 were used in the military but are not licensed for civilian use.[40,42] Other control measures are swimming-pool chlorination, careful hand washing, and, in the instance of nosocomial keratoconjunctivitis, use of gloves and proper sterilization of equipment.

CORONAVIRUSES

Classification

Coronaviruses are moderate-sized (100 to 150 nm), enveloped, single-stranded RNA viruses named for their distinctive club-shaped surface projections, which resemble a crown. Three antigenic types of human respiratory coronaviruses (229E, OC43, and NL63) have been identified, separately from SARS-CoV.

Epidemiology and Transmission

Coronaviruses are the second most frequently documented

cause of common colds. Coronaviruses account for 4% to 15% of cases of acute respiratory disease annually and as many as 35% during peak periods. Most coronavirus infections occur in winter and early spring, but infections have been detected throughout the year. Immunity to infection is incomplete, and reinfection is common. SARS-CoV causes a clinical syndrome unique among the coronaviruses and is discussed separately [*see* SARS Coronavirus, *below*].

Diagnosis

Clinical features The incubation period of coronavirus colds ranges from 2 to 5 days, longer than that of rhinovirus colds. Infections produce a typical coryzal illness that is indistinguishable from colds caused by other viruses. Lower respiratory tract manifestations include pneumonia in children, military recruits, and possibly immunocompromised hosts; exacerbation of asthma in children; and exacerbation of chronic airway disease in adults. Reported associations with GI disease, including necrotizing enterocolitis in infants, are controversial.

Laboratory findings Virus isolation is insensitive; infections are usually identified by serology or by detection of coronavirus RNA. Culture of virus in human embryonic trachea cells is the most sensitive cell culture system for recovering human respiratory tract coronaviruses but is impractical.

Treatment

Effective antivirals or vaccines are unavailable, although intranasal IFN-α is protective against experimental coronavirus colds. Treatment is symptomatic.

SARS CORONAVIRUS

Epidemiology

SARS-CoV is a novel coronavirus identified as the cause of a clinical syndrome, SARS, that was first recognized as an unusual atypical pneumonia in Guangdong Province, China, in November 2002. Over the ensuing 6 months, the virus spread to multiple areas of the world and resulted in over 8,000 illnesses and 774 deaths. China, Hong Kong, Singapore, Taiwan, and Toronto, Canada, were most severely affected. The virus is of animal origin, but the primary reservoir remains uncertain. It possibly originated from Himalayan palm civets found in live-animal markets, but it is infectious for a wide variety of species, including civets, raccoon dogs, ferrets, cats, mice, and monkeys.

Molecular epidemiology has shown that SARS viruses from outbreaks in Hong Kong, Vietnam, Singapore, Toronto, and Taiwan are clonally related to the index case from Hong Kong, whereas viruses from Guangdong Province are genetically more diverse. It is possible that different strains of SARS-CoV have different characteristics, including efficiency of transmission and virulence. Future SARS outbreaks may differ from the outbreak of 2002–2003. Unlike diseases from other respiratory coronaviruses, SARS does not have any recognized seasonality.

Transmission

SARS-CoV spreads efficiently between humans. The primary mode of transmission appears to be through close personal contact: infectious droplets from the cough or sneeze of an infected person travel through the air a short distance and land on respiratory or, possibly, conjunctival mucous membranes or are deposited there indirectly. Other possible modes of spread include fomites, with hand contamination and subsequent self-inoculation; small-particle aerosols; and perhaps fecal-oral transmission. Transmission may be amplified by certain aerosol-generating procedures, such as endotracheal intubation, bronchoscopy, and treatment with aerosolized medications. Recently, modeling was used to substantiate airborne spread of SARS as the cause of the large outbreak at the Amoy Gardens housing complex in Hong Kong.[50] Person-to-person spread has been especially common in health care and hospital settings, but transmissions have occurred in homes and hotels, in the workplace, on aircraft, and in taxis. Laboratory transmission of SARS-CoV and presumed acquisition from animals have also occurred.[51] No transmission of SARS has been documented before the onset of symptoms or more than 10 days after resolution of fever.

Diagnosis

SARS is diagnosed on the basis of epidemiologic evidence, clinical suspicion, and diagnostic testing. The current case definition of SARS, as well as the most current recommendations on diagnosis, can be found at the Centers for Disease Control and Prevention Web site (http://www.cdc.gov/ncidod/sars).

Epidemiologic evidence SARS should be included in the differential diagnosis of pneumonia in patients of all ages who have one or more of the following risk factors:

- A history of recent travel to mainland China, Hong Kong, or Taiwan or close contact (within 10 days before symptom onset) with ill persons with a history of recent travel to such areas.
- Employment in an occupation that involves particular risk for SARS-CoV exposure, including health care with direct patient contact or work in a laboratory that contains live SARS-CoV.
- Association with a cluster of cases of atypical pneumonia without an alternative diagnosis during periods of known SARS circulation.

Clinical features The incubation period of SARS typically ranges from 2 to 7 days but may be as long as 10 days or even, in rare cases, 14 days. Patients present with fever, myalgia, malaise, and chills and may have a nonproductive cough. Other upper respiratory symptoms are usually absent. Fever may be absent, particularly in the elderly, in the initial phase of the illness. Diarrhea may occur.

Laboratory findings Lymphocytopenia is common in SARS, as are elevations in D-dimer levels and activated partial thromboplastin time. Chest radiographs show evidence of pneumonia in 60% to 100% of patients. Distinctive radiographic findings include a predominant peripheral lung involvement; initial unilateral (typically, in the right lung) focal air-space opacity; and absence of cavitation, lymphadenopathy, and pleural effusion.[52] High-resolution CT scans are abnormal in up to 67% of patients with normal chest radiographs.

Current diagnostic tests for SARS include RNA detection by RT-PCR, virus culture, and serology. Virus is detectable in respiratory secretions (from the nasopharynx, throat, nose, and lower respiratory tract), as well as in feces, serum, and plasma. Initial RT-PCR techniques were associated with poor sensitivity, particularly in early infection, but improved extraction methods and real-time RT-PCR assays have been developed that allow for

more sensitive testing during the first days of infection.[53] Any positive test result must be confirmed by testing another clinical sample, reextracting and testing the original specimen, or retesting with an assay that targets different parts of the viral genome. Measurement of specific antibodies at 21 days or later after illness onset using whole-virus immunofluorescence or ELISA remains the gold standard for retrospective confirmation of SARS-CoV infection, because a negative RNA assay does not rule out infection.

Treatment

Initial treatment in patients with suspected SARS is with empirical antimicrobials directed against the typical pathogens in community-acquired pneumonia. There have been no prospective studies of antiviral agents in the treatment of SARS. Ribavirin, lopinavir-ritonavir, IFN-α, and traditional Chinese medicines were used during the 2002–2003 outbreak. In vitro studies, animal testing, and limited human experience suggest that IFN-α has activity against SARS-CoV; IFN-β also has efficacy in vitro.[54] Ribavirin is not active in vitro at clinically achievable concentrations and was associated with significant toxicity and no obvious antiviral effects in SARS. Neutralizing antibodies, including recently described humanized monoclonal antibodies, are active in animal models[55] and are promising for prophylaxis and perhaps early treatment.

Lung biopsies in patients with SARS suggest a possible immune component; the samples reveal diffuse alveolar damage with desquamation of pneumocytes, inflammatory infiltrates, edema, and hyaline membrane formation. Consequently, high-dose methylprednisolone has been used to modify the disease course and has produced short-term reductions in fever and infiltrates. However, steroid therapy offers uncertain overall benefit and poses such risks as enhanced viral replication, superinfection, and late aseptic necrosis. Thymic peptides, intravenous immune globulin (IVIg), and plasma from patients in the convalescent phase of illness are likewise of unclear benefit. Neutralizing human monoclonal antibodies against S protein are active in experimental animal infection and may prove useful in prophylaxis or possibly early treatment.[56]

Prevention of exposure is the key to limiting future outbreaks. All patients with suspected SARS should be isolated for at least 10 days; in patients with documented SARS, isolation should be continued for at least 10 days after defervescence. Quarantine of contacts has been used in some outbreaks. Current recommendations regarding appropriate infection control practices can be found at the CDC Web site (http://www.cdc.gov/ncidod/sars). In health care settings, precautions against transmission through airborne respiratory droplets and contact should be strictly enforced, with enhanced airborne precautions used during aerosol-generating procedures.

Prognosis

One third of patients with SARS defervesce and improve clinically. The remainder experience progressive illness, with diarrhea and increasing tachypnea, shortness of breath, and abnormal findings on pulmonary examination and radiography; 20% to 30% of patients require admission to an intensive care unit, usually for mechanical ventilation, and approximately 10% succumb. Death typically results from respiratory failure, multiple organ failure, sepsis, or intercurrent medical illness. More severe disease and higher mortality occur in older adults (≥ 60 years) and those with underlying medical conditions.

HUMAN METAPNEUMOVIRUS

hMPV is a respiratory pathogen that causes infections ranging from colds to severe bronchiolitis and pneumonia. The first metapneumovirus associated with human infection, hMPV was discovered in 2001 when viruses that had been isolated from children presenting with RSV-like illnesses failed to be identified by standard techniques. After random-primer RT-PCR was used, the virus was identified as a new metapneumovirus related to turkey tracheitis virus. Serologic studies demonstrated that by 5 years of age, all children were seropositive and that sera originally collected in 1958 were also positive for hMPV antibodies.[57] Two genetic clusters of hMPV that correspond to two different serotypes of hMPV have been recognized on every continent.[58]

Epidemiology

Infections by hMPV occur worldwide and year-round, with a winter predominance. The season peaks between December and February in the northern hemisphere, with a longer season in temperate climates. hMPV can be isolated from 5.5% to 6.5% of children hospitalized with respiratory symptoms. The peak incidence is between 4 and 6 months of age, with most children being younger than 5 years. Coinfection with hMPV and RSV has been documented frequently, and several cases of concomitant hMPV and SARS-CoV infection have been documented.

Asymptomatic or mild illness appears to be much more common with hMPV. hMPV has been detected in 20% of ambulatory young children presenting with respiratory illness in whom no other cause was found. Most cases occurred between December and April.[59] In infirm elderly patients, the incidence is 6.5%. The incidence of hMPV in general-community persons presenting with influenzalike illness is only 2%, whereas hMPV can be isolated from 3% to 6.6% of the general community with acute respiratory illnesses.

Diagnosis

Clinical features hMPV causes clinical syndromes indistinguishable from RSV, including bronchiolitis, croup, asthma exacerbation, and pneumonia. Studies attempting to differentiate hMPV from other respiratory viruses have found that hMPV infection appears to occur at a slightly older age and causes slightly milder symptoms than RSV. Infections in adults manifest as colds, influenzalike illness, bronchitis, exacerbations of underlying airway disease, or, uncommonly, pneumonia. hMPV infections in immunocompromised patients can be severe and have been associated with at least three deaths.

Laboratory tests RT-PCR has become the standard method of detecting hMPV in respiratory samples. Methods that use primers targeted at the polymerase (L) and fusion (F) protein genes have shown adequate sensitivities. The presence of antibodies is not diagnostic by itself, although seroconversion or a greater than fourfold rise in titer is indicative of recent infection. The virus can be grown in cell culture, but the cytopathic effect may not be seen for up to 14 days.

Treatment

In vitro data suggest that ribavirin has activity against hMPV similar to that against RSV. Likewise, neutralizing antibody titers against hMPV in IVIg are similar to titers against RSV. Clinical studies are required to determine the possible clinical efficacy of ribavirin and IVIg.[60]

Classification and Pathogenesis

Influenza viruses belong to the orthomyxovirus family and consist of types A, B, and C. These medium-sized (80 to 120 nm), enveloped, single-stranded RNA viruses contain eight gene segments (seven for influenza C). The segmented nature of the genome allows reassortment of RNA segments between two influenza viruses during dual infection and facilitates antigenic variation. Surface glycoprotein spikes possess either hemagglutinin or neuraminidase activity. Hemagglutinin mediates cell attachment and fusion of virus and cell membranes. By cleaving terminal sialic acid residues and destroying the receptors recognized by hemagglutinin, neuraminidase promotes release of virus from infected cells and spread within the respiratory tract.

Influenza A viruses are further classified into subtypes on the basis of their surface proteins (15 hemagglutinins and nine neuraminidases are recognized in animal influenza viruses). Three A hemagglutinin subtypes (H1, H2, and H3) and two neuraminidases (N1, N2) have caused extensive human infections. Influenza C viruses have seven gene segments and lack a neuraminidase. Influenza viruses are named by the type; location of isolation; isolate number; year of recovery; and, for influenza A type viruses, the subtype (e.g., A/Texas/36/91[H1N1]).

The surface glycoproteins induce host humoral and cellular immune responses and are responsible for the changing antigenicity of influenza viruses. Two major types of antigenic change can occur: drift and shift. Antigenic drift refers to relatively minor changes in hemagglutinin and, less often, neuraminidase antigenicity that occur frequently (usually every few years) and sequentially in the setting of selective immunologic pressure in the population. Drift results from point mutations of the corresponding RNA segment. Antigenic shift occurs only in influenza A viruses and results from acquisition of a new gene segment for hemagglutinin with or without one for neuraminidase. This may occur through genetic reassortment during dual infections with human and animal influenza type A viruses; by the reintroduction of a virus that has not circulated recently in the human population; or by direct transmission to humans of an animal influenza virus that is capable of efficient human-to-human transmission.

Aquatic fowl are the main reservoir for influenza A viruses in nature, although some subtypes also infect other species, including swine, horses, and marine mammals. Swine are susceptible to infection with viruses from both birds and humans and may serve as a so-called mixing vessel, providing an opportunity for the generation of new pathogenic viruses.

Epidemiology and Transmission

Influenza viruses A and B cause annual outbreaks of illness affecting approximately 5% to 10% of adults, with higher rates in children. In the United States, influenza causes an average of over 36,000 deaths[61] and 130,000 to 170,000 hospitalizations during each epidemic.[21] The appearance of a new strain for which most of the population lacks immunity can result in worldwide outbreaks, or pandemics. Pandemic strains are associated with global spread over months and with high attack rates. Three such pandemics occurred during the 20th century; the most severe was the Spanish influenza pandemic in 1918 and 1919, which caused 20 to 40 million deaths worldwide and over 500,000 deaths in the United States.

Epidemic influenza occurs annually in temperate areas, typically between the months of December and March in the Northern Hemisphere, and follows the reintroduction of virus each year. Influenza activity usually occurs in May through August in the Southern Hemisphere and can be year-round in the tropics. Regional outbreaks caused by a particular strain are usually short (6 to 8 weeks), although successive waves of infection by different influenza viruses can occur. Influenza activity in the community is marked by increased medical contacts for febrile respiratory illness, increased absenteeism from school and the workplace, subsequent increased hospitalizations for pneumonia and other cardiopulmonary disorders, and increased mortality. Pneumonia hospitalizations increase by two to five times in high-risk patients. Persons 65 years of age and older constitute nearly 50% of excess hospitalizations and over 85% of deaths from influenza.[62]

Influenza viruses are transmitted principally via large and small aerosolized particles. Direct transmission of influenza A virus to humans from animals has been documented.[63] Although animal-to-human transmission has typically been from swine, direct transmission from birds caused an epizootic of avian influenza A H5N1 subtype virus in Hong Kong and Southeast Asia, with several dozen human infections, many of which were fatal.[64,65] In the cluster of H5N1 avian virus in Hong Kong,[66] the source was domestic poultry, although human-to-human transmission may have occurred in several cases. Additionally, avian H9N2 influenza virus infection has been documented in several children, and a large outbreak of H7N7 avian influenza A virus in the Netherlands was associated with at least one death.[67] H7 subtype viruses have also caused an outbreak, predominantly of conjunctivitis, in British Columbia, Canada,[67] and infected an immunocompromised man in New York. Influenza H5N1 or other avian viruses may pose a reemerging pandemic threat in the future.[68]

Diagnosis

Clinical features The incubation period for influenza virus is short, averaging 2 days (range, 1 to 4 days). Classic influenza is distinguished by abrupt onset of prominent systemic symptoms, including fever, chills, headache, myalgia, malaise, and anorexia. Fever usually lasts for an average of 3 days in adults. Sore throat, dry cough, photophobia, and pain on eye movement occur frequently early in the illness. Mild conjunctivitis, clear nasal discharge, pharyngeal injection, and small, tender cervical lymph nodes are also common. As systemic illness abates, respiratory symptoms become more apparent. The most troubling respiratory symptom is protracted cough, which results from viral tracheobronchitis. Airway hyperactivity and abnormalities in pulmonary function may last from weeks to several months in previously healthy persons. Exacerbations of asthma and other types of preexisting airway disease are often severe. Infections may be subclinical or cause milder illness, including colds.

Primary influenza virus pneumonia is a heterogeneous condition, ranging from mild disease with patchy infiltrates to rapidly fatal infection. Severe pneumonia generally accounts for 2% of influenza-associated pneumonia, but during pandemics, it can account for up to 20%; influenza A viruses cause more than 90% of cases.[69] As many as 40% of patients with influenza pneumonia have no prior underlying disease. Pneumonia usually begins with typical influenza, followed within 1 to 3 days by rapidly progressive dyspnea, cyanosis, diffuse rales, and wheezing. Pleuritic chest pain and blood-tinged sputum or frank he-

moptysis occurs. Patients with influenza virus pneumonia have a high mortality.

Laboratory tests Multiple rapid assays are commercially available in the United States to detect influenza A and B antigens or neuraminidase activity; some of these assays differentiate between influenza A and B, and several can be performed by clinical personnel at the point of care [*see Table 2*]. The specificity of these assays is good to excellent, but the sensitivity varies between approximately 60% and 90%, depending on the sample type, the age of the patient, and the duration of the illness.[68,70] Diagnosis can also be made by viral culture or by RT-PCR. When viral pneumonia is present, Gram stain of sputum shows few to many polymorphonuclear leukocytes, but only rarely does it show bacteria. The chest radiograph shows bilateral infiltrates that may be in the form of diffuse interstitial infiltrates, perihilar pulmonary edema, or dense opacifications. On blood counts, leukocytosis with a left shift is variably present.

A definitive diagnosis of influenza can have a significant impact on medical management. In a pediatric population, detection of influenza A antigen resulted in a decrease in antibiotic use, a decrease in duration of antibiotic use in hospitalized patients, and an increase in antiviral use.[71]

Complications

Secondary bacterial pneumonia should be suspected when fever, increasing cough, and sputum production develop after several days of improvement. *Streptococcus pneumoniae* is the most common bacterial pathogen, but *Staphylococcus aureus,* including community-acquired methicillin-resistant strains, causes up to 25% of cases and is associated with high mortality. *S. aureus* and certain other bacteria produce proteolytic enzymes that activate influenza hemagglutinin and enhance viral replication. *Haemophilus influenzae* and *Streptococcus pyogenes* are also recognized as causes of bacterial complications. Bacterial infections of the sinuses and ears are frequent. Toxic-shock syndrome and invasive meningococcal disease have also been known to complicate influenza.

Uncommon complications are myositis with rhabdomyolysis, renal failure, disseminated intravascular coagulopathy, myocarditis, pericarditis, myelitis, Guillain-Barré syndrome, and Reye syndrome. Neurologic complications, including encephalopathy or encephalitis, are unusual and occur mainly in children.[63,72]

Treatment

A variety of antiviral agents are available for treatment of influenza [*see Table 3*]. The M2 inhibitors amantadine and rimantadine are active against influenza A only, although recent human isolates of avian H5N1 viruses are resistant.[31,68] Oral amantadine and rimantadine reduce the duration of fever and symptoms of uncomplicated influenza A virus infection by 1 to 2 days and provide more rapid overall functional recovery. Effectiveness in preventing complications or treating severe illness in hospitalized patients is uncertain. Resistant virus may arise during treatment and be transmissible on close contact.[73]

The neuraminidase inhibitors, zanamivir and oseltamivir, are active against influenza A and B viruses.[32] Zanamivir is administered by inhalation and may, in rare cases, cause bronchospasm, which can be severe. Oseltamivir is administered orally and is associated with self-limited GI upset in about 10% to 15% of treated patients; this can be reduced by taking the medication with food. Treatment of acute uncomplicated influenza in adults with inhaled zanamivir or oral oseltamivir provides symptomatic relief, reduces time to functional recovery, and decreases the likelihood of lower respiratory tract complications leading to antibiotic use.[22,23] In children 1 to 12 years of age, oseltamivir provides symptomatic relief and also reduces the likelihood of otitis media.[21] Oseltamivir treatment has been associated with reduced risk of hospitalization in both previously healthy and high-risk or elderly adults.[74] Emergence of resistance appears to be very uncommon.

Influenza pneumonia Treatment of influenza virus pneumonia is primarily supportive. Improvements in assisted ventilation techniques have raised the survival rate above 50%, although pulmonary fibrosis develops in some patients. M2 inhibitors, NA inhibitors, and aerosolized or I.V. ribavirin, which is active against influenza A and B viruses, have been used with uncertain benefit. Combination therapies (e.g., an M2 inhibitor plus a neuraminidase inhibitor for influenza A) show enhanced activity in animal models. Although unstudied, the use of neuraminidase inhibitors, either alone or in combination with other agents, seems reasonable in the treatment of influenza virus pneumonia.

Prevention

Chemoprophylaxis Antiviral chemoprophylaxis with amantadine or rimantadine is about 70% to 90% effective in preventing illness caused by influenza A virus. Chemoprophylaxis can provide several weeks' protection to patients immunized after influenza A activity has begun, can be given throughout the season to those who cannot receive influenza vaccine (e.g., those with egg allergy) or who are unlikely to respond to the vaccine, or can be used for protection of high-risk persons when the epidemic strain diverges significantly from the vaccine antigens. Side effects of amantadine are GI upset and minor, reversible central nervous system symptoms (e.g., insomnia, dizziness, and difficulty with concentration). Rimantadine appears to be equally effective as amantadine and is associated with a lower risk of CNS side effects.

The neuraminidase inhibitors are also effective for prophylaxis of influenza A and B infections. Both inhaled zanamivir[75,76] and oral oseltamivir[77,78] prevent influenza when used for seasonal prophylaxis or after exposure (e.g., for family or nursing home contacts), but only oseltamivir has been approved by the Food and Drug Administration for this indication. Oseltamivir has been found to be safe for treatment of children as young as 1 year[79]; inhaled zanamivir has been found to be safe in children as young as 5 years. Of note, both the M2 and the neuraminidase inhibitors may reduce the efficacy of live attenuated influenza vaccine, if the vaccine and the antiviral agent are given together.

Immunization Influenza vaccines are available in two forms: (1) an intramuscular preparation containing formalin-inactivated virus and purified surface antigen and (2) an intranasal spray containing live attenuated viruses.[21] Both are made from egg-grown virus. Vaccine composition is reviewed annually and adjusted to reflect changes in antigenicity and anticipated circulation of viral strains; current vaccines contain one influenza B and two influenza A (H1 and H3 subtypes) antigens.[21] The efficacy of these vaccines is approximately 70% to 90% in young adults, especially when the vaccine antigen and the circulating strain are closely matched. Immunization in

Table 3 Agents Used to Prevent and Treat Influenza[111,112]

Drug	Adult Dosage		Efficacy for Documented Influenza		Dosage Adjustment	
	*Prophylaxis**	*Treatment†*	*Prophylaxis*	*Treatment*	*State*	*Dosage*
Amantadine	100 mg b.i.d.	100 mg b.i.d.	63% efficacy[95]	Shorter duration of fever and symptoms	C_{Cr} 30–50 C_{Cr} 15–30 C_{Cr} < 15 Hemodialysis Elderly	100 mg q.d 100 mg q.o.d. 100 mg q. wk. 100 mg q. wk. ≤ 100 mg q.d.
Rimantadine	100 mg b.i.d. or 200 mg q.d.	100 mg b.i.d. or 200 mg q.d.	72%–83% efficacy[95]	Shorter duration of fever and symptoms	Severe hepatic dysfunction Elderly C_{Cr} < 10	100 mg q.d. 100 mg q.d. 100 mg q.d.

Oseltamivir	75 mg q.d.	75 mg b.i.d.	87% efficacy[96]	24 to 36 hr faster recovery from illness Reduction in severity of illness, number of nights of disturbed sleep, and use of relief medications Reduction in complications that require antibiotic treatment, hospitalization	C_{Cr} < 30	Treatment, 75 mg q.d. Prophylaxis, 75 mg q.o.d.

*Duration of prophylaxis depends on the clinical circumstances: 7–10 days after close contact for postexposure prophylaxis; 2 wk after immunization of an adult; 4–6 wk after a community outbreak; and at least 1 wk (preferably 2 wk) after the last case in outbreak control.
†First dose should be given within 48 hr of the onset of illness to be effective. Therapy should be continued for 5 days.
‡The Food and Drug Administration has not approved zanamivir for this indication.
C_{Cr}—creatinine clearance

healthy working adults is associated with fewer upper respiratory illnesses and fewer visits to physicians' offices.[80,81] The intranasal vaccine is currently approved only for healthy persons 5 to 49 years of age; it appears to be less effective in the elderly but possibly superior to inactivated vaccine in young children. Immunization with inactivated vaccine reduces influenza-related hospitalizations, including acute cardiovascular events and COPD exacerbations,[82] and reduces mortality in ambulatory elderly patients by 40% to 60%.[83] Wide-scale immunization of schoolchildren may reduce influenza-related mortality in older adults.[84] Although inactivated vaccine is less effective in infirm elderly patients, it provides partial protection against pneumonia and death.

The highest priority for vaccination should be given to persons at increased risk for influenza-related complications and their contacts [*see Table 4*]. Administration of the inactivated vaccine is associated with soreness at the injection site in as many as one third of recipients, but fever or systemic reactions are uncommon in adults. Influenza vaccination does not adversely affect $CD4^+$ T cell counts or accelerate progression to AIDS or death in HIV-infected patients.[85]

The intranasal vaccine causes transient coryza and sore throat. Vaccine viruses are recoverable from nasal samples in low titers for up to 1 week in adults and are genetically stable. Although viral transmission is rare between children and has not been documented in adults to date, vaccine recipients should avoid close contact with highly immunocompromised hosts (e.g., stem cell transplant recipients) for 1 week after immunization.[21]

PARAINFLUENZA VIRUSES

PIV infections are the most commonly recognized cause of croup, accounting for up to 75% of cases with a documented viral etiology, and they are a leading cause of lower respiratory tract disease resulting in hospitalization of infants. Infection with PIV induces partial immunity that moderates disease severity; reinfection in older children and adults produces milder respiratory illness and colds.

Classification and Pathogenesis

Human PIVs are medium-sized (120 to 150 nm), enveloped RNA viruses belonging to the Paramyxoviridae family and are classified into four antigenically stable types (1, 2, 3, and 4); type 4 is further classified into subtypes A and B. PIV replicates in epithelial cells of the upper and lower respiratory tract, and antibodies to the two major envelope surface glycoproteins—namely, the hemagglutinin-neuraminidase protein and the fusion protein—confer protection against infection. These proteins are necessary for attachment of virus to host cell receptors and

Table 4 Indications for Influenza Vaccination*[21]

PERSONS AT INCREASED RISK FOR COMPLICATIONS
All adults 65 yr of age and older
Residents of nursing homes and other long-term care facilities that house persons of any age who have chronic medical conditions
Adults and children with chronic cardiopulmonary disorders, including asthma
Adults and children who have required regular medical follow-up or hospitalization during the preceding year because of chronic metabolic diseases (including diabetes), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medication or by HIV)
Children and teenagers (6 mo to 18 yr of age) who are receiving long-term aspirin therapy and therefore may be at risk for Reye syndrome
Women who will be pregnant during the influenza season
Children 6–23 mo of age
PERSONS 50–64 YR OF AGE†
PERSONS WHO CAN TRANSMIT INFLUENZA TO THOSE AT HIGH RISK
Physicians, nurses, and other personnel in both hospital and outpatient care settings, including medical emergency response workers (e.g., paramedics and emergency medical technicians)
Employees of nursing homes and long-term care facilities who have contact with patients or residents
Employees of assisted-living and other residences for persons in groups at high risk
Home care providers for persons at high risk
Household contacts of high-risk persons

*Both the inactivated influenza vaccine and live, attenuated influenza vaccine (LAIV) can be used to reduce the risk of influenza. Healthy persons 5–49 yr of age who are not contacts of severely immunosuppressed persons can receive either LAIV or inactivated influenza vaccine; all other persons should receive inactivated influenza vaccine. In addition to persons for whom annual influenza vaccination is recommended, influenza vaccine should be given to any person who wishes to reduce the likelihood of becoming ill with influenza, if vaccine availability permits.
†Vaccination is recommended for persons 50–64 yr of age because of the increased prevalence of persons with high-risk conditions in this group.

membrane-fusing activity. PIV type 1 and type 2, which cause croup and laryngitis, probably replicate principally in the major airways, whereas PIV-3 causes lower respiratory tract infections.

Epidemiology and Transmission

PIV infections occur initially during childhood; PIV-3 infections often occur during infancy and are an important cause of illness in infants younger than 6 months, as well as in immunocompromised persons. The incidence of croup and respiratory disease caused by PIV-1 or PIV-2 infections is highest between the ages of 6 months and 5 years. PIV-1 typically causes epidemics lasting several months, peaking in October or November of alternating years, whereas PIV-2 activity is more sporadic. PIV-3 causes infections throughout the year, with outbreaks during the spring and summer.

PIVs are transmitted from person to person, either by direct contact with respiratory secretions or by large aerosol droplets. Transmission occurs readily in families, and reinfections in older children and adults are common. Outbreaks occur in nurseries, day care centers, and hospitals, with attack rates of 40% or higher in susceptible patients.

Diagnosis

Clinical features The incubation period of PIVs is approximately 3 to 6 days. Virus replication is generally limited to the respiratory tract, although viremia and CNS infections[86] have been rarely documented. Initial infections cause fever, rhinitis, pharyngitis, laryngitis, croup, and bronchitis in children.

Laboratory tests Immunofluorescence testing of respiratory secretions and RT-PCR have been used for rapid PIV detection. Culture is generally slow, requiring days to weeks. Serologic assays, including complement fixation, ELISA, and hemagglutination assays, are used for retrospective diagnosis.

Treatment

Specific antiviral therapy of proven value has not been established. Early treatment with aerosol ribavirin may benefit some immunocompromised patients with serious infections, and intravenous ribavirin has been used for treatment of PIV pneumonia in BMT patients.[87]

Prevention

An effective PIV vaccine is not yet available, but live attenuated vaccines derived from either human or bovine PIV have been developed and appear to be safe and immunogenic in children. Infection control measures, with an emphasis on exclusion of sick caregivers and isolation protocols, may reduce the risk of nosocomial acquisition in compromised hosts.

Complications

In adults and older children, reinfections are often asymptomatic but may cause serious lower respiratory tract disease, including exacerbations of chronic airway disease and pneumonia. During periods of circulation, about 2% to 3% of cases of community-acquired pneumonia in adults are linked to PIV infection.[88] Severe pneumonia, sometimes in the absence of upper respiratory tract illness, occurs in immunosuppressed adults and children, particularly after BMT.[5]

RESPIRATORY SYNCYTIAL VIRUS

Classification and Pathogenesis

RSV is a paramyxovirus with surface glycoproteins that have neither hemagglutinin nor neuraminidase activity. The F protein is responsible for fusion of the viral envelope with the host cell membranes. Antibody against this protein neutralizes RSV infectivity and blocks syncytial cell formation. The G protein is responsible for attachment. Two major subgroups (A and B) are distinguished primarily by antigenic differences in the G glycoprotein, and multiple strains are recognized within each subgroup.

Epidemiology and Transmission

RSV is the major cause of lower respiratory tract disease in infants and young children, accounting for 45% to 90% of bronchiolitis cases and up to 40% of pneumonia cases. Approximately 40% of infections in the first year of life cause lower respiratory tract illness and 1% to 2% result in hospitalization; about 10% of hospitalized infants require ventilatory support.

As many as 100,000 hospitalizations and 510 deaths of infants and children are attributed to RSV each year in the United States.[89] RSV is also increasingly recognized as a cause of lower respiratory tract disease in older adults and immunocompro-

mised persons.[90,91] Mortality is usually less than 1% in previously healthy infants but is much higher in persons with primary immunodeficiency, persons undergoing cancer chemotherapy, and persons with preexisting pulmonary and heart disease.[92] The number of RSV-related deaths in the elderly is estimated to be 10-fold higher than that in infants.[93] In elderly persons, it is estimated that RSV is associated with 2% to 9% of hospitalizations or deaths caused by pneumonia[90] and about 10% of hospitalizations for acute cardiopulmonary conditions.[89] Each year, RSV is responsible for an estimated 11,321 excess deaths in the United States.[61]

RSV causes prolonged outbreaks of infection from late fall to spring annually in temperate climates.[94] Most outbreaks peak between January and March in the Northern Hemisphere, but sporadic cases can occur year-round. Epidemics are associated with increased pediatric hospitalizations and deaths from lower respiratory tract illness. Essentially all children are infected within several years after birth. Immunity is incomplete, and reinfections in children and adults are common. Higher titers of circulating and mucosal antibody occur with successive infections and appear to be associated with milder illness.

RSV appears to be spread by large-particle aerosols during close personal contact and by hand contamination with self-inoculation of the eye or nose. RSV is a major nosocomial pathogen, and high attack rates occur during outbreaks in hospitals, transplantation units, day care centers, and geriatric homes.[95] Illness rates are commonly 20% to 50% among hospital staff and patients during epidemics. In households, secondary infection occurs in about one third of adults.

Diagnosis

Clinical features The incubation period of RSV averages 4 to 5 days but ranges up to 1 week. In infants and young children, almost all primary infections are symptomatic, and 40% or more are associated with bronchiolitis or pneumonia. Febrile upper respiratory tract illness and otitis media are common.

Most recurrent infections in adults are associated with upper respiratory tract illness. Adults typically experience coryza, pharyngitis, and cough, often with low-grade fever. Bronchitis, influenzalike illness, pneumonia, and exacerbations of asthma and chronic bronchitis also occur. In the elderly, the clinical manifestations and outcomes of RSV infections are similar to those of influenza.[89,94] Elderly adults hospitalized with RSV commonly have dyspnea, wheezing, and sputum production. Viral bronchopneumonia or secondary bacterial pneumonia appears to complicate a high proportion of RSV infections in such patients.

RSV causes severe lower respiratory tract disease in immunosuppressed patients, particularly BMT recipients and acute leukemia patients receiving chemotherapy.[6] Most cases are nosocomial; mortality exceeds 60% when pneumonia develops. Rhinitis with sinusitis or otitis often precedes the development of pneumonia by several days and may provide a clue to diagnosis.

Laboratory tests Testing of bronchoalveolar lavage samples with RSV antigen or RNA detection provides rapid diagnosis in pneumonia cases. Commercially available ELISAs are sensitive to RSV in children, but nasopharyngeal samples are an insensitive means of detecting RSV antigen in adults, who have low titers of virus in the upper respiratory tract. RT-PCR is a reasonably sensitive technique to detect RSV infection, whereas culture of virus is slow and less sensitive. Serology is more sensitive than cell culture for diagnosis in adults but is slow because of the need for paired sera.[89]

Treatment

The value of aerosolized ribavirin in the management of RSV disease in hospitalized children remains controversial, and studies of its value in mechanically ventilated infants have yielded conflicting results.[23] Aerosolized ribavirin should be considered for infants hospitalized with RSV infections who are at high risk for severe or complicated illness (e.g., those with congenital heart disease, bronchopulmonary dysplasia, cystic fibrosis, and immunodeficiency), for those who are already severely ill, and for those who are younger than 6 weeks. Treatment with polyclonal or monoclonal RSV antibodies does not provide clear therapeutic benefit for RSV-infected infants and young children. Aerosol ribavirin may reduce progression from upper to lower respiratory tract disease in highly immunocompromised hosts. Early treatment with aerosolized ribavirin plus IVIg, RSV immunoglobulin, or palivizumab appears to benefit immunosuppressed patients with RSV pneumonia.[96]

Prevention

Passive immunoprophylaxis by monthly administration of high-titer anti-RSV immunoglobulin or anti-F monoclonal antibody (palivizumab) reduces the risk of lower respiratory tract RSV disease and hospitalization in high-risk infants and children. Palivizumab is approved for prophylaxis in premature infants and children younger than 2 years with bronchopulmonary dysplasia and is appropriate for infants and young children with hemodynamically significant congenital heart disease.[97] A phase 1 study has found that palivizumab appears to be safe and well tolerated in recipients of hematopoietic stem cell transplants.[98] No vaccine against RSV is available yet, but studies of intranasal live-attenuated vaccine in children and injected subunit vaccine in elderly persons are ongoing.

Interruption of nosocomial transmission may be facilitated by thorough hand washing,[99] decontamination of fomites, early identification and rapid isolation of infected infants and other potential RSV cases,[100] and cohorting of staff with infected infants.[101] Regular use of gowns, gloves, disposable eye-nose goggles, and possibly masks by hospital staff caring for infected children may further reduce the risk of nosocomial RSV spread.

RHINOVIRUS

Classification and Pathogenesis

Rhinoviruses are small (30 nm), nonenveloped viruses that belong to the Picornaviridae family. They have a single-stranded RNA genome and are composed of four structural proteins. Three of the proteins induce neutralizing antibodies and form the basis for serotyping. The large number of serotypes (> 110) makes the development of an effective vaccine unlikely. Nearly 90% of rhinovirus serotypes use intercellular adhesion molecule–1 as a common cellular receptor. Although replication of rhinovirus was thought to be limited to the upper respiratory tract, increasing data suggest that rhinovirus can replicate and cause disease in the lower airways.[102]

Epidemiology and Transmission

Rhinoviruses cause approximately one infection per person per year in adults, and rates are even higher in children. Rhinovirus causes about 50% of colds in adults each year and up to

90% during the fall months.[103] Immunity to rhinovirus is serotype specific and relatively enduring after infection, although reinfection can occur. Rhinoviruses cause infections year-round but are most prevalent in early fall and late spring. The relative importance of fomite spread with hand contamination and self-inoculation into the eyes or nose and aerosols in rhinovirus transmission is uncertain under natural conditions.

Diagnosis

Clinical features The incubation period of rhinoviruses averages about 2 days, with a range of 1 to 5 days. Rhinovirus colds vary in severity from mild episodes characterized by 1 to 2 days of coryza or scratchy throat to illnesses with profuse rhinorrhea, pharyngitis, and tracheobronchitis. Symptoms usually peak on the second and third days of illness, and the median duration is 1 week.

Rhinovirus infections are associated with more frequent lower respiratory tract illness in the elderly and with bronchospasm and protracted cough in persons with preexisting airway disease.[104,105] Rhinovirus is the major infectious cause of asthma exacerbations in children and in adults. In addition, rhinovirus infections are associated with acute sinusitis,[106] otitis media,[107] exacerbations of chronic bronchitis, and lower respiratory tract disease in infants and young children. In BMT recipients, rhinovirus infection has been associated with pneumonia and poor prognosis.[1]

Laboratory tests No rapid diagnostic test for rhinovirus infection is routinely available; detection is usually by virus isolation and, more recently, by RT-PCR.[108]

Treatment

No antiviral therapy of proven clinical value is currently available, but several approaches are under investigation. Oral administration of the capsid-binding antirhinoviral compound pleconaril reduces the severity and duration of uncomplicated rhinovirus colds in adults but is associated with risk of drug interactions.[109] Nonselective regimens such as high-dose vitamin C, *Echinacea* preparations, inhalation of heated air, and zinc lozenges are of doubtful value.

Prevention

Barrier control measures may be beneficial, although tissues impregnated with virucides have proved disappointing in this regard. Hand washing and avoidance of finger-to-nose and finger-to-eye contact should reduce the risk of infection. Because of the risk of nosocomial transmission of rhinovirus infections, adherence to infection control precautions in cases of upper respiratory tract illness is important.

HANTAVIRUS

Hantavirus causes hantavirus cardiopulmonary syndrome (HCPS).[110] Most HCPS cases have occurred in young to middle-aged adults with no underlying disease. The largest number of cases have occurred in New Mexico, Arizona, and California, but cases have also been identified throughout western North America and sporadically in the eastern United States. HCPS is typically a zoonosis; the principal animal reservoir is the deer mouse. Human infections occur by inhalation of aerosols of infectious excreta. Detailed discussion of HCPS is provided elsewhere [*see 7:XXXI Viral Zoonoses*].

INTERNET RESOURCES

A listing of Internet resources with information about respiratory viral infections is provided [*see Sidebar* Internet Resources for Respiratory Viral Infections].

XXVI HERPESVIRUS INFECTIONS

MARTIN S. HIRSCH, M.D.

Human and Animal Herpesviruses

The herpes group of viruses is composed of at least eight human viruses and numerous animal viruses [*see 7:XXXI Viral Zoonoses*]. The human herpesviruses include herpes simplex virus types 1 and 2 (HSV-1 and HSV-2), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human herpesvirus types 6 (HHV-6), 7 (HHV-7), and 8 (HHV-8, also known as Kaposi sarcoma–associated herpesvirus [KSHV]).

All human herpesviruses are of similar size and morphology and are characterized by a core, 30 to 60 nm in diameter, that contains a double-stranded DNA genome; a nucleocapsid, 95 to 100 nm, that exhibits icosahedral symmetry; and a lipoprotein envelope with glycoprotein projections that has a diameter of 120 to 250 nm. Herpesviruses replicate primarily in cell nuclei, and a protein envelope is added as the virus passes through the nuclear membrane.

Human herpesviruses share the properties of latency and reactivation. Members of the group can cause productive lytic infections, in which infectious virus is produced and cells are killed, or nonproductive lytic infections, in which viral DNA persists but complete replication does not occur and cells survive. After acute lytic infections, herpesviruses often persist in a latent form for years; periodic reactivations are followed by recurrent lytic infections. Sites of latency vary: HSV and VZV persist in neural ganglion cells, EBV persists in B cells, and CMV probably remains latent in many cell types. The sites of latency for HHV-6 and HHV-7 have not been identified, although both herpesviruses have been detected in salivary glands.

All human herpesviruses have a worldwide distribution [*see Sidebar* Herpesvirus Information on the Internet]. Considerable efforts are being directed toward the development of vaccines and antiviral agents that will be active against herpesviruses.

Herpes Simplex Virus

HSV-1 and HSV-2 can be distinguished by a variety of properties, including clinical and epidemiologic patterns, antigenicity, DNA base composition, biologic characteristics, and sensitivity to various physical and chemical stresses.[1] Advances in molecular biology technology have proved that HSV-1 and HSV-2 share certain antigens (e.g., glycoprotein B) but differ with respect to other antigens (e.g., glycoprotein G). Restriction enzyme analysis of HSV DNA and other molecular techniques are used to identify individual isolates.

EPIDEMIOLOGY AND ETIOLOGY

Humans are the only known natural hosts for HSV, although animals can readily be infected experimentally. HSV-1 primary infection occurs mainly in childhood, whereas HSV-2 infection occurs predominantly in sexually active adolescents and young adults. The prevalence of HSV-2–specific antibodies in the United States increases from less than 6% in those younger than 19 years to more than 25% in those older than 30 years.[2] In older age groups, changes in prevalence are negligible. Independent predictors of HSV-2 seropositivity include female gender, black race, increasing age, less education, more lifetime sex partners, prior occurrence of syphilis or gonorrhea, and lack of HSV-1 antibody.[3] In the United States, changes in sexual mores resulted in an age-adjusted seroprevalence of HSV-2 infection in the 1990s that was 30% higher than the seroprevalence in the 1970s; HSV-2 is now detectable in one of five persons older than 12 years.[2] Approximately one third of new HSV-2 infections are symptomatic.[4] Prevalence of antibody to HSV-1 in different populations ranges from 44% in persons 12 to 19 years of age to above 80% in those older than 60 years.[2] Between 10% and 25% of adults are dually infected with HSV-1 and HSV-2.[2]

Direct contact with infected secretions is the principal mode of transmission. HSV-1 is usually transmitted by an oral route and HSV-2 by a genital route. Although virus titers are higher and

Guidelines for prevention of herpesvirus simiae (B virus) infection

transmission is more likely when lesions are present, asymptomatic excretion of the virus is common. HSV-2 shedding from the genital tract can occur in seropositive persons who have no history of genital HSV infection.[5] Thus, transmission occurs frequently, even in the absence of lesions. HSV-2 is transmitted more efficiently from males to females than from females to males. Autoinoculation to other skin sites also occurs, more often with HSV-2 than with HSV-1. Spread of infection through contact with oral secretions may be an occupational hazard for respiratory care and dental care providers; thus, gloves should be worn when fingers are placed in patients' mouths. Fomites, including toilet seats and towels, are not important modes of transmission. Recurrences are frequent with both HSV-1 and HSV-2 infections, usually as a result of endogenous reactivation. In the United States, lip or perioral recurrences develop in 20% to 40% of the population. Precipitating factors are sunlight, wind, local trauma, fever, menstruation, and emotional stress. Ocular herpes is present in about 5% of all patients seen at ophthalmology clinics; 25% to 50% of ocular HSV infections recur within 2 years. Of all the primary cases of genital herpes in the United States each year, 60% to 80% will recur. Although most genital recurrences represent reactivation, exogenous reinfection can also occur. Clinically significant recurrences tend to decrease over time.[6]

PATHOGENESIS

After the initial replication of the virus in epithelial cells, cytolysis and local inflammatory reactions develop, resulting in the characteristic lesion—a superficial vesicle on an inflammatory base. Multinucleated cells and Cowdry type A inclusion bodies are present. Subsequent lymphatic spread to regional nodes and viremic spread to other organs may occur, depending on the immune competence of the host. Viremia can be demonstrated in malnourished children, in certain adults with depressed T cell–mediated immunity, and, occasionally, in immunocompetent persons.

After initial infection, HSV travels along sensory nerve pathways to ganglion cells, the site of latent infection. The viral DNA persists, only to become reactivated by certain stresses. After reactivation, the virus reverses its course and spreads peripherally by sensory nerve pathways. Once HSV reaches cutaneous sites, cell-to-cell spread occurs until host immune mechanisms limit further dissemination. Various mechanisms are engaged in host responses to HSV, including T cell and natural killer cell cytotoxicity, macrophage activation, production of antibody, and production of interferon.

CLINICAL SYNDROMES

Oral-Labial Herpes

In patients younger than 5 years, primary HSV-1 infection is most often asymptomatic; when symptomatic, it presents as gingivostomatitis or pharyngitis. After an incubation period of 2 to 12 days, fever and sore throat develop. Small vesicles are observed on the oral mucosa and pharynx. Mouth pain may be severe, breath is fetid, and cervical adenopathy is present. In adolescents and young adults, posterior pharyngitis and tonsillitis may be the primary problem. The differential diagnosis includes streptococcal pharyngitis, aphthous stomatitis, Stevens-Johnson syndrome, herpangina, and infectious mononucleosis. Symptoms and signs often persist for 10 to 21 days, and autoinoculation to other sites, such as fingers and eyes, is common. Oral shedding may persist for several weeks (mean, 7 to 10 days).

Recurrent herpes labialis is a shorter and milder affliction, often heralded by local pain or tingling for a few hours. HSV-1 oral-labial lesions recur more often than HSV-2 oral-labial lesions.[3] Vesicles appear most often on the vermilion border and are painful. The lesion is usually small (< 1 cm^2), and the progression from vesicle to ulcer to crust is rapid (< 96 hours). Healing is complete within 8 to 10 days. Systemic complaints are uncommon in recurrent herpes labialis.

Ocular Herpes

Most ocular herpetic infections are caused by HSV-1. Primary infections may present as unilateral follicular conjunctivitis, blepharitis, or corneal epithelial opacities. Healing is usually complete within 2 to 3 weeks. Recurrences may take the form of keratitis (more than 90% of cases are unilateral), blepharitis, or keratoconjunctivitis. Branching dendritic ulcers, usually detected by fluorescein staining, are virtually diagnostic and are often associated with diminished visual acuity. Deep stromal involvement may result in scarring, corneal thinning, and abnormal vascularization, with resultant blindness or rupture of the globe.

Genital Herpes

HSV-2 is the causative agent in 70% to 95% of primary genital herpesvirus infections. After an incubation period of 2 to 7 days, fever, malaise, and inguinal adenopathy develop; these symptoms are associated with the appearance of vesicular lesions. In men, lesions are often on the glans penis or penile shaft [*see Figure 1*]; in women, lesions may involve the vulva, perineum, buttocks, cervix, or vagina. The differential diagnosis includes syphilis, chancroid, Behçet syndrome, erythema multiforme, and candidiasis. In women, lesions rapidly ulcerate and become covered with exudate, with resultant vaginal discharge. Urethral involvement sometimes results in dysuria or urinary retention. Signs and symptoms of primary genital herpes often persist for several weeks before complete healing. Previous infection with HSV-1 may reduce the severity and duration of a first episode of genital herpes caused by HSV-2.

Extragenital lesions develop during the course of primary infection in 10% to 18% of patients. Aseptic meningitis is not uncommon during primary genital herpes, particularly in women, and in rare instances, herpetic sacral radiculomyelitis occurs.

Figure 1 **Herpes simplex virus genital lesions in men often present as grouped vesicles on the penile shaft.**

Figure 2 **Perianal herpes simplex infections in patients with compromised immunity may be severe and prolonged.**

Figure 3 **Herpetic whitlows, which occur on fingers, are often misdiagnosed as staphylococcal infections.**

Urinary retention may occasionally complicate primary genital herpes, particularly in women.

Recurrent episodes of genital herpes are usually shorter and milder than primary episodes but still affect women more severely than men. Genital HSV-2 infections recur more often than genital HSV-1 infections, and on rare occasions, the two infections can be found simultaneously in lesions.[7,8] Moreover, patients dually infected with HSV-1 and HSV-2 have fewer recurrences of genital herpes than those infected with HSV-2 alone.[2] With either virus type, after a variable prodrome of tenderness, itching, or tingling, lesions develop on the penis, labia minora, labia majora, perineum, mons pubis, or buttocks. Healing occurs in 6 to 10 days and is usually uncomplicated; frequent asymptomatic shedding occurs, however, particularly in women.[5,9] HSV-2 may also cause benign, recurrent lymphocytic meningitis that may be associated with recurrent genital lesions.[10]

Perianal and Anal Herpes

Perianal and anal HSV-2 infection is an important problem in men who have sex with men. Pain, itching, tenesmus, discharge, fever, chills, sacral paresthesias, headache, and difficulty in urinating may all occur. Vesicles and ulcerations may lead to an erythematous cryptitis with inguinal adenopathy. Herpes proctitis is often prolonged and severe in patients with AIDS [*see Figure 2*].

Other Herpes Syndromes

Herpetic whitlow Primary finger infections, or whitlows, usually involve one digit and are characterized by intense itching or pain followed by the formation of deep vesicles that may coalesce [*see Figure 3*]. Among the general public, whitlows are most often caused by HSV-2, whereas among medical and dental personnel, HSV-1 is the principal culprit. The lesions gradually resolve in 2 to 3 weeks, unless they are mistakenly incised, in which case healing may be delayed by secondary bacterial infection. Recurrent whitlows commonly appear and are sometimes associated with severe local neuralgia.

Neurologic complication Encephalitis, a severe form of HSV infection, is discussed elsewhere [*see 11:XVI Acute Viral Central Nervous System Diseases*]. HSV-1 has also been implicated as an etiologic agent in Bell palsy[11] and in rare cases of recurrent self-limited meningitis (Mollaret meningitis).[12]

Infection in the immunocompromised host Disorders of T cell–mediated immunity are associated with more severe HSV infections. In clinical settings such as organ transplantation, lymphoreticular neoplasm, or AIDS, HSV infection is often slow to heal and may disseminate cutaneously or to visceral organs. Certain skin conditions, such as eczema and burns, are associated with cutaneous but not visceral dissemination. In rare instances, HSV infection during pregnancy or in the elderly is complicated by visceral dissemination, particularly to the liver. Intubation or catheterization of debilitated patients may facilitate the spread of infection; for instance, herpes esophagitis often complicates long-term use of nasogastric tubes.

Neonatal infection Between one in 2,500 and one in 10,000 births are complicated by HSV infection, usually HSV-2. HSV neonatal infection can be localized or disseminated and results from transmission of the virus to the infant at the time of delivery, either by ascending infection after premature membrane rupture or by passage of the infant through an infected genital tract. The risk of transmission is increased in premature births, after prolonged membrane rupture, and with the use of fetal scalp monitor electrodes. About 40% to 50% of infants born to mothers with primary infections are at risk for the development of severe disease, whereas fewer than 8% of those born to women with recurrent herpes are at risk for severe disease.[1,13] Maternal infection is often asymptomatic at the time of delivery, and asymptomatic shedding may occur in women with no known history of genital herpes. In women with a history of genital HSV infection, genital HSV can be detected at delivery in approximately 2% by use of tissue culture and in 14% by use of polymerase chain reaction (PCR) techniques.[14]

Infection becomes apparent several days to weeks after delivery. Newborns often present with vesicles or conjunctivitis, or a syndrome resembling neonatal sepsis may be evident. Neurologic signs such as seizures, cranial nerve palsies, and lethargy often predominate and are accompanied by cerebrospinal fluid pleocytosis. Disseminated infection may involve the liver, lungs, or adrenal glands. If untreated, disseminated or central nervous system infection is fatal in more than 70% of patients, whereas localized disease is generally self-limited. Treatment has greatly

reduced the mortality from severe infection [*see 11:XVI Acute Viral Central Nervous System Diseases*].

DIAGNOSIS

A variety of tissue culture systems support the replication of HSV, and virus isolation from specimens collected early in the course of infection is the diagnostic method of choice. The characteristic cytopathic effect of the virus is often detectable within a period of 24 to 48 hours. Typing of isolates can be accomplished most readily by immunofluorescence with monoclonal antibodies directed against type-specific antigens. Scrapings or tissue specimens can sometimes be tested directly for herpesvirus antigens by immunofluorescence or immunohistochemistry. Alternatively, scrapings may be prepared by Giemsa or Wright stain and examined for the presence of multinucleated giant cells, which indicates infection with HSV or VZV. Serologic techniques that accurately differentiate HSV-1 from HSV-2 infections are now commercially available. Such tests can be used to confirm a diagnosis of primary HSV infection, but they are seldom helpful in diagnosing recurrences. Serologic techniques can also establish a diagnosis in patients with atypical complaints, identify asymptomatic carriers, and identify persons at risk.[15] PCR detection of HSV DNA in CSF has become the standard means of diagnosing HSV encephalitis. For patients with HSV encephalitis, PCR results are often positive within 24 hours of the onset of symptoms, and test results may remain positive during the first week of illness.[16]

PREVENTION

No HSV vaccine has been approved for general use, although preliminary studies of glycoprotein-D-adjuvant vaccines suggest efficacy in certain populations (i.e., women seronegative for both HSV-1 and HSV-2) but not others.[17] Prophylactic measures that prevent contact with the virus may help in avoiding primary infection. For instance, the use of condoms may prevent sexual transmission when either sexual partner has a history of genital HSV infection. Application of sunscreens to susceptible skin areas before exposure to ultraviolet light can prevent reactivation of HSV. Medical and dental personnel who treat HSV-positive patients should wear gloves to prevent contact with infected areas.

The best strategy for the prevention of neonatal herpes may be close physical examination at the time of labor.[18] Cesarean section is indicated to prevent perinatal infection when lesions consistent with the diagnosis of genital herpes are noted during labor. If primary genital herpes is detected during the third trimester of pregnancy, acyclovir in conventional doses should be considered for the mother during the peripartum period and for the newborn post partum [*see* Treatment, *below*]. Acyclovir in late pregnancy may also be useful in women with recurrent genital HSV infections; placebo-controlled trials have shown that 400 mg three times daily reduced lesions and HSV excretion at delivery.[19,20]

TREATMENT

Two decades of carefully controlled trials and clinical experience have made acyclovir the treatment standard for HSV infections, although the prodrug valacyclovir (which is converted to acyclovir) and famciclovir (which is converted to penciclovir) now provide alternative options [*see Table 1*].[1] Either oral acyclovir (200 mg five times daily) or intravenous acyclovir (5 mg/kg three times daily) for 7 to 10 days is recommended for treatment of primary genital herpes or mucocutaneous herpes (HSV-1 or HSV-2). Alternatively, valacyclovir (500 to 1,000 mg twice daily) or famciclovir (250 mg three times daily) may be used. Short-term (1 to 3 days), high-dose acyclovir or valacyclovir regimens are promising therapies for both genital and orolabial recurrent HSV infections.[21,22]

Suppression of severe and frequently recurring genital herpes can also be accomplished by the administration of oral acyclovir (200 to 400 mg twice daily), oral famciclovir (250 mg twice daily), or oral valacyclovir (500 to 1,000 mg daily) [*see Table 2*]. Once-daily valacyclovir (500 mg) not only suppresses recurrences of genital herpes but also reduces genital excretion of HSV-2 and transmission to partners.[23] Intravenous acyclovir, in a dosage of 10 to 15 mg/kg three times daily for 14 to 21 days, is the treatment of choice for herpes encephalitis. Neonatal HSV infections are treated with intravenous acyclovir in a dosage of 20 mg/kg every 8 hours for 14 to 21 days.

In immunocompromised persons and, in rare instances, in immunocompetent persons, acyclovir-resistant HSV-2 may lead to chronic progressive infections.[24] Intravenous foscarnet (40 mg/kg two to three times daily for 2 to 3 weeks) is useful against acyclovir-resistant HSV-2 infection. Topical preparations of foscarnet, cidofovir, and trifluridine are also under study for acyclovir-resistant HSV.[25-27]

Varicella-Zoster Virus

VZV is the causative agent of varicella (chickenpox) and herpes zoster (shingles). Because it is a strongly cell-associated member of the human herpesvirus group, it is difficult to detect or isolate in cell-free specimens. Its host range is largely limited to human cells. As with other herpesviruses, latency and reactivation are characteristic features of VZV.

EPIDEMIOLOGY

Varicella

Varicella is a highly communicable disease of childhood. More than 90% of patients are children younger than 9 years; most adults have antibody to the virus. Infection is spread by respiratory droplets or by direct contact with active lesions. Fomites are not an important mode of transmission. Chickenpox occurs most frequently in the winter and the spring and spreads rapidly to susceptible household members. The incubation period ranges from 11 to 20 days.

Herpes Zoster

Herpes zoster results from the reactivation of VZV infection. Varicella in one patient cannot produce herpes zoster in another; however, persons who are exposed to patients who have herpes zoster can contract varicella. There is no seasonal pattern for herpes zoster. The likelihood of reactivation is related to both age and immune status.[28] The incidence of disease in patients older than 60 years is two to three times higher than that in younger persons. The incidence in immunosuppressed patients, particularly those with depressed T cell function (e.g., patients who have lymphomas, leukemias, organ transplants, or AIDS), is as much as 100 times higher than that in immunocompetent hosts.

Herpes zoster occurs more frequently in patients with neoplasms. The risk of developing herpes zoster is 13% to 15% for patients with Hodgkin disease, 7% to 9% for patients with other lymphomas, and 1% to 3% for patients with solid tumors. Approximately 15% to 30% of patients with Hodgkin disease and

HSV-2—herpes simplex virus type 2 NA—not available

herpes zoster exhibit significant dissemination; however, mortality in such patients is low. Localized and disseminated herpes zoster are more common in patients with advanced malignant disease who are receiving intensive chemotherapy or irradiation. The incidence of herpes zoster is also increased after organ or bone marrow transplantation. The incidence of herpes zoster is approximately 8.6% in solid-organ transplant recipients, and it may be more common in women and in patients who are following certain immunosuppressive and prophylactic antiviral regimens.[29] In patients with advanced HIV-1 infection, chronic, nonhealing VZV ulcers may persist for several months, and herpes zoster may be precipitated by the introduction of highly active antiretroviral therapy.

CLINICAL SYNDROMES

Varicella

After local replication of VZV at the site of virus entry, the virus is carried by blood leukocytes to focal skin areas and visceral organs. Replication at skin sites results in vesicle formation accompanied by degeneration of epithelial cells, accumulation of edema fluid, and infiltration of inflammatory cells; multinucleated giant cells containing intranuclear inclusions are present.

Clinical features Subclinical infections are rare (< 4% of cases). Illness usually presents as a generalized vesicular eruption that is followed by a variable prodrome of headache, fever, and malaise. Vesicles often appear initially on the face or trunk [*see Figure 4*]. During the next 4 to 7 days, successive crops of lesions appear. Most childhood cases are uncomplicated and resolve in 7 to 10 days without producing scarring.

Complications In adolescents and adults, pneumonia may develop that is characterized by cough, tachypnea, and diffuse reticulonodular infiltrates, which may calcify with time. Pulmonary oxygen diffusion difficulties may persist for a period of weeks to months. Varicella pneumonia may be particularly severe in pregnant women and, among them, is more common in smokers and those with more than 100 skin lesions.[30] Although varicella encephalopathies are uncommon, they can occur at any age and can take several forms; the presenting feature may be hyperexcitability, which can progress to coma or cerebellar ataxia. Other rare complications of varicella infection are Reye syndrome (fulminating encephalopathy and fatty liver), thrombocytopenia, arthritis, ocular involvement, carditis, gastrointestinal bleeding, nephritis, orchitis, and bacterial superinfection. A pregnant woman who contracts varicella during the first 20 weeks of pregnancy has a small (< 2%) risk of giving birth to an infant with congenital varicella syndrome, which includes limb hypoplasia, skin scarring, and ocular defects.[31]

Disseminated disease is more likely to develop after varicella infection in children with leukemia, lymphoma, or Hodgkin disease. Visceral dissemination occurs in 20% to 35% of children with cancer who are receiving chemotherapy; mortality in such patients is 7% to 30%. Clinical reinfection, with resultant atypical generalized varicella, can occur in the severely immunocompromised host; such reinfection tends to be mild and self-limited.

Herpes Zoster

Herpes zoster occurs in patients previously infected with varicella. After an initial episode of varicella infection, the virus persists in neurons of sensory ganglia in a relatively quiescent, ex-

Figure 4 **The lesions characteristic of varicella-zoster virus infection often appear initially on the face and trunk and may present as maculopapules, vesicles, and scabs simultaneously.**

trachromosomal, cytoplasmic state.[32,33] Both subclinical and clinical reactivations occur. Clinical VZV reactivation is enhanced by many factors, including increasing age, immunosuppression, and local skin injury.

Clinical features Attacks of herpes zoster are often preceded by pain, which may persist for several days before lesions appear. The vesicular eruption is unilateral and most often appears on the thorax [*see Figure 5*]. Individual attacks are usually limited to one to three dermatomes, although a few isolated skin lesions at sites distant from this area are not uncommon. Vesicles surrounded by an erythematous base may continue to develop for several days; the lesions then dry and crust. Superinfections are common, and scarring can occur.

Complications The most common complication of herpes zoster is postherpetic neuralgia, which may be severe, particularly in the elderly. Postherpetic neuralgia may be refractory to treatment and persist for months to years [*see 11:XVI Acute Viral Central Nervous System Diseases*]. Other neurologic syndromes associated with herpes zoster are segmental myelitis, Guillain-Barré syndrome, acute retinal necrosis, and Ramsay Hunt syndrome.[33] Ramsay Hunt syndrome is an infection of the geniculate ganglion of the seventh cranial nerve, producing facial paralysis; vesicles on the eardrum and side of the tongue can also occur.

VZV encephalitis, another infrequent complication of herpes zoster, may present in two forms.[33] Large vessel encephalitis (granulomatous arteritis) occurs predominantly in immunocompetent persons; it is characterized by acute focal deficits that occur weeks after the appearance of zoster lesions in the contralateral trigeminal pattern of distribution. Angiography demonstrates segmental narrowing, primarily in the internal carotid and middle or anterior cerebral arteries. Microscopic examination shows arterial inflammation, multinucleated giant cells, and virus particles. Small vessel encephalitis occurs almost exclusively in immunocompromised persons and is characterized by headache, fever, mental changes, seizures, and focal deficits. Imaging studies show ischemic or hemorrhagic infarcts of gray and white matter, and CSF examination demonstrates mononuclear pleocytosis and both VZV DNA and VZV antibody.

DIAGNOSIS

Varicella and herpes zoster can usually be diagnosed solely on clinical grounds. Varicella is sometimes confused with disseminated herpes simplex, impetigo, insect bites, or scabies; on rare occasions, HSV infection presents with zosteriform eruptions. Diagnosis of VZV infection can be confirmed by virus isolation, direct immunofluorescence of lesions, PCR detection of viral DNA, or demonstration of a fourfold rise in antibodies to viral antigens. Herpes zoster provokes a more rapid and greater rise in antibodies than varicella.

PREVENTION

A live attenuated VZV vaccine is available in the United States and appears both safe and effective. It is recommended for persons older than 1 year who are in good health and have no history of clinical VZV infection. A single subcutaneous dose is recommended for children 1 to 12 years of age, whereas two doses separated by 4 to 8 weeks are recommended for susceptible adolescents and adults. Varicella has declined markedly in surveillance areas secondary to vaccine use.[34,35] However, breakthrough infections in vaccinated children suggest that booster doses of vaccine may be necessary to maintain optimal immunity.[36]

Nosocomial transmission of VZV has been reported. Thus, hospitalized patients with varicella or herpes zoster should be isolated to prevent spread of virus to other susceptible persons. Susceptible immunocompromised patients who are exposed to infected persons should receive prophylaxis with varicella-zoster immune globulin (one dose up to 4 days after exposure) to prevent or modify clinical illness. Small studies suggest that high-dose acyclovir (40 to 80 mg/kg for 7 days, beginning 7 to 9 days after exposure) or VZV vaccine (one dose on the day of exposure or up to 3 days after exposure) may also be useful in postexposure prophylaxis.[32]

TREATMENT

Considerable success in the treatment of VZV infections in immunocompromised hosts has been achieved with parenteral administration of acyclovir (for adults, 10 mg/kg every 8 hours for 7 days). High-dose oral acyclovir (800 mg five times

Figure 5 **Herpes zoster is most often thoracic and dermatomal in distribution. Cutaneous dissemination, as seen in this patient, as well as visceral dissemination, may occur when immunity is severely compromised.**

NA—not available

daily for 7 days), when begun early, may also shorten the course and reduce the severity of herpes zoster in otherwise healthy hosts. Oral valacyclovir (1 g three times daily) or famciclovir (500 mg three times daily) may also be used [*see Table 3*]. The use of corticosteroids in combination with acyclovir for the treatment of acute herpes zoster remains controversial.[37,38] Steroid use may be justified in persons older than 50 years who have no relative contraindications, such as diabetes, hypertension, or glaucoma.[28]

Acyclovir resistance has been described in VZV isolates from patients with HIV infection who received long-term acyclovir therapy. Foscarnet (40 mg/kg every 8 hours) is the drug of choice for acyclovir-resistant VZV infections in immunocompromised hosts [*see Table 3*].[39] Acyclovir, famciclovir, and valacyclovir are also effective in reducing the severity and shortening the course of chickenpox in patients who are immunologically competent, although children are generally not treated for uncomplicated varicella.

Postherpetic neuralgia, the most common complication of herpes zoster, is difficult to treat, particularly in elderly patients; suggested treatments include topical anesthetics, oral analgesics, tricyclic antidepressants, gabapentin, and intrathecal methylprednisolone acetate.[28]

Cytomegalovirus

Although cytomegalic inclusion disease of infants was recognized as a clinical entity at the turn of the 20th century, the etiologic agent, CMV, was not isolated until the mid-1950s. CMV has since become recognized as a nearly ubiquitous virus that plays an important role in many diseases, including a form of mononucleosis and disseminated disease in the immunocompromised host.

EPIDEMIOLOGY AND ETIOLOGY

CMV has a worldwide distribution. Approximately 1% of newborns in developed countries are infected with CMV, and the incidence is much higher in developing areas. In immunocompromised patients (e.g., organ or bone marrow transplant recipients and patients with AIDS), CMV infection is a major cause of morbidity and mortality.

Transmission occurs by close contact with infected persons, most commonly by the sharing of secretions or leukocyte-containing blood products. CMV is shed in semen, cervical secretions, saliva, maternal milk, and urine. In late adolescence and adulthood, genital transmission is common. Primary infection in pregnant women may result in transplacental spread to the fetus, sometimes with devastating consequences. Naturally acquired immunity substantially reduces the likelihood of congenital infection, although infection with a different CMV strain can occur and lead to symptomatic infection of the newborn.[40,41] Perinatal infection is also common because of spread from maternal milk or other secretions. Communal living and poor personal hygiene facilitate transmission. Spread of CMV in day care centers is common; the infected child often serves as a source of transmission to other family members. Blood transfusions and organ transplantation may also transmit CMV from an asymptomatic donor to a recipient. The proportion of CMV antibody–negative liver transplant recipients receiving organs from CMV antibody–positive donors appears to be increasing.[42]

PATHOGENESIS

Once infected, one probably carries the virus for life. Generally, such infections remain dormant, but reactivation occurs during periods of immune compromise. Reactivation is particularly common in patients with compromised T cell function (e.g., transplant recipients or patients with lymphoid neoplasms or AIDS). Reinfections with new strains of CMV can also occur in immunosuppressed patients.

In the fetus, primary infection may result in disseminated cytomegalic inclusion disease with numerous congenital abnormalities, in localized disease affecting the auditory system or the CNS, or in subclinical involvement. Perinatal infection is usually asymptomatic, although protracted interstitial pneumonitis, hepatitis, and failure to thrive may result.

Symptomatic disease is more likely to be produced by primary CMV infection than by viral reactivation. The sites of latent infection are poorly defined, although it appears likely that CMV persists in numerous cell types in many organs. If host immune responses become compromised, virus reactivation and increased replication can occur and result in various syndromes. CMV replication can further suppress immune responses, leading to profound lymphocyte hyporesponsiveness and severe opportunistic infections with protozoa (e.g., *Pneumocystis carinii* and *Toxoplasma gondii*), fungi, or bacteria. The mechanisms by which CMV replication inhibits host responses are complex and involve virus interactions with both host lymphocytes and monocyte-macrophages.

CMV Mononucleosis

Clinical features CMV mononucleosis occurs in patients of any age but is most common in sexually active young adults. A vigorous host T cell response may contribute to the syndrome, which is characterized by fever, malaise, fatigue, and myalgia. Headache and splenomegaly are also often present. Mild liver enzyme abnormalities are common, and atypical lymphocytes are present in the peripheral blood. Heterophile antibodies are not formed in response to CMV infection; however, mild immunologic abnormalities, including the presence of rheumatoid factor and antinuclear antibodies, are common.

Complications Occasionally, hemolytic anemia, thrombocytopenia, neurologic complications (e.g., Guillain-Barré syndrome), or other organ involvement (liver, lung) occurs and is severe.[43] Acute infections generally resolve in 2 to 4 weeks, but postviral asthenia and viral excretion often persist for months.

CMV Infection in the Immunocompromised Host

CMV appears to be the most frequent and important viral pathogen in patients who have had organ transplants. Most commonly, such patients with CMV syndromes present with fever and leukopenia, which may progress to pneumonitis or, in rare instances, to disseminated disease. The period of highest risk is 1 to 4 months after transplantation and appears to relate to the degree of host immunosuppression. CMV may also increase the risk of graft loss after organ transplantation.[44] CMV pneumonia occurs in nearly 20% of marrow transplant recipients; mortality in such patients, if they remain untreated, is about 90%.

CMV is recognized as an important pathogen in patients with AIDS. The virus often contributes to the immunosuppression observed in such patients and may cause disseminated disease affecting the eyes, GI tract, or CNS. At least 50% of patients with AIDS have CMV viremia, and 90% or more have evidence of CMV infection at autopsy.[45] Ulcers of the esophagus, stomach, small intestine, or colon may be present and may lead to bleeding or perforation.[46] It is critical to recognize CMV polyradiculopathy or encephalitis in this setting because this disorder is potentially reversible with therapy.[47,48] Similarly, CMV retinitis is an important treatable cause of blindness in patients with AIDS.[49]

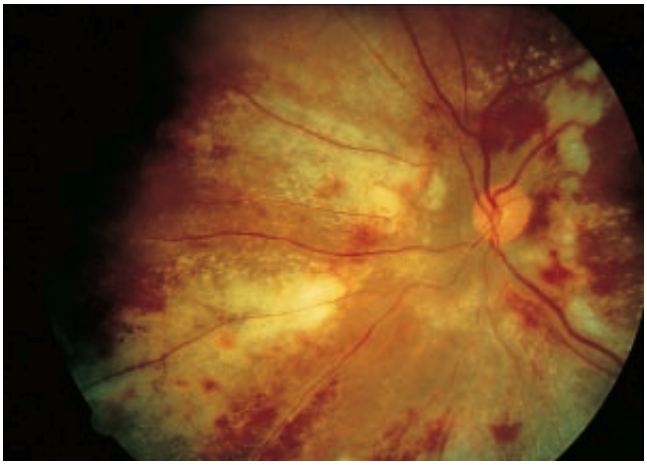

Figure 6 **Cytomegalovirus retinitis may result in hemorrhage exudates and, eventually, blindness.**

Early lesions consist of small white areas of retinal necrosis that progress in a centrifugal manner and are subsequently accompanied by hemorrhage, vessel sheathing, and retinal edema [*see Figure 6*]. CMV and HIV have been shown to potentiate each other's replication in vitro, and it is possible that such interactions occur in dually infected organs (e.g., the retina and brain of an AIDS patient who has CMV infection).

Two forms of CMV encephalitis are clinically and pathologically distinguishable in patients with AIDS: multifocal micronodular encephalitis, which resembles HIV encephalitis and presents with progressive dementia, and ventriculoencephalitis, which is characterized by acute cranial nerve deficits, ventriculomegaly, nystagmus, lethargy, and disorientation.[48,50]

DIAGNOSIS

CMV infection cannot be reliably diagnosed on clinical grounds alone. Virus can be isolated from a variety of secretions or infected tissues, but definitive identification can take several weeks. Use of shell vial centrifugation and immunocytochemical analysis for CMV early antigens can facilitate rapid diagnosis and help monitor outcome, as can the application of immunofluorescence or PCR-based assays to plasma or peripheral blood leukocytes.[51-53] Demonstration of viremia is a better indicator of acute infection than the detection of virus in urine or saliva. The use of PCR to detect CMV DNA in CSF is helpful in the diagnosis of CMV encephalitis and polyradiculopathy.[48,50]

PREVENTION

Several specific and nonspecific prophylactic measures to prevent CMV syndromes are under investigation. Matching of seronegative transplant or transfusion recipients with seronegative organ or blood donors may reduce the likelihood of transmission. Use of blood that has been frozen and thawed, washed with saline, or filtered through cotton wool can prevent transfusion-associated CMV infection. CMV immune globulin may be useful in certain seronegative bone marrow transplant recipients. Experimental CMV vaccines are under investigation.

TREATMENT

Management of CMV Mononucleosis

CMV mononucleosis is generally self-limited and requires only supportive care. Specific antiviral therapy is not indicated.

Management of CMV in the Immunocompromised Host

Intravenous ganciclovir, an analogue of deoxyguanosine, and oral valganciclovir, a prodrug for ganciclovir, are effective treatments for CMV infections (e.g., retinitis) in immunocompromised hosts [*see Table 4*]. Both ganciclovir administered intravenously (5 mg/kg twice daily for 21 days followed by 5 mg/kg daily maintenance) and oral valganciclovir (900 mg twice daily for 21 days followed by 900 mg daily maintenance) result in stabilization or improvement in 70% to 90% of patients with CMV retinitis.[54] If the immunocompromised state persists, prolonged maintenance therapy may be required to maintain improvement of retinitis.[55] Maintenance therapy can be safely discontinued in patients with AIDS whose CD4 cell counts increase substantially with antiretroviral therapy, but relapses occur if CD4 cell counts fall below 50/mm^3.[56]

Foscarnet (90 mg/kg twice daily for 2 to 3 weeks, followed by 90 to 120 mg/kg daily) is effective in treatment of CMV retinitis and GI disease, and cidofovir (5 mg/kg weekly for 2 weeks, fol-

Table 4 Drug Treatment for Cytomegalovirus Infection

Drug	*Dose*	*Efficacy Rating*	*Comment*
Ganciclovir	5 mg/kg I.V. b.i.d. for 21 days, then 5 mg/kg I.V. q.d. for maintenance	First choice	For CMV retinitis and other advanced CMV infections in immunocompromised patients
Ganciclovir + ocular implants	1.5 g p.o., t.i.d.	—	For long-term therapy of CMV retinitis in patients with HIV infection
Valganciclovir	900 mg p.o., b.i.d., for 21 days, then 900 mg p.o., q.d., for maintenance	First choice	For CMV retinitis and other advanced CMV infections in immunocompromised patients
Foscarnet	90 mg/kg I.V. b.i.d. for 2-3 wk, then 90–120 mg/kg I.V. q.d.	Alternative	For CMV retinitis or GI disease; combine with ganciclovir for severe CNS infections in patients with AIDS
Cidofovir	5 mg/kg I.V. once a week for 2 wk, then 5 mg/kg I.V. every 2 wk	Alternative	For CMV retinitis

CMV—cytomegalovirus CNS—central nervous system GI—gastrointestinal NA—not available

lowed by 5 mg/kg every 2 weeks) may be useful in CMV retinitis. Ganciclovir ocular implants in combination with oral ganciclovir (1.5 g three times daily) is effective for long-term treatment of CMV retinitis in persistently immunocompromised patients with HIV infection.[57] The combination of ganciclovir and foscarnet may be necessary for severe CNS infections in patients with AIDS.[58] Resistance to ganciclovir and other anti-CMV drugs may complicate prolonged therapy.[59,60]

Prophylactic or suppressive ganciclovir may be useful in other high-risk patients, such as CMV-seropositive bone marrow or solid-organ transplant recipients. Several preventive or preemptive regimens of ganciclovir or valganciclovir are under study in both susceptible transplant recipients and patients with AIDS.[61-63]

Epstein-Barr Virus

EBV has a very limited cell tropism; its host range is generally restricted to human B cells and epithelial cells of the nasopharynx and uterine cervix. It is the cause of heterophile antibody–positive infectious mononucleosis and has been implicated in a variety of other disorders, including Burkitt lymphoma, nasopharyngeal carcinoma, oral hairy leukoplakia, and a variety of B cell and possibly T cell lymphoproliferative disorders.[64-66]

EPIDEMIOLOGY AND ETIOLOGY

In developing countries, most of the population is exposed to EBV at an early age. In the United States, approximately 50% of the population seroconvert by 5 years of age; there is also a high rate of seroconversion in adolescence and young adulthood. Clinical infectious mononucleosis develops primarily in persons who contract primary EBV infection when they are between 10 and 20 years of age; in younger persons, primary EBV infection is usually clinically inapparent. Thus, most cases of infectious mononucleosis occur in members of higher socioeconomic groups in developed countries, where viral transmission is often delayed until the patients are older than 10 years. Approximately 12% of susceptible college-age young adults seroconvert each year; about 50% of them acquire infectious mononucleosis. As a result, EBV infection has important public health implications for young adult populations, including students and military personnel.

EBV is shed from the oropharynx in approximately 15% of the adult seropositive population at any given time, and all EBV-seropositive individuals may shed virus in their saliva at some time.[67] Shedding occurs much more frequently in patients with infectious mononucleosis and in immunocompromised persons, such as renal transplant recipients and patients with AIDS. Transmission requires close contact, usually oral to oral, with a person shedding EBV. On rare occasions, virus can be transmitted by other routes, including blood transfusion. EBV infection of the uterine cervix has been documented, genital ulcerations have been observed in patients with infectious mononucleosis, and sexual activity is a highly significant risk factor for EBV seropositivity,[68] suggesting the possibility of genital transmission of EBV to sexual partners and newborns.

PATHOGENESIS

Infection is initiated by the binding of EBV envelope proteins gp350/120 to the cell surface molecule CD21. After initial replication in nasopharyngeal cells or B cells, B cells apparently carry the virus to other parts of the body. In the nasopharynx, infectious virus is actively replicated. In contrast, in B cells, the viral genome is present, but mature infectious virus particles are not produced. In B cells in which EBV remains latent, its DNA exists as a circular episome; in cells in which infectious virus is produced, EBV DNA exists in a linear form. Infected B cells are referred to as immortalized (i.e., capable of continuous proliferation) and may produce a variety of antibodies as a consequence of polyclonal B cell activation. One of the antibodies they produce, the heterophile antibody, is a useful diagnostic marker of infection. Once infection is initiated, the host mounts a T cell response against new antigens on infected cells and a B cell antibody response against several EBV-associated antigens, including viral capsid antigen, early antigen, and Epstein-Barr nuclear antigen.[64] Antibody patterns vary according to the stage of infection and the syndrome expressed (see below).

CLINICAL SYNDROMES

Age and immunocompetence greatly influence the expression of EBV infection. Young children usually have asymptomatic or trivial infections and often do not produce heterophile antibodies. In the elderly, EBV infection may present as a persistent febrile syndrome in which the patient tests negative for heterophile antibodies. The most common clinical manifestation of primary EBV infection is infectious mononucleosis.

Infectious Mononucleosis

Clinical features Patients usually present with fever, pharyngitis, and lymphadenopathy. Hepatosplenomegaly, a palatal enanthema, periorbital edema, and jaundice are less common features. A maculopapular diffuse rash occurs in 10% of pa-

tients, particularly in patients who have been given ampicillin. Hematologic abnormalities include a peripheral blood lymphocytosis; usually more than 10% of the leukocytes in the peripheral blood consist of atypical lymphocytes. The total leukocyte count may be normal, low, or high; a relative and absolute neutropenia is observed in 60% to 90% of patients. Thrombocytopenia is also common, and hepatocellular enzymes are abnormal in about 90% of patients. Cryoproteins and antigranulocyte antibodies are frequently present but are usually of little clinical significance. Most cases of infectious mononucleosis resolve in 1 to 3 weeks, although malaise and fatigue occasionally persist for several weeks to months.

Complications Complications of infectious mononucleosis can affect most organ systems. Tonsillar enlargement can be extreme, causing respiratory embarrassment. Splenic rupture is rare but must be considered when abdominal pain develops, particularly during the second and third weeks of illness. Patients with splenic rupture usually have left upper quadrant pain and tenderness, often accompanied by signs of peritoneal irritation and laboratory evidence of a falling hematocrit. Splenectomy may be required when a diagnosis of splenic rupture is confirmed, although splenic preservation is sometimes possible with intensive supportive care.

Neurologic complications occur in fewer than 1% of patients with infectious mononucleosis; these complications include encephalitis, aseptic meningitis, transverse myelitis, Guillain-Barré syndrome, optic neuritis, and peripheral neuropathies. EBV encephalitis often presents as a cerebellitis, but it may mimic the temporal lobe presentation of herpes encephalitis [*see 11:XVI Acute Viral Central Nervous System Diseases*]. Despite the severity of the neurologic complications, most patients with such complications recover completely.

Autoimmune hemolytic anemia mediated by cold agglutinins directed against antigens may occur, usually during the second or third week of illness. Aplastic anemia, thrombocytopenia with bleeding, and severe granulocytopenia with superinfection are rare but potentially fatal complications. EBV has been detected in bone marrow specimens by in situ hybridization. Cardiac and pulmonary complications are rare. A rare chronic syndrome of fever, persistent hepatitis, extensive lymphadenopathy, hepatosplenomegaly, pancytopenia, uveitis, and interstitial pneumonia has been associated with persistent EBV infection.[69]

EBV Infection in the Immunocompromised Host

Immunocompromised hosts are susceptible to overwhelming EBV lymphoproliferative syndromes. A familial X-linked disorder, Duncan disease, has been associated with fatal infectious mononucleosis, as well as agammaglobulinemia and lymphoma. All of these disorders are apparently related to EBV infection in genetically predisposed persons. The gene involved encodes for a 128 amino acid protein that may be involved in T cell signal transduction.[70] Occasionally, in transplant recipients receiving cyclosporine and in patients with AIDS, overwhelming EBV infections develop that culminate in B cell lymphoproliferative syndromes.

Oral hairy leukoplakia is a nonmalignant hyperplastic lesion of epithelial cells that occurs in immunocompromised patients, particularly those with HIV infection, and presents as raised, white, corrugated lesions on the lateral aspect of the tongue. It is associated with active EBV replication and expression of lytic viral proteins.[71]

EBV Infections and Cancer

The nature of the association of EBV with Burkitt lymphoma and nasopharyngeal carcinoma remains unresolved. Nearly all African patients with Burkitt lymphoma and East Asian patients with nasopharyngeal carcinoma have elevated EBV antibody titers, and EBV DNA is found in the tumors themselves. A single clonal form of EBV has been associated with nasopharyngeal carcinoma and with preinvasive lesions, although it is not clear whether or how the virus is involved in the etiology of these neoplasms. EBV has also been associated with some cases of primary CNS B cell lymphoma, T cell lymphoma, smooth muscle tumors, lymphomatoid granulomatosis, and Hodgkin disease.[64-66]

DIAGNOSIS

In most cases of infectious mononucleosis, the diagnosis is confirmed by detection of heterophile antibodies and abnormalities in the blood, characterized by the presence of atypical lymphocytes that frequently account for more than 10% of the leukocytes in the peripheral blood. Heterophile antibodies, often detected with monospot or slide tests, are not directed against viral antigens but rather against erythrocyte antigens of a variety of species, including sheep, horses, and goats. These acute-phase reactants, present in about 90% of patients at some point during the illness, must be distinguished from naturally occurring Forssman antibodies and the antibodies present in patients with serum sickness; differentiation can be accomplished by proper absorption tests. Heterophile antibodies may be present at the onset of clinical illness or may appear later in the course of disease; they usually disappear 3 to 4 months after the onset of illness but may persist for longer periods. False positive reactions are rare.

Heterophile antibody-negative infectious mononucleosis may be caused by CMV, EBV, or other viruses. For heterophile antibody–negative cases of infectious mononucleosis and for other possibly EBV-associated syndromes, measurement of EBV-specific antibodies may be useful. Antibodies to viral capsid antigen appear early in the course of infection and are present in 85% of patients at the time of their initial physician visit. The presence of IgM antibodies to viral capsid antigen suggests acute infection, whereas IgG antibodies to viral capsid antigen indicate past infection. Antibodies to early antigen appear transiently during active infections and are also found in patients with the African variant of Burkitt lymphoma and in patients with nasopharyngeal carcinoma. Antibodies to Epstein-Barr nuclear antigen appear late in the course of illness and persist after recovery. Thus, the pattern of specific EBV antibody responses may indicate the stage of infection.

Cultures are usually not helpful in making a diagnosis. Although EBV can be isolated from the nasopharynx, culture techniques are cumbersome and time consuming. EBV DNA detection by PCR techniques may be useful for monitoring progression in certain diseases, such as encephalitis or lymphoproliferative syndromes.[72-74]

PREVENTION

Experimental EBV vaccines are under study, although appropriate indications for their use are unclear.[64]

TREATMENT

Management of Infectious Mononucleosis

Treatment is supportive. The administration of corticosteroids may be helpful in certain situations, such as impending airway obstruction, severe thrombocytopenia, or hemolytic anemia.

Short-course regimens (1 to 2 weeks) are adequate. Specific antiviral agents such as acyclovir or ganciclovir are not recommended for most EBV-related disorders.[75] Although intravenous acyclovir can reduce viral shedding in patients with infectious mononucleosis, clinical benefit appears to be minimal.

Management of Infection in the Immunocompromised Host

Infusion of donor leukocytes or EBV-specific cytotoxic T cells has also been useful in some EBV-related lymphoproliferative diseases after bone marrow transplantation.[64,76] No antiviral agents have shown benefit in EBV-associated diseases.

Human Herpesvirus Type 6

In 1986, a newly recognized herpesvirus, HHV-6, was isolated from the peripheral blood leukocytes of six persons with various lymphoproliferative disorders.[77] It was initially designated human B lymphotropic virus but was renamed when subsequent studies demonstrated that the virus replicated in cells of T cell origin.[78] Two genetically distinct variants of HHV-6—namely, HHV-6A and HHV-6B—are recognized. Disease is most commonly associated with HHV-6B infection; however, HHV-6A may have greater neurotropism.[79] An immunomodulatory protein, CD46, is a cellular receptor for HHV-6.[80]

HHV-6 infection typically occurs during infancy as the level of maternal antibody wanes (peak between 6 to 9 months), although intrauterine infection can also occur.[81] As many as 80% of adults are seropositive for HHV-6. Infection can present as exanthema subitum (roseola infantum), a common illness characterized by fever followed by a rash or by a febrile illness without rash but often with febrile seizures.[82] HHV-6 has been associated with encephalitis, and it has been suggested, though not proved, that HHV-6 is a causal agent in multiple sclerosis.[83] HHV-6 may be transmitted by saliva and possibly by genital secretions, blood, or transplanted organs, and HHV-6 infection may cause a mononucleosis-like syndrome.[84] After primary infection, the viral genome may persist in peripheral blood mononuclear cells and in salivary glands. Reactivation accompanies immunosuppression, and 30% to 45% of bone marrow transplant recipients develop HHV-6 viremia in the first few weeks after grafting.[85] In immunocompromised adults, HHV-6 may be associated with a rash resembling graft versus host disease and may cause pneumonitis, encephalitis, graft rejection, or disseminated disease, although its etiologic relationship to any of these remains unproven.[85-88] There is no antiviral agent with proven clinical efficacy against HHV-6, although ganciclovir and foscarnet have been suggested as possible therapies.[89]

Human Herpesvirus Type 7

In 1990, another lymphotropic human herpesvirus, tentatively called HHV-7, was isolated from human T cells obtained from a healthy 26-year-old man.[90] Its role in human disease has not been established, although it appears frequently in the saliva of healthy adults.[91] Infection generally occurs by age 5, and approximately 90% of adults are seropositive.[92] The HHV-7 genome can also be detected in peripheral blood leukocytes and cervical secretions. HHV-7 may account for some cases of roseola or febrile seizures[93,94] and may be associated with graft dysfunction after solid-organ transplantation.[88] Although it has been suggested that both HHV-6 and HHV-7 are etiologic agents in chronic fatigue syndrome and pityriasis rosea, supportive evidence is lacking.[95,96]

Human Herpesvirus Type 8

Several reports in late 1994 and 1995 provided convincing evidence of unique herpesvirus-like sequences in Kaposi sarcoma (KS) and body cavity–based lymphoma tissue from patients with AIDS.[97-100] Using representational difference analysis, researchers found that more than 90% of the KS tissue studied contained these sequences; appropriate control tissue tested negative, except for 15% of non-KS tissue from AIDS patients.[97] The same herpesvirus-like DNA sequences were subsequently reported in KS tissue from patients who did not have AIDS[98-100] and in lymph node biopsy specimens from patients with multicentric Castleman disease.[101]

HHV-8 has been propagated in cell cultures and closely resembles a recently identified gamma herpesvirus of rhesus monkeys. Several serologic assays have been developed.[102-104] One, which detects antibody to a latency-associated nuclear antigen, finds seropositivity in 1% to 2% of HIV-negative blood donors; in 30% of HIV-positive hemophiliacs, transfusion recipients, and women; and in more than 80% of patients with HIV infection and KS.

The natural history and clinical spectrum of diseases caused by HHV-8 is not yet well characterized. Primary infection in immunocompetent children may be associated with fever and a maculopapular rash, and a finding of HHV-8 DNA in saliva suggests salivary transmission.[105] One individual developed fever, hepatosplenomegaly, angiolymphoid hyperplasia, and transient KS during seroconversion.[106] Family studies suggest transmission to children via nonsexual routes and between spouses via sexual routes.[107] Transmission has also been demonstrated in the intrapartum and postpartum periods, and intrauterine infection may also occur.[108] Among men who have sex with men, risk factors for transmission include increased number of sex partners, amyl nitrite use, and occurrence of lymphadenopathy within the previous 6 months.[109] Risk factors for transmission in North American women include HIV infection, increasing age, history of syphilis, injection drug use, and black race.[110,111]

Molecular and serologic evidence strongly suggests a causal role for HHV-8 in KS and associations with body cavity–based lymphomas and multicentric Castleman disease. Although it has been suggested that HHV-8 is associated with both multiple myeloma and sarcoidosis, confirmatory evidence is lacking. Studies of HHV-8 susceptibility to antiviral drugs suggest relative resistance to acyclovir and penciclovir but susceptibility to ganciclovir, foscarnet, and cidofovir.[112,113] However, one pilot trial of cidofovir showed no effect on either HHV-8 viral load or on KS lesions.[114] In contrast, effective antiretroviral infection in individuals dually infected with HIV-1 and HHV-8 may reduce the HHV-8 load and may be associated with KS regression.[115]

The author has received grants for clinical research from Takeda Pharmaceuticals North America, Inc., and has served as a consultant to GlaxoSmithKline, Bristol-Myers Squibb Co., and Schering-Plough Corp.

XXVIII ENTERIC VIRAL INFECTIONS

Nino Khetsuriani, m.d., ph.d.
Umesh D. Parashar, m.d., m.p.h.

Enterovirus Infections

Human enteroviruses belong to the genus Enterovirus, family Picornaviridae. They are divided into five species (human enterovirus A, B, C, and D, and poliovirus) comprising 68 currently recognized serotypes: polioviruses (types 1 to 3); coxsackieviruses A (types 1 to 14, 16, 17, 19 to 22, and 24) and B (types 1 to 6); echoviruses (types 1 to 7, 9, 11 to 21, 24 to 27, and 29 to 33); and numbered enteroviruses (types 68 to 71 and 73 to 78).[1] Enteroviruses are small (approximately 30 nm), nonenveloped, single-stranded RNA viruses with an icosahedral capsid composed of 60 subunits consisting of four structural proteins (VP1 to VP4). Enterovirus RNA is approximately 7.5 kb long and codes structural proteins, RNA polymerase, other polypeptides necessary for viral replication, and two untranslated regions at the 5´ and 3´ ends of the RNA molecule. New enteroviruses continue to be identified as molecular techniques of enterovirus typing become increasingly available. In addition, some serotypes have been found to be identical to other enteroviruses (e.g., echovirus 8 is the same as echovirus 1) or have been reclassified as members of other genera (e.g., echoviruses 22 and 23 are now human parechoviruses 1 and 2, respectively).

epidemiology

Enteroviruses are among the most common viruses worldwide. In temperate climates, the incidence of enterovirus infections peaks during the summer and fall months (June through October in the United States), whereas in the tropics, transmission occurs year-round.

Several enterovirus serotypes commonly cocirculate in the community, and predominant serotypes tend to change over time. The serotypes most commonly reported in the United States included echoviruses 30, 11, 9, 6, and 7 (from 1997 to 1999[2]), echoviruses 13 and 18 (from 2000 to 2001[3]), and echoviruses 9 and 30 (in 2003).[4] The appearance of new predominant enterovirus serotypes is often accompanied by large-scale outbreaks. For example, large outbreaks of aseptic meningitis were reported in 2001, when previously rare echoviruses 13 and 18 became the predominant serotypes in the United States.[3,5]

Illnesses associated with enteroviruses affect predominantly children, but persons of any age may be susceptible. In addition to young age, predisposing factors for enterovirus illness include male sex, lower socioeconomic status, residence in urban areas, poor sanitation, large household size, and crowded living conditions.[6]

The enteroviruses are universally found in the environment (e.g., in sewage; surface water, such as rivers, lakes, and other reservoirs; and seawater), because they are excreted in large amounts by infected persons. The lack of a lipid envelope and the presence of a dense protein capsid allow enteroviruses to survive in the environment for long periods, especially at low temperatures. Enteroviruses are inactivated by extreme heat, ultraviolet light, drying, and chlorine. A high concentration of organic matter prevents inactivation of enteroviruses by chlorine.[7]

Enteroviruses are most often transmitted from person to person by the fecal-oral or the respiratory route, but transmission by fomites also occurs. Young children are the most important transmitters of enteroviruses and are often the index case in family or school outbreaks.

pathogenesis

Enteroviruses gain entry into the host cell after binding to specific cellular receptors. Several different receptors with tropism to different serotypes have been identified. Initial virus replication takes place in submucosal lymphatic tissues of the pharynx and the gut (Peyer patches). The virus then spreads to the regional lymph nodes, enters the bloodstream ("minor" viremia), and reaches the reticuloendothelial system (i.e., deep lymph nodes, bone marrow, spleen, and liver). If viral replication is not contained by host defense mechanisms at this stage, symptomatic infection occurs, resulting in "major" viremia and dissemination of the virus to target organs. Certain enteroviruses (e.g., polioviruses) may spread along neural pathways as well. Tissue tropism of the serotype determines target organs for further replication. The histopathologic lesions in target organs consist of inflammation and necrosis of various degrees.

The incubation period for enteroviruses usually is 3 to 7 days (range, 1 to 35 days). Shorter incubation periods are observed in children and for certain specific clinical presentations of enterovirus infections (e.g., upper respiratory illnesses and acute hemorrhagic conjunctivitis).

Excretion of enteroviruses by an infected individual starts at the end of the incubation period, and patients are most infectious shortly before and after onset of illness. Depending on the stage of the infection and the clinical syndrome, enteroviruses are found in oropharyngeal secretions, stool, cerebrospinal fluid, blood, and vesicular fluids. In immunocompetent hosts, viral shedding in oropharyngeal secretions and circulation in the blood or CSF usually lasts up to 1 week, but fecal excretion may persist for up to 2 months after infection, even after clinical symptoms resolve. Long-term persistence of enteroviruses (in some cases, for several years) may occur in individuals with impaired humoral immunity.[8,9]

immunity

Immunity to enteroviruses is long lasting and serotype specific and is primarily mediated by humoral mechanisms. Primary infection results in an IgM response and is followed by IgG and IgA production. Secondary infections induce an anamnestic response, resulting in high antibody titers. Circulating IgG and IgM antibodies have a neutralizing effect on enteroviruses during the extracellular phase of replication, and secretory IgA antibodies mediate local mucosal immunity. The importance of antibodies in providing protective immunity against enteroviruses is emphasized by the occurrence of severe chronic enterovirus infections in patients with defective humoral immunity.

clinical syndromes

The vast majority of enterovirus infections are clinically inapparent or result only in a minor febrile illness. A smaller proportion of infected individuals develop more serious diseases, and

Table 1 Diseases Associated with Enteroviruses

Disease	Associated Enteroviruses*					Clinical Features
	Polio	*Coxs (Group A)*	*Coxs (Group B)*	*Echo*	*Numbered EV*	
Febrile illness	+	+	+	+	+	Mild, transient, febrile illness with or without rash or respiratory symptoms; resolves within a few days
Neurologic illnesses						
Aseptic meningitis	+	+	+ (Coxs B5)	+ (Echo 30, 9, 11, 6, 4, 7, 13, 18)	+ (EV 71)	Acute onset of fever, severe headache with meningeal irritation; meningeal symptoms in young infants may not be obvious
						CSF findings: mild to moderate pleocytosis (< 1,000 cells/mm^3) that is predominantly lymphocytic; rarely, normal cell counts; an initial predominance of polymorphonuclear cells in CSF with a subsequent shift to lymphocytosis may be observed, particularly in young children; CSF glucose level, normal; protein level, normal or elevated; CSF bacterial cultures, negative; enteroviruses often are detected in CSF by culture or PCR; often accompanied by other symptoms of enteroviral infection (respiratory symptoms, rashes, or myalgia)
						Usually resolves with no neurologic deficits in about 1 wk; illness and convalescence in adults may last longer
Encephalitis	+	+	+ (Coxs B5)	+ (Echo 30, 11, 6, 9, 24)	+ (EV 71)	Clinical presentation of meningoencephalitis; symptoms of aseptic meningitis plus confusion, lethargy, seizures; rarely, coma, cerebellar ataxia, choreiform movements, and paresthesias; diffuse encephalitis more common than focal; CSF profile similar to that of aseptic meningitis
						Outcome usually favorable; residual neurologic deficits uncommon; severe illness and deaths mostly in neonates and with EV 71 infection
Paralytic illness	+	+ (Coxs A7)	+	+	+ (EV 70, 71)	Usually preceded or accompanied by febrile illness
						Poliomyelitis: acute, usually asymmetrical, rapidly progressive flaccid paralysis; decreased or absent deep tendon reflexes; normal sensory function; respiration and swallowing may be compromised; the extent of paralysis depends on the location of CNS damage (spinal, bulbar, or spinobulbar forms)
						Muscle weakness associated with nonpolio enteroviruses usually milder than polio and transient; other manifestations of enteroviral infection common
						Residual permanent paralysis occurs in paralytic poliomyelitis but is rare after infection with nonpolio enteroviruses
						Death: in fewer than 10% of patients with poliomyelitis, mostly in patients with bulbar involvement; fatal bulbar involvement with nonpolio enteroviruses uncommon
Skin/mucosal syndromes						
Nonspecific rashes		+	+	+ (Echo 9, 11, 16)	+	Variety of exanthems and enanthems (e.g., maculopapular, roseolous, vesicular), rarely as a sole manifestation of enteroviral illness; resolve within a few days
Herpangina		+ (Coxs A10, 16, 2, 4, 5, 8)				Acute onset; fever, headache, malaise, sore throat with 10 to 12 vesicular enanthems, usually ulcerating, on soft palate, anterior tonsillar pillars, or posterior pharynx
						Self-limiting illness; complete recovery in a few days
Hand, foot, and mouth disease		+ (Coxs A16)			+ (EV 71)	Benign illness with acute onset; fever and mild pharyngitis 1 to 2 days before rash onset; lesions initially maculopapular but evolve into whitish-gray tender, flat, often oval vesicles; lesions on oral mucosa, dorsal surface of hands and feet, sometimes buttocks; peripheral distribution of rash on the limbs
						Recovery usually complete in a few days; CNS complications with fatalities observed in outbreaks of hand, foot, and mouth disease caused by EV 71

on relatively rare occasions, conditions with substantial sequelae or death may occur.

Of host factors influencing the clinical outcome of enterovirus infection, age and the degree of immunocompetence are the most important. Agent factors, such as the serotype or intratypic strain of the virus and tissue tropism, are also important. Depending on preferential target organs, enteroviruses can affect several organ systems and tissues, including the respiratory system, central nervous system, heart, skin, muscles, and gastrointestinal tract. Associations between distinctive clinical syndromes and serotypes have been established [*see Table 1*], but there is considerable overlap.

Minor Febrile Illness

Enteroviruses are a common cause of febrile illness, particularly during the summer and fall months. Fever may be the sole symptom, or infection may be accompanied by rashes or respiratory symptoms (the "summer cold"); in infants, symptoms include irritability, lethargy, anorexia, vomiting, and diarrhea. Because of the need to rule out potentially serious bacterial infec-

Table 1 (continued)

Disease	Associated Enteroviruses*					Clinical Features
	Polio	*Coxs (Group A)*	*Coxs (Group B)*	*Echo*	*Numbered EV*	
Muscle diseases						
Myopericarditis		+ (Coxs A4, A16)	+ (All serotypes)	+ (Echo 9, 22)		Both myocardium and pericardium are affected, but signs of either myocarditis or pericarditis predominate Dyspnea, chest pain, fever, malaise; ECG abnormalities (ST segment elevation, nonspecific ST segment and T wave abnormalities, ventricular tachyarrhythmias and heart block); cardiomegaly; serum levels of myocardial enzymes frequently elevated Severity varies; permanent myocardial injury possible in approximately 30% of cases; may later lead to chronic dilated cardiomyopathy Deaths in acute period rare (< 5%), mostly in patients with severe myocardial involvement; mortality in neonates approximately 50%
Pleurodynia			+			Synonyms: epidemic myalgia, Bornholm disease Attacks of spasmodic paroxysmal pain of variable intensity in the chest or upper abdomen with fever, which subsides as the pain recedes; pain usually more intense in adults; affected muscles painful by palpation; may be swollen; chest auscultation and x-ray normal Usually resolves within 1 wk; multiple relapses possible
Systemic infections						
Neonatal systemic infection			+ (All serotypes)	+ (Echo 11)		Overwhelming sepsislike illness Initial symptoms (fever, poor feeding, irritability, lethargy, hypotonus, and vomiting) are followed by multiple organ involvement; dominant syndromes include encephalomyocarditis (severe myocarditis, often accompanied by heart failure, and meningoencephalitis) and hemorrhage-hepatitis (overwhelming hepatitis with hepatic failure and DIC) High mortality (50% to 83%); most deaths within 1 wk of onset; the risk of fatal outcome highest with onset in infants younger than 2 wk
Chronic EV infection in immunocompromised host				+		Occurs in patients with B cell defects; chronic, persistent infection of CNS (meningoencephalitis), skeletal muscles (dermatomyositis-like syndrome), and other organs Progressive course; outcome usually fatal
Acute hemorrhagic conjunctivitis		+ (Coxs A24 variant)			+ (EV 70)	Acute eye pain, photophobia, swelling of eyelids, subconjunctival hemorrhages; transient corneal involvement possible Complete recovery in less than 10 days; permanent poliolike paralysis with onset after a few weeks of the EV 70 illness has been described
Respiratory illnesses		+ (Coxs A21, A24)	+ (Coxs B2)	+ (Echo 11, 9, 4, 18)	+ (EV 71)	Acute febrile illness; both upper (coryza, pharyngitis) and lower (bronchitis, tracheobronchitis, bronchiolitis, pneumonia) respiratory manifestations occur Course usually benign with complete recovery, except in neonatal systemic illness; fatal pulmonary edema observed in Southeast Asian outbreaks of EV 71
Diarrhea		+	+	+ (Echo 11, 14, 18)		Diarrhea usually febrile, accompanying other symptoms of enterovirus infection; recovery complete

*The most commonly associated serotypes are indicated in parentheses. More common serotypes are listed first.
CNS—central nervous system Coxs—coxsackievirus CSF—cerebrospinal fluid DIC—disseminated intravascular coagulation Echo—echovirus EV—enterovirus PCR—polymerase chain reaction Polio—poliovirus

tions, a high proportion of infants with enteroviral febrile illness require evaluation for bacterial sepsis or meningitis.[10]

Aseptic Meningitis

Aseptic meningitis is the most common CNS illness associated with enteroviruses; enteroviruses account for more than 90% of cases of aseptic meningitis for which a causative organism is identified.[11] Patients experience the acute onset of fever, headache, nuchal rigidity, photophobia, nausea, and vomiting. The fever may be biphasic, subsiding for several days and then recurring; development of meningeal symptoms occurs after recurrence of fever. A variable degree of lethargy, irritability, and drowsiness may be present, but considerable changes in mental status are uncharacteristic. Meningeal signs may not be obvious in young infants. Other manifestations of enterovirus infection, such as respiratory symptoms, exanthems, enanthems, or myalgia, are often present.

Examination of the CSF reveals a mild to moderate pleocytosis, with a predominance of lymphocytes (usually < 1,000 cells/mm^3). In some patients—particularly young children—

polymorphonuclear cells may predominate initially, with the subsequent development of lymphocytosis. In rare cases, CSF cell counts are normal. CSF glucose levels are normal; protein levels may be normal or elevated.

Symptoms usually resolve in about 1 week, although CSF pleocytosis may persist for some time thereafter. Severe illness and fatal outcome are uncommon except in the immediate neonatal period. Recovery is usually complete, with no significant sequelae.

Encephalitis

Enteroviral encephalitis results from progression of enteroviral meningitis; therefore, most patients with enteroviral encephalitis have symptoms of meningoencephalitis. Meningoencephalitis usually starts as aseptic meningitis, but it is accompanied by changes in mental status or cerebral involvement, characterized by somnolence, lethargy, generalized or focal seizures, and psychiatric symptoms. Coma, cerebellar ataxia, choreiform movements, and paresthesias are rare. Diffuse symptoms are more common than focal symptoms. The outcome is favorable in the majority of cases, but severe residual neurologic damage and death have been reported. In neonates, the disease is part of a systemic illness. In such patients, the disease follows a much more severe course; the prognosis is guarded, and there is a higher risk of neurologic sequelae and death.[12] In Southeast Asia, fulminant, rapidly fatal bulbar encephalitis has occurred in young children during outbreaks of enterovirus 71 infection.[13]

Poliomyelitis and Poliolike Paralytic Illness

Muscle paralysis is primarily associated with poliovirus infection but has also been observed, sometimes in outbreaks, with several nonpolio enteroviruses, such as coxsackievirus A7, enteroviruses 70 and 71, and several echoviruses. Through successful immunization programs, control of poliomyelitis has been achieved in numerous countries worldwide, including the entire Western Hemisphere, but wild polioviruses continue to circulate in some countries of sub-Saharan Africa and Southeast Asia. It is likely that the large-scale Polio Eradication Initiative, led by the World Health Organization since 1988, will result in global polio eradication[14]; until that occurs, there remains a risk of importation of poliomyelitis into the United States.

Paralysis in poliomyelitis results from the replication of polioviruses in the anterior horn of the spinal cord or in the brain stem, causing the destruction of motor neurons. Depending on the location of the damage, spinal, bulbar, or spinobulbar forms of poliomyelitis may occur. Clinical hallmarks of paralytic poliomyelitis include the acute onset of flaccid, usually asymmetrical, rapidly progressive paralysis that is more severe proximally than distally and that is characterized by decreased or absent deep tendon reflexes without sensory loss. Respiration and swallowing may be compromised if respiratory muscles, cranial nerves, or respiratory centers are affected. Death occurs in fewer than 10% of cases; the majority of deaths involve cases of bulbar poliomyelitis. Recovery of muscle function takes place during the first few months after disease onset, but some degree of permanent paralysis usually remains.

Paralysis associated with nonpolio enterovirus infections results more from inflammatory changes than motor neuron destruction; therefore, it is usually milder and transient, rarely resulting in residual paresis. Fatal bulbar involvement is uncommon.

Myopericarditis

Carditis caused by enteroviruses (predominantly group B coxsackieviruses) occurs mostly in newborns, adolescents, and young adults and usually affects both pericardium and myocardium. Electrocardiographic abnormalities of varying degree are present; these range from ST segment elevation or nonspecific ST segment and T wave abnormalities to ventricular tachyarrhythmias and heart block. Cardiomegaly caused by pericardial effusion or acute cardiac dilatation is common. Serum levels of myocardial enzymes are frequently elevated. Death in the acute period is rare (< 5%) and mostly occurs in patients with severe myocardial involvement. Most patients recover without complications, but permanent myocardial injury occurs in about 30% of cases. Residual damage includes persistent ECG abnormalities, cardiomegaly, and chronic congestive heart failure and may later lead to dilated cardiomyopathy.[15,16]

Pleurodynia

Pleurodynia is characterized by attacks of spasmodic paroxysmal pain in the chest or upper abdomen accompanied by fever, which subsides as the pain recedes. The intensity of pain varies and is usually greater in adults. Affected muscles are painful on palpation and may be swollen. Normal auscultatory examination and chest x-ray are helpful in the differential diagnosis. The disease resolves within 1 week, but some patients experience multiple relapses.

Exanthems and Enanthems

Skin and mucosal lesions seldom appear as a sole presentation of enterovirus infection. Maculopapular rashes are most commonly associated with echoviruses; they appear simultaneously with fever, and spread from the face to the chest, neck, and extremities. Roseoliform rashes appear on the face and upper chest after defervescence. Of the vesicular rashes, the most distinctive clinical syndrome is hand, foot, and mouth disease. This disease is most often caused by coxsackievirus A16, but it can also be caused by enterovirus 71. Most cases of hand, foot, and mouth disease occur in children, who present with fever, vesicular lesions in the mouth, and macular rash on the limbs and sometimes buttocks; these lesions may later become vesicular. The disease generally resolves in a few days, but CNS complications with fatalities occurred in Southeast Asia during large outbreaks of hand, foot, and mouth disease caused by enterovirus 71.[13,17] The most common example of enterovirus enanthems is herpangina, a common illness of young children that is characterized by fever, sore throat, and vesicular enanthems on the soft palate; symptoms resolve within a few days.

Neonatal Systemic Infection

Enterovirus infections in infants usually are benign, self-limited illnesses similar to those observed in older persons. In some neonates, especially during the first 2 weeks of life, enteroviruses may cause an overwhelming sepsislike illness.[18,19] In most cases, infection is transmitted from the sick mother (either transplacentally or during delivery), but nosocomial infections, including nursery outbreaks, also occur. The initial symptoms associated with neonatal enteroviral sepsis are nonspecific and include fever, poor feeding, irritability, lethargy, hypotonia, and vomiting. There subsequently occurs involvement of multiple organs, notably the heart, CNS, liver, lungs, pancreas, and adrenal glands. The dominant features of the encephalomyocarditis syndrome, which is associated with group B coxsackieviruses, are

severe myocarditis, often accompanied by heart failure, and meningoencephalitis. The leading clinical features of the hemorrhage-hepatitis syndrome, predominantly associated with echovirus 11, are overwhelming hepatitis with hepatic failure and disseminated intravascular coagulation. Neonatal enteroviral sepsis is often fatal (reported case fatality ranges from 50% to 83%), and most deaths occur within 1 week of onset.[12,18,19]

Chronic Enterovirus Infection in Immunocompromised Hosts

Neutralizing antibodies play a critical role in the immune response to enteroviruses. Thus, enteroviruses often persist in patients with inherited or acquired defects of humoral immunity; this results in chronic infections of the CNS, skeletal muscles, and the GI system. Most commonly, the condition occurs in children with X-linked agammaglobulinemia, but it may also develop in children with severe combined immunodeficiency syndrome and, rarely, in bone marrow transplant recipients.[8,9] Chronic progressive meningoencephalitis is the predominant clinical feature. More than half of patients experience a dermatomyositis-like syndrome. Chronic hepatitis is commonly present. The course of illness is progressive; although periodic improvements may occur, the overall prognosis is poor, and the disorder is usually fatal.[9]

Acute Hemorrhagic Conjunctivitis

Acute hemorrhagic conjunctivitis occurs in explosive outbreaks, mostly in tropical areas, and is caused by coxsackievirus A24 variant and enterovirus 70. The disease is highly contagious; unlike other enteroviruses, the primary mode of transmission is direct introduction of the virus into the eye by fingers or fomites. The symptoms include eye pain, photophobia, swelling of eyelids, and characteristic subconjunctival hemorrhages of various intensity. The symptoms initially affect one eye and then spread to the other. The disease usually resolves in less than 10 days. Corneal involvement may occur but is transient and leaves no permanent scars. A permanent poliolike paralysis has been reported in persons who had recently had acute hemorrhagic conjunctivitis caused by enterovirus 70.

Other Illnesses

The respiratory syndromes in enterovirus infections involve both upper and lower respiratory tracts and range from the so-called "summer cold" to pneumonia. These infections are usually mild, except when associated with systemic illness in neonates. Fatal pulmonary edema, apparently of neurogenic origin, was reported to have occurred in association with the 1998 outbreak of enterovirus 71 infection in Taiwan.[17]

GI symptoms are often associated with other manifestations of enterovirus infections. In young children, outbreaks of febrile diarrhea associated with some echoviruses have been described, but in general, enteroviruses are not a major cause of gastroenteritis.

Enteroviruses are also known to cause hepatitis and pancreatitis, usually as part of generalized infection. An association of enterovirus infections, particularly group B coxsackievirus infection, with type 1 (insulin-dependent) diabetes mellitus has been suggested, but no conclusive evidence is available.[20,21]

DIAGNOSIS

Isolation of the virus with subsequent serotyping has traditionally been the gold standard for the laboratory diagnosis of enterovirus infections. Most enteroviruses can be grown in susceptible cell lines and identified by observing a characteristic cytopathic effect, but for almost all group A coxsackieviruses, inoculation of suckling mice is needed. The use of several cell lines and multiple specimen types from the patient increases the diagnostic yield. However, viral culture is relatively insensitive, laborious, and time consuming; these factors limit the utility of viral culture for patient care.[22]

The most widely accepted method for the identification of individual enterovirus serotypes is neutralization reaction, using intersecting pools of internationally standardized antisera. Immunofluorescence assay with monoclonal antibodies is also available for several common enteroviruses.

Compared with viral culture for enterovirus detection, reverse transcriptase polymerase chain reaction (RT-PCR) assays have been shown to be more sensitive, as specific, and much more rapid. These assays are being used increasingly in clinical practice with demonstrated clinical utility, particularly for the diagnosis of enterovirus meningitis.[18,22,23] The primers most often used in enterovirus RT-PCR have broad specificity for enteroviruses in general; this precludes serotype identification, but specific primers for individual serotypes are becoming available.[5,24] Molecular typing by sequence analysis, based on the close correlation of the serotype with the nucleotide sequence of the *VP1* gene, is a new modality for enterovirus identification that has led to identification of several previously unknown serotypes.[1,25]

Detection of the virus in normally sterile sites (e.g., CSF, blood, pericardial fluid, tissue specimens) is considered diagnostic. Because enteroviruses are ubiquitous and because asymptomatic infections commonly occur, positive results from testing of nonsterile sites (e.g., stool sample, throat swab) should be interpreted with caution.

Serology has a limited role in the diagnosis of enterovirus infections; it is helpful only if paired sera are available for testing. Demonstration of a greater than fourfold increase in titers of antibodies against the implicated serotype is indicative of recent infection. Of various serologic methods, virus neutralization reaction is preferred.

TREATMENT

Most patients with enterovirus infections recover uneventfully after a few days of supportive care, but patients with potentially serious illnesses require intensive support. No antiviral therapy for enterovirus infections is currently available.

Immunoglobulin preparations are used both for treatment and prophylaxis of enterovirus infections in patients with humoral immunodeficiencies.[9] The occurrence of chronic enterovirus meningoencephalitis has declined notably since the introduction of regular prophylactic immunoglobulin treatment. The benefit for patients with established chronic enterovirus meningoencephalitis is less clear. Most commonly, immunoglobulin preparations are administered intravenously. Results of intramuscular and intrathecal administration are mixed.[9] Intravenous immunoglobulin is sometimes used for neonatal enterovirus infections, but the data on the effectiveness of this therapy are limited.[18,26]

PREVENTION AND CONTROL

Two types of highly effective vaccines—inactivated poliovaccine (IPV) and live, attenuated oral poliovaccine (OPV)—are available for prevention and control of poliovirus infection. Since 2000, IPV has been the recommended vaccine for routine use in the United States.[27]

In the absence of vaccines, prevention and control of nonpolio enteroviral illnesses are primarily accomplished through adherence to good personal hygiene (e.g., thorough hand washing, especially after diaper changes). To prevent neonatal infections, routine infection-control measures in neonatal nurseries must be strictly enforced, and pregnant women near term should be advised to avoid contact with patients with known or suspected enterovirus infections. Control of enterovirus transmission is complicated by the fact that the majority of infections are asymptomatic and by the relatively long duration of viral shedding. For similar reasons, the effectiveness of isolation of symptomatic persons is questionable.

Viral Gastroenteritis

Viral gastroenteritis occurs in two distinct epidemiologic forms: sporadic disease that commonly affects children, and epidemic disease that afflicts both children and adults. Sporadic childhood viral gastroenteritis is primarily caused by rotaviruses (group A), human caliciviruses (including both noroviruses [previously called Norwalk-like viruses] and sapoviruses [previously called Sapporo-like viruses]), enteric adenoviruses, and astroviruses. Epidemic viral gastroenteritis is caused most often by norovirus.

ROTAVIRUS INFECTIONS

In 1973, Bishop and colleagues visualized by electron microscopy a 70-nm triple-layered virus in the duodenal epithelium of children with diarrhea.[28] This virus, designated as rotavirus because of its morphologic appearance (in Latin, *rota* means wheel), belongs to the family Reoviridae; its genome consists of 11 segments of double-stranded RNA. The segmented genome of rotavirus allows reassortment during coinfection, a property that has been utilized in the development of rotavirus vaccines and is probably important in virus evolution. There are seven major groups of rotavirus (groups A to G); human illness is caused by rotaviruses of groups A, B, and C. Two outer capsid proteins, the glycoprotein (G protein) and the protease-cleaved protein (P protein), determine the serotype specificity and form the basis of the binary classification (G and P types) of rotaviruses. Both G protein and P protein induce neutralizing antibodies.

Epidemiology

Rotaviruses are ubiquitous, infecting 95% of children worldwide by the time they are 3 to 5 years of age.[29] Neonatal infections, although common, are often asymptomatic. The incidence of clinical illness peaks in children 4 to 23 months of age. Globally, rotaviruses are the most common agents of severe childhood gastroenteritis; they are estimated to cause about one third of all gastroenteritis hospitalizations and 500,000 deaths a year.[30] Rotavirus infections in adults are usually subclinical but occasionally cause illness in parents of children with rotavirus diarrhea and in immunocompromised individuals, the elderly, and travelers.

In temperate climates, rotavirus disease predominantly occurs during the fall and winter months. A study from Japan showed that, unlike in children, rotavirus diarrhea in adults did not show significant winter seasonality.[30] In the United States, rotavirus activity peaks in the Southwest in autumn (October through December) and migrates across the continent, peaking in the Northeast during spring (March through May).[31] In tropical settings, rotavirus disease occurs year-round.

During episodes of diarrhea, rotaviruses are shed in large amounts in stool; fecal shedding detectable by antigen enzyme immunoassays usually subsides within a week but may persist for more than 30 days in immunocompromised persons. Viral shedding may be detected for longer periods using more sensitive assays, such as PCR. Transmission of rotavirus occurs predominantly through the fecal-oral route. Transmission through respiratory secretions, person-to-person contact, or contaminated environmental surfaces has been postulated.

In humans, most rotavirus diseases, including endemic childhood diarrhea, are caused by group A rotaviruses. Group B rotaviruses have caused large epidemics of severe gastroenteritis in China since 1982 and have also been identified in India.[32,33] Group C rotaviruses have been associated with epidemic gastroenteritis worldwide, and some studies indicate a possible association with extrahepatic biliary atresia in infants.[34]

Rotavirus strains that infect animals differ from those that infect humans. Although some strains of human rotavirus possess a high degree of genetic homology with animal strains, animal-to-human transmission is uncommon.

Pathogenesis

Rotaviruses infect the mature enterocytes in the middle or upper villous epithelium of the small intestine. Ultimately, the epithelium becomes necrotic and sloughs off. The loss of absorptive villous epithelium coupled with proliferation of secretory crypt cells reverses the inherent absorptive state of the epithelium, resulting in secretory diarrhea. Levels of brush-border enzymes characteristic of differentiated cells (e.g., sucrase and lactase) are reduced, leading to the accumulation of unmetabolized disaccharides in the gut lumen, with consequent osmotic diarrhea. The toxinlike effect of a nonstructural rotavirus protein, NSP4, increases intracellular calcium through the opening of a cation channel, causing an efflux of chloride and, thus, sodium and water, contributing to the secretory diarrhea.[35] Furthermore, rotavirus appears to evoke the secretion of intestinal fluids through activation of the enteric nervous system.[36]

Recent data indicate that a transient antigenemia that peaks 1 to 3 days after onset of symptoms is common in children with rotavirus infection. It remains to be proved whether the presence of antigenemia is correlated with increased severity of disease or with extraintestinal manifestations that are sometimes seen in children with rotavirus infection.[37,38]

Immunity

Protection against rotavirus disease is correlated with the presence of virus-specific secretory IgA antibodies in the feces and serum.[39,40] Because virus-specific IgA is short-lived at the intestinal surface, complete protection against natural rotavirus disease is only temporary. Memory B and T cells in the lamina propria are believed to be important in reducing the severity of disease resulting from reinfection.[41]

Diagnosis

Clinical manifestations The clinical spectrum of rotavirus infection ranges from subclinical illness to severe gastroenteritis associated with life-threatening dehydration. The onset of illness is abrupt; vomiting frequently precedes the development of diarrhea. Up to one third of patients may have a temperature greater than 39° C (102.2° F). GI symptoms generally resolve in 3 to 6 days.

Respiratory symptoms have been observed in children with rotavirus infection, as have symptoms of CNS involvement, but

these associations have not been well studied.[42] Rotavirus infection has been observed in patients with a variety of other clinical syndromes, including sudden infant death syndrome, Reye syndrome, necrotizing enterocolitis, intussusception, Kawasaki syndrome, disseminated intravascular coagulation, and Crohn disease. A causal relationship has not been confirmed between any of these syndromes and rotavirus infection.

In immunodeficient children, rotavirus can cause a protracted diarrhea with prolonged viral excretion and, in rare instances, can disseminate systemically and cause hepatic infection.[43]

Laboratory tests Illness caused by rotavirus is difficult to distinguish clinically from that caused by other enteric viruses. Because a large number of viruses are shed in feces, the diagnosis usually can be confirmed by using one of a wide variety of commercial immunoassays or by techniques for detecting viral RNA, such as gel electrophoresis, probe hybridization, or RT-PCR.

Treatment and Prevention

Treatment relies primarily on replacement of fluids and electrolytes; antibiotics and antimotility agents should be avoided.[44] Although oral rehydration therapy is successful in most children, intravenous fluid replacement may be required for children who have severe dehydration or are unable to tolerate oral therapy. A variety of other therapeutic agents have been evaluated, including probiotics,[45] bismuth salicylate,[46] and enkephalinase inhibitors,[47] but their therapeutic roles are not clearly defined.

In 1998, only 25 years after the identification of rotavirus in humans, a live, attenuated rhesus-human reassortant rotavirus vaccine (Rotashield, Wyeth Laboratories, Marietta, Pennsylvania) with 80% efficacy against severe rotavirus disease was licensed in the United States and was recommended for routine immunization of infants. This vaccine was withdrawn, however, in 1999, after it was confirmed that its use was associated with intussusception.[48] Efforts are ongoing to develop other rotavirus vaccines. Two large clinical trials that each involved more than 60,000 infants have recently been completed. The trials examined two leading vaccine candidates—one developed by Merck (a multivalent bovine-human reassortant rotavirus vaccine)[49] and the other by GlaxoSmithKline (an attenuated single human strain rotavirus vaccine).[50] These trials demonstrated the safety of both vaccines with respect to intussusception and other potential adverse events,[51,52] and they indicated that the vaccines have an efficacy of more than 90% against severe rotavirus disease.[49,50] Data on the Merck vaccine, which is administered orally to infants in three doses at 2, 4, and 6 months of age, were submitted for licensure to the Food and Drug Administration in April 2005; a decision is expected in 2006.

HUMAN CALICIVIRUS INFECTIONS

In 1972, using immune electron microscopy, Kapikian and colleagues identified the 27-nm Norwalk agent in stool filtrates of a volunteer challenged with fecal specimens from patients affected by an outbreak of gastroenteritis.[53] Several related but genetically and antigenically diverse single-stranded RNA viruses of positive polarity measuring 27 to 35 nm were subsequently identified; these organisms are currently classified as noroviruses (previously called Norwalk-like viruses), in the family Caliciviridae. The Caliciviridae family also includes the sapoviruses (previously called Sapporo-like viruses), which cause gastroenteritis in children and adults, and Lagovirus and Vesivirus, neither of which is pathogenic for humans.

Epidemiology

Studies indicate that infections with the Norwalk and related caliciviruses are more common than previously believed; a majority of children and nearly all adults demonstrate antibodies to these viruses. Acquisition of antibody occurs at an earlier age in developing countries, as would be expected, given the presumed fecal-oral mode of transmission of these viruses. Although their role in sporadic illness in children and adults is still being defined, noroviruses are clearly recognized as the most common cause of epidemics of gastroenteritis worldwide.[54] Epidemics occur throughout the year and are often linked to consumption of fecally contaminated water and foods; often, food and water become contaminated by an infectious food handler. Dispersion of virus through direct contact, vomitus, or airborne droplets has been postulated in situations in which an alternative mode of transmission cannot be established.

Pathogenesis

Because no animal model exists for calicivirus gastroenteritis, the data on pathogenesis of disease arise exclusively from studies of human volunteers. After challenge of volunteers with either Norwalk virus or Hawaii virus, which is a related calicivirus, biopsy demonstrates lesions in the proximal small intestine; these lesions are characterized by villus shortening, crypt hyperplasia, and infiltration of the lamina propria by polymorphonuclear cells and lymphocytes.[55] The lesions persist for at least 4 days after the person's symptoms disappear and are associated with malabsorption of carbohydrates and fats and a decreased level of brush-border enzymes. No changes are observed in the stomach or colon, but gastric motor function is delayed, which probably contributes to the characteristic nausea and vomiting.[56]

Immunity

Approximately 50% of persons challenged with Norwalk virus become ill and acquire short-term homologous immunity (i.e., immunity against the same strain) that is correlated with serum antibody levels; immunity does not appear to persist for longer than 2 years.[57] Some reports indicate, paradoxically, that persons with higher levels of preexisting antibody to Norwalk virus are more susceptible to illness.[58]

Diagnosis

Clinical manifestations Gastroenteritis caused by Norwalk virus and related enteric caliciviruses occurs with sudden onset after a viral incubation period of 12 to 48 hours. The illness generally lasts 12 to 60 hours and is characterized by nausea, vomiting, abdominal cramps, and diarrhea. In children, vomiting is more prevalent than diarrhea, whereas in adults, diarrhea is more prevalent. Constitutional symptoms, such as headache, fever, chills, and myalgias, are frequently reported. Death is rare and usually occurs from severe dehydration in vulnerable persons, such as the elderly with debilitating health conditions.

Laboratory tests Cloning and sequencing of the genome of Norwalk virus and a few other human caliciviruses has allowed the development of sensitive detection methods based on PCR amplification and Southern blot analysis; strains can be further characterized by sequencing of nucleotide products. Expression

of capsid proteins in a recombinant baculovirus vector produces viruslike particles that have been used to develop immunoassays. Diagnostic assays, however, are not widely available.

Treatment and Prevention

Treatment is generally not required, because the disease is self-limited.[44] Rehydration may be required for patients with volume depletion.

Epidemic prevention relies on situation-specific measures, such as control of contamination of food and water, prevention of the handling of food by persons who are ill, and reduction of person-to-person spread through good personal hygiene. Calicivirus vaccines are being developed and may be particularly useful for groups for whom the impact of short-term morbidity from gastroenteritis is great (e.g., military troops) or those who are at high risk for severe disease (e.g., the elderly in nursing homes).

GASTROENTERITIS CAUSED BY OTHER VIRAL AGENTS

Enteric adenoviruses have double-stranded DNA and measure 70 to 80 nm; they belong to the family Adenoviridae. Serotypes 31, 40, and 41 cause approximately 10% of diarrheal illness in young children. Unlike their counterparts that cause respiratory illness, enteric adenoviruses are difficult to cultivate in cell lines. Their detection requires the use of immunoassays to the adenovirus hexon antigen and subsequent serotyping using monoclonal antibodies.

Astroviruses have positive-sense, single-stranded RNA and measure 28 to 30 nm; they belong to the family Astroviridae. Although at least seven different serotypes have been identified, strains of serotype 1 are most common. Preliminary epidemiologic studies indicate that astroviruses may be important causes of mild to moderate diarrhea in children, causing half as many illnesses as rotavirus.[59] The availability of simple immunoassays to detect virus in fecal specimens and of molecular methods to confirm and further characterize strains will allow for a more comprehensive assessment of the etiologic role of these agents in endemic childhood diarrhea.

Other viruses, including toroviruses, picobirnaviruses, coronaviruses, pestiviruses, and parvoviruses, have been identified in the feces of patients with diarrhea, but their etiologic role has not been well studied. It appears from preliminary studies that some of these agents, such as picobirnaviruses, may be important causes of diarrhea in HIV-infected persons.[60,61]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XXIX MEASLES, MUMPS, RUBELLA, PARVOVIRUS, AND POXVIRUS

MARTIN S. HIRSCH, M.D.

Measles

Measles (rubeola) is a highly infectious disease caused by a paramyxovirus of worldwide distribution. The measles virus was once one of the most common and important global pathogens, but infections caused by this agent are now becoming rare in developed countries, where vaccine use is widespread. In areas where vaccines are not widely used, measles remains a major health problem. It is estimated that worldwide, over 800,000 deaths occur each year from measles.[1]

EPIDEMIOLOGY

Humans are the principal reservoirs of measles virus, which is spread by respiratory droplet aerosols produced by sneezing and coughing. The disease may be contagious from several days before the onset of rash to up to 5 days after lesions appear. The attack rate for exposed susceptible contacts may exceed 90%; asymptomatic infections are rare.

Vaccines have dramatically reduced the incidence of indigenous measles in the United States and have eliminated the disease altogether in some developed countries. However, large outbreaks still occur in unvaccinated or suboptimally vaccinated populations, and an outbreak has even been reported in a highly vaccinated population.[2-4] In the United States, women born after the licensure of measles vaccine transfer less measles antibody to their infants than do older women, which may leave infants of vaccinated mothers with heightened susceptibility to measles.[5]

In undernourished children in developing countries, measles can cause a devastating illness, and case-fatality rates may reach or exceed 25%.[6] Before widespread vaccine use, epidemics occurred every 2 to 3 years in developed countries, and the illness developed in 95% of urban dwellers before they reached 15 years of age. Outbreaks occurred primarily in late winter and early spring. In 1989, the World Health Assembly instituted major efforts to reduce measles morbidity and mortality through implementation of control strategies. By 1996, estimated incidence and death rates were reduced by 78% and 88%, respectively.[1,7,8] In the Americas, between 1990 and 1996, the number of new measles cases decreased from 246,607 to 2,109 (a decrease of 99%), and vaccine coverage increased from 77% to 85%. In 2000, only 100 confirmed measles cases were reported in the United States, the lowest number on record.[1] Molecular epidemiologic studies suggest that most cases in the United States now result from importation of virus.[1,9,10]

PATHOGENESIS

The portals of entry for measles virus include cells of the respiratory tract and possibly the conjunctivae. After undergoing local replication and spreading to regional lymph nodes, measles virus is disseminated to distant sites, particularly skin and mucous membranes, by a leukocyte-associated viremia. Lesions on mucous membranes (Koplik spots) appear as bluish-white specks on an erythematous base. Histologically, Koplik spots are composed of epithelioid giant cells with cytoplasmic and nuclear inclusions that contain microtubular aggregates; inflammatory cells and intercellular edema are present. Lesions of the skin also demonstrate inclusions and microtubular aggregates, suggesting that active viral replication occurs in skin as well as in mucous membranes. Infectious virus can be isolated from leukocytes, urine, conjunctivae, and respiratory secretions. Antibody appears in the serum as viremia ceases. Leukopenia may accompany the illness, together with lymphocyte hyporesponsiveness.

DIAGNOSIS

Clinical Features

Approximately 9 to 11 days after a person is initially exposed to the virus, malaise, fever, conjunctivitis, photophobia, periorbital edema, coryza, and cough develop. Cough may be severe, although generally nonproductive, and temperature may reach 40.6° C (105.1° F). Within 2 to 3 days, Koplik spots may appear on the buccal mucosa and occasionally on the conjunctivae. The skin rash, which erupts 2 to 3 days later, usually appears at the hairline and spreads downward during the next 3 days as systemic symptoms subside [*see Figure 1*]. Lesion density is greatest above the shoulders, where macular lesions may coalesce. The rash lasts 4 to 6 days and then fades from the head downward. Desquamation may be present but is usually not severe. Complete recovery without scarring generally occurs within 7 to 10 days from the onset of the rash.

A severe atypical presentation of measles may appear in persons who were immunized between 1963 and 1967 with killed measles virus vaccine and who were later exposed to the wild virus. After a prodrome of fever, headache, abdominal pain, and myalgias, a rash develops on the hands and feet and advances toward the head. The eruption may be vesicular, urticarial, maculopapular, or hemorrhagic and is most prominent along body creases. Pneumonia, pleural effusion, and hilar lymphadenopathy are common in atypical measles. All persons vaccinated after 1967 received the live attenuated measles vaccine, which is rarely, if ever, associated with the atypical measles syndrome.

Laboratory Tests

In an epidemic setting, observation of the characteristic rash, fever, coryza, and conjunctivitis is sufficient to establish the diagnosis. However, as measles declines in prevalence, clinical acumen in diagnosis also diminishes. Multinucleated giant cells can often be detected in stained smears of nasal secretions, and measles antigen can be demonstrated in such cells by immunofluorescence. The virus can be isolated from nasal secretions or urine by cultivation of such materials on primate cell monolayers. A rise in hemagglutination inhibition antibodies during a period of 2 to 3 weeks confirms the diagnosis. Confirmation by measles-specific IgM enzyme immunoassay is also available.

DIFFERENTIAL DIAGNOSIS

Sporadic cases of measles must be differentiated from other viral exanthems, secondary syphilis, scarlet fever, and drug reactions. Atypical measles may resemble Rocky Mountain spotted fever, meningococcemia, or varicella.

COMPLICATIONS

Measles is usually benign and uncomplicated. Complications occur more commonly in adults, malnourished children, and immunocompromised patients. Measles is associated with severe pulmonary and neurologic complications in up to 80% of immunocompromised children and adults with cancer or HIV infection, with case-fatality rates of 40% to 70%; rash is absent in 30%.[11,12] Measles virus may further suppress host immune responses, leading to reactivation of latent tuberculosis or superimposition of new bacterial pneumonia, particularly in malnourished children.

Measles virus infection often involves the central nervous system, but clinically apparent encephalomyelitis is rare (one in every 1,000 to 2,000 measles patients). CNS involvement may precede the rash but usually begins 4 to 7 days after the eruption appears. The onset of encephalomyelitis is often precipitous and is characterized by a rise in fever, sudden mental deterioration, and seizures; motor defects and cerebellar ataxia are common. An autoimmune demyelinating process may be involved in the pathogenesis of measles encephalomyelitis, which is fatal in about 10% of patients.

Subacute measles encephalitis may complicate measles in immunocompromised hosts 1 to 7 months after exposure; the patient has seizures and altered mental status, but results of cerebrospinal fluid analysis are normal.[13] Diagnosis may require brain biopsy for histology, immunocytochemical analysis, or polymerase chain reaction (PCR) detection of viral RNA.[12] In rare instances, a subacute sclerosing panencephalitis occurs as a complication of measles in children infected before 2 years of age, but the panencephalitis develops after a latent period of several years. Other measles complications include thrombocytopenia with associated purpura or bleeding, myocarditis, pericarditis, hepatitis, and severe keratitis progressing to blindness.

TREATMENT AND PREVENTION

Therapy for measles is mainly supportive. A meta-analysis has suggested that in areas where vitamin A deficiency may be present, an oral dose of 200,000 IU of vitamin A for 2 days can reduce morbidity and mortality in children.[14] Ribavirin, either intravenous or aerosolized, has been proposed for certain complications of measles (i.e., encephalitis or pneumonitis),[11,12] but controlled trials are lacking.

Postexposure prophylaxis can be provided for high-risk patients (e.g., pregnant women and immunosuppressed children) by administering immunoglobulin intramuscularly at a dosage of 0.25 to 0.50 ml/kg body weight within 6 days after exposure.[15]

In vaccination guidelines in the United States, two immunizations are suggested for children before school enrollment to reduce the chance of primary vaccine failure. Vaccination is recommended for nonpregnant women of childbearing years and may be considered for institutionalized adults or individuals working in day care centers [*see CE:V Adult Preventive Health Care*]. Severely immunocompromised individuals should avoid measles vaccination because of the risk of vaccine-associated diseases, such as inclusion body encephalitis or pneumonitis.[16,17]

The effort to eradicate measles from the United States relies on identification and immunization of susceptible children, adolescents, and adults; on strict enforcement of more comprehensive school immunization requirements; and on strengthening of surveillance and outbreak-control measures.

Figure 1 **A case of measles in a young man is characterized by maculopapular rash and conjunctivitis.**

Mumps

Mumps virus is a pleomorphic, enveloped, single-stranded RNA paramyxovirus capable of causing parotitis, epididymoorchitis, and CNS disease. Because of widespread vaccination efforts, its role as a major cause of childhood morbidity has greatly diminished.

EPIDEMIOLOGY

Mumps virus has worldwide distribution, and infection is seen more commonly in winter and spring. Humans are the only natural host. Infection is uncommon in persons younger than 1 year, and congenital infection is rare but can lead to fetal loss in the first trimester. Approximately 11% of cases of mumps are observed in children between 1 and 4 years of age, 52% in children between 5 and 14 years of age, and 11% in children older than 15 years.

A live mumps virus vaccine was approved for use in the United States in 1967; its use was facilitated by subsequent incorporation with measles and rubella (MMR) vaccine. Since its widespread use, mumps cases have fallen by over 99.5%, from 185,691 cases in 1968 to 906 cases in 1995.[15] Healthy People 2010, a comprehensive set of health objectives created under the auspices of the United States Department of Health and Human Services, has targeted mumps for elimination in the United States by 2010.[18]

PATHOGENESIS

Mumps virus spreads from person to person by direct contact with nasopharyngeal secretions. Virus is shed in saliva from as long as 6 days before to 5 days after clinical onset. Incubation ranges from 2 to 4 weeks (mean, 18 days). Initial replication occurs in the pharynx, followed by viremic dissemination. Both humoral and cell-mediated immune responses are induced and correlate with cessation of viremia and salivary virus excretion.

DIAGNOSIS

Clinical Features

Two thirds of cases are symptomatic, with initial symptoms of malaise and fever predominating. Painful swelling of the parotid gland is the characteristic feature of infection. It may be unilateral, and other salivary glands may be involved. However, parotitis occurs in only 30% to 40% of all cases of mumps virus infection.

An unvaccinated child who presents with tender parotitis generally has mumps; further diagnostic testing is not required. In older age groups, other entities (sarcoidosis, tumors, alcohol abuse, drug side effects, and other viral or bacterial infections) should be considered. In persons without parotitis who have orchitis, aseptic meningitis, encephalitis, or other obscure syndromes (e.g., myocarditis or pancreatitis), mumps should be considered [*see* Complications, *below*].

Laboratory Tests

Definitive diagnosis of mumps can be made by virus isolation from the oropharynx, CSF, or urine or by virus serology. Rapid detection by PCR techniques is now possible in some laboratories.[19]

COMPLICATIONS

Epididymo-orchitis occurs in up to 38% of postpubertal males with mumps and is usually unilateral. Subsequent sterility is uncommon, although testicular atrophy may occur.

CSF pleocytosis occurs in at least 50% of patients with mumps,[20] although symptomatic meningitis is less common. A lymphocytic pleocytosis is seen, with an elevated protein level and a normal to low (10%) glucose level. Symptomatic encephalitis occurs in one of 6,000 cases and presents as decreased consciousness and focal neurologic deficits. Most patients with encephalitis recover completely, although 0.5% to 2.3% of patients with mumps encephalitis may die. Other neurologic complications may include hydrocephalus; deafness; and rare cases of demyelinating disorders, transverse myelitis, Guillain-Barré syndrome, and cerebellar ataxia.[21] Deafness may be sudden, unilateral, and permanent.[15]

Pancreatitis, mastitis, and oophoritis have been observed in patients with mumps. Myocarditis occurs and in rare cases can be fatal.[22] Endocardial fibroelastosis, an infrequent sequela of myocarditis, has been associated with mumps infection.[23] Mumps can cause polyarticular or monoarticular arthritis; it generally affects adult males and is self-limited (usually less than 8 weeks).[24]

TREATMENT AND PREVENTION

Treatment of patients with mumps is largely supportive, although anti-inflammatory agents may be useful in cases of severe orchitis or arthritis. Administration of immune globulin does not prevent mumps and is not recommended. Prevention can be achieved in well over 90% of persons by the use of live attenuated mumps vaccine, administered twice as part of the recommended MMR vaccine regimen[15] [*see CE:V Adult Preventive Health Care*].

Rubella

Rubella, or German measles, is usually a benign febrile exanthem, but when it occurs in pregnant women, it can produce major congenital malformations. The infective agent is a single-stranded RNA virus of the Togaviridae family.

EPIDEMIOLOGY

Humans are the only known natural hosts for the rubella virus, which appears to be spread by respiratory droplets. The virus is moderately contagious but less so than measles. Before the introduction of a rubella vaccine, in 1969, epidemics occurred in the United States at 6- to 9-year intervals, predominantly in children younger than 15 years. Since the widespread use of rubella vaccine, the incidence of rubella has decreased by 99%.[25] Outbreaks continue to occur, primarily in young adults in hospitals, colleges, prisons, and prenatal clinics, but no major epidemics have occurred in the United States since 1964. Susceptibility rates in young adults vary, with the greatest proportion of cases now seen among persons of Hispanic origin.[25,26] Rubella outbreaks have recently been identified in processing plants for meat and poultry where many foreign-born workers are employed.[26] Less than 10 confirmed cases of congenital rubella syndrome are reported in the United States annually, almost all of them in infants of foreign-born mothers.[26]

PATHOGENESIS

Initially, the rubella virus replicates in the nasopharynx and regional lymph nodes. After the virus invades the bloodstream, it may spread to the skin and distal organs or, transplacentally, to the developing fetus. The virus may be present in throat washings or blood for several days before the appearance of the rash and up to 2 weeks after its onset. In rare cases of rubella arthropathy, the virus may persist in peripheral leukocytes or in synovial cells for months to years.

A pregnant woman infected with rubella is at risk for transmitting the virus to her fetus. Damage to the fetus is most likely to occur if the mother is infected within the first 2 months of gestation (fetal abnormalities are observed in 40% to 85% of such cases).[27,28] Infection within the third month is associated with fetal defects in 20% to 40% of cases, whereas infection during the fourth month is associated with fetal defects in 10% of cases. Mechanisms of fetal damage are not clear but may include viral cytolysis, chromosomal breaks, reduced cell multiplication, and alteration of fetal blood supply. As a result, fetal growth may be retarded, and defects may develop in multiple organ systems. Despite the production of fetal antibodies, the rubella virus can persist in the fetus and newborn and can be excreted for months to years after birth.

DIAGNOSIS

Clinical Features

After an incubation period of 12 to 23 days, a mild prodrome of malaise, headache, fever, and mild conjunctivitis may develop. Postauricular, suboccipital, and posterior cervical lymphadenopathy often precede the rash, which begins on the face and forehead. Within 1 to 5 days, the discrete maculopapular lesions spread over the trunk and extremities and may coalesce. The rash usually disappears within 3 days.

Laboratory Tests

The presence of rubella can be confirmed by virus isolation, by PCR detection, or by demonstration of seroconversion in response to rubella antigens. Virus isolation is often difficult because rubella virus does not cause cytopathic effects on the cell lines that are generally employed in diagnostic laboratories. Antibodies are often present shortly after rash appears and increase in titer during the next 2 to 3 weeks. Measurements of specific IgM antibodies to rubella virus are particularly useful in newborns: raised IgM levels denote recent infection and are specific

for fetal infection because IgM antibodies do not cross the placenta. Elevated IgM antibodies may return to nondiagnostic levels by 3 to 6 months, and persistence of IgG antibodies beyond this period may also help diagnose neonatal infection.[25]

DIFFERENTIAL DIAGNOSIS

Rubella may be confused with other viral exanthems (e.g., those caused by enteroviruses, parvoviruses, or adenoviruses), scarlet fever, or drug eruptions.

COMPLICATIONS

The most common complications of rubella are arthropathies of the fingers, wrists, and knees; they occur predominantly in young women. Such arthropathies consist of arthralgia or frank arthritis, and recurring joint symptoms may persist for a year or more. Encephalitis and thrombocytopenia are rare complications of acute rubella. Encephalitis occurs in one in 6,000 cases,[15] and thrombocytopenia, which is sometimes associated with purpura or hemorrhage, occurs most often in children.

Congenital rubella syndrome, also a rare complication of acute rubella, may manifest itself as defects in one or many organ systems. Hearing impairment is the most common single defect (60%).[25] Heart malformations, particularly patent ductus arteriosus and peripheral pulmonic stenosis, are also common (45%), as are cataracts (25%), microcephaly (27%), and mental retardation (13%). Malformation of bone metaphyses may also be present, together with hepatosplenomegaly, thrombocytopenia, interstitial pneumonitis, myocarditis, and thrombocytopenic purpura. Congenitally infected infants are often of low birth weight (23%), and they excrete rubella virus for prolonged periods. Late complications may result from imbalances of cellular and humoral immunity, from immune complex deposition, or from prolonged viral replication. Diabetes mellitus and other endocrine abnormalities may be late complications of congenital rubella, as is subacute sclerosing panencephalitis.[29]

TREATMENT AND PREVENTION

Beyond the fetal period, rubella is mild and self-limited. Current treatment of congenital rubella syndrome is only supportive. The Centers for Disease Control and Prevention (CDC) has developed detailed recommendations for dealing with rubella outbreaks focused on patient isolation, identification and vaccination of susceptible persons who have no contraindications to rubella vaccine, and counseling of susceptible pregnant women.[26] These recommendations are available on the Internet at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5012a1.htm.

Pregnant women infected with rubella virus who are asymptomatic may still transmit rubella to their fetuses. Thus, testing of immune status is advisable for women of childbearing age and for hospital employees who have no history of rubella vaccination. About 10% to 15% of such persons are seronegative and should be vaccinated when not pregnant. Women should avoid becoming pregnant for 28 days after vaccination against rubella.[30]

Measles, Mumps, and Rubella Vaccine

Because they fear possible complications from MMR vaccination, some parents question the safety of the vaccine, and in some cases, they are refusing its use in their children. These parents may cite research suggesting that MMR vaccination may be a risk factor for inflammatory bowel disease[31] and autism.[32] Subsequent research, however, has not supported this hypothesis.[33,34] In addition, although receipt of the MMR vaccine has been associated with an increased risk of febrile seizures 8 to 14 days after vaccination, those children were not found to be at higher risk for subsequent seizures or neurodevelopmental disabilities.[35]

Parvovirus

Although only recently recognized as a human pathogen, parvovirus B19 is now appreciated as a cause of several syndromes in both children and adults. Parvovirus B19, a small (20 to 26 nm), single-stranded DNA virus, causes erythema infectiosum (fifth disease) in normal persons, aplastic crises in persons with underlying hemolytic disorders, chronic anemia in immunocompromised hosts, and fetal loss in pregnant women.[36-40]

EPIDEMIOLOGY

Parvovirus B19 infection occurs most commonly in school-age children in outbreaks during late winter and spring. Only 2% to 15% of pre–school-age children have antibodies, but seroprevalence increases to 35% to 60% by 11 to 19 years of age and to greater than 75% in persons older than 50 years.[41] Respiratory transmission is likely and is facilitated by close contact. Hospital outbreaks have also been described and are often traced to patients with aplastic crises who carry large amounts of virus in blood and respiratory secretions.[42,43] Maternal infection can lead to fetal anemia, hydrops fetalis, heart failure, and death, resulting in spontaneous abortion, most commonly 4 to 6 weeks after infection. When women are infected during the first 20 weeks of pregnancy, the risk of parvovirus-related fetal death is approximately 9% to 10%.[44,45] Routine antenatal screening is not recommended.[38,46]

PATHOGENESIS

Replication of parvovirus B19 has been demonstrated in human erythroid progenitor cells, and the receptor appears to be the P blood group antigen globoside, a neutral glycosphingolipid, which occurs in erythrocytes, erythroblasts, megakaryocytes, endothelial cells, placenta, and fetal liver and heart cells.[47] Expression of this glycosphingolipid in tissues helps to determine parvovirus B19 tropism.[48] Persons who lack erythrocyte P antigen (p phenotype) are naturally resistant to infection,[37,49] and the distribution of parvovirus in infected individuals is linked to the presence of the P antigen. Although little is known about the pathogenesis of parvovirus, antiviral antibodies—particularly those directed against the capsid protein VP1—appear to be responsible for viral clearance. The presence of certain HLA class I and class II alleles may be associated with more symptomatic parvovirus infections.[50]

DIAGNOSIS

Clinical Features

The rash caused by parvovirus B19, erythema infectiosum, usually appears without prodromal symptoms after an incubation period of 4 to 14 days. The exanthem progresses through three stages. Initially, a fiery-red rash develops on both cheeks (giving them the appearance of having been slapped), accompanied by relative pallor around the mouth. From 1 to 4 days later, an erythematous maculopapular eruption appears on the proximal extremities and spreads to the trunk in a lacelike, reticular pattern. The third stage, during which the eruption waxes and wanes, may persist for several weeks and may be precipitated by skin trauma, exposure to sunlight, or extremes of tempera-

ture. Arthralgia and arthritis are seen in up to 80% of infected adults; arthralgia is particularly common in women, may occur without rash, and may linger for weeks. Joint involvement is often symmetrical in the hands, wrists, knees, and ankles. Hemolytic anemias and encephalopathies are rare complications.

Laboratory Tests

Parvovirus-specific IgM antibodies usually appear within 3 days after symptoms develop; these antibodies persist for several weeks and then rapidly decline. IgG antibodies, however, persist for years. Viral DNA can also be detected in blood, tissues, and secretions, although culture techniques for virus isolation are unsatisfactory.

COMPLICATIONS

Transient aplastic crises associated with parvovirus B19 occur in patients who have sickle cell anemia, hereditary spherocytosis, thalassemia, and various other hemolytic anemias.[51] These aplastic crises are abrupt in onset and associated with giant pronormoblasts in the bone marrow. They generally last 1 to 2 weeks and go into remission spontaneously. In immunocompromised hosts (e.g., patients with HIV infection), acute infection may lead to viral persistence and chronic bone marrow suppression.[40] A significant proportion of patients with AIDS who develop severe anemia while receiving zidovudine (AZT) have persistent parvovirus infection.[51] Pneumonia, hepatitis, and myocarditis have also been associated with parvovirus infections in immunocompromised as well as immunocompetent adults and children.[52-57] Although parvovirus B19 has been implicated in a variety of rheumatic diseases, there is no definitive evidence for a causal role.

TREATMENT

Pooled human immune globulin contains anti–parvovirus B19 antibodies and has been used to treat persistent infections as well as acute exposures.[40] Prevention of nosocomial infections is of great concern: pregnant health care workers should not care for patients with aplastic crises. Droplet isolation is recommended for such patients, including the use of gowns, gloves, and masks during close contact. Because certain blood products (e.g., clotting factors) contain parvovirus B19 DNA, screening of products, donors, and recipients has been suggested.[58]

Poxvirus Infections

Poxviruses are the largest (200 to 320 nm) and most complex human viruses. They replicate in cell cytoplasm and may produce eosinophilic cytoplasmic inclusion bodies. They preferentially infect skin epithelial cells and may cause a variety of human diseases. Smallpox (variola), once among the most devastating and feared worldwide pestilences, has been virtually eliminated. Other human poxvirus diseases include vaccinia, molluscum contagiosum, orf (contagious pustular dermatitis), and paravaccinia (milker's nodules).

SMALLPOX

No naturally acquired cases of smallpox (variola) have been observed since 1977, as a result of a global eradication effort that was initiated by the World Health Organization in the 1960s.[59] Several biologic features of the smallpox virus favored its eradication: only one serotype existed, a stable and effective vaccine had been developed, and there were no nonhuman reservoirs and no human carriers of the smallpox virus. For a time, smallpox was considered a disease of purely historical interest. However, laboratory stocks of the virus were never totally destroyed, and the possibility of dissemination of the stores held in the former Soviet Union has raised concerns that smallpox virus might be used as an agent of biological warfare [*see 8:V Bioterrorism*].[60]

Table 1 Contraindications to Nonemergency Smallpox Vaccination

Conditions in the Patient or a Household Member
Eczema or atopic dermatitis (even if it is currently inactive or mild or was experienced in childhood)
Skin conditions such as burns, chickenpox, shingles, impetigo, herpes, severe acne, or psoriasis
Weakened immune system (e.g., from corticosteroid treatment, cancer chemotherapy, posttransplantation immunosuppression, HIV infection, or severe autoimmune disorders)
Pregnancy or intent to become pregnant within 1 mo after vaccination
Conditions in the Patient
Allergy to the vaccine or any of its ingredients
Age less than 12 mo*
Moderate or severe short-term illness
Current breast-feeding
Use of steroid eyedrops

Note: Persons who have been directly exposed to the smallpox virus should be vaccinated, regardless of their health status. More information on smallpox vaccination is available at www.cdc.gov/smallpox.
*The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention advises against nonemergency use of smallpox vaccine in children younger than 18 yr, and the vaccine manufacturer does not recommend nonemergency use of the vaccine in geriatric patients.

Pathogenesis

Variola is spread by the respiratory route. Mucosal seeding is followed by spread to lymph nodes, a brief viremia, and spread to the reticuloendothelial system over the next 4 to 14 days. Thereafter a second viremia leads to infection of skin and mucous membranes. Neutralizing antibodies appear during the first week of infection and persist for years.[61] Cytotoxic T lymphocyte reactivity also occurs early and persists.[62]

Diagnosis

Clinical features A prodrome characterized by fever, headache, and backache lasts for 2 to 3 days, after which an oropharyngeal enanthem appears. Smallpox can take several clinical forms [*see 8:V Bioterrorism*]. In its most common form (ordinary smallpox), the disease causes a rash that goes through several stages: papules to vesicles to pustules to crusts over 1 to 2 weeks. Lesions begin on the face and extremities but spread all over the body. Differential diagnosis involves a variety of viral diseases, most notably varicella (chickenpox). The principal clinical differences between smallpox and chickenpox are that, in smallpox, lesions are all in the same stage of development and tend to cluster on the face and extremities (including the palms of the hands and soles of the feet), whereas, in chickenpox, lesions tend to be in various stages of development and to cluster on the torso [*see 8:V Bioterrorism*]. Smallpox must also be differentiated from drug-induced rashes, most notably Stevens-Johnson syndrome.

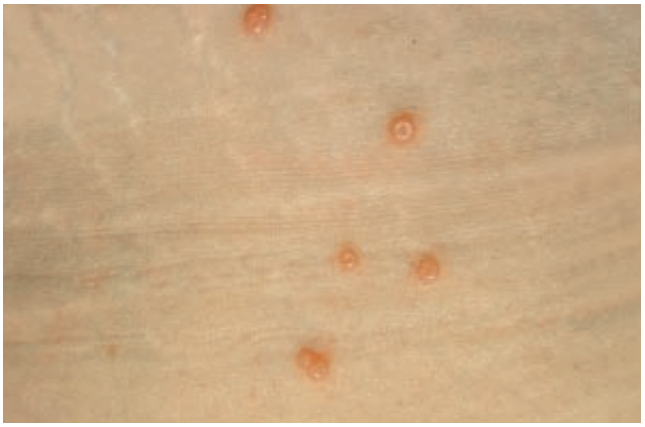

Figure 2 **The pearly white papular lesions of molluscum contagiosum shown here are 2 to 5 cm in diameter, with a central umbilication.**

Complications Visceral involvement can lead to encephalitis (< 1%), arthritis (2%), hypotension, hemorrhage, pneumonia, and death. Case-fatality rates of up to 30% have been reported, often associated with secondary bacteremias.[61]

Laboratory tests If facilities are available, direct examination of specimens by electron microscopy can readily distinguish variola from other viruses. Antigens can be detected by immunohistochemical techniques, DNA can be studied by PCR, and variola virus can be isolated in cell cultures.

Treatment

Strict respiratory and contact isolation is essential, preferably in a room with negative air pressure. Hydration is critical because of fluid losses. Vaccination is recommended in patients with early disease (see below).[61] Cidofovir has activity against related viruses (vaccinia, cowpox, monkeypox) in animal models and may be tried in severe cases, though it has considerable nephrotoxicity and no proven benefit.

Prevention

Smallpox prevention consists of infection control measures and use of vaccine containing live vaccinia virus.[61-63] The exact origin of vaccinia virus is not clear (the virus has no known natural hosts), but vaccinia has long been used as the source of smallpox vaccines. Although the duration of benefit of vaccinia vaccine has never been measured in controlled trials, epidemiologic studies suggest that increased protection against smallpox may persist for more than 10 years after vaccination.[64]

In healthy patients, injection of vaccinia virus usually induces a localized papular eruption at the injection site. However, patients with compromised immune function or with skin conditions such as eczema may experience more severe disease after vaccination. Progressive generalized vaccinia, vaccinia gangrenosa, and eczema vaccinatum may complicate such disorders [*see 8:V Bioterrorism*]. Vaccinia immune globulin and antiviral agents (e.g., cidofovir) have been suggested as possible therapies for vaccinia complications, but their effectiveness has not been established.

Since 1971, routine smallpox vaccination has not been recommended in the United States. Despite concern regarding the use of smallpox as a bioterrorism weapon, vaccination of the general public is still not recommended. Instead, targeted vaccination may be a more effective intervention against bioterrorist smallpox.[65] In October 2002, the CDC's Advisory Committee on Immunization Practices (ACIP) recommended voluntary vaccination of people designated to respond to or care for individuals suspected or confirmed of being infected with smallpox.[66] Because of the risk of complications, nonemergency vaccination is contraindicated in some cases [*see Table 1*]. Recently vaccinated persons may transmit vaccinia through contact with susceptible persons, so infection control measures are important. Current information and recommendations on smallpox and smallpox vaccination are available from the CDC at http://www.bt.cdc.gov/agent/smallpox/reference/resource-kit.asp.

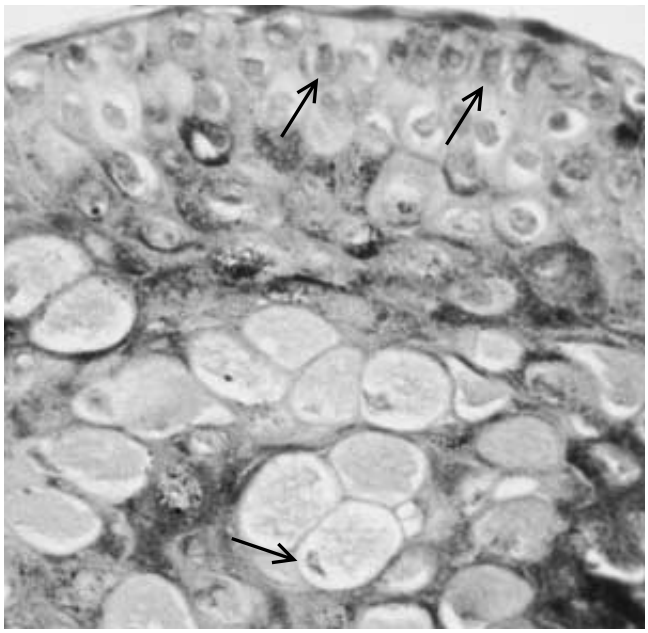

Figure 3 **Micrograph of a molluscum contagiosum lesion demonstrates basophilic molluscum bodies (arrow) in epidermal cell cytoplasm.**

Figure 4 **Papillomatous lesions of orf (pustular dermatitis) can be observed on the finger of a sheep handler.**

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is characterized by multiple painless, pearly white nodules 2 to 5 mm in diameter with a central umbilication. They can appear anywhere on the body except the palms and soles [*see Figure 2*]. The nodules, which are most commonly found in anogenital regions, rupture easily and may be spread by sexual routes, by autoinoculation, or by close familial contact under conditions of poor hygiene. Cases occur predominantly in children, sexually active adults, sports participants who have skin-to-skin contact, and persons with impaired cellular immunity.[67] The infection has worldwide distribution, and incidence rates of clinically apparent infection range from 0.1% to 4.5%. Incubation periods vary from several days to several weeks, and lesions may clear rapidly or persist for up to 18 months. Molluscum contagiosum is common in patients with AIDS, in whom the lesions may be large, atypical, and severe[68] [*see 2:I Cutaneous Manifestations of Systemic Diseases*]. Lesions near the eye may be complicated by chronic conjunctivitis or superficial keratitis.

The molluscum contagiosum virus (MCV) has been visualized by electron microscopy but has not been cultivated in vitro. Microscopic observation of large cytoplasmic inclusions, called molluscum bodies [*see Figure 3*], in appropriately stained, expressed lesion contents or histologic sections confirms a clinical diagnosis. Restriction endonuclease cleavage patterns of DNA from purified virus obtained from skin lesions indicate that there are two distinct MCV genotypes.[69]

The lesions resolve spontaneously without scarring. A small number of lesions can be removed by gentle curettage, laser, or caustic chemicals if desired. In immunocompetent patients, successful topical treatment with imiquimod 5% cream has recently been reported.[70]

PARAVACCINIA, ORF, AND MONKEYPOX

Human paravaccinia, orf, and monkeypox infections result from direct contact with natural animal reservoirs of these agents; humans are only incidental hosts.

Paravaccinia is an infection that produces lesions on the teats and oral mucosa of calves and milk cows. When humans are infected by direct contact, so-called milker's nodules develop on the fingers or hands and occasionally are associated with lymphadenitis. Lesions develop over a period of 1 to 2 weeks and resolve in 3 to 8 weeks.

The orf virus causes papillomatous lesions (pustular dermatitis) on the mucous membranes and corneas of sheep and goats. Lesions in humans [*see Figure 4*] are caused by direct contact with infected animals and resemble those caused by paravaccinia, although paravaccinia and orf viruses are distinct. Most cases are benign, but immunocompromised patients have been successfully treated with cidofovir.[71]

Monkeypox is caused by an orthopoxvirus related to the smallpox virus. Vaccination against smallpox also protects against monkeypox. Human monkeypox infections occur sporadically in small villages in African tropical rain forests; monkeypox infections also occur in captive monkeys in European and North American laboratories. Smallpoxlike diseases caused by monkeypox virus have been noted in central Africa in humans who live in close proximity to monkeys.[72] Although the primary reservoir for the monkeypox virus remains uncertain, humans appear to be incidental hosts for the virus. Person-to-person transmission has been described. In animal models, cidofovir has been effective for treating monkeypox infections.[71]

The author has served as a consultant for Bristol-Myers Squibb Company, GlaxoSmithKline, Millennium Pharmaceuticals, Inc., Schering-Plough Corporation, and Takeda Pharmaceuticals North America, Inc.

XXX SEPSIS

Steven M. Opal, m.d.
Christian E. Huber, m.d.

Sepsis, along with the multiorgan failure that often accompanies the systemic inflammatory response syndrome (SIRS), is a leading cause of mortality in the intensive care unit.[1,2] As many as 700,000 patients develop sepsis annually in the United States.[3] Nearly half of these patients manifest severe sepsis and septic shock. The mortality for septic shock remains approximately 35% to 45%, despite a concerted effort to improve the treatment options and outcome.[1-3]

Septic shock has become a major focus of critical care research. Although modest improvements in the prognosis have been made over the past 2 decades and promising new therapies have appeared in the past few years, innovations in the management of septic shock are still required.[4] This chapter reviews some of the remarkable advances achieved in the understanding of the molecular pathophysiology of sepsis, the diagnostic and therapeutic strategies emerging from this research, and the current management of septic shock.

Definitions of Sepsis

Sepsis, septic shock, SIRS, and multiple organ dysfunction syndrome (MODS) were defined at the American College of Chest Physicians/Society for Critical Care Medicine (ACCP/SCCM) Consensus Conference on Definition [*see Table 1*].[5] The definitions take into account the finding that sepsis may result from a multitude of infectious agents and microbial mediators and may or may not be associated with actual bloodstream infection. Despite the clinical logic, intrinsic simplicity, and widespread acceptance of these consensus definitions, their clinical applicability has been justifiably criticized.[6,7] The SIRS definition is so broad and nonspecific that it lacks discriminatory power; many patients admitted to general medical services and most ICU patients have conditions that meet the definition of SIRS. The current definition of sepsis fits virtually every person within the first 24 hours of an episode of influenza because the SIRS criteria are met and an infectious agent (an orthomyxovirus) causes the syndrome; however, clinicians do not generally regard the flu as sepsis. Nevertheless, a consensus conference held in 2001 to address some of these concerns concluded that, apart from a need to expand the list of signs and symptoms of sepsis to reflect clinical bedside experience, no evidence existed to support a change in the definitions.[8]

One of the tenets on which these definitions are based is that the inflammatory response itself, not the infectious organism, drives the septic process. This hypothesis may be largely correct, but the nature of the microbial pathogen responsible for sepsis clearly contributes to the ultimate fate of the patient. Microbial pathogens differ in their susceptibility to host defenses, their potential for developing antimicrobial resistance, and their ability to generate toxins—all of which affect their pathogenicity.[9] Failure to account for these intrinsic differences in microbial virulence limits the utility of current sepsis definitions.

Although the definition of septic shock includes hypotension that is unresponsive to fluid challenge, there is disagreement regarding the level of fluid resuscitation necessary to distinguish between sepsis and hypovolemia. In addition, the amount of vasopressor agent necessary to allow one to confidently conclude that the patient has true septic shock continues to be debated. Controversy also surrounds the difficulty in distinguishing preexisting morbidities and organ dysfunction from morbidity and

Table 1 The Terminology of Sepsis

Term	*Definition*	*Comments*
ARDS* (acute respiratory distress syndrome)[106]	Acute onset Bilateral infiltrates on chest radiograph Hypoxemia (P_aO_2/F_IO_2 ratio ≤ 200 mm Hg No evidence of left atrial hypertension (pulmonary arterial wedge pressure ≤ 18 mm Hg)	Severity can be scored by use of clinical parameters such as presence of hypoxemia, radiologic evidence of lung consolidation and compliance, and PEEP data from mechanical ventilation (Murray lung injury score)[107]
Bacteremia	Detection of viable bacteria in the bloodstream	Transient bacteremia without clinical symptoms is common; may or may not be found in sepsis
SIRS (systemic inflammatory response syndrome)	Temperature > 38.5° C (101.3° F) or < 36° C (96.8° F) Tachypnea (> 20 breaths/minute) Tachycardia (> 90 beats/minute) White blood cell count > 12,000 cells/mm^3 or > 10% immature forms or < 4,000 cells/mm^3	Two or more criteria needed; may be caused by infectious and noninfectious etiologies; clinical features may be caused by release of inflammatory mediators into circulation
Sepsis	SIRS caused by an invasive infection	May be caused by viral, bacterial, fungal, or parasitic pathogens; bloodstream infection need not be present
MODS (multiple organ dysfunction syndrome)	Major organ dysfunction from sepsis	A primary determinant of outcome in sepsis
Severe sepsis	Sepsis accompanied by major organ dysfunction (CNS, renal, pulmonary, hepatobiliary, hematologic, or metabolic)	Sometimes referred to as sepsis syndrome
Septic shock	Severe sepsis with hypotension not responsive to fluid challenge	Systolic blood pressure < 90 mm Hg despite adequate fluid resuscitation

*European-American Consensus Committee on ARDS definition.
F_IO_2—fraction of inspired oxygen P_aO_2—arterial oxygen tension PEEP—positive end-expiratory pressure

organ dysfunction induced by the septic process itself. Many patients with sepsis have major underlying organ dysfunction from a variety of disease entities. The degree to which sepsis contributes to further disordered organ function may be difficult to determine with accuracy. The same can be said for the degree to which sepsis contributes to the mortality in patients who suffer from other serious underlying diseases. All these factors limit the discriminatory value of the consensus definitions of sepsis and jeopardize valid comparisons between different study populations, compromising the ability to pool data and generalize the findings.

Further refinements in sepsis terminology may be possible when rapid diagnostic techniques become available to assess the immune status of septic patients. Functional genomics and proteomics (the study of human gene sequences and protein sequences, respectively) may assist in characterizing septic patients in the future. In the meantime, the current consensus definitions will be used despite their limitations.

Epidemiology

Between 1979 and 2000, the incidence of sepsis increased by 8.7% annually, from 82.7 to 240.4 per 100,000 population.[3,10] This trend will probably continue in the foreseeable future because sepsis has largely become a disease of medical progress. Successful management of a variety of severe medical and surgical diseases has produced a large patient population with critical illness and impaired host defenses; these patients have a greatly increased risk of developing sepsis. Innovations in organ transplantation, implanted prosthetic devices, and long-term vascular access devices continue to expand this patient population. The gradual aging of the population in many developed countries and the increasing prevalence of antibiotic-resistant microbial pathogens also contribute to the rising incidence of septic shock.

Pathogenesis: Microbial Factors

CAUSATIVE MICROORGANISMS

The microbiology of sepsis has undergone a remarkable transition in the past 25 years. The predominant microbial pathogens responsible for sepsis in the 1960s and 1970s were gram-negative bacilli and *Pseudomonas aeruginosa,* but there has been a progressive increase in the incidence of sepsis caused by gram-positive bacteria[4,11,12] and opportunistic fungi. The rapid evolution of antibiotic-resistance genes in gram-positive bacterial pathogens and the frequent occurrence of vascular catheter–related bacterial sepsis may account for the increasing prevalence of gram-positive pathogens as a cause of sepsis.

THE ROLE OF BACTERIAL ENDOTOXIN

Bacterial endotoxin, which is composed of lipopolysaccharide (LPS), is an intrinsic component of the outer membrane of gram-negative bacteria and is essential for the viability of enteric bacteria.[13] The unique potency of endotoxin is illustrated by the recent isolation of an endotoxin-deficient strain of *Neisseria meningitidis* that is at least 100-fold less potent an inducer of cytokine production than wild-type bacteria.[14] Endotoxin may enter the human circulatory system in its free form (released from dead organisms or shed from the membrane of viable organisms) or bound to the cell wall of intact bacteria. Whether free or bound, endotoxin appears to function essentially as an alarm molecule that alerts the host to the presence of invading gram-negative bacteria,[14,15] and its presence provokes a rigorous systemic inflammatory response. The host response to the endotoxin, rather than the endotoxin itself, accounts for the endotoxin's potentially lethal properties. As a species, humans are especially susceptible to the profound immunostimulant properties of endotoxin; even minute doses may be lethal.

Toll-like Receptors

On human immune cells, the Toll-like receptor (TLR) family is the transmembrane receptor for endotoxin and many other microbial mediators, such as peptidoglycan, lipopeptides, and lipoteichoic acid.[16] Ten TLRs have been identified to date. TLR4 is the principal endotoxin receptor,[17] whereas TLR2 and perhaps other TLRs recognize and signal the presence of a variety of microbial mediators, including endotoxin.[18,19] Comparative genomics in mice and fruit flies allowed for the identification of these critical receptors for microbial mediators on human cells.[20] Another TLR, TLR9, has been identified as the cellular receptor for unmethylated CpG motifs found in bacterial DNA but not in eukaryotic DNA. Upon recognition of bacterial DNA, TLR9 mediates an intense inflammatory response.[21,22]

TLRs belong to a family of pattern-recognition molecules that alert the innate immune response system to the presence of a microbial invader. Other pattern-recognition molecules include alternative complement components, mannose-binding lectin,[23] and CD14.[24,25] The innate immune system is by nature a rather nonspecific antimicrobial defense system. It lacks the precision of the acquired immune system (B cells and T cells), but its immediate action—phagocytosis and clearance of pathogens—in the initial stages of infection makes the innate immune response a critical survival mechanism. Activation of the innate immune system and its cellular components (neutrophils, monocytes, macrophages, and natural killer [NK] cells) are primarily responsible for the pathogenesis of septic shock.[26]

LPS Signaling

LPS is a phosphorylated, polar macromolecule that contains hydrophobic elements in the fatty acids of its lipid A core structure and hydrophilic elements in its repeating polysaccharide surface components. LPS forms microaggregates in biologic fluids and then rapidly interacts with a variety of serum or membrane-bound lipophilic proteins. Three receptors for LPS have been recognized in human cells: (1) soluble or membrane-bound CD14 molecules, (2) CD11/CD18 molecules (β2 integrins), and (3) scavenger receptors for lipid molecules. Soluble and membrane-bound CD14 greatly potentiate the host response to small quantities of LPS and other microbial mediators.[27]

In human blood and body fluids, LPS signaling is mediated by interactions with a hepatically derived, acute-phase plasma protein known as LPS-binding protein (LBP).[27] LBP functions primarily as a shuttle molecule that binds to polymeric LPS aggregates and transfers LPS monomers to CD14, which is a glycosyl phosphatidylinositol-linked protein found on the cell surfaces of such immune effector cells as the monocyte-macrophage and the neutrophil. After docking to membrane-bound CD14, LPS is delivered to an adjacent cell surface LPS receptor TLR4, along with an extracellular accessory protein known as MD2. This complex then triggers a signal to the intracellular space, subsequently activating LPS-responsive genes. CD14 also binds to bacterial peptidoglycan and lipopeptides and delivers these microbial ligands to TLR2 for intracellular signaling.

Through a well-characterized sequence of tyrosine and threonine/serine kinases, intracellular signaling leads to phosphorylation of inhibitory κB (IκB). This releases nuclear factor κB (NFκB) from the cytoplasm, allowing it to translocate into the nucleus. Clotting elements and acute phase proteins, cytokines, and nitric oxide synthase genes have NFκB binding sites in their regulatory elements. The outpouring of inflammatory cytokines and other inflammatory mediators after LPS exposure contributes to SIRS and is central to the pathogenesis of septic shock induced by gram-negative bacteria.[28,29]

Bactericidal/Permeability-Increasing Protein

Another important endotoxin-binding protein found in human plasma is bactericidal/permeability-increasing protein (BPI). This protein is 456 amino acids long, is produced by human neutrophils, and is found in greatest quantities in the azurophilic (primary) granules.[30] Its amino acid sequence is 45% homologous with LBP but has a distinctly antagonistic function with respect to LPS handling: unlike LBP, which facilitates LPS delivery to CD14 and thereby activates cells, BPI inhibits LPS delivery to CD14. BPI competes with LBP for LPS binding in biologic fluids.[30] The relative concentrations of these two endotoxin-binding proteins primarily determine the net effect of LPS release.

In human plasma, the concentration of LBP is two to three orders of magnitude higher than that of BPI. The opposite appears to be the case in abscess cavities, where BPI is present in much greater quantities than LBP.[19] This favors LPS-activating activity in the plasma and LPS-inhibitory activity in abscess cavities. Thus, BPI functions as an endogenous anti-endotoxin molecule; it may become a component of treatment for endotoxin-induced injury.[27,30]

Endotoxin Tolerance

The phenomenon of endotoxin tolerance (or reprogramming) has been well characterized in experimental models of sepsis and probably also occurs in human sepsis.[31] Endotoxin tolerance is the desensitization to endotoxin-induced lethality after a priming (small) dose of endotoxin before an otherwise lethal challenge dose of endotoxin. This phenomenon appears to be primarily mediated at the transcription level, with down-regulation of inflammatory cytokine genes. The precise molecular explanation for endotoxin tolerance is not fully characterized. The desensitizing dose of endotoxin may induce endogenous corticosteroids or anti-inflammatory cytokines such as interleukin-10 (IL-10), decrease cell surface expression of TLRs, alter nuclear translocation of signal transduction molecules, or decrease the stability of messenger RNA (mRNA) for cytokine genes.

The significance of endotoxin tolerance in humans is unclear, but some degree of endotoxin tolerance has been observed in patients treated with monophosphoryl lipid A.[31] Unquestionably, endotoxin is an important mediator in the pathogenesis of septic shock. Thus, efforts to limit LPS synthesis, prevent activation of host immune response elements, and enhance the clearance of LPS are important therapeutic strategies for the future treatment of septic shock.

BACTERIAL SUPERANTIGENS

Another important microbial mediator in the pathogenesis of septic shock is bacterial superantigen. Although they comprise a diverse group of protein-based exotoxins from streptococci, staphylococci, and other pathogens, superantigens share an unusual immunologic property: the capacity to activate large numbers of $CD4^+$ T cells in a short period by bypassing the usual mechanism of antigen processing and presentation.[32]

Conventional bacterial antigens are internalized by antigen-presenting cells (APCs) and undergo limited proteolysis and processing within the endosomal component of the macrophage. Appropriate peptide sequences of the microbial antigens (epitopes) are inserted into the central groove of major histocompatibility (MHC) class II molecules and are then expressed on the cell surface of APCs. Specific $CD4^+$ T cells that recognize the unique epitope are then activated. Clonal expansion of this small subset of T cells results in a physiologic immune response to the newly introduced antigen. Superantigens, in contrast, do not require intracellular processing by APCs. Superantigens bind directly to class II antigens adjacent to the epitope-specific peptide groove on APCs. Superantigens also bind to a limited number of Vβ regions of the T cell receptor on $CD4^+$ T cells. This binding brings $CD4^+$ T cells and macrophages into close proximity, which activates both the monocyte-macrophage and T cell populations.

Whereas a conventional peptide antigen stimulates only about one in 105 circulating lymphocytes that can recognize its unique structural epitope, a superantigen (e.g., toxic shock syndrome toxin–1 from *Staphylococcus aureus,* which binds to the $V\beta_2$ region of T cells) stimulates 10% to 20% of circulating human lymphocytes. Thus, a single bacterial superantigen can activate as much as 10% of the entire lymphocyte population.[33] This results in excessive activation of both lymphocytes and macrophages, which, in turn, leads to the uncontrolled synthesis and release of inflammatory cytokines.

Superantigen-induced immune activation may terminate in septic shock if the process is left unchecked. Polymicrobial infections with pathogens that release both bacterial superantigens and endotoxin may be particularly injurious to the host; the toxicity of bacterial endotoxin may be greatly enhanced by superantigens that prime the immune system to react to endotoxin in an overly sensitized manner [*see Figure 1*].

OTHER MICROBIAL MEDIATORS

Peptidoglycan from the cell wall of bacteria, capsular antigens, lipoteichoic acid, lipopeptides, microbial DNA, microbial toxins, and procoagulant substances produced by microbial pathogens may all contribute to the pathogenesis of sepsis. It has been observed that peptidoglycan from gram-positive bacteria interacts with CD14 molecules and activates inflammatory cells via TLR2 in a manner comparable to that observed with bacterial endotoxin.[18,19,33,34] CD14-dependent activation of mononuclear cells may occur from both gram-positive and gram-negative bacteria, although the level of activation is quantitatively less with gram-positive components.[35,36] TLR9-dependent, CD14-independent recognition of the unmethylated CpG motifs found in bacterial DNA also results in a vigorous inflammatory response.[22]

Moreover, gram-positive bacterial and fungal pathogens may induce systemic hypotension, resulting in redistribution of blood flow and in splanchnic vasoconstriction. The ischemia and subsequent reperfusion of the gastrointestinal tract may disrupt the intestinal mucosal barrier to bacterial products. Translocation of intact microbial pathogens as well as bacterial endotoxin from the GI tract to the circulation may occur during periods of severe stress and during periods of hypoperfusion of the GI mucosa.[37] Bacterial endotoxin and perhaps other gut-derived microbial mediators may play a pathogenic role in the ongoing inflammatory process after systemic hypotension produced by infectious and noninfectious insults. This finding has initiated interest in at-

tempts to strengthen the GI mucosal barrier through immunonutrition, epithelial growth factors, and selective decontamination of the GI tract in critical illness. These treatments remain potentially viable options and are areas of active research in the management of sepsis.

Pathogenesis: Host-Derived Mediators

CYTOKINE NETWORKS

Inflammatory cytokines play a pivotal role in the pathogenesis of sepsis. In animal studies, the administration of human tumor necrosis factor–α (TNF-α), an endogenous monocyte-macrophage–derived protein, was shown to have lethal consequences; in human volunteers, dramatic hemodynamic, metabolic, and hematologic changes were observed after administration of TNF-α.[38,39] The injurious effects of systemic levels of IL-1β have also been demonstrated.[40]

The major inflammatory cytokines, TNF-α and IL-1β, induce their hemodynamic and metabolic effects in concert with an expanding group of host-derived inflammatory mediators that work in a coordinated fashion to produce the systemic inflammatory response [*see Figure 1 and Table 2*].[40,41] The cytokine system functions as a network of communication signals between neutrophils, monocytes, macrophages, and endothelial cells. Autocrine and paracrine activation results in synergistic potentiation of the inflammatory response once it is activated by a systemic microbial challenge (e.g., endotoxemia). Much of the inflammatory response is localized and compartmentalized in the primary region of initial inflammation (e.g., lung tissue or the GI tract). If left unchecked, the inflammatory response spills over into the systemic circulation, resulting in a generalized reaction and culminating in diffuse endothelial injury, coagulation activation, and septic shock. The endocrinelike effect of the systemic release of cytokines and chemokines drives the inflammatory process and causes coagulopathies throughout the body.[1,2]

The multitude of inflammatory cytokines and chemokines found in excess quantities in the bloodstream in patients with septic shock is impressive and is matched by an equally daunting group of anti-inflammatory mediators [*see Table 2*]. The inflammatory mediators tend to predominate in the early phases of sepsis (the first 12 to 24 hours), whereas the endogenous anti-inflammatory components often prevail in the later phases of sepsis.[41] It has been observed that mice deficient in T cells and B cells respond to endotoxin challenge in the same way as normal mice.[42] Thus, monocyte-macrophage–generated cytokines are sufficient to drive the early septic process. However, lymphocyte-derived cytokines and interferons become important in the regulation of later phases of sepsis and may ultimately determine the outcome in septic shock.

$CD4^+$ T Cells

Important functional differences exist within $CD4^+$ T cells. Activated, yet uncommitted, $CD4^+$ T cells (T_{H0} cells) have two major pathways of functional differentiation. T_{H0} cells exposed to IL-12 in the presence of IL-2 are driven toward a T_{H1}-type functional development. These cells produce large quantities of interferon gamma (IFN-γ), TNF-α, and IL-2 and promote an inflammatory, cell-mediated immune response. In contrast, T_{H0} cells exposed to IL-4 will preferentially develop into a T_{H2}-type phenotype; T_{H2} cells secrete IL-4, IL-10, and IL-13. These cytokines promote humoral immune responses and attenuate macrophage and neutrophil activity.

Of interest is that T_{H1}-type cytokines suppress the expression of T_{H2}-type cytokines; IFN-γ inhibits the synthesis of IL-10. Conversely, IL-10 from T_{H2} cells is a potent inhibitor of TNF-α and IFN-γ synthesis by T_{H1} cells. The nature of the initial lymphocyte response is critical because the system tends to polarize over time into either a T_{H2}-type or T_{H1}-type response.[43] Evidence now

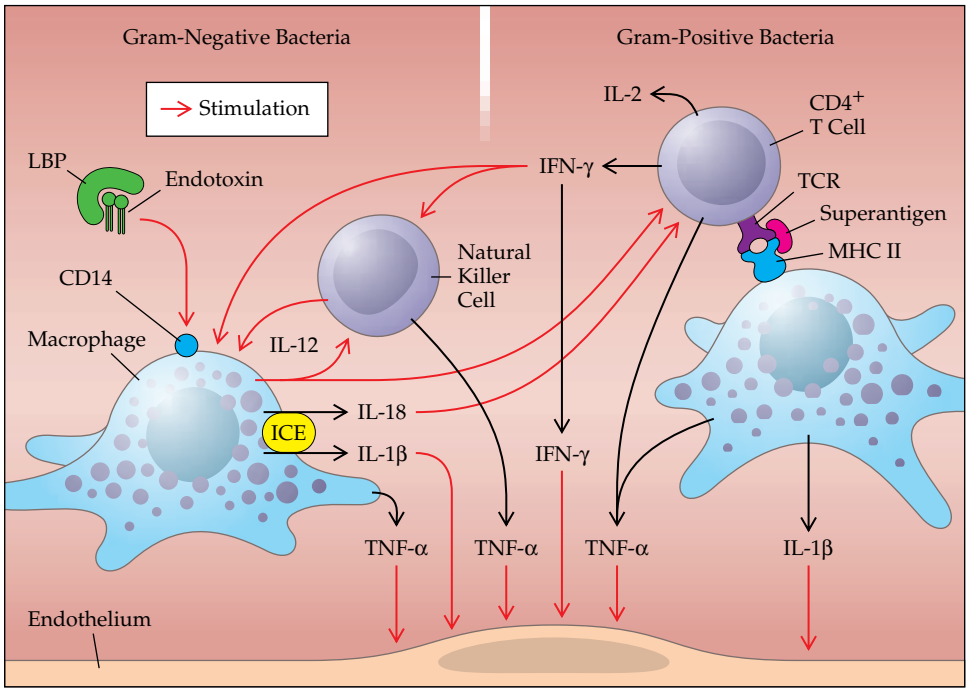

Figure 1 **Interactions between bacterial endotoxin and bacterial superantigens are shown. (ICE—interleukin-1β–converting enzyme; IFN-γ—interferon-gamma; IL—interleukin; LBP—LPS-binding protein; TNF-α—tumor necrosis factor-α)**

Table 2 Host-Derived Inflammatory Mediators in Septic Shock

Proinflammatory Mediators	*Anti-inflammatory Mediators*
Tumor necrosis factor–α	Interleukin-1 receptor antagonist
Interleukin-1β	Soluble tumor necrosis factor receptor
Interferon gamma	Soluble interleukin-1 receptor
Lymphotoxin-α	Transforming growth factor–β
Interleukin-2	Interleukin-4
Interleukin-8	Interleukin-6
Interleukin-12	Interleukin-10
Interleukin-18	Interleukin-11
Complement	Interleukin-13
Leukotriene B_4	Prostaglandin E_2
Platelet-activating factor	Granulocyte colony-stimulating factor

Granulocyte-macrophage colony-stimulating factor	Interferon beta
Chemokines	
Macrophage inhibitory factor	

suggests that similar forms of functional differentiation exist for CD8 cells as well ($CD8^+$ type 1 and type 2 cells).[44]

This process of functional differentiation is clinically relevant because sepsis is often accompanied by a late T_{H2}-type response after an initial septic insult. The stress hormone response in septic shock—expression of adrenocorticotropic hormone, corticosteroids, and catecholamines—promotes a T_{H2} response after systemic injury. This may lead to a phase of relative immune refractoriness (immune paralysis) in which the patient may be at increased risk for secondary bacterial or fungal infection.[41] This pathophysiologic state is associated with endotoxin tolerance; anti-inflammatory cytokine synthesis; and deactivation of monocytes, macrophages, and neutrophils. Methods to detect this immunosuppressed state and restore immune competence are under investigation. Patients with depressed expression of MHC class II antigens (e.g., HLA-DR) on the cell surface of macrophages may be in a functionally immunosuppressed state and may benefit from IFN-γ treatment.[45]

THE COAGULATION SYSTEM

Activation of the coagulation cascade and generation of a consumptive coagulopathy and diffuse microthrombi are well-recognized complications of severe sepsis. Studies of endotoxin challenge and TNF challenge in normal human volunteers indicate that the extrinsic pathway (tissue factor pathway) is the predominant mechanism by which the coagulation system is activated in human sepsis.[46,47] The contact factors in the intrinsic pathway are also activated, which secondarily initiates vasodilation through the generation of bradykinin.[47] Activation of intravascular coagulation results in microthrombi and may contribute to the multiorgan failure that occurs in septic patients. Depletion of coagulation factors and activation of plasmin, antithrombin III, and protein C may subsequently lead to a hemorrhagic diathesis. Depletion of these endogenous anticoagulants may secondarily lead to a procoagulant state and portend a poor prognosis.[48]

Current interest in the administration of tissue factor pathway inhibitor, activated protein C, and antithrombin III[49] for treatment of sepsis attest to the potential therapeutic value of regulation of the coagulation system in sepsis.[50] A phase 3 clinical trial in which 1,690 patients were treated with recombinant human activated protein C (drotrecogin alfa activated) was stopped when an interim analysis revealed a survival benefit for patients receiving activated protein C; mortality was 24.7% in treated patients versus 30.8% in placebo recipients ($P < 0.005$).[51] In contrast, a 2,300-patient multicenter trial with antithrombin III did not show any benefit.[49] Results of a phase 3 trial with tissue factor pathway inhibitor are pending at the time of this writing.

NEUTROPHIL–ENDOTHELIAL CELL INTERACTIONS

The recruitment of neutrophils to an area of localized infection is an essential component of the host inflammatory response. Localization and eradication of invading microbial pathogens at the site of initial infection is the principal objective of the immune response to microbial pathogens. This physiologic process may become deleterious if diffuse neutrophil–endothelial cell interactions occur throughout the circulation in response to systemic inflammation.

Complex mechanisms govern the migration of neutrophils from the intravascular space into the interstitium, where invasive microorganisms may reside [*see Figure 2*]. Activated neutrophils degranulate, exposing endothelial surfaces and surrounding structures to reactive oxygen intermediates, nitric oxide, and a variety of proteases. This process contributes not only to microbial clearance but also to diffuse endothelial injury in the setting of generalized systemic inflammatory responses. Regulation of neutrophil activity may represent a new area for therapeutic intervention in the management of sepsis.[52]

NITRIC OXIDE

Nitric oxide is a highly reactive free radical that plays an essential role in the pathophysiology of septic shock. It has a very short half-life (1 to 3 seconds), which tends to limit its activity to local tissues, where it is first generated by one of three isoforms of nitric oxide synthase. Regulation of the nitric oxide synthases is complex. Full expression of inducible nitric oxide synthase requires TNF-α, IL-1, LPS, and probably other regulatory elements.

Nitric oxide is the major endothelial-derived relaxing factor that initiates the vasodilatation and systemic hypotension observed in septic shock. Nitric oxide activates guanylate cyclase, which increases cyclic guanosine monophosphate levels inside vascular smooth muscle cells. This results in systemic vasodilatation and decreased vascular resistance. Within minutes of administration of an inhibitor of nitric oxide synthesis, blood pressure in hypotensive patients in septic shock moves toward normal levels.[53]

The other major physiologic effects of nitric oxide in septic shock are increased intracellular killing of microbial pathogens and regulation of platelet and neutrophil adherence. Nitric oxide is a highly diffusible gas that does not require specific receptors to enter eukaryotic or prokaryotic cells. In the presence of superoxide anion, nitric oxide leads to the formation of peroxynitrite. The peroxynitrite subsequently decays into highly cytotoxic molecules such as hydroxyl radicals and nitrosyl chloride, which, in turn, initiate lipid peroxidation and cause irreversible cellular damage. Nitric oxide inhibits a variety of key enzymes in the tricarboxylic acid pathway, the glycolytic pathway, DNA repair systems, electron transport pathways, and energy-exchange pathways. Because of its potent reactivity, nitric oxide alters the function of many metalloenzymes, carrier proteins, and structural elements.

Like many other components of the host inflammatory response, nitric oxide may have both advantageous and disadvantageous properties in sepsis. Nitric oxide regulates microcirculation to vital organs and contributes to intracellular killing of mi-

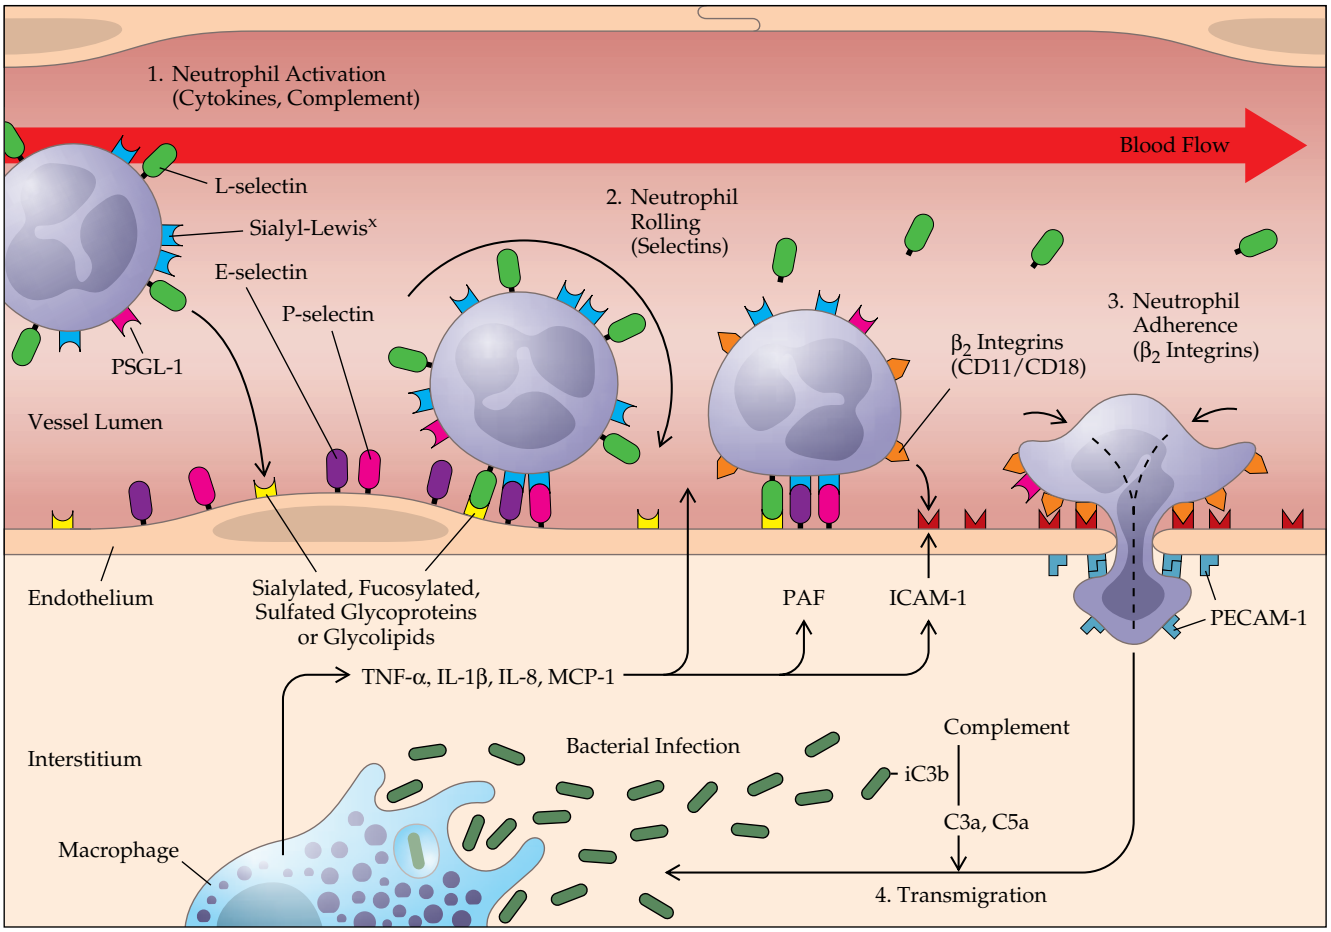

Figure 2 **Neutrophil–endothelial cell interactions in sepsis. crobial pathogens. However, excessive and prolonged release of nitric oxide results in generalized vasodilatation and the systemic hypotension of septic shock. For those reasons, nitric oxide has become a target for therapeutic strategies in the management of sepsis.[54] Nonselective inhibitors of nitric oxide synthase, for example, have been shown to improve the hemodynamics of septic patients.[53] Unfortunately, this finding was not confirmed in a phase 3 trial.[55]

OTHER HOST-DERIVED MEDIATORS

At least two additional host-derived mediators contribute to the pathogenesis of septic shock. Macrophage migration inhibitory factor (MIF) is a late mediator that activates immune cells, upregulates TLR4 expression, and contributes to lethal septic shock.[56] This corticosteroid-regulated mediator promotes inflammation and has become a target for therapeutic agents in sepsis. High-mobility group–1 (HMG-1) protein also appears to contribute to late-onset inflammatory activities in septic shock. Inhibitors of HMG-1 may prove to have a therapeutic role in sepsis as well.[57]

Pathogenesis: Organ Dysfunction

The diffuse endothelial injury accompanying septic shock results in organ dysfunction distant from the original site of the septic insult. The signal that results in diffuse endovascular injury is thought to be relayed by plasma factors (e.g., inflammatory cytokines, complement, kinins, and other host-derived inflammatory mediators) or by a cellular element found in one or more of the immune effector cells.

Inadequate blood supply to vital tissues produces MODS. The failure of the microcirculation to support tissue maintenance may be the result of hypoperfusion of capillary beds, redistribution of blood flow within vascular beds, functional arteriovenous shunting, obstruction of blood flow from microthrombi, platelet or white blood cell aggregates, or abnormal deformability of red blood cells. Direct endothelial injury from nitric oxide, reactive oxygen intermediates, inflammatory cytokines, and inducers of apoptosis may directly damage endothelial surfaces. Endothelial swelling from the movement of intravascular fluid into the extravascular and intracellular spaces may mechanically obstruct the lumens of the capillary beds as well.

Although the origin of multiorgan failure in sepsis is principally related to microvascular effects, myocardial performance and pulmonary function also diminish over the course of septic shock and may contribute significantly to the development of MODS. Myocardial contractility decreases in response to a variety of myocardial depressant factors found in the plasma of septic patients. TNF-α is a prominent cause of myocardial dysfunction; IL-1, nitric oxide, and other host-derived inflammatory me-

Table 3 Standard Laboratory Values in Sepsis

Laboratory Study	*Typical Findings*	*Comments*
White blood cell count	Leukocytosis or leukopenia	Stress response, increased margination of neutrophils in sepsis; toxic granulation may be seen; occasionally, bacteria may be found in the peripheral blood smear
Platelet count	Thrombocytopenia	Look for evidence of fragmentation hemolysis in the peripheral blood smear; thrombocytopenia may or may not be accompanied by disseminated intravascular coagulation
Glucose	Hyperglycemia or hypoglycemia	Acute stress response, inhibition of gluconeogenesis
Clotting measurements	Elevated prothrombin time, activated partial thromboplastin time, low fibrinogen levels, and evidence of fibrinolysis	Coagulopathy often seen with systemic endotoxin release
Liver enzymes	Elevated alkaline phosphatase, bilirubin, and transaminases; low albumin	—
Blood cultures	Bacteremia or fungemia	The presence of positive blood culture does not make the diagnosis, and its absence does not exclude the diagnosis
Plasma lactate	Mild elevations (> 2.2 mmol/L)	Hypermetabolism, anaerobic metabolism, inhibition of pyruvate dehydrogenase
C-reactive protein	Elevated	Acute-phase reactant, sensitive but not specific for sepsis
Arterial blood gases	Respiratory alkalosis (early); metabolic acidosis (late)	Measurements of O_2 content and mixed venous O_2 saturation useful in management

diators may be contributing factors.[58] Acute lung injury occurs in septic shock as a result of damage to the pulmonary vascular circulation and the alveolocapillary membranes. A supply-dependent dysoxia (cytopathic hypoxia) may contribute to tissue injury in multiorgan failure in sepsis.[59]

Diagnostic Approach to Septic Shock

GENERAL FEATURES

In his classic treatise on human nature (*The Prince*, circa 1505), Machiavelli states, "Hectic fever [i.e., sepsis by current consensus definitions] at its inception is difficult to recognize but easy to treat; left untended, it becomes easy to recognize but difficult to treat." This statement is as true today as it was 500 years ago. Fully developed septic shock is a readily apparent clinical syndrome that is seldom confused with other pathologic states. However, the early phases of septic shock may be quite subtle even in carefully monitored patients. Early signs and symptoms may include confusion, apprehension, or decreased sensorium. Although fever is characteristic, hypothermia may occur and connotes a poor prognosis. An unexplained decrease in urinary output, sudden onset of cholestatic jaundice, unexplained metabolic alkalosis, excess bleeding at venipuncture sites, or even sudden unexplained hypotension may be the presenting finding in septic shock. It is essential that clinicians recognize these early signs and symptoms because successful management of septic shock depends on early recognition and appropriate intervention.

A variety of clinical, laboratory, and hemodynamic abnormalities are recognized in septic shock [*see Tables 3 and 4*]. Unfortunately, no single clinical or laboratory test is sufficiently specific and sensitive to reliably confirm the diagnosis of septic shock.

Table 4 Hemodynamic Findings in Sepsis

Parameter	*Typical Findings*	*Comments*
Heart rate	> 100 beats/min	Major compensatory mechanism for low systemic vascular resistance
Mean arterial blood pressure	< 65 mm Hg	Hallmark of septic shock
Cardiac index (cardiac output/m^2 [surface area])	> 4 L/min/m^2	Cardiac index elevated in early septic shock; may be depressed in late septic shock
Pulmonary arterial wedge pressure	4–10 mm Hg	Must be sure that hypovolemia is not the cause of hypotension; perform fluid resuscitation until pulmonary arterial wedge pressure returns to normal
Systemic vascular resistance (SVR)	< 800 dyne/sec/cm^{-5}	SVR often low in early septic shock; may become elevated in later phases of septic shock
Oxygen delivery (DO_2) Cardiac index (CI) × arterial O_2 content (A)	< 550 ml/min/m^2	Try to provide sufficient DO_2 to maintain adequate mixed venous O_2 saturation
Mixed venous O_2 saturation	< 70%	Low mixed venous O_2 indicates inadequate O_2 delivery to tissues in sepsis
Oxygen consumption (VO_2) (CI) × (A-VO_2) × 10	> 180 L/min/m^2	Typically increased in early septic shock

Table 5 Multiple Organ Dysfunction Syndrome in Severe Sepsis

Organ System	*Clinical-Metabolic Abnormalities*	*Histopathologic Findings*
CNS	Encephalopathy, decreased sensorium	Cerebral edema, microthrombi
Cardiac	Decreased myocardial performance	Altered calcium influx, interstitial edema
Lung	Acute respiratory distress syndrome	Exudation of fluid into the alveolar spaces, neutrophil plugging, hyaline membrane formation
Kidney	Acute tubular necrosis	Hypoperfusion, focal ischemia, microthrombi
Adrenal	Relative adrenal insufficiency, adrenal hemorrhage	Focal or diffuse hemorrhage, ischemic necrosis
Hepatobiliary system	Cholestatic jaundice, decreased hepatic synthesis of albumin, presence of clotting factors	Zonal necrosis, acalculous cholecystitis
Gut	Translocation of bacterial endotoxin and microorganisms, increased permeability	Diffuse interstitial edema, breaks in the epithelial membrane integrity, mucosal necrosis

Patients may have positive or negative blood cultures, leukocytosis or neutropenia, hyperglycemia or hypoglycemia, and respiratory alkalosis or metabolic acidosis. It is the constellation of signs and symptoms that leads to a diagnosis of septic shock.

The most common hemodynamic findings in early septic shock are a high cardiac output and a low systemic vascular resistance state, with initial maintenance of the systolic blood pressure as the heart attempts to compensate for the loss of systemic vascular tone. Myocardial performance is diminished even in the early phases of septic shock.[60] Without adequate intervention, circulating blood volume is continually lost into the interstitial space and intracellular locations. The heart can no longer compensate sufficiently, and systolic hypotension results. Deterioration of myocardial performance, accompanied by diffuse vasoconstriction, marks the late refractory state of septic shock.

MULTIPLE ORGAN DYSFUNCTION SYNDROME

One of the hallmarks of septic shock is the development of MODS. A constellation of clinical and metabolic abnormalities characterizes this syndrome [*see Table 5*]. The development of organ failure at the onset of sepsis or during its course is a poor prognostic factor and is a primary determinant of outcome.[61]

Acute Respiratory Distress Syndrome

The acute respiratory distress syndrome (ARDS) remains a major cause of morbidity and mortality in septic shock.[62] Increased capillary permeability in these patients results in pulmonary edema, which manifests clinically as dyspnea and cough; a standard anteroposterior chest x-ray will typically show bilateral, symmetrical alveolar opacities in all four quadrants [*see 14:X Pulmonary Edema*].

EXPERIMENTAL DIAGNOSTIC TECHNIQUES

The current assays used to diagnose septic shock are cumbersome and slow. Research to develop better assays is ongoing.

Plasma Endotoxin Levels

The measurement of plasma endotoxin levels may prove useful in helping to predict the development of shock.[63] Unfortunately, endotoxin levels are not uniformly elevated in patients with septic shock and may be spuriously elevated in patients with gram-positive infections or other hypotensive disorders. Also, the host responsiveness to endotoxin is variable and does not correlate with circulating endotoxin levels.

Bacterial Superantigen Levels

Circulating levels of bacterial superantigens have been successfully measured in selected patients with toxic shock syndrome.[64] Such measurements may prove useful in specific clinical situations.

IL-6 Levels

IL-6 is a cytokine that has myriad biologic activities, some of which are inflammatory and others of which are anti-inflammatory. IL-6 has been considered an indicator of cytokine activation because it is reliably present after activation of TNF-α and IL-1β. Patients with elevated IL-6 levels may respond favorably to anti-cytokine therapies.[65] In several studies, elevations of IL-6, as well as failure of IL-6 levels to fall after initiation of treatment for sepsis, was associated with a poor outcome. [65-68] Unfortunately, IL-6 levels are not specific for sepsis and may be elevated in a variety of inflammatory and infectious states. This lack of specificity limits the reliability of IL-6 measurement as a diagnostic method for septic shock.

Procalcitonin Levels

Procalcitonin, the propeptide of calcitonin, is normally produced by C cells in the thyroid.[69] In septic patients, procalcitonin is generated by numerous extrathyroidal tissues; its precise origin in this situation is unclear.[70,71] Procalcitonin has attributes that make it a potential marker for sepsis. It has a long half-life (approximately 24 hours), and measured levels will increase from undetectable to over 100 ng/ml during the course of septic shock. Procalcitonin levels do not become elevated as rapidly as IL-6 or IL-8 levels; elevated levels of procalcitonin are seen 4 to 6 hours after a systemic challenge with endotoxin or other septic stimuli.[72]

Of interest is that procalcitonin levels are elevated in severe sepsis but not in localized infections,[71] severe viral infections, or inflammatory conditions of noninfectious origin. In organ transplant recipients, procalcitonin levels may allow differentiation between the fever associated with rejection and that associated with sepsis.[71] Although the precise physiologic role of procalcitonin in sepsis has yet to be defined, procalcitonin elevation appears to be the most sensitive and reasonably specific indicator of severe sepsis currently available.[70,72]

Other Potential Markers

C-reactive protein and plasma lactate have been used as potential markers for sepsis, but their lack of specificity and sensi-

tivity limits their diagnostic value. IL-8 may prove useful, with or without IL-6, as an indicator of sepsis.[73]

Phospholipase A_2 is essential for the generation of platelet-activating factor and arachidonic acid derivatives, including thromboxane, prostacyclin, prostaglandins, and leukotrienes. Phospholipase A_2 or its precursor, type I prophospholipase A_2 propeptide, may prove to be a marker for sepsis, but the diagnostic value of measurements of this enzyme needs to be confirmed in clinical studies.[74]

Management of Septic Shock

There are four goals in the management of septic shock: (1) early recognition and resuscitation; (2) reestablishment of tissue perfusion and arterial blood pressure; (3) provision of optimal supportive care; and (4) timely initiation of treatment to eradicate the causative septic focus. After 2 decades in which the means for achieving these goals remained largely the same, the treatment approach has now changed, with the use of drotrecogin alfa activated,[51] low-dose corticosteroids,[75] and other supportive strategies for the management of septic shock.[76,77] In addition, modest improvements in outcome have accrued as the result of improved nutrition and supportive care and the skillful use of vasopressor agents.

The key determinant in survival is early recognition of sepsis and initiation of treatment while the process is readily reversible. This requires constant vigilance by the clinician caring for patients with a variety of medical and surgical illnesses.

FLUID RESUSCITATION

Fluid resuscitation is a mandatory first step in the treatment of septic shock. The diffuse vascular leak that occurs in septic shock necessitates provision of adequate circulating blood volume to maintain tissue perfusion.

Debate continues regarding the appropriateness of colloid versus crystalloid fluids. The lack of clear evidence of benefit of colloid agents (e.g., albumin, dextran, and plasma expanders) and their high cost have generally resulted in the use of saline solutions for volume expansion. A 1998 meta-analysis of studies comparing colloid versus crystalloid in sepsis found a slight worsening of outcome with colloid solutions.[78] Further review of these data indicate that differences in outcome are equivocal at best, and debate continues on the relative merits of colloids in sepsis.

The optimal amount of fluid for resuscitation of patients in septic shock remains a source of controversy. A delicate balance is required between maintenance of tissue perfusion and prevention of fluid overload, with its attendant risk of lung injury. Decreased myocardial performance in sepsis may necessitate a higher filling pressure for adequate cardiac output; however, exudation of fluids into the alveolar space in lung tissue and into the interstitium in other vital organs continues to be a major problem. Maintenance of a pulmonary arterial occlusion pressure of approximately 12 mm Hg is considered a reasonable starting point in patients who have hemodynamic monitors in place.[79] Rapid resuscitation with the goal of establishing normal mean central venous pressure and oxygen delivery to tissues has been shown to be of clinical value.[76] Diligent care and maintenance of central lines will reduce the frequency of catheter-related sepsis.[80]

VASOPRESSOR THERAPY

When patients fail to improve hemodynamically with fluids alone, vasopressor agents are often employed to reestablish systemic arterial blood pressure. Clinicians may choose among several vasopressor agents; however, the use of any vasopressor agent in septic shock carries with it certain risks and should be reserved for patients with significant hemodynamic instability that is unresponsive to fluid therapy.

Dopamine

Dopamine has been the vasopressor agent of choice for the past 2 decades because of its presumed favorable effects on renal perfusion (through promotion of renal vasodilation) and its modest inotropic effects. However, the validity of the privileged status of this choice has been questioned.[81] Dopamine effects are complicated by the fact that this catecholamine has its own receptors (D_1 and D_2 dopamine receptors) as well as variable affinities for alpha- and beta-adrenergic receptors. The effects of dopamine depend on the receptor density in specific vascular beds, the blood volume, and the dose used. Higher doses of dopamine increase the systemic vascular resistance by the drug's effects on alpha-adrenergic receptors in the peripheral circulation. Dopamine may have adverse effects on splanchnic blood flow,[82] and it has never been shown to be clearly beneficial to septic patients in an adequately controlled clinical trial.

Norepinephrine

Norepinephrine is a potent vasoconstrictor that is being used more frequently to treat the hemodynamic effects of septic shock. Earlier concerns regarding adverse consequences of norepinephrine on renal blood flow may have been overstated; studies suggest that norepinephrine may actually increase urine output and creatinine clearance in septic patients.[83] Norepinephrine may rapidly restore perfusion pressure within the glomerulus and result in improved glomerular filtration in patients with adequate fluid resuscitation.

Vasopressin

Vasopressin, which has its own vascular receptors distinct from adrenergic receptors, has gained favor as a vasopressor in sepsis. The clinical utility of vasopressin and related molecules (e.g., terlipressin) will ultimately be determined through large clinical comparative trials with other vasopressor agents.

Dobutamine

Dobutamine, a beta agonist, may improve cardiac output and oxygen delivery in some patients in septic shock who have low cardiac output. However, dobutamine may result in peripheral vasodilatation, which may be harmful in septic patients. Moreover, dobutamine increases myocardial oxygen consumption by its positive inotropic effects, which also may be detrimental. In one randomized trial in a heterogeneous group of critically ill patients, the use of dobutamine to boost the cardiac index and systemic oxygen delivery failed to improve outcome.[84]

VASODILATOR THERAPY

Another approach to improving the delivery of oxygen to the tissues of patients with septic shock is the use of vasodilators to open up poorly perfused capillary beds. Spronk and colleagues[85] recently presented a study of nitroglycerin therapy after intravascular volume resuscitation. Using an optical device to measure microcirculatory flow (orthogonal polarization spectral imaging), improved microvascular flow rates were achieved in septic patients who received adequate fluid repletion. This is an

Table 6 Suggested Empirical Antibiotic Choices in Severe Sepsis

Source of Infection	*Antimicrobial Choice*
Community-acquired pneumonia	Third-generation cephalosporin with a macrolide (alternative: fluoroquinolones)
Hospital-acquired pneumonia	Third- or fourth-generation cephalosporins, extended-spectrum penicillins with or without an aminoglycoside (alternatives: fluoroquinolones, carbapenems, β-lactam–β-lactamase inhibitor)
Urinary tract infections	Extended-spectrum β-lactam agent with or without an aminoglycoside (add ampicillin or vancomycin when enterococci are present)
Intra-abdominal infections	Third- or fourth-generation cephalosporins with or without metronidazole or clindamycin or extended-spectrum penicillins or β-lactam–β-lactamase inhibitor with or without an aminoglycoside (alternatives: carbapenem, trovafloxacin)
Biliary tract infections	Extended-spectrum penicillin with or without an aminoglycoside
Neutropenic patients	Extended-spectrum β-lactam agent with an aminoglycoside (add vancomycin when there is evidence of gram-positive infection)

appealing strategy to improve tissue oxygenation in septic shock, and it deserves further clinical trials.

The most reliable indicator to assess the adequacy of tissue perfusion in septic shock is not known. Numerous methods of measurement of tissue oxygenation (e.g., gastric tonometry, hepatic venous oxygen measurements, direct tissue oxygen measurements, and microcirculatory probes) have been developed to better measure and understand the critical requirements for oxygen delivery to tissues of septic patients. However, the practical value of these measurements in the clinical management of sepsis remains unclear. Moreover, there remains evidence that even with adequate oxygen delivery, dysoxia may develop in patients with sepsis because intracellular oxygen utilization is impaired by dysfunction of respiratory enzymes.

PREVENTING AND TREATING ARDS

Efforts to prevent lung injury include innovations in respiratory support, avoidance of trauma to the alveolocapillary units from excessive tidal and fluid volume, avoidance of oxidant-induced lung injury, salvage of functional alveolocapillary units through position change (prone position), and judicious fluid management.[86] Measurable improvements in the outcome of patients with ARDS have occurred, but considerable room for improvement remains in regard to the sparing of pulmonary function in patients with septic shock.

A major finding in regard to ARDS management was recognition of the hazard of providing excessive tidal volume through overly high ventilator settings. The resulting overdistention of airways can promote the progression of lung injury and the release of inflammatory mediators into the systemic circulation.[87] The ARDS clinical trials network study demonstrated conclusively that low stretch tidal volume settings (6 ml/kg) are clearly superior to the previous conventional high tidal volume setting (12 ml/kg).[88] Consequently, low tidal volume ventilation is now the standard of practice in the management of most forms of acute lung injury.

BLOOD TRANSFUSIONS

The role of blood transfusions in improving the oxygen-carrying capacity of blood has been the subject of considerable debate.[89] Humans have been shown to be remarkably resistant to adverse effects from isovolumetric reduction in hemoglobin values.[90] Banked, stored RBCs are less deformable, are less efficient at releasing oxygen from their 2,3-biphosphoglycerate–depleted hemoglobin stores, and may have immunosuppressive effects.[91] Promotion of endogenous erythrocyte production with erythropoietin may prove to be superior to blood transfusions[92]; further clinical trials with this treatment approach are warranted.

The hemoglobin level at which transfusion is indicated in septic shock has not been defined, but it appears to be considerably lower than the traditional threshold of less than 10 g/dl. Recent studies in ICU patients indicate that a conservative threshold, set as low as 7 g/dl, may in fact be preferable.

MANAGEMENT OF MULTIORGAN FAILURE

Expert management of acute renal failure [*see 10:VI Acute Renal Failure*], ARDS [*see 14:X Pulmonary Edema*], hepatic decompensation, coagulopathy, acid-base disturbances, and disordered hemodynamics is of paramount importance in the management of sepsis. Multiorgan failure is potentially reversible if rapid interventions correct the hemodynamic and inflammatory abnormalities.

NUTRITIONAL SUPPORT

Nutritional support in septic shock has changed considerably over the past 2 decades. Reliance on total parenteral nutrition has given way to early and extensive use of enteral hyperalimentation. Enteral feeding of septic patients has been shown to benefit enterocyte function, help maintain the intestinal permeability barrier, and help prevent gut-derived endotoxin and cytokine generation.[93] Nutritional supplementation with glutamine, arginine, and omega-3 fatty acids has experimental support and is increasingly being used in septic patients[94] [*see 4:XIII Enteral and Parenteral Nutrition*]. The incremental value of such enriched enteral formulations over standard enteral alimentation has not yet been confirmed in large clinical trials.

MANAGEMENT OF FEVER

Fever is a common concomitant of severe sepsis and appears to be an advantageous response.[95] In experimental animals with *Klebsiella pneumoniae* peritonitis, infection resolved and subjects recovered more rapidly when they were allowed to develop fever, compared with control animals in which normothermia was maintained externally.[96] Heat-shock proteins function as intracellular chaperones to stabilize and prevent denaturation of host proteins. Heat-shock protein induction may actually decrease the mortality associated with experimental endotoxin challenge.[97] Efforts to lower body temperature with cooling blankets are largely ineffective and may not benefit the patient in septic shock. This strategy should generally be avoided unless true hyperthermia is present.[98]

ANTIMICROBIAL THERAPY

The most appropriate antimicrobial therapy in sepsis depends on the source of infection, susceptibility patterns of microbial pathogens within a given institution, prior antimicrobial exposure, presence or absence of pregnancy, hepatic and renal function, and history of drug allergy. In septic shock, combinations of bactericidal antimicrobial agents are generally given on an empirical basis [*see Table 6*]. Antibiotic combinations decrease the

Table 7 Current Adjuvant and Experimental Therapies in the Treatment of Septic Shock

Experimental Agent	*Treatment Target*	*Comment*
Bactericidal/permeability-increasing protein	Endotoxin	Endotoxin-neutralizing human protein
Anti-CD14 antibody	Endotoxin/peptidoglycan	Endotoxin and peptidoglycan blocker
E5564	Endotoxin	Lipid A antagonist
Polymyxin B–binding columns	Endotoxin	Endotoxin-binding antibiotic
Platelet-activating factor (PAF)–acetylhydrolase	PAF	Rapid metabolism of PAF
FAB 2′ anti–tumor necrosis factor (TNF) monoclonal antibody	TNF	Neutralizes TNF in the circulation
Low-dose corticosteroids*	Adrenal function	Treat adrenal hypofunction of sepsis
Activated protein C†	Coagulation system	Inhibits disseminated intravascular coagulation, microthrombi
Hemoperfusion systems	Cytokines and endotoxin	Remove inflammatory mediators and endotoxin during hemoperfusion
Nitroglycerin infusion	Disordered microcirculation	Opens up poorly perfused capillary beds along with I.V. fluids
Arginine, glutamine, nucleic acids, micronutrients	Immunonutrition	Improve immune function and provide antioxidants
Caspase inhibitors	Cellular apoptosis	Block excess apoptosis of immune cells and endothelial cells

*One recent clinical trial demonstrated benefit; another study is ongoing.

†Approved for use in severe sepsis in patients at high risk of mortality (such as an APACHE II [Acute Physiology and Chronic Health Evaluation-II] score > 24 or multiorgan failure); its use in early, less severe sepsis is currently under investigation.

risk that a multidrug-resistant microbial pathogen will be missed and increase the probability that all of the important pathogenic microorganisms will be inhibited by at least one of the antimicrobial agents. Concern continues regarding antibiotic-induced endotoxin release in sepsis, but the clinical relevance of this effect has not been demonstrated and should not affect antibiotic choices for septic shock patients.[99]

MANAGEMENT OF BLOOD GLUCOSE LEVELS

Tight regulation of blood glucose levels is an important supportive management technique in sepsis. Van den Berghe and colleagues[77] reported improved survival, shorter ICU stays, and less bacteremia in patients with strict glycemic control (target was continuous euglycemia) versus conventional care in a cardiovascular ICU setting.

New Therapies for Sepsis

Over the past 15 years, more than 30 double-blind, placebo-controlled, multicenter, phase 2 or phase 3 trials have been conducted to study the efficacy of new experimental agents in the treatment of septic shock.[1,26,100-102] After a long list of disappointments, two recent studies have now shown convincing positive results. The study of recombinant human activated protein C (drotrecogin alfa activated; see above) represents the first successful phase 3 international trial in severe sepsis.[51] This clinical trial resulted in Food and Drug Administration approval of drotrecogin alfa activated (Xigris) for the treatment of adult patients with severe sepsis who have an especially high risk of dying from sepsis. Carefully selected patients benefit from this treatment regardless of the type of infecting microorganism that caused their sepsis. The drug is given as a continuous infusion at 24 µg/kg/hr for 4 days. Because protein C is an endogenous anticoagulant, the major side effect of treatment is bleeding.[50]

The second successful trial was a multicenter clinical study of low-dose corticosteroids. Annane and coworkers reported a significant improvement in survival in patients with vasopressor-dependent septic shock through the use of hydrocortisone (50 mg every 6 hours for 7 days) and fludrocortisone (50 µg/day for 7 days).[75] This treatment strategy is based on the frequent occurrence of relative adrenal insufficiency in patients with septic shock. In fact, low-dose corticosteroid therapy was effective only in those patients who showed evidence of inadequate adrenal response when given a short corticotropin test.[100] A large clinical trial is under way in Europe and Israel to confirm and extend these exciting results; meanwhile, a German study in 40 patients with septic shock has provided supporting evidence.[103] A follow-up study with a larger number of patients would be worthwhile (the Annane study involved 299 patients), but to date, low-dose corticosteroids appear to be a cost-effective, readily available, and relatively safe treatment option for patients with refractory septic shock.

These improvements in treatment strategies for septic patients reflect the newly heightened understanding of molecular events that underlie sepsis pathophysiology. It is anticipated that forthcoming innovations in therapy [*see Table 7*] will lead to further improvements in outcome in severe sepsis/septic shock. The genomics era has already provided insights into variations in the risk of developing sepsis[104] and differential responses to therapeutic agents.[105] Much work remains to be done to provide optimal care of the ever-growing septic patient population.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XXXI VIRAL ZOONOSES

Lyle R. Petersen, m.d., m.p.h.
Duane J. Gubler, sc.d.

Zoonoses are human diseases caused by pathogens that normally infect animals. About 534 zoonotic viruses from eight taxonomic families have been identified, 120 of which are known to cause human illness [*see Tables 1 and 2*]. The natural hosts of zoonotic viruses are usually unaffected by the viruses. Infection in humans may cause no obvious illness, a nonspecific viral syndrome, or more severe illness that generally falls into one of three categories: hemorrhagic fever, encephalitis, or rash arthralgia [*see Table 1*].

Transmission of Zoonotic Viruses

Zoonotic viruses replicate in the reservoir animal host and are usually transmitted to humans by direct contact or the bite of a hematophagous (blood-sucking) arthropod. Transmission by direct contact normally involves a bite by the infected reservoir animal or handling of the animal's tissues or materials contaminated by the animal's body fluids. Most viral zoonoses require a blood-sucking arthropod for transmission to humans. Mosquitoes are the most important arthropod vectors, followed by ticks, sandflies, and midges. Arthropod vector–borne viruses are called arboviruses and are maintained in complex life cycles involving a nonhuman primary vertebrate host and a primary arthropod vector [*see Figure 1*]. The arthropod vector usually becomes infected when it ingests virus while feeding on the blood of a viremic animal. Virus replicates in the arthropod tissues, ultimately infecting the salivary glands. The arthropod then transmits the virus to a new host when it injects infective salivary fluid while taking a blood meal. This extrinsic incubation period (i.e., the time between ingestion and transmission of the virus) is usually 8 to 12 days, depending on environmental factors, the virus, and the vector species.

Arthropod-borne viruses generally remain undetected until humans encroach on the natural enzootic focus or until the virus escapes the primary cycle via a secondary vector or vertebrate host [*see Figure 1*]. Although humans may become ill, they are generally considered dead-end hosts because they do not develop sufficient viremia to infect feeding vectors and thus do not contribute to the transmission cycle. Notable exceptions include dengue, yellow fever, chikungunya, and Ross River virus infection [*see Table 1*].

Hemorrhagic Fevers

Hemorrhagic fevers are diseases, generally viral, that often cause extensive bleeding in humans. Specific laboratory diagnosis of hemorrhagic fevers usually requires special serologic or virologic tests, such as enzyme-linked immunosorbent assays (ELISAs) to detect virus-specific immunoglobulin M (IgM) or immunoglobulin G (IgG) antibody, or other tests such as hemagglutination-inhibition, complement fixation, and neutralization tests on paired serum samples taken during the acute and convalescent phases of illness. Some viruses produce viremia [*see Table 1*] and can be isolated from, or detected in, the acute-phase serum or cerebrospinal fluid by polymerase chain reaction (PCR) or immunohistochemistry (IHC) testing of autopsy tissues. Clinicians who suspect a hemorrhagic fever in one of their patients can have samples sent through their state health department to the Centers for Disease Control and Prevention (CDC) for testing.

VIRUSES OF THE FAMILY FLAVIVIRIDAE

Dengue Fever

The dengue virus complex (family Flaviviridae, genus *Flavivirus*) consists of four antigenically related serotypes (DEN-1, DEN-2, DEN-3, and DEN-4). Although there is extensive cross-reactivity between dengue virus serotypes in serologic tests, there is no lasting cross-protective immunity in humans; cross-protection lasts for only a few months. Thus, individuals can have as many as four dengue infections in their lifetime, one from each serotype.[1]

Epidemiology All four dengue virus serotypes have a worldwide distribution in the tropics and are maintained in tropical rain forests of Asia and Africa in a mosquito-monkey-mosquito cycle and in most tropical urban centers in a mosquito-human-mosquito transmission cycle.[1] The forest cycle is not considered important in terms of public health. A map of countries reporting dengue can be found at www.cdc.gov/ncidod/dvbid/dengue/index.htm. In many urban centers, multiple virus serotypes cocirculate (a phenomenon known as hyperendemicity). An estimated 50 to 100 million infections occur annually. The principal mosquito vector is *Aedes aegypti,* an African species that spread around the world during the 17th, 18th, and 19th centuries via the slave trade and shipping industry. *Ae. aegypti* became well adapted to living in intimate association with humans and is a highly efficient epidemic vector in urban settings. Secondary vectors include other *Aedes (Stegomyia)* species such as *Ae. albopictus, Ae. polynesiensis*, and *Ae. scutellaris*. These secondary vector species can transmit dengue viruses during outbreaks, but they are more important as maintenance vectors.

Diagnosis In the United States, dengue fever should be suspected in a traveler who falls abruptly ill within 2 weeks of returning from the tropics. Infection with dengue viruses can be inapparent or can cause a spectrum of clinical illness ranging from a mild, nonspecific viral syndrome to classic dengue fever to severe and fatal hemorrhagic disease. The classic form usually affects adults and older children; in young children, the illness is usually mild but may be severe. After an infective mosquito bite, there is an incubation period of 3 to 14 days (average, 4 to 7 days), followed by the sudden onset of fever (which is often biphasic—with 2 to 5 days of fever, followed by a 1- to 2-day afebrile period, and then 1 to 2 days of fever), severe headache, chills, retro-orbital pain, and generalized, severe pain in the muscles and joints. A maculopapular rash generally appears on the trunk between the third and fifth days of illness and spreads to the face and extremities. Nausea, vomiting, lymphadenopathy, anorexia, constipation, and altered taste sensation are common. Occasionally, petechiae are seen on the dorsum of the feet, legs, hands, axillae, and palate late in the illness. The illness generally lasts 5 to 7 days, after which recovery is complete, although convalescence may be prolonged. Leukopenia with a relative lym-

phocytosis and thrombocytopenia may occur. Liver enzyme levels may be elevated, and hemorrhagic manifestations may occur. Neurologic manifestations such as encephalopathy and seizures may occur during the disease's febrile stage.[2,3]

The diagnosis of dengue infections should be based on clinical signs and symptoms and on epidemiologic information such as travel history. Laboratory testing is useful only for confirmation of the clinical diagnosis. The IgM-capture ELISA is the serologic test of choice for dengue infection.

Treatment and prevention Treatment of dengue fever is supportive; there are no antiviral agents that are effective for the disease. Prevention consists of environmental control (see below).

Table 2 Principal Hantaviruses That Cause Human Disease

Virus	*Disease*	*Geographic Distribution*	*Primary Host in Nature*
Dobrava	HFRS (severe)	Balkans	*Apodemus flavicollis* (yellow-necked field mouse)
Hantaan	HFRS (severe)	Asia	*Apodemus agrarius* (striped field mouse)

Sin Nombre	HPS	North America	*Microtus pennsylvanicus* (meadow vole)

HFRS—hemorrhagic fever with renal syndrome HPS—hantavirus pulmonary syndrome

Dengue Hemorrhagic Fever

Epidemiology Dengue hemorrhagic fever (DHF) is a severe form of dengue infection that is most commonly observed in children younger than 15 years in Southeast Asia and in all age groups in the Americas and the Pacific region.[4,5]

Pathogenesis The pathogenesis of DHF is still not well understood. Classic DHF with a vascular leak syndrome may have a unique immunopathologic basis that is associated with enhancement of viral infection of mononuclear phagocytes in patients with dengue antibodies from a previous infection with a different serotype (heterologous antibody).[6] Infection of mononuclear phagocytes stimulates the release of vasoactive mediators, leading to a cascade of events that result in increased vascular permeability.

Although the risk of DHF is higher in patients experiencing a second dengue infection, DHF also occurs in patients who have primary infections; thus, heterologous dengue antibody (previous infection) is not a prerequisite for DHF. Furthermore, some strains of dengue viruses cannot be enhanced in vitro. Both field evidence and laboratory evidence support a more prominent role of viral factors in the pathogenesis of DHF and suggest that virus strain and serotype are also important risk factors for severe disease.[1,3,6-8] Hemorrhage may occur without vascular leakage, suggesting another pathogenetic mechanism.[3,9]

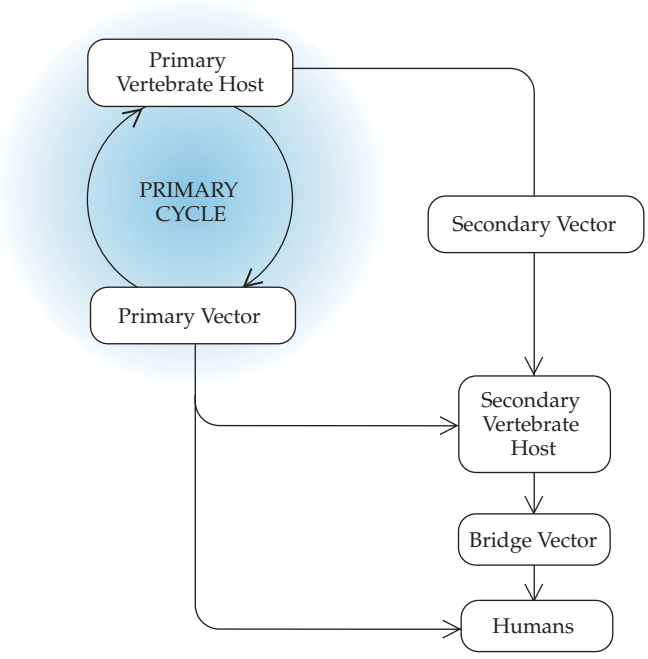

Figure 1 **Generalized arbovirus maintenance cycle.**

Diagnosis DHF is characterized by sudden onset of fever, usually lasting 2 to 7 days, and nonspecific signs and symptoms.[1] The critical stage of DHF occurs between 24 hours before and 24 hours after the patient's temperature falls to or below normal. During this time, hemorrhagic manifestations usually occur, and signs of circulatory failure may appear. The patient may become restless or lethargic, experience acute abdominal pain, and have cold extremities and oliguria, usually on or after the third day of illness. Clinical laboratory tests at this time will show thrombocytopenia (platelet count < 100,000/mm^3), a low serum total protein level, a low albumin level, and a rise in hematocrit secondary to plasma leakage from the vascular compartment. Another indication of vascular leakage is pleural effusion. Loss of intravascular volume may result in hypovolemia, shock, and death if not corrected. The most common hemorrhagic manifestations are skin hemorrhages, but epistaxis, bleeding gums, gastrointestinal hemorrhage, and hematuria may occur.

Treatment and prevention Early diagnosis and prompt management with fluid replacement therapy can substantially reduce case-fatality rates.[10] Initial management and treatment decisions should not be delayed pending results of serologic tests. Clinical laboratory tests should be used to monitor vascular leakage.[10]

There is no licensed vaccine for dengue/DHF, although significant progress is being made toward the development of live attenuated and recombinant candidate vaccines using infectious clone technology.[11,12] Currently, disease prevention depends exclusively on mosquito control and personal protective measures such as the use of mosquito repellents.

Yellow Fever

Epidemiology Yellow fever virus (family Flaviviridae, genus *Flavivirus*) is believed to have originated in Africa. The disease is now present in tropical America and Africa but does

not occur in Asia. Like dengue, yellow fever virus has two transmission cycles: jungle and urban. The jungle or forest transmission cycle involves canopy-dwelling mosquitoes and monkeys. The urban cycle involves humans as the vertebrate host and *Ae. aegypti* as the principal vector. In the past 30 years, *Ae. aegypti* has reinvaded Central and South America, putting the American tropics at the highest risk for urban epidemics of yellow fever in over 60 years. Epidemics in Africa often occur in moist savanna regions; forest or peridomestic *Aedes* mosquitoes and humans are the viremic hosts. In dry areas and urban centers where water storage practices promote the breeding of domestic *Ae. aegypti,* this mosquito is responsible for epidemic transmission. Several hundred thousand people are infected yearly, and outbreaks are frequent. Cases among unvaccinated travelers are rare; however, since 1996, six travelers have died in the United States and Europe of yellow fever acquired in South America and Africa.

Diagnosis Yellow fever varies from an inapparent infection to a deadly fulminating hemorrhagic disease. Three clinical stages are commonly recognized: infection, remission, and intoxication.[13,14] After an incubation period of 3 to 10 days, the period of infection begins with sudden onset of fever, rigors, headache, and backache. In severe cases, the patient is intensely ill and restless, with flushed face, swollen lips, bright-red tongue, congested conjunctivae, and bleeding. There may be bradycardia relative to fever (Faget sign). This stage is followed after 2 to 3 days by a brief period of remission. Remission is often not obvious. The period of intoxication occurs on the third to sixth day after illness onset in about 15% of patients. This period consists of moderate or severe disease with jaundice. Fever returns with relative bradycardia, along with nausea, vomiting, a hemorrhagic diathesis, hypotension, albuminuria, oliguria, and anuria.

Most patients with severe disease will have leukopenia, thrombocytopenia, elevated levels of serum creatinine and liver enzymes, and coagulation defects. The jaundice, which gives the disease its name, is generally apparent only in convalescing patients. In fatal cases, death usually occurs within 7 to 10 days; case-fatality rates vary widely, but they can exceed 50% in clinically ill patients.[15] At autopsy, the organs most affected are the liver, spleen, kidneys, and heart. Typically, the liver shows midzonal hyaline necrosis and Councilman inclusion bodies.

The initial diagnosis of yellow fever should be based on clinical signs and symptoms and on epidemiologic information such as vaccination history and recent travel to an endemic area [*see CE:VII Health Advice for International Travelers*]. Laboratory diagnosis is made by detection of virus, viral antigen, or viral nucleic acid or by serologic examination. Virus is often isolated from blood during the first 4 days of illness. Serologic tests may be negative during the first week of illness. Diagnostic testing for yellow fever may be obtained by request to the CDC through state and local health departments.

Treatment and prevention Treatment is supportive. Yellow fever is an international reportable disease, and immunization is required for travelers to many countries of sub-Saharan Africa and tropical America. The live, attenuated 17D vaccine, delivered as a single 0.5 ml subcutaneous dose, is highly effective. Immunity is probably lifelong, but for travel certification, revaccination is recommended every 10 years. Information about indications for yellow fever vaccine and requirements for international travel are available at www.cdc.gov/travel/reference.htm.[16,17] For patients who require immunization, the locations of designated yellow fever vaccination centers can be obtained through local health departments. The CDC also provides an extensive list of yellow fever vaccination clinics on its Web site.

Although the 17D vaccine is one of the safest vaccines, rare cases of severe and fatal infection from vaccination have been reported. The elderly may experience a higher incidence of serious adverse events.[18,19] Persons with documented egg allergy should not be immunized or should be skin-tested with the vaccine. The vaccine must not be given to children younger than 6 months, in whom there is a risk of postvaccinial encephalitis, and it is best to delay vaccination until 9 months of age. On theoretical grounds, persons with immunosuppression, including those with clinical AIDS, should not be immunized. Immunization during pregnancy is generally contraindicated.

Other Flaviviruses

Other hemorrhagic diseases caused by flaviviruses include Kyasanur Forest disease in India and Saudi Arabia and Omsk hemorrhagic fever in Russia [*see Table 1*]. Both are tick-borne diseases and are rare in comparison with disease from mosquito-borne flaviviruses.

VIRUSES OF THE FAMILY BUNYAVIRIDAE

Crimean-Congo Hemorrhagic Fever

Epidemiology and etiology Crimean-Congo hemorrhagic fever (CCHF) virus (family Bunyaviridae, genus *Nairovirus*) is transmitted by ticks, primarily of the genus *Hyalomma*, over a broad geographic range that includes sub-Saharan Africa, eastern Europe and Russia, the Middle East, and western China.[14,20] Humans become infected after a tick bite; after parenteral exposure to, or contact with, blood from acutely ill patients[20]; or, on occasion, after the slaughter of sick domestic animals. Disease may be seasonal in humans, reflecting the natural abundance of ticks.

Table 3 Arenaviruses That Cause Significant Human Illness

Virus	*Disease*	*Geographic Distribution*	*Primary Host in Nature*
Lymphocytic choriomeningitis virus	Lymphocytic choriomeningitis	Americas, Europe, parts of Asia	*Mus musculus* (house mouse)
Lassa virus	Lassa fever	West Africa	*Mastomys* species (rodent)
Junin virus	Argentine hemorrhagic fever	Argentina	*Calomys musculinus* (rodent)
Machupo virus	Bolivian hemorrhagic fever	Bolivia	*Calomys callosus* (rodent)
Guanarito virus	Venezuelan hemorrhagic fever	Venezuela	*Zygodontomys brevicauda* (rodent) *Sigmodon alstoni* (?) (rodent)
Sabia virus	Hemorrhagic fever	Brazil	Unknown

Diagnosis In the United States, CCHF should be suspected in a traveler who falls abruptly ill less than 2 weeks after returning from an endemic area. The incubation period for CCHF is 3 to 7 days for nosocomial infections and up to 12 days for those infected by a tick bite, followed by abrupt onset of fever, headache, myalgia, weakness, nausea, and vomiting. This initial phase may last 2 to 3 days, followed by remission of several hours' duration in one third to two thirds of patients. The second phase of illness is associated with hemorrhagic manifestations, which may last from 3 days to as long as 10 days and includes, most commonly, petechiae over the chest and abdomen, epistaxis, ecchymoses, bleeding from puncture sites, melena, and hematuria. Those surviving the hemorrhagic phase enter a convalescent phase characterized by normalization of fever, cessation of hemorrhages, occasionally transient hair loss, and prolonged fatigue and dizziness.[20] Mortality ranges from 9% to 40%.

Treatment and prevention Treatment is supportive and focuses on the hemorrhagic manifestations. The antiviral drug ribavirin has been administered to a limited number of patients with apparent success.[21] Persons in endemic areas should take protective measures to prevent exposure to infected ticks, and barrier methods should be used in hospitals where patients with suspected CCHF are being treated.

Hantavirus Infections

Hantaviruses (family Bunyaviridae, genus *Hantavirus*) are rodent-borne viruses causing human diseases known as hemorrhagic fever with renal syndrome (HFRS) in Europe and Asia and as hantavirus pulmonary syndrome (HPS) in the Americas.[22] The prototype hantavirus is Hantaan virus, which causes epidemic hemorrhagic fever in China and Korea, but many different hantaviruses are now recognized. Hantaviruses are maintained in nature by chronic infection of rodent hosts, and each is principally associated with a specific rodent host [*see Table 2*]. Antibodies against hantaviruses are also present in domestic and wild animals such as cats, dogs, pigs, cattle, and deer. German investigators are examining whether hantaviruses can be transmitted from rats to cattle, because the incidental infection of species other than rodents has the potential to influence the pathogenicity and virulence of the virus.[23]

Humans are infected after aerosol exposure to infectious excreta or occasionally by bites. Apparent human-to-human transmission was noted in one outbreak with the Andes virus.[24]

The incidence of hantavirus infections in humans often fluctuates with rodent densities and human activities that increase contact with contaminated materials. Commonly infected groups are military personnel on field maneuvers, shepherds, woodcutters, campers, and others involved in outdoor activities.

Hemorrhagic fever with renal syndrome Along with Hantaan virus, other hantaviruses causing HFRS are Seoul virus, Puumala virus, and Dobrava/Belgrade virus. Classic HFRS caused by Hantaan or Dobrava virus infection has a variable incubation period and is characterized by five phases: (1) a febrile phase of 3 to 7 days, with fever, malaise, headache, abdominal pain, nausea, vomiting, facial flushing, petechiae, and conjunctival hemorrhage; (2) a hypotensive phase of a few hours to 3 days, when hypotension, shock, blurred vision, hemorrhagic signs, and a drop in blood pressure occur; (3) an oliguric phase of 3 to 7 days, during which oliguria or anuria predominates and hemorrhagic manifestations may worsen; (4) a diuretic phase of days to weeks, when polyuria predominates; and (5) a prolonged convalescent phase of weeks to months.[22] Mortality in classic HFRS results from shock, multiorgan hypoperfusion, or uremia and ranges from 1% to 10%. Infection with Puumala virus or Seoul virus produces milder disease, with lower mortality. Serology is the main diagnostic tool, but it should be used only for confirmatory retrospective diagnosis.[22]

Early treatment with ribavirin may reduce hemorrhage, renal failure, and mortality in HFRS.[25] Commercially available inactivated vaccines for Hantaan virus or bivalent Hantaan/Seoul virus vaccines are produced in Korea and China; other vaccines are in development.[26] Control of HFRS relies on reduction of human-rodent contact through good sanitation and waste management, rodent control, and making buildings rodent proof.

Hantavirus pulmonary syndrome Since its discovery in 1993 during an outbreak in the southwestern United States, several hundred cases of HPS have been identified in the Americas.[27] The Sin Nombre virus, which is carried by deer mice, caused the initial outbreak; subsequently, a number of related hantaviruses hosted by other sigmodontine rodents have been identified as a cause of human disease [*see Table 2*].

Diagnosis HPS should be suspected on the basis of the clinical picture, clinical laboratory results, and radiologic findings; confirmation of diagnosis is by serologic testing. Diagnostic information about HPS, including instructions on submitting suspected HPS specimens for serologic testing, can be obtained from the CDC at www.cdc.gov/ncidod/diseases/hanta/hps/index.htm.

The incubation period of HPS probably ranges from 9 to 33 days. Clinical disease can be divided into four phases: febrile, cardiopulmonary, diuretic, and convalescent.[28] The febrile phase, typically lasting 3 to 5 days, is characterized by fever, myalgia, and malaise. Headache, dizziness, anorexia, nausea, vomiting, and diarrhea may occur. The cardiopulmonary phase is marked by pulmonary edema and shock. Once pulmonary edema develops, the rapid onset of circulatory compromise and hypoxia often leads to death. During the diuretic phase, pulmonary edema clears, along with resolution of fever and shock. The convalescent phase may last several months; complete recovery is the rule. Renal insufficiency has been reported with the Sin Nombre virus and is a more constant feature of many of the newly recognized American hantaviruses causing HPS, suggesting that HPS and HFRS are not as clinically distinct as previously thought. Thrombocytopenia is almost universally present. Mortality is approximately 40% but varies with the infecting virus.

Treatment of patients with HPS remains supportive. Early intensive care management is important, with prompt correction of electrolyte, pulmonary, and hemodynamic abnormalities. Vaccines are in development.[26] Despite its in vitro activity against Sin Nombre virus, ribavirin failed to produce a dramatic reduction in case fatality in an open-label trial.[29]

Rift Valley Fever

Epidemiology and etiology Rift Valley fever (RVF) is caused by the RVF virus (family Bunyaviridae, genus *Phlebovirus*). First described during a fatal epizootic in sheep that occurred in the Rift Valley of Kenya in 1931, RVF is a mosquito-borne disease affecting domestic ungulates, especially goats and sheep.[14] Large epizootics occur during periods of heavy rainfall. Humans become infected through the bite of an infected mosquito, by infec-

Table 4 Viral Zoonoses Endemic in the United States

Disease	*Region*	*Vector/Host*	*Clinical Manifestations*
Colorado tick fever	Mountainous areas of western states	Wood ticks	Flulike illness, rash, leukopenia
Eastern equine encephalitis	Focal locations along eastern seaboard, Gulf Coast, and some midwestern states	Mosquitoes	Mild flulike illness to encephalitis
Hantavirus pulmonary syndrome	Most prevalent in southwestern states	Deer mice and other rodents (aerosol exposure to infected excreta, or bites)	Febrile, cardiopulmonary, diuretic, and convalescent phases
La Crosse virus	Widespread; most prevalent in rural upper Midwest	Mosquitoes	Mild flulike illness to encephalitis, often with focal seizures
Powassan virus encephalitis	Northeastern states	*Ixodes* ticks	Encephalitis, with localizing neurologic signs and convulsions
Rabies	All except Hawaii	Wild carnivores, bats	Encephalomyelitis
St. Louis encephalitis	All lower 48 states; epidemics in Midwest and Southeast	Mosquitoes	Febrile headache to encephalitis
West Nile virus infection	Eastern states	Mosquitoes	Febrile illness to encephalitis
Western equine encephalitis	Western states	Mosquitoes	Mild flulike illness to encephalitis

tious aerosols when sick animals are slaughtered, or by occupational exposure (e.g., veterinarians attending to infected animals). Large human outbreaks have occurred in sub-Saharan Africa, Egypt, and more recently on the Saudi Arabian peninsula.[14] RVF virus is a potential agent of bioterrorism.

Diagnosis The incubation period in humans is 2 to 6 days. This is followed by abrupt onset of fever, headache, chills, and malaise. Uncomplicated illness usually resolves within 2 to 3 days. Retinitis, hemorrhagic fever, and encephalitis occur in rare instances.

Treatment and prevention Treatment is supportive, although the antiviral drug ribavirin has been effective in the treatment of related viruses of the family Bunyaviridae and deserves further investigation. Inactivated and live attenuated vaccines have been produced for use in domestic animals and appear to be efficacious. No vaccine is commercially available for use in humans, although an experimental inactivated vaccine has been used to protect select populations at risk for laboratory or occupational exposure.[14]

VIRUSES OF THE FAMILY ARENAVIRIDAE

Significant human illnesses caused by Arenaviridae viruses include lymphocytic choriomeningitis; Lassa fever; and Argentine, Bolivian, and Venezuelan hemorrhagic fever. Arenaviruses are transmitted directly to humans after close rodent-human contact, such as touching objects or eating food contaminated with rodent excreta [*see Table 3*]. Human-to-human transmission of Lassa fever has occurred. Several of the arenaviruses are considered potential agents of bioterrorism.

Diagnosis

Arenaviral infections typically begin with fever, malaise, headache, and GI symptoms. More severe cases may involve the heart, lungs, liver, and kidneys. Fulminant and often fatal hemorrhagic shock occurs in a minority of cases (e.g., about 20% of hospitalized Lassa fever patients). Lassa fever is especially severe in pregnant women, often causing death in both mother and fetus. Hearing loss (of varying degrees) is a common sequela of Lassa fever, even in mild cases.

Several cases of Lassa fever have been imported into Europe, Japan, and the United States in recent years. Consequently, the clinician should consider the diagnosis in patients who experience a febrile illness within 3 weeks after travel to endemic countries in West Africa (i.e., Nigeria, Guinea, Liberia, and Sierra Leone). South American arenaviruses should be considered in the differential diagnosis of hemorrhagic fever in patients with a history of travel to that region. Because its symptoms are varied and nonspecific, arenavirus infection can be confirmed by serology, most commonly with ELISA, which can be requested from the CDC through state and local health departments.

Treatment and Prevention

The antiviral drug ribavirin reduces mortality from Lassa fever, especially if started within the first 6 days after the onset of fever. Ribavirin may be of value in the treatment of other arenaviral infections as well, although efficacy cannot be fully validated because of a lack of clinical experience.[30] A live, attenuated vaccine of proven efficacy has been developed for Junin virus and is available in Argentina[31]; vaccine candidates for Lassa fever are in development.

VIRUSES OF THE FAMILY FILOVIRIDAE

Marburg and Ebola viruses are among the most severe and mysterious viral pathogens to emerge in the 20th century.[32] Filoviruses share common morphology as long, pleomorphic rods but are antigenically and genetically distinct. Current understanding of these agents is largely restricted to investigations of human outbreaks and limited experimental studies conducted at the few laboratories worldwide that are able to safely handle filoviruses.

There is no vaccine or effective chemotherapy for any known filovirus. Marburg and Ebola viruses are considered potential agents of bioterrorism.

Marburg Virus

African green monkeys, *Cercopithecus aethiops,* imported from Uganda for use in research and vaccine production, were the source of the initial 31-person outbreak that led to the discovery of the Marburg virus in 1967. Human fatality was 23%.[32] In 2005, the World Health Organization confirmed an outbreak of Marburg virus infection in 124 persons in Angola.[33] Information for travelers to Angola is available from the CDC at http://www.dcd.gov/travel/other/marburg_vhf_angola_2005.htm. The ecology of Marburg virus remains virtually unknown. Marburg virus disease presents as an acute febrile illness; it can progress within 6 to 8 days to severe hemorrhagic manifestations. Clinical manifestations include fever, chills, headache, myalgia, maculopapular rash, nausea, vomiting, chest pain, and abdominal pain. Signs and symptoms can become increasingly more severe. Clinicians should consider the diagnosis of Marburg virus for febrile patients who, within 10 days before onset of fever, have traveled in northern Angola, had direct contact with blood or other body fluids of a person suspected of having hemorrhagic fever, or have worked in a laboratory that handles hemorrhagic fever viruses. No vaccine or curative treatment is available; treatment is supportive.

Ebola Virus

Epidemiology At least 1,000 persons have died from Ebola virus infection since its discovery in Sudan in 1976. Of the four known genetic subtypes of Ebola virus—Zaire, Côte d'Ivoire, Sudan, and Ebola-Reston—the first three have been associated with human disease in West and central Africa.[32] Ebola-Reston was discovered in macaques imported from the Philippines for medical research.[34] Occupational exposure to Ebola-Reston from nonhuman primates is infrequent and results in asymptomatic infection.[35]

The natural history of Ebola virus remains a mystery. Outbreaks of Ebola hemorrhagic fever are associated most often with the introduction of the virus into the community by one infected person, followed by dissemination by person-to-person transmission, often within medical facilities.[32,36]

Diagnosis Ebola virus infection has an incubation period of approximately 6 days, which is commonly followed by two clinical phases.[37] Early symptoms include fever, asthenia, diarrhea, nausea and vomiting, anorexia, abdominal pain, headaches, arthralgia, and back pain. Bilateral conjunctivitis, nonpruritic rash, and sore throat with odynophagia, when present, suggest Ebola virus infection. The second phase, characterized by hemorrhagic manifestations, neuropsychiatric abnormalities, and oligoanuria, portends a worse outcome. In recent outbreaks, bleeding occurred in a minority of patients.[32,36] Mortality during outbreaks typically exceeds 50%.

The clinical diagnosis is challenging, because the presentation is nonspecific. To exclude other infections, patients with clinical manifestations consistent with Ebola virus infection should have a blood smear examination for malaria, a blood culture, and a stool culture if they have bloody diarrhea. ELISA, PCR, and virus isolation can be used to confirm Ebola virus infection within a few days of the onset of symptoms.[38] Detailed diagnostic information is available from the CDC at http://www.cdc.gov/ncidod/dvrd/spb/mnpages/dispages/ebola.htm.

Treatment and prevention Treatment is supportive. Outbreak control rests on initiation of case finding, case isolation, and other infection-control practices, including barrier nursing procedures.[32,36]

Encephalitis

Viral encephalitis is caused by a number of arboviruses belonging to the families *Flaviviridae, Togaviridae, Bunyaviridae,* and *Reoviridae,* as well as other zoonotic viruses. Specific laboratory diagnosis of encephalitis from zoonotic viruses requires special serologic tests, such as hemagglutination-inhibition, complement fixation, and neutralization tests. ELISAs are used to detect virus-specific IgM or IgG antibody in serum or CSF samples. As with the flaviviruses, serologic tests must be cautiously interpreted, because there is considerable serologic cross-reactivity among many of these viruses of the same genus. Viruses can also be isolated and detected by PCR or immunohistochemistry in autopsy tissue. Assistance with serologic diagnosis can be obtained from the CDC at www.cdc.gov/ncidod/dvbid/index.htm and through state and local health departments.

VIRUSES OF THE FAMILY BUNYAVIRIDAE

La Crosse Encephalitis

Epidemiology La Crosse (LAC) virus (family Bunyaviridae, genus *Bunyavirus*) is the most pathogenic member of the California encephalitis serogroup, which includes the California encephalitis, trivittatus, snowshoe hare, and Jamestown Canyon viruses. LAC is maintained in a cycle involving *Ae. triseriatus* mosquitoes and a number of mammalian hosts, including the eastern chipmunk, tree squirrels, and foxes.

Human infections occur in the central and eastern United States, mostly as sporadic cases in school-age children from July through September [*see Table 4*].[39]

Diagnosis Most infections are asymptomatic. After an incubation period of 3 to 7 days, headache, fever, and vomiting develop. Seizures are a presenting finding in about half of cases, and focal neurologic abnormalities in about one fifth.[39] The combination of fever, focal signs, and focal seizures may mimic herpes simplex encephalitis. Mortality is 1%. About 10% of children have residual neurologic sequelae, including focal neurologic deficits and decreased intelligence. Diagnosis can be confirmed serologically by the CDC on the request of state and local health departments.

Treatment and prevention Treatment is supportive; management of cerebral edema and seizures is important [*see 11:XVI Acute Viral Central Nervous System Diseases*]. Ribavirin has been used, but efficacy is unproved.[39] Prevention rests on avoidance of mosquito bites.

VIRUSES OF THE FAMILY FLAVIVIRIDAE

Japanese Encephalitis

Epidemiology Japanese encephalitis (JE) is the most important global cause of arboviral encephalitis; 30,000 to 45,000 cases are reported annually. JE virus (family Flaviviridae, genus *Flavivirus*) is widespread throughout Asia. In recent years, the disease has been detected in Australia and other areas in the Pacific region. Epidemics occur in late summer in temperate regions, but the virus is enzootic and occurs throughout the year in many tropical areas of Asia. JE virus is maintained in a natural enzoot-

ic cycle involving *Culex* mosquitoes and water birds. The virus is transmitted to humans by *Culex* mosquitoes, primarily *C. tritaeniorhynchus* and related species, which breed in rice fields. Pigs are the primary amplifying hosts in the peridomestic environment.

Diagnosis Only about one in 250 infections results in symptomatic illness. The incubation period of JE is 5 to 14 days. Symptomatic illness is primarily seen in children. Mild clinical illness, such as aseptic meningitis and simple febrile illness with headache, usually goes undetected. In severe cases, the onset of symptoms is usually sudden, with fever, headache, and vomiting. The illness resolves in 5 to 7 days if there is no central nervous system involvement. Patients with CNS involvement commonly are lethargic, with expressionless faces, and have sensory and motor disturbances affecting their speech, eyes, and limbs. They may have confusion and delirium progressing to coma; in children, convulsions are sometimes a presenting sign. Weakness and paralysis may affect any part of the body. Neck rigidity and a positive Kernig sign are found, and reflexes are abnormal. Signs of extrapyramidal involvement are characteristic. Initial leukocytosis is followed by leukopenia. Mortality is 5% to 30%, with higher case-fatality rates in young children. Approximately one third of patients who recover have neurologic sequelae. The diagnosis can be confirmed serologically by the CDC on request of state and local health departments.

Prevention A formalin-inactivated mouse brain vaccine prepared with the Nakayama strain of JE virus is used internationally. Vaccination is recommended to residents in JE-endemic areas and to certain travelers to those areas. The risk to travelers is generally low, but vaccination is recommended for visitors to endemic or epidemic areas during the transmission season, especially when potential exposure will be prolonged and when there is a high likelihood of exposure to vectors.[40] Treatment is supportive. Interferon alfa was not effective against JE in a double-blind, placebo-controlled trial.[41] Further information on JE is available at www.cdc.gov/ncidod/dvbid/jencephalitis/index.htm. Mosquito control and improved animal husbandry and rice-growing practices are needed to decrease transmission risk in endemic areas.

Murray Valley Encephalitis

Epidemiology Murray Valley encephalitis (MVE) virus (family Flaviviridae, genus *Flavivirus*) was first isolated in 1951. MVE occurs only in Australia and New Guinea.[42] Like other flaviviruses, MVE virus is believed to be maintained in a natural cycle involving water birds and *Culex* mosquitoes. Viremia has not been documented in humans, who are likely dead-end hosts.

Diagnosis Only one in 1,000 to 2,000 infections results in clinical illness. Clinical illness resembles JE. Illness is characterized by the sudden onset of fever, headache, nausea and vomiting, anorexia, and myalgias, followed by drowsiness, malaise, irritability, mental confusion, and meningismus. In severe cases, there may be hyperactive reflexes, spastic paresis, convulsions, coma, and death. Of patients with neurologic disease, approximately one third die and one quarter have residual neurologic deficits.

Prevention There is no vaccine for MVE virus. Prevention relies on mosquito control and avoidance of mosquito bites.

Saint Louis Encephalitis

Epidemiology St. Louis encephalitis (SLE) virus (family Flaviviridae, genus *Flavivirus)* is prevalent throughout the Western Hemisphere from Canada to Argentina. In North America, the infection is maintained between wild birds and *Culex* mosquitoes. Although clinical illness has been sporadically reported throughout much of this region, most infections occur in North America during sporadic epidemics in the Midwest and Southeast.

Diagnosis The ratio of infection to clinical illness is high, ranging from 800 to 1 in children younger than 10 years to 85 to 1 in persons older than 60 years. Illness ranges from fever with headache to aseptic meningitis to encephalitis. Advanced age is the strongest risk factor for both symptomatic disease and severe encephalopathy. SLE should be considered in the differential diagnosis of adult viral encephalitis cases during the summer months in the United States. After an incubation period of 4 to 21 days, the illness begins with fever, headache, chills, nausea, and dysuria. Within 1 to 4 days, CNS signs appear, with meningismus, tremor, abnormal reflexes, ataxia, cranial nerve palsies, convulsions (especially in children), stupor, and coma. About 25% of very young infants have residual mental deficits, personality changes, muscle weakness, and paralysis. Overall, the case-fatality rate is about 6%, but the disease is generally milder in children (case-fatality rate of those younger than 5 years is 1%). The diagnosis can be confirmed serologically by the CDC on request of state and local health departments.

Treatment and prevention Treatment is supportive; no specific therapy is available. A pilot study indicated that early initiation of therapy with interferon alfa-2b may reduce the severity and duration of complications such as quadriplegia and quadriparesis, but a randomized trial is required to better assess the efficacy of this therapy.[43] No vaccine is available. Prevention is aimed at mosquito-bite avoidance and mosquito abatement.

Tick-Borne Encephalitis

Epidemiology and etiology Tick-borne encephalitis (TBE) is caused by two closely related viruses of the family Flaviviridae, genus *Flavivirus.*[44] The eastern subtype of the TBE virus is transmitted by *Ixodes persulcatus* and causes Russian spring-summer encephalitis, which occurs from Eastern Europe to China. The western subtype is transmitted by *I. ricinus* and causes Central European encephalitis, which occurs from Scandinavia in the north to Greece and Serbia and Montenegro in the south. Of the two subtypes, Russian spring-summer encephalitis is the more severe infection, having a mortality of 5% to 20%, compared with less than 2% for the western subtype. Both viruses are maintained in natural cycles involving a variety of mammals and ticks. Human exposure occurs through work or recreational activities in the spring and summer months in temperate zones and in fall and winter in the Mediterranean, when the ticks are most active. Infection may also occur through the ingestion of raw milk or cheese from cows, sheep, or goats.

Diagnosis The incubation period of TBE is usually 7 to 14 days. The western subtype typically produces a biphasic illness. Infection usually presents as a mild, influenzalike illness lasting 2 to 7 days, followed by an afebrile or relatively asymptomatic period lasting 2 to 10 days. Approximately one third of patients then develop higher fevers with aseptic meningitis or menin-

goencephalitis. The eastern subtype usually progresses without an asymptomatic phase. Permanent paresis develops in 2% to 10% of patients with the western subtype and in 10% to 25% of patients with the eastern subtype. Rarely, cases occur in United States citizens who visit enzootic areas. Infections can be confirmed serologically by the CDC on request of state and local health departments.

Treatment and prevention Treatment of TBE is supportive. Inactivated vaccines against both eastern and western subtypes of TBE viruses are available in Europe, but they are not commercially available in the United States[44]; candidate vaccines are in development in the United States.[45] Prevention strategies include avoiding tick bites and pasteurizing milk.

West Nile Virus

Epidemiology and etiology West Nile virus (family Flaviviridae, genus *Flavivirus*), first isolated in 1937 in the West Nile district of Uganda, has historically had a wide geographic distribution in Africa, Asia, the Middle East, and Europe.[46] The virus was first recognized in the Western Hemisphere during an epizootic among birds and horses and a human encephalitis outbreak in the New York City area in 1999.[47] From the 1950s to the 1970s, human outbreaks were reported infrequently, mostly in the Middle East. However, since the mid-1990s, outbreaks of neurologic disease in humans and horses, with an increase in death rates, may have marked the evolution of a new West Nile virus variant.[46,48] By 2002, the virus's known geographic distribution extended to southeastern Canada, the Grand Cayman Islands, and throughout the eastern United States.[48,49] Up-to-date maps of the virus's spread in the United States are available at www.cdc.gov/ncidod/dvbid/westnile/surv&control.htm. The virus has a natural maintenance cycle involving wild birds and *Culex* mosquitoes and is thought to spread via migrating birds.[46,48] In temperate climates, the incidence of infection peaks during late summer and early fall; however, year-round transmission is possible in more tropical areas. Human infections result primarily from infectious mosquito bites; however, in 2002, five new modes of transmission were recognized: blood product transfusion, organ transplantation, transplacental transmission, breast-feeding, and occupational exposure in laboratory workers.[48]

Diagnosis The incubation period of West Nile virus ranges from 3 to 14 days. Serologic surveys during recent outbreaks suggest that approximately 20% of persons who are infected develop a systemic febrile illness.[50] Common symptoms are fever; headache; myalgia; GI complaints; and an erythematous macular, papular, or morbilliform skin rash.[46,47] Lymphadenopathy may be present, but it has been reported less frequently in recent outbreaks. Overall, fewer than 1% of infected persons develop encephalitis.[50] Older persons are at increased risk for meningitis or encephalitis; once these complications develop, such individuals have a higher case-fatality rate and a higher incidence of residual neurologic deficits.[47] Of note, muscle weakness and flaccid paralysis, when present, may provide a clue to a West Nile virus etiology. Overall, case-fatality rates in severe cases are about 10%. The diagnosis is most efficiently confirmed serologically; testing can be obtained through state and local health departments.

Treatment and prevention Treatment of West Nile virus infection is supportive. Prevention relies on mosquito control and protection from mosquito bites. There is no human vaccine for West Nile virus infection. An equine vaccine is available.

Powassan Virus

Powassan virus (family Flaviviridae, genus *Flavivirus*) is related to the Eastern Hemisphere's tick-borne encephalitis viruses. It was thought to be a rare cause of encephalitis in eastern Canada and the northern United States; however, West Nile virus surveillance has increased the recognition of this pathogen.[51] The case-fatality rate is 5% to 10%, with a high incidence of residual neurologic dysfunction in survivors. Serologic surveys indicate an antibody prevalence of 1% to 4%. The virus is transmitted between *Ixodes* ticks and rodents; humans become infected via tick bites. The clinical features are those of viral encephalitis, with localizing neurologic signs and convulsions.[44] There is no specific treatment or vaccine.

VIRUSES OF THE FAMILY TOGAVIRIDAE

Eastern Equine Encephalitis

Epidemiology Eastern equine encephalitis (EEE) virus (family Togaviridae, genus *Alphavirus*) is widely distributed throughout North, Central, and South America and the Caribbean; however, little is known about the epidemiology of EEE outside North America. In the United States, human infections are usually sporadic, and small outbreaks occur each summer, mostly in the upper Midwest and along the Atlantic and Gulf coasts. In North America, wild birds and *Culiseta melanura* (a mosquito found in swamp areas that support cedar, red maple, and loblolly bay trees) maintain the virus. In central Alabama, high rates of EEE virus infection were found in *Uranotaenia sapphirina*, a mosquito that commonly feeds on amphibians and reptiles, which suggests that species other than birds may serve as a reservoir for EEE in hardwood swamps in the southeastern United States and elsewhere.[52]

Diagnosis The incubation period of EEE exceeds 1 week; onset is abrupt, with high fever. About 2% of infected adults and 6% of infected children develop encephalitis. EEE causes the most severe of the arboviral encephalitides, with a mortality of 50% to 75%. Symptoms and signs include dizziness, decreasing level of consciousness, tremors, seizures, and focal neurologic signs. Death can occur within 3 to 5 days after onset. Sequelae, which are common in nonfatal encephalitis, include convulsions, paralysis, and mental retardation. Illness from EEE in South America is less severe. Infection can be confirmed serologically by the CDC on request of state and local health departments.

Treatment and prevention No specific treatment is available. Prevention focuses on avoidance of mosquito bites and mosquito control in suburban areas. Inactivated vaccines have been used successfully in horses, and an inactivated vaccine has been used in laboratory workers or others at high risk of exposure, but it is not commercially available.

EEE is a potential agent of bioterrorism through the aerosol route.

Venezuelan Equine Encephalitis

In the Venezuelan equine encephalitis (VEE) virus (family Togaviridae, genus *Alphavirus*) complex, six subtypes (I to VI) have been identified. Five antigenic variants exist in subtype I (IAB, IC, ID, IE, and IF). These subtypes and variants are classified as

epizootic or enzootic on the basis of their apparent virulence and epidemiology. Epizootic variants of subtype I (IAB and IC) cause equine epizootics and are associated with more severe human disease. Enzootic strains (ID to IF, II [Everglades], III [Macambo, Tonate, Paramana], IV [Pixuna], V [Cabassou], VI [unnamed]) do not cause epizootics in horses, but they may produce sporadic disease in man. Epizootic strains are transmitted by many different types of mosquitoes; enzootic strains are transmitted by culicine mosquitoes. VEE has a widespread geographic distribution, from Florida to South America, where it is an important veterinary and public health problem. Focal outbreaks occur periodically, but occasionally, large regional epizootics occur, with thousands of equine and human infections.

VEE is infectious via aerosols, making it an occupational risk to certain laboratory workers and a potential agent of bioterrorism.

Diagnosis After an incubation period of 1 to 6 days, there is a brief febrile illness of sudden onset, characterized by malaise, nausea or vomiting, headache, and myalgia.[53] Fewer than 0.5% of adults and fewer than 4% of children develop encephalitis. Long-term sequelae and fatalities are uncommon.

Treatment and prevention Treatment is supportive. Effective prevention of both human and equine disease can be accomplished by immunizing horses and other equine animals, which serve as the primary amplification host for the epizootic VEE viruses and without which there would be little human disease. During epidemics, mosquito vectors can be controlled by insecticides. Live attenuated and inactivated vaccines have been used for laboratory workers; however, human vaccines are not commercially available.

Western Equine Encephalitis

Western equine encephalitis (WEE) virus (family Togaviridae, genus *Alphavirus*) is a complex of closely related viruses found in North and South America. Flooding, which increases breeding of culicine mosquitoes, may precipitate summer outbreaks of WEE. Large outbreaks in humans and horses occurred in the western United States in the 1950s and 1960s; however, a declining horse population, equine vaccination, and improved vector control have reduced disease incidence. The younger the patient, the greater the likelihood of symptomatic infection: the ratio of asymptomatic to symptomatic infection is less than 1:1,000 in adults but increases to 1:1 in infants.

Diagnosis After an incubation period of about 7 days, headache, vomiting, stiff neck, and backache are typical in WEE. In children, restlessness and irritability are seen, and convulsions are common. Neurologic sequelae are relatively common in infants, but they are rare in older children and adults. The case-fatality rate is 3% to 7%. The diagnosis can be confirmed serologically by the CDC on request of state and local health departments.

Treatment and prevention No specific treatment is available for WEE. Prevention focuses on mosquito control and personal measures to avoid mosquito bites. Inactivated vaccine is available for horses. Although inactivated vaccine has been used for laboratory staff and others at high risk for exposure, it is not commercially available for use in humans. WEE is a potential agent of bioterrorism through the aerosol route.

Rabies

Epidemiology The rabies virus (family Rhabdoviridae, genus *Lyssavirus*) occurs worldwide. Dogs remain the major source of human rabies worldwide. In the United States, however, vaccination has sharply limited canine rabies, and consequently, wildlife rabies has increased in importance. About 90% of all reported cases of animal rabies in the United States now occur in wildlife, particularly wild carnivores (e.g., raccoons, skunks, foxes, coyotes, and bobcats) and bats.[54,55]

The major wildlife reservoir for rabies in the United States is the raccoon, which accounts for 37% of all reported cases of rabies in animals; skunks (29%), bats (17%), and foxes (6%) represent the other major reservoirs for animal rabies.[54] Raccoon rabies is the most prevalent in the eastern states; skunk rabies is predominant in the central and western states.[54] Rodents (e.g., squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, and mice) and lagomorphs (rabbits and hares) are rarely infected and have not been identified as sources of human rabies in the United States.[55] In the United States since 1990, indigenous rabies virus variants associated with insectivorous bats and foreign canine rabies virus variants have accounted for 30 of the 32 human cases. Although 74% of the 32 cases since 1990 have been attributed to bat-associated variants of the virus, a history of a bite was established in only three cases.[56]

Etiology and pathogenesis In most cases of rabies, an infected animal inoculates saliva containing rabies virus into the patient, and the virus may replicate in muscle cells near the bite. After replication, the virus spreads via retrograde axoplasmic flow in unmyelinated motor or sensory nerves to the CNS. It then replicates in the brain before moving via the nerves into other tissues, including the salivary glands, from which it can be shed.

Clinical manifestations The infectivity of rabies virus varies with the site and mode of transmission. A bite on the face presents a 60% chance of disease; a bite on the hand or arm reduces the chance of disease to between 15% and 40%, and a bite on the leg presents only a 3% to 10% chance of disease. The risk of disease from a bite is almost 50 times greater than the risk from scratches by a rabid animal. Although a less common mode of transmission, the virus also can be inhaled, which accounts for rabies in laboratory workers exposed to viral aerosols and in a few explorers of bat-infested caves.

The incubation period of rabies ranges from 12 days to many years and probably averages 30 to 90 days or less. The clinical course is quite variable. The initial clinical presentation is a prodromal phase typically lasting a day or two. It is marked by pain and paresthesias in the area of the bite, GI and upper respiratory symptoms, irritability, apprehension, and a sense of impending death. Hydrophobia and aerophobia occur in some patients and, like the history of a bite, call attention to this disease. Thereafter, the patient enters an excitation state, marked by hyperventilation, hyperactivity, disorientation, and even seizures. During the next few days, the patient becomes lethargic and begins to show paralysis, particularly in areas innervated by the cranial nerves and in the somatic muscles, bladder, and bowels. Gradual involvement of cardiac muscles and paralysis of respiratory muscles lead to death. Rabies virus infection in humans is uniformly fatal once symptoms occur.

Diagnosis Rabies should be considered if classic signs of hydrophobia, aerophobia, and excited behavior are present or in any case of encephalitis or myelitis of unknown etiology, even in the absence of an exposure history. The CSF shows nonspecific elevation in levels of leukocytes and protein, as occurs in other viral encephalitides. Fluorescent antibody staining, virus isolation, and reverse transcriptase/PCR constitute the most accurate means of diagnosing rabies infection.[57] Circulating antibodies may be detected in unvaccinated persons as early as the sixth day of illness and usually appear within the first 2 weeks after infection. Rabies virus can be isolated from the second day through the second week of illness from a throat swab or saliva sample, as well as from tears, urine sediment, and CSF.

Treatment and prevention Three rabies vaccines are currently available in the United States: human diploid cell rabies vaccine (HDCV), rabies vaccine absorbed (RVA), and purified chick embryo cell vaccine (PCEC).[58] Each is licensed for preexposure or postexposure vaccination. Clinical trials with RVA and PCEC have demonstrated immunogenicity equivalent to that of HDCV.[58] Corticosteroids, other immunosuppressing agents and conditions, and antimalarials may interfere with the development of active immunity after vaccination. Preexposure prophylaxis is indicated for persons in high-risk groups such as certain laboratory workers, persons whose occupation puts them in frequent contact with animal species at risk for having rabies, and certain international travelers.[58]

Disease onset can be prevented by prompt postexposure prophylaxis. Postexposure prophylaxis begins with immediate and thorough washing of all bite wounds with soap and water and irrigation with a virucidal agent such as a povidone-iodine solution. Previously unimmunized persons should receive human rabies immunoglobulin and rabies vaccine. Guidelines for the indications and dosing schedules for postexposure prophylaxis are available from the CDC at www.cdc.gov/ncidod/dvrd/rabies/.[55] Local or state public health officials should be consulted if questions arise about the need for rabies prophylaxis.

At present, therapy for clinical rabies is supportive. In unvaccinated patients, the disease is invariably fatal. A patient with rabies or suspected rabies should be kept in isolation, and standard infection control precautions should be followed, although laboratory-confirmed person-to-person transmission has not been documented.

VIRUSES OF THE FAMILY PARAMYXOVIRIDAE

Nipah virus

Nipah virus (family Paramyxoviridae) is closely related to the Hendra virus, which has rarely caused fever, pneumonia, and encephalitis in persons exposed to ill horses in Australia. Nipah virus was newly discovered in Malaysia during an outbreak involving 265 persons, with 105 deaths in 1998 and 1999; in 2004, outbreaks involving 25 persons occurred in Bangladesh.[59] Most affected persons had contact with live pigs and were pig farmers. The reservoir for Nipah virus is believed to be fruit bats, and it is thought that humans are infected by contact with an infected bat or by contact with an intermediate animal host such as pigs.

Diagnosis The incubation period is unknown, but more than 90% of the hospitalized Malaysian patients had had contact with pigs in the previous 2 weeks. Among hospitalized patients, fever was almost invariably present, with headache, dizziness, and vomiting common presenting symptoms. Predominant neurologic symptoms were decreased level of consciousness, segmental myoclonus, meningismus, and seizures. Pneumonia was noted in 25% of the patients in Singapore, but it was not prominent in the Malaysian patients. The diagnosis can be confirmed serologically by viral culture or by detection of viral nucleic acid.

Treatment Treatment is supportive. An open-label trial suggested that ribavirin reduced mortality.[60] Prevention is avoidance of pig farms.

VIRUSES OF THE FAMILY REOVIRIDAE

Colorado Tick Fever

The Colorado tick fever virus (family Reoviridae, genus *Coltivirus*) is transmitted to humans in the western United States and Canada mainly by the wood tick, *Dermacentor andersoni*. Human incidence corresponds to the wood tick's geographic distribution in mountainous areas at elevations of 4,000 to 10,000 ft. Transmission occurs from March to September, but it peaks from April to June.

Diagnosis The mean incubation period for Colorado tick fever virus is 3 to 4 days. In 90% of cases, the patient reports a tick bite or tick exposure. Fever, chills, myalgias, and prostration are common presenting symptoms. A petechial or maculopapular rash occurs in 15% of patients.[61] Although acute symptoms last about a week, fever may recur several days later. Fatigue is often prolonged. Meningitis or encephalitis develops in 5% to 10% of children; fatal cases with hemorrhage and shock have been rarely reported. Leukopenia is very common. The virus infects marrow erythrocytic precursors, which accounts for the ability to recover the virus from peripheral blood up to 6 weeks after illness onset. Transmission via blood transfusion has been reported. The diagnosis can also be confirmed serologically by the CDC on request through state and local health departments.

Treatment Treatment is supportive. Prevention rests on avoiding tick bites in endemic areas.

Rash Arthralgia

VIRUSES OF THE FAMILY TOGAVIRIDAE

Several alphaviruses belonging to the family Togaviridae can cause a viral syndrome associated with rash and arthralgias or arthritis. Diagnosis requires serologic testing of paired acute-phase and convalescent-phase serum. Virus can also be isolated from or detected in acute-phase serum samples.

There are no vaccines available for general use against alphaviruses. Prevention depends on mosquito control and decreasing exposure to mosquitoes.

Barmah Forest Virus

Barmah Forest virus (family Togaviridae, genus *Alphavirus*) causes sporadic disease and epidemics in Australia.[42] Clinically, Barmah Forest virus causes a Ross River virus–like illness, but the rash tends to be more florid, and true arthritis is less common. Outbreaks have coincided with Ross River virus outbreaks, and Barmah Forest virus has been identified in the same mosquito species as Ross River virus.[42,62]

Chikungunya

Chikungunya (CHIK) virus (family Togaviridae, genus *Alphavirus*) is found in Africa and Asia and is transmitted by *Aedes* mosquitoes. After a 20-year hiatus, outbreaks of CHIK virus infection occurred in Indonesia from September 2001 to March 2003, suggesting a reemergence of the virus.[63] In urban settings, the virus is transmitted from human to human via *A. aegypti* mosquitoes. Explosive urban epidemics occur during the rainy season. The native name for the disease means "doubled up," because of the excruciating joint pains.

Diagnosis In patients with CHIK, after an incubation period of 2 to 4 days, there is a sudden onset of fever and crippling joint pains, accompanied by chills, flushed face, headache, myalgias, backache, and photophobia. Arthralgias are polyarticular, are migratory, and mostly involve the small joints. Papular or maculopapular skin rashes, typically on the trunk and limbs, usually occur during the second to fifth day of illness. The clinical picture resembles that of dengue fever, with which chikungunya is often confused.[64] Most infections are probably asymptomatic. Arthralgias may last several months. In Asia, but not Africa, mild hemorrhagic manifestations have been reported; CHIK virus is not a cause of severe hemorrhagic disease. The diagnosis can be confirmed serologically by the CDC on request through state and local health departments. Confirmation by culture or detection of viral nucleic acid is possible early in illness.

Treatment There is no specific treatment for CHIK. Anti-inflammatory drugs may relieve arthralgia. Chloroquine phosphate has been used for refractory arthralgias. Prevention depends on mosquito control and decreasing mosquito exposure.

Mayaro Virus

Mayaro (MAY) virus (family Togaviridae, genus *Alphavirus*) is closely related to CHIK virus and causes a similar illness. The virus has been isolated from mosquitoes (mostly *Haemagogus*) in various countries in the Caribbean and South America. Little is known about the natural history of the disease. MAY virus causes febrile illness with headache, backache, myalgias, epigastric pain, chills, nausea, photophobia, arthralgias, and maculopapular rash. Polyarthritis occurs and may persist for several weeks. Arthralgia may recur, as indicated in a report of a patient with a previous case of MAY virus infection.[65] Cases of MAY disease have been imported into the United States.[66] MAY virus infection should be considered in the differential diagnosis in patients with a recent travel history to South America. Diagnosis can be confirmed serologically by the CDC on request through state and local health departments.

O'nyong-nyong

O'nyong-nyong (ONN) virus (family Togaviridae, genus *Alphavirus*) was first isolated during an epidemic in Uganda in 1959 and spread to an estimated two million people in neighboring countries by 1962. Another ONN epidemic began in south-central Uganda in 1996.[67] ONN virus is transmitted to humans by *Anopheles* and other mosquitoes. Clinically, ONN fever is similar to CHIK, although fever is less pronounced and lymphadenopathy is more common in ONN.

Ross River Fever

Ross River virus (family Togaviridae, genus *Alphavirus*) has caused so-called epidemic polyarthritis in Australia, southwestern Pacific Islands, and Fiji.[42] Several species of *Aedes* and *Culex* mosquitoes are important vectors.[42] The natural maintenance cycle of Ross River virus is not fully known. Although the magnitude, regularity, seasonality, and locality of outbreaks are wide ranging, rainfall seems to be the single most important risk factor.[68] Humans have significant viremia, and the virus may follow a human-mosquito-human transmission cycle.[69]

After an incubation period of 2 to 21 days, the illness begins suddenly with myalgia and marked arthralgias in the small joints of the hands and feet. True arthritis occurs in over 40% of patients. A maculopapular rash occurs in 50% of patients within 2 days after onset. Myalgia, headache, anorexia, nausea, and tenosynovitis are common, but temperature is only slightly elevated. Arthralgia frequently persists for several weeks or longer—sometimes for longer than a year.

VIRUSES OF THE FAMILY FLAVIVIRIDAE

Dengue

In addition to their role in hemorrhagic fever (see above), dengue viruses are a common cause of rash and arthralgia.[70]

OTHER VIRUSES CAUSING RASH AND ARTHRALGIA

There are a number of other viral zoonoses that cause similar nonspecific febrile illness in humans, but they occur infrequently or are rare. These include Igbo-Ora (family Togaviridae, genus *Alphavirus*) in Africa; Sindbis and Sindbis-like viruses (family Togaviridae, genus *Alphavirus*) in Africa, Asia, Australia, and Europe; Group C arboviruses (family Bunyaviridae, genus *Bunyavirus*) in South America; Oropouche (family Bunyaviridae, genus *Bunyavirus*) in South and Central America; Sandfly fever (family Bunyaviridae, genus *Phlebovirus*) in the Mediterranean, Middle East, West Asia, and South America; Zika virus (family Flaviviridae, genus *Flavivirus*) in Africa and Asia; and vesicular stomatitis virus (family Rhabdoviridae, genus *Vesiculovirus*) in the Americas.

Miscellaneous Viral Zoonoses

MONKEY B VIRUS DISEASE

Monkey B virus (*Herpesvirus simiae* or B virus) causes persistent latent infections in at least 70% of captive adult macaques. Monkey B virus disease in humans usually results from macaque bites or scratches; most documented infections have occurred in laboratory personnel working with apparently healthy rhesus, cynomolgus, or African green monkeys or their tissues, including kidney cell cultures.[71] Human infection from a mucocutaneous exposure to the eye and one human-to-human transmission have been reported. In humans, monkey B virus causes acute ascending myelitis and fulminant meningoencephalitis, which leads to death within days.

Infection can be diagnosed in humans by demonstrating a rise in antibody titer and by isolating the virus from the CNS. Cardiopulmonary support is the most important aspect of management. Human infection carries a high mortality; however, patients treated early with intravenous acyclovir or ganciclovir have survived. Significant neurologic residua are common in survivors. Monkey handlers should wear protective clothing and a face mask.[72] Bites, scratches, or mucosal surfaces exposed to macaque biologic materials should be cleansed thoroughly.[69] Postexposure management should include referral to a medical consultant knowledgeable about monkey B virus.

RUMINANT AND PRIMATE POXVIRUS DISEASES

Several ruminant and primate poxviruses rarely cause human illness. Cowpox (vaccinia virus) is an orthopoxvirus related to variola. In humans, it produces vesicular lesions on the hands. Generalized infections are rare. Monkeypox, the only other orthopoxvirus of significance to humans, is enzootic in monkeys and squirrels in western and central Africa; infection in humans is sporadic and produces a vesicular rash similar to variola. Secondary infections occur. The case-fatality rate is 1.5%.[73] Tanapox virus is a yatapoxvirus that causes vesicular lesions in monkeys along the Tana River in Kenya and Zaire. It produces a monkeypoxlike illness in humans. The parapoxviruses produce disease in humans through direct contact with infected animals. These include bovine papular stomatitis virus, milkers' nodule (pseudocowpox) in cattle, and orf in sheep and goats. Infection results in vesicles that progress to pustules and scabbing at the site of contact with the original infected species or contaminated objects.

NEWCASTLE DISEASE VIRUS INFECTION

Newcastle disease is an often fatal systemic infection of poultry that is caused by a paramyxovirus. The virus is occasionally transmitted to humans from infected birds or in the laboratory, presumably by direct inoculation. In humans, the illness appears as acute, sometimes hemorrhagic conjunctivitis without corneal involvement. It can be accompanied by lymphangitis, headache, malaise, and chills but is usually self-limited. Patients recover within 2 weeks.

VESICULAR STOMATITIS VIRUS INFECTION

Vesicular stomatitis virus is a rhabdovirus whose structure resembles that of rabies virus. The agent is responsible for oral ulcers in cattle. Occasionally, laboratory workers become infected and experience fever, vesicular enanthemas, headache, and myalgias.

FOOT-AND-MOUTH DISEASE

Foot-and-mouth disease is a highly infectious viral infection of cloven-hoofed animals. The causative agent of the disease is aphthovirus, a member of the family Picornaviridae that is indistinguishable morphologically from rhinovirus. Persons contacting infected animals occasionally have fever, vesicular lesions on the hands, and an increase in neutralizing and complement-fixing titers. The infection is mild and transient, but relapses occur.

XXXII HUMAN RETROVIRAL INFECTIONS

Robert W. Coombs, m.d., ph.d.

Retroviruses have been recognized as important animal pathogens for more than 70 years. However, retroviruses were identified as etiologic agents in human disease only within the past 2 decades.[1,2] Three retroviruses have been recognized to cause infections in humans and to produce well-defined clinical disease: human T cell lymphotropic virus type I (HTLV-I), HIV type 1 (HIV-1), and HIV type 2 (HIV-2). One retrovirus (human T cell lymphotropic virus type II [HTLV-II]) has been associated with certain rare hematologic malignancies, but evidence confirming an etiologic role of HTLV-II in these disorders is lacking. In addition, human foamy virus (HFV), a member of the genus *Spumavirus*, is likely acquired as a zoonotic infection after severe primate bites, but it has not been associated with human disease.[3]

Definition and Classification

Retroviruses are named for the action of a unique viral-encoded enzyme called reverse transcriptase. The normal flow of genetic information is from DNA to RNA to protein. In a reversal of that process, reverse transcriptase makes a double-stranded DNA copy (complementary DNA, or cDNA) of the single-stranded viral RNA genome—hence, the prefix retro. Retroviruses are characterized morphologically by their appearance on electron microscopy and by their genomic, antigenic, and pathophysiologic characteristics.[4] The family Retroviridae comprises a large group of ubiquitous viruses that infect all classes of vertebrates. On the basis of similarities in amino acid sequences in the reverse transcriptase proteins of retroviruses, seven retrovirus genera have been classified. Humans can be or have been infected with several retroviruses from five of the seven retrovirus genera [*see Table 1*]. The alpharetroviruses, betaretroviruses, and gammaretroviruses are considered simple retroviruses; the deltaretroviruses, epsilonretroviruses, lentiviruses, and spumaviruses are considered complex. The simple retroviruses encode only structural and envelope proteins, whereas the complex retroviruses encode these proteins and also small regulatory proteins with a range of functions.[4] With regard to clinical infections in humans, the most important retroviruses (HTLV and HIV) and the least important retroviruses (human retrovirus type 5 [HRV-5][5] and HFV) are acquired by exogenous infection (i.e., by sexual transmission or by transmission from mother to infant through breast-feeding or by parenteral exposure).

A defining feature of retroviruses is the integration of the reverse-transcribed viral cDNA into the genome of the host cell. The integrated viral cDNA is termed the provirus; it serves as the template for viral replication. A persistent infection may result from this process of integration, or the infected cell may be transformed and a malignancy induced. Although many retroviruses can cause cytopathology in the host cell, most replicate without killing the infected cell. For the endogenous human retroviruses (human endogenous retrovirus type K [HERV-K], HERV-W, and several others) [*see Table 1*], multiple copies of endogenous proviral DNA sequences are integrated into chromosomal DNA and are transmitted in the germline. Interestingly, endogenous proviral sequences represent 0.1% or more of human DNA sequences and were acquired sometime in our evolutionary past.[4]

Retroviral Biology

structure and replication

All human retroviruses are similar in structure, genomic organization, and mode of replication.[4] The virus particles are approximately 100 nm in diameter and have a lipid envelope composed of components from the host cell–derived plasma membrane.[6] The envelope renders the virus particles very susceptible to inactivation by environmental drying and by the action of detergents and various chemical disinfectants. The lipid envelope surrounds a dense nucleocapsid core that contains two copies of the unique single-stranded RNA genome. The RNA genomes range from 8 kb in length for HTLV to approximately 10 kb in length for HIV. In the virion, the RNA genomes are associated with the virus-encoded reverse transcriptase, integrase, vpr protein in HIV-1, vpx protein in HIV-2, and a primer transfer RNA (tRNA) that is derived from the host cell.[7] The HIV virion must also incorporate a cellular protein, cyclophilin A, which binds to viral capsid matrix protein p17; this protein is necessary for successful viral disassembly.[8] The tightly packaged HIV nucleocapsid protein protects the enclosed RNA genome from degradation by ribonuclease (RNase) in plasma and other body fluids. As a durable marker of HIV-1 replication, the measurement of viral particle–associated RNA plays a central role in monitoring HIV disease progression and response to therapy.[9,10]

The retroviral RNA genome and the cDNA provirus contain both noncoding and coding sequences **[***see Figure 1***]**. The noncoding sequences, which are important recognition sites for DNA or RNA synthesis, integration, and polyadenylation, are located at the 5′ and 3′ terminal ends of the genome. All retroviruses are terminally redundant and contain identical se-

Table 1 Genera of the Family Retroviridae*

Genus	*Examples*
Alpharetrovirus	Rous sarcoma virus
Betaretrovirus	Human retrovirus type 5
Gammaretrovirus	Human endogenous retrovirus type W* Murine leukemia virus Feline leukemia virus
Deltaretrovirus	Human T cell lymphotropic virus types I and II Bovine leukemia virus
Epsilonretrovirus	Snake retrovirus Walleye dermal sarcoma virus
Lentivirus	Human immunodeficiency virus types 1 and 2 Simian immunodeficiency virus Equine infectious anemia virus Feline immunodeficiency virus Caprine arthritis encephalitis virus Maedi/visna virus
Spumavirus	Human foamy virus Feline foamy virus Bovine foamy virus Simian foamy virus

*Several other human endogenous retroviruses have been identified but are not listed.

quences, called long terminal repeats (LTRs). The coding sequences include the *gag* gene, which encodes group-specific structural antigens; the *pol* gene, which encodes RNA-dependent DNA polymerase or reverse transcriptase, integrase, and protease; and the *env* gene, which encodes envelope structural proteins. The *gag* gene encodes a precursor polypeptide that is cleaved by viral-encoded protease to form several internal structural proteins—namely, matrix protein (MA), capsid protein (CA), and nucleic acid binding protein (nucleocapsid, or NC).[4]

In addition, the 3′ end of the *gag* gene reading frame overlaps with the *pol* gene reading frame to encode for the virus-specific protease. The *pol* gene encodes for a precursor polypeptide that is cleaved by the virus-specific protease enzyme to form three enzymes: protease, reverse transcriptase, and integrase. The *env* gene encodes for a 160 kd precursor protein, which is cleaved posttranscriptionally into two noncovalently associated envelope glycoproteins during transport through the endoplasmic reticulum and the Golgi complex by host proteases, termed furins. The first env protein is gp120, which is a highly charged glycoprotein that is external to the viral envelope; gp120 binds to cell-specific viral receptors (e.g., $CD4^+$ T cell receptor in the case of HIV) and ancillary coreceptors (e.g., chemokine receptors for HIV-1). There are five domains of the *env* gene—V1 through V5. Some of these are highly variable (of these domains, the V3 loop is the most highly variable). These variable domains are responsible for defining multiple variants or quasispecies that contribute to viral evasion from neutralizing antibodies produced by the host in response to viral infection. The second env protein, gp41, is a hydrophobic transmembrane glycoprotein that anchors the oligomeric surface subunit glycoprotein to the viral envelope membrane. The virion surface is studded with approximately 72 knobs; each is composed of three heterodimers of the gp120env / gp41env complex.[7,11] Fusion of the retroviral envelope with the target cell plasma membrane is facilitated by the transmembrane glycoprotein through conformational change mediated by a helix coiled-coil mechanism. This mechanism is present in enveloped viruses other than retroviruses (e.g., influenzavirus)[12] [*see Figure 2*].

The complexity of the human retroviruses is best exemplified by the array of viral proteins that are responsible for regulating viral replication and the host cell response to infection.[4,7] HTLV-I has a region between the *env* gene and the 3′ LTR that encodes for two regulatory proteins, tax and rex, which are produced from messages that are spliced differently from distinct overlapping reading frames. The tax protein induces the expression of cell transcription factors that alter host cell gene expression, and the rex protein regulates the expression of viral messenger RNA (mRNA). The HIV viruses have a larger genome than HTLV. In addition, HIV has a larger translated region (regulatory genes) between the *pol* and *env* genes, which encode portions of several regulatory proteins that depend on the overlapping open reading frame (ORF) into which the mRNA is spliced.

These retroviral regulatory proteins express the following functions[13,14] [*see Table 2*]. The tat protein augments the expression of virus from the LTR region. The rev protein regulates RNA splicing and RNA transport, or both, in HIV and may function in a manner similar to that of the rex protein in HTLV. The nef protein downregulates CD4 protein, which is the cellular receptor for HIV; it alters host T cell activation pathways by decreasing major histocompatibility complex (MHC) class I antigen expression; and it enhances viral infectivity. The vif protein is necessary for the proper assembly of the HIV nucleoprotein core; without the vif protein, viral cDNA is not efficiently produced. The vpr protein (in HIV-1) and the vpx protein (in HIV-2) facilitate transport of the viral cDNA into the nucleus

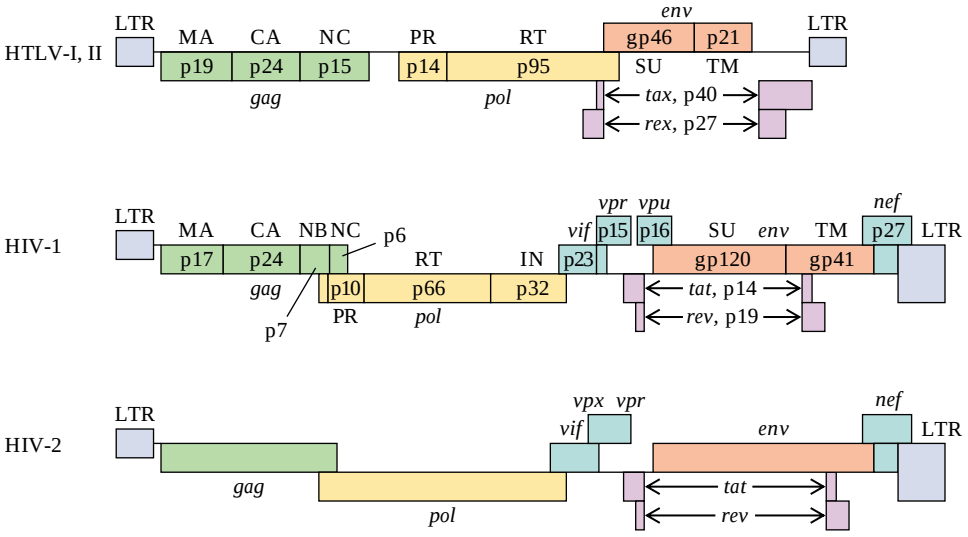

Figure 1 **Depicted is the genomic organization of the three most important human retroviruses. The linear double-stranded proviral DNA forms of HTLV and HIV-1 show similar patterns of genomic organization. The structural genes *gag, pol,* and *env* give rise to several proteins: matrix (MA), capsid (CA), nucleic–acid binding (NB), nucleocapsid core proteins (NC), protease (PR), reverse transcriptase (RT), surface subunit glycoprotein (SU), and a smaller transmembrane protein (TM). In addition, HIV *pol* encodes an integrase (IN). There are additional regulatory gene products translated. HTLV-I and HTLV-II have *tax* and *rex* genes with exons on either side of the *env* gene. HIV-1 and HIV-2 have six accessory gene products: tat, rev, vif, nef, vpr, and either vpu (in HIV-1) or vpx (in HIV-2). Further information about these gene products is provided[131] [*see Table 2*].**

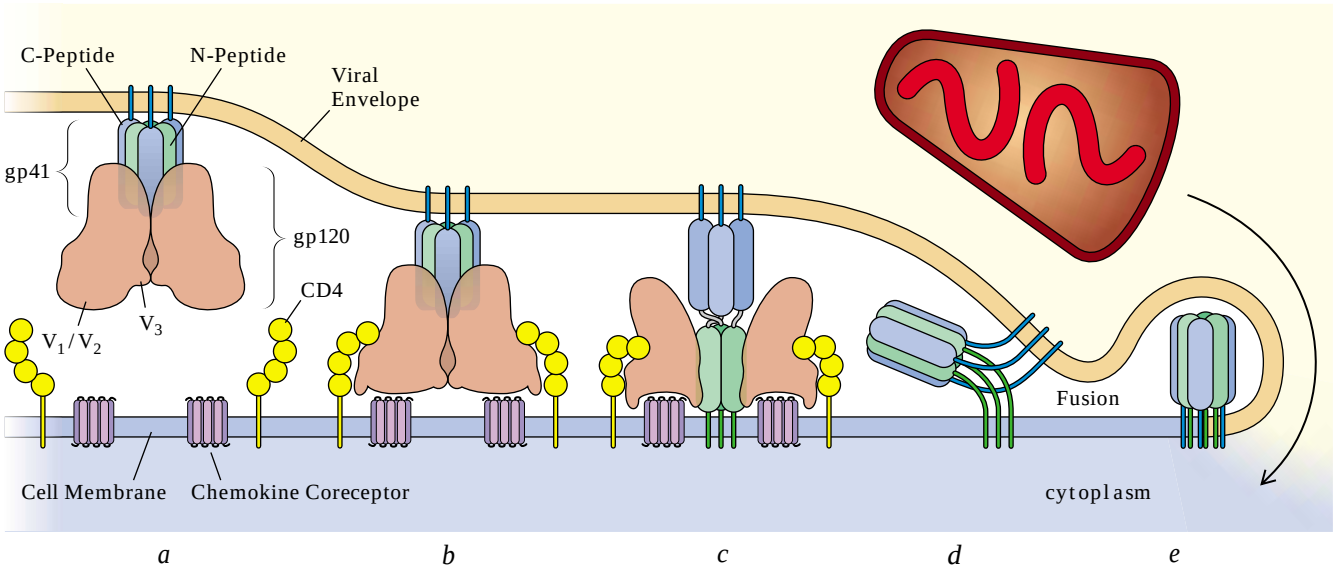

Figure 2 **Illustrated is the binding of HIV-1 with a CD4+ T cell. In unbound virions, gp41 exists in a stable, nonfusogenic conformation in which the fusion peptides are buried within the envelope trimer complex (*a*). When gp120 binds to the CD4 receptor, a conformational change exposes the chemokine receptor attachment site on gp120 (either CXC chemokine receptor–4 [CXCR4] or CC chemokine receptor–5 [CCR5]) (*b*). This in turn triggers a transition of gp41 to the prehairpin intermediate (*c*), with exposure of the fusion peptide attached to the trimeric coiled-coil N-peptide region. The fusin peptide inserts into the target membrane (*c*). In this form, the C-peptide has not associated with the N-peptide because of continued association with gp120; at this stage, the intermediate gp41 polypeptide is vulnerable to C-peptide inhibition (e.g., T-20). When the C-peptide region binds to the N-peptide region coiled-coil, the complex adopts a helical conformation of the fusion-active hairpin, which brings the two membranes into apposition (*d*). The precise mechanism of membrane fusion is not clear, but after fusion is complete, the fusion peptide and transmembrane segment of gp41 lie in the same membrane (*e*). A similar mechanism presumably applies to the fusion of a cell infected with HIV-1 that expresses viral envelope on the plasma membrane surface with an uninfected $CD4^+$ T cell, which leads to syncytium formation among infected and uninfected cells in vitro.[12,132]**

and cause an arrest in the G_2 stage of the cell cycle, which is necessary for optimal viral infection. As such, the vpr protein appears to facilitate the infection of nondividing cells by HIV, a property not shared by HTLV. The vpu protein promotes the degradation of CD4 protein in the endoplasmic reticulum and stimulates the release of virions from infected cells.

pathogenetic tryptic

The biologic properties of the human retroviruses, summarized above, orchestrate a viral pathogenesis tryptic defined by latency, transformation, and cytopathicity; this process occurs through two replication phases [*see Figure 3*]. In the first replication phase, the viral-encoded proteins that are packed within the virion nucleocapsid enter the cell; this eventually results in the formation of the integrated cDNA provirus. In the second replication phase, the enzymatic machinery of the host cell is utilized to replicate the viral RNA genome and to transcribe and translate viral proteins from the provirus. With the exception of retroviral latency, the pathogenesis tryptic leads to cell dysfunction (and sometimes cell death), with eventual immunosuppression and clinical disease. Both HTLV-I and HTLV-II immortalize primary human peripheral blood T cells in vitro. Immortalization is defined as interleuken-2 (IL-2)–dependent, long-term growth in culture. Subsequently, cells become fully transformed—that is, they are subject to continuous cell proliferation in the absence of IL-2. Cellular transformation is an early step in the pathogenic process of HTLV and is distinct from oncogenesis or malignancy.[4] As such, HTLV transformation of T cells results in a pool of proliferating cells that are not oncogenic themselves but that provide a population from which a malignant clone may subsequently arise.[4] This accounts for the long latent period between infection and tumor development in HTLV disease. In contrast, HIV does not transform the infected cell but rather produces a cytopathic effect that results in cell dysfunction and, eventually, cell death.

The first phase of viral replication starts when the retrovirus binds to a specific cell receptor, which for HIV is the CD4 molecule on the cell surface and an associated chemokine coreceptor.[15] The HTLV receptors have not been characterized; however, cellular targets for HTLV-I include several types of T cells, the primary one being the $CD4^+$ T cell. HTLV-II preferentially infects $CD8^+$ T cells.[16] The retroviral nucleocapsid complex enters the cell cytoplasm, and the viral genomic RNA is reverse-transcribed to a slightly longer, double-stranded cDNA molecule that actively enters the nucleus as a nucleoprotein-preintegration complex and integrates permanently at a single random site in the cell chromosome. The integration of linear viral cDNA occurs during division of the cell; as such, nondividing cells are generally resistant to retroviral infection. However, the one exception to this is HIV, which is able to infect resting cells (the G_1 phase of the cell cycle), albeit less efficiently than activated cells in the S phase of the cell cycle. The inhibition of reverse transcription by combinations of nucleotide, nucleoside, or non-nucleoside reverse transcriptase inhibitors (NNRTIs) is a cornerstone of current HIV-1 therapeutics.[10]

The second replication phase begins with the production of viral genomic RNA and mRNA and protein synthesis; the production of mRNA and protein synthesis occur almost exclusive-

Table 2 Genes and Proteins of HIV[13]

Gene	*Gene Product*	*Size (kd)*	*Function*
gag	Capsid matrix protein	p17	Interacts with gp41; binds cyclophilin A in the virion
	Nucleocapsid core protein	p24	Forms nucleocapsid along with p6
	Nucleocapsid core protein	p6	Forms nucleocapsid along with p24; binds to vpr
	Nucleic acid binding protein	p7	Binds to viral RNA
		p1, p2	Cleavage products of gag precursor protein
pol	Protease	p10	Proteolytic cleavage of gag, pol, and env precursor polypeptides
	Reverse transcriptase	p66/51	Polymerase and ribonuclease H activity (p66 only)
	Integrase	p32	Integration of viral DNA (vDNA) into host cell chromosome
env	Envelope protein	gp120	Trimeric external envelope protein; glycosylated protein with five variable domains (V1 through V5) and four invariant regions (C1 through C4); binds to CD4 receptor and chemokine coreceptor
	Transmembrane protein	gp41	Trimeric protein that attaches gp120 to virion envelope; facilitates fusion of the viral envelope with the cell plasma membrane; each molecule is composed of two α-helical regions that form a six-helix bundle; coiled-coil state is basis for "spring-loaded" interaction that leads to virus cell fusion
vif	Virion infectivity protein	p23	Efficient cell free transmission; required for proper assembly of nucleoprotein core
vpr	Viral protein R	p15	Enhances viral replication in primary cells; G2/M phase arrest; nuclear localization in cell; transports vDNA in preintegration complex to the nucleus; virion-associated protein
tat	*Trans*-activator of transcription	p14	Major viral *trans*-activator
rev	Regulator of expression of virion protein	p19	Enhances expression of unspliced and singly spliced RNA molecules; regulates transport of messenger RNA; shuttles back and forth between nucleus and cytoplasm
*vpu**	Viral protein U	p15-16	Enhances release of virion from cells; downregulates CD4 on cell
nef	Negative regulatory factor	p27	Inhibits or enhances viral replication, depending on strain and cell type; down-regulates CD4 and MHC class I receptor
vpx†	Virion protein X	p25	Packaged into the virion

*HIV-1 only.
†HIV-2 only.

ly through the enzymatic machinery of the host cell under the influence of viral gene regulatory products. Processing of virion proteins begins in the endoplasmic reticulum and Golgi complex. Virion assembly begins at the plasma membrane, and the nascent virions are released from the cell surface through budding. The budding viral envelope, which has a phospholipid composition different from that of the plasma membrane of the cell, may incorporate some cell membrane surface proteins (e.g., β_2-microglobulin and MHC class I and II proteins), along with virus-specific glycoproteins.[6,7] Extracellular HIV undergoes further maturation by continued proteolytic cleavage of the nucleocapsid polypeptide, which results in the mature infectious virion with a distinctive cone-shaped nucleocapsid core. The inhibition of viral protease through virus-specific protease inhibitor therapy, in combination with reverse transcriptase inhibitor therapy, is an important aim of current antiretroviral therapeutics. However, inhibition of reverse transcriptase with combinations of nucleoside reverse transcriptase inhibitors (NRTIs) and NNRTIs is equally efficacious in many cases.[10]

Pathogenesis of Retroviral Infection

The clinical consequences of retrovirus infection reflect a precarious balance between the type of invading retrovirus, its tropism for specific cells and tissues, and the patient's natural and acquired resistance. The pathophysiologic model of retrovirus infection can be approached by understanding viral mechanisms of infection, latency and persistence, cell injury, and immune system evasion and modulation. Some aspects of this model are shared by other RNA and DNA viruses; other aspects are unique to the human retroviruses.

viral entry, target cell tropism, and virus receptor interactions

Human retrovirus transmission requires parenteral or intimate mucous membrane exposure to the virus. Transmission by fomites is unlikely because the viral envelope of retroviruses is easily damaged in the environment by exposure to high temperatures, detergents, and chemical disinfectants and through drying. The concentration of virus in body fluids to which a person is exposed is a very important determinant of transmission.[17] For HIV, the blood level of virus may or may not reflect the virus level in genital fluids and breast milk.[18-20]

Receptors

The cellular receptor for HTLV has not been identified. Only T cells are productively targeted by HTLV, but infection of B cells and other cell types has been detected. Much more is known about the manner by which HIV enters the host cell. Susceptible cells must be available for the process of adsorption, penetration, and uncoating of the virus to occur. The receptor for HIV is the CD4 molecule, which is present on T cells and defines the subset of $CD4^+$ helper-inducer T cells. The HIV-1 gp120env protein binds specifically to the CD4 receptor; in ad-

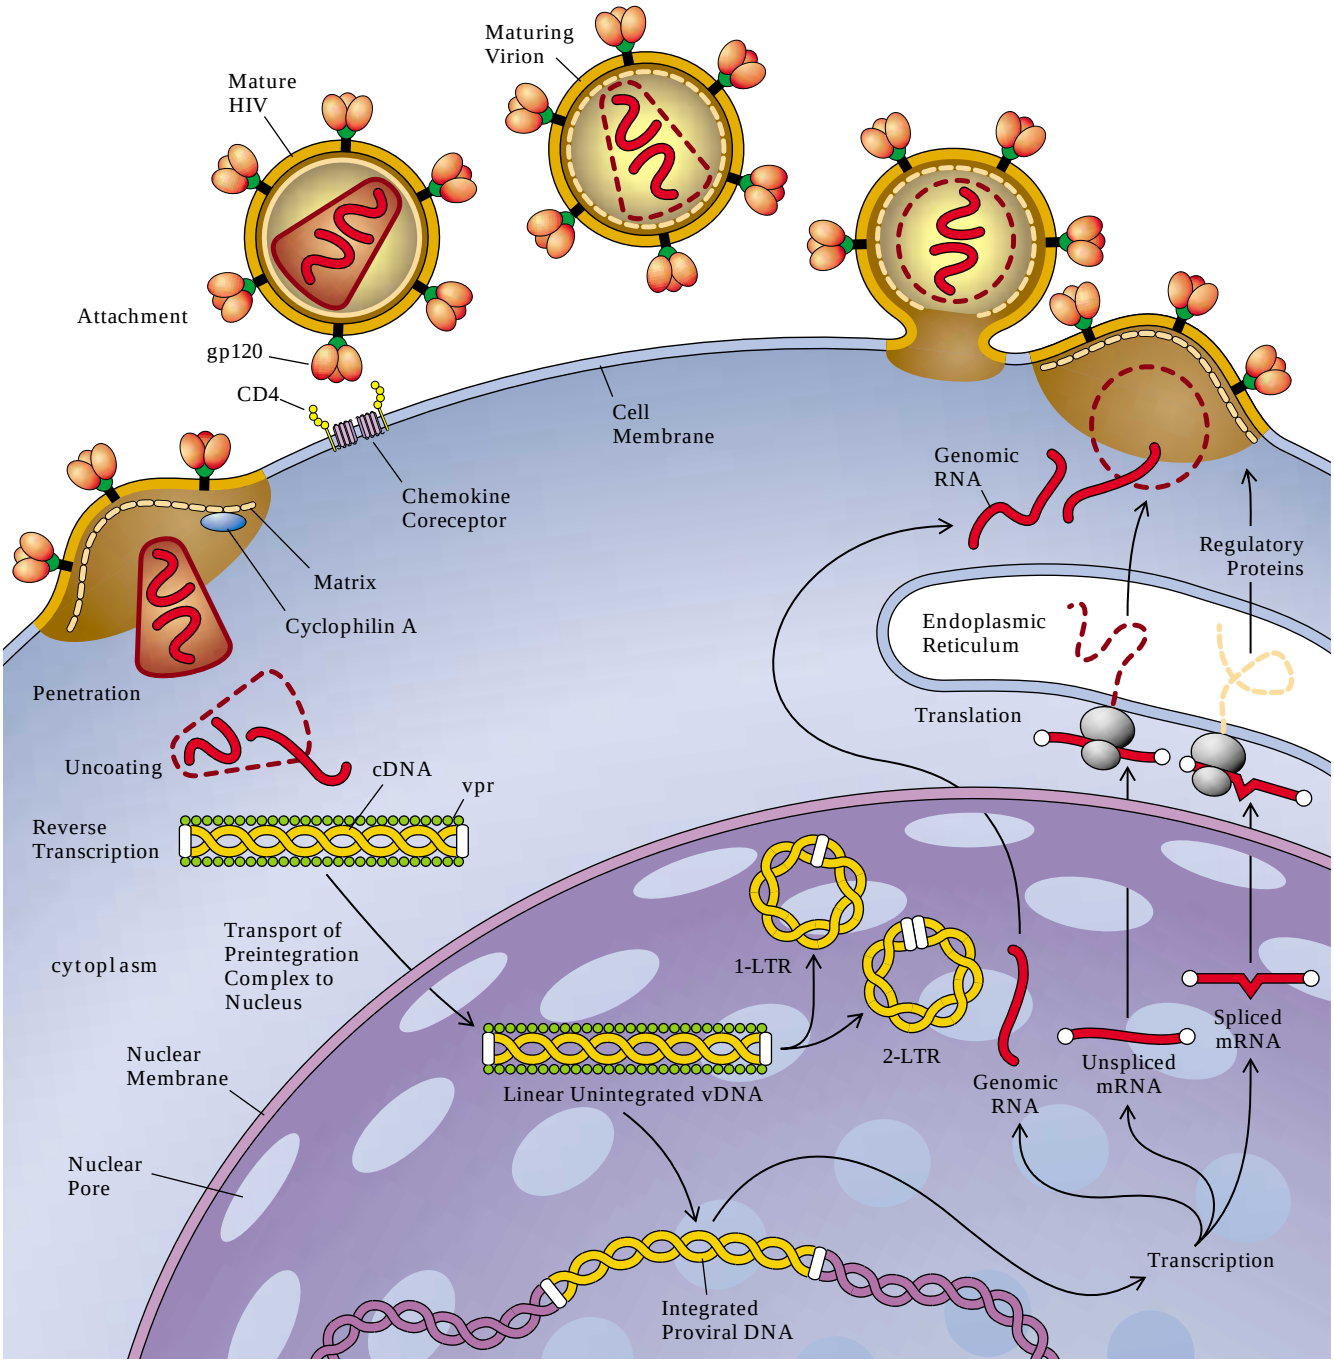

Figure 3 **Illustrated is the replication cycle of HIV-1. The virus must first attach to the CD4 receptor and chemokine coreceptor on the cell surface [*see Figure 2*]. After fusion of the viral envelope with the plasma membrane of the target cell, the nucleocapsid undergoes uncoating, which is facilitated by the presence of cyclophilin A. The viral RNA genome is reverse-transcribed to double-stranded viral DNA (vDNA), which enters the nucleus as a preintegration complex that contains vpr protein and integrase. Only linear vDNA is capable of integrating randomly into the host chromosome; other forms of partially transcribed linear vDNA fragments and 1-long-terminal repeat (LTR) and 2-LTR circularized, episomal vDNA are not capable of integration. The integrated linear vDNA (now termed the provirus) serves as the template for viral transcription. Transcription of the proviral DNA template yields genomic viral RNA, and alternative messenger RNA (mRNA) splicing creates spliced viral mRNA species that encode the viral accessory proteins and the unspliced viral mRNA species that encode the viral structural polyproteins [*see Table 2*]. All of the transcripts are exported to the cytoplasm, where translation processing and assembly begins to occur in the endoplasmic reticulum and Golgi complex. The viral polypeptides, protease, viral RNA, and other constituents of the viral core condense at areas of the plasma membrane that have already accumulated viral envelope proteins (gp120/gp41). Budding of the virion ensues, and the immature virion nucleocapsid core undergoes further proteolytic maturation in the extracellular milieu.[133]**

dition, other cell surface proteins, such as the chemokine receptors, serve as essential coreceptors for different strains of HIV.[15]

Coreceptors

The HIV-1 coreceptors belong to the superfamily of protein-coupled receptors that bind guanosine triphosphate (GTP). These receptors have a characteristic structure of seven transmembrane segments and are coupled with the G protein.[21] The two principal HIV-1 coreceptors, CC chemokine receptor–5 (CCR5) and CXC chemokine receptor–4 (CXCR4), and their chemokine ligands are involved in diverse biologic processes, such as immunomodulation, inflammation, hematopoiesis, and organogenesis.[22] Three cytokines released by $CD8^+$ T cells—RANTES (regulated on activation, normal T cell expressed and secreted), macrophage inflammatory protein–1α (MIP-1α), and MIP-1β—bind to the CCR5 receptor and may suppress HIV macrophage tropic virus. Similarly, stromal cell–derived factor–1α (SDF-1α), which is the natural ligand for CXCR4, and AMD-3100, which is a small molecule inhibitor of SDF-1α, can inhibit R4 virus.[23,24] Clinical development of AMD-3100 was abandoned in May 2001 because of possible cardiac toxicity and limited efficacy. It has been proposed that aberrant signaling through binding of gp120env with the chemokine receptors may cause apoptosis and contribute to the decrease in the $CD4^+$ T cell count in patients with AIDS.[25]

Infection with strains of virus that recognize the CXCR4 coreceptor generally results in cell fusion or syncytium formation in vitro; such strains are termed syncytium-inducing (SI), T-tropic, or R4 strains. Strains of virus that recognize the CCR5 coreceptor generally result in infection without syncytium formation in vitro; such strains are termed non–syncytium-inducing (NSI), monocytotropic, or R5 strains. Dual-tropic strains are able to use both chemokine coreceptors. Other chemokine receptors have also been shown to facilitate HIV infection of susceptible cells in vitro.[26] Thus, chemokine coreceptor use may be a determinant of viral virulence and disease progression.[27] For example, a 32-base-pair deletion in the *CCR5* gene, which is found as a homozygous mutation in less than 1% of the Western European white population, prevents surface expression of the truncated CCR5 receptor protein. This deletion is associated with slower progression of HIV-1 infection and a decrease in HIV-1 infection of peripheral mononuclear blood cells in vitro.[28] Even heterozygosity for this gene defect, which is observed in 20% of Western European whites, may provide some degree of protection against disease progression.[28-30]

HIV-1 gp120env also binds to a dendritic cell–specific C-type lectin, DC-SIGN (dendritic cell–specific intracellular adhesion molecule–grabbing nonintegrin), which is highly expressed on dendritic cells in mucosal tissues.[31] DC-SIGN does not function as a receptor per se for viral entry into dendritic cells; rather, it promotes infection of T cells that express CD4 and chemokine receptors.[32] As such, DC-SIGN efficiently captures HIV-1 in the periphery, stabilizes the virus, and facilitates its transport to secondary lymphoid organs rich in $CD4^+$ T cell targets.[31]

HIV infection is associated with a loss of CD4 antigen on the infected T cell and ultimately leads to the death of the infected T cell. This in turn contributes to a decrease in the ratio of $CD4^+$ T cells to $CD8^+$ T cells—a hallmark of HIV-induced immunosuppression. However, the $CD4^+$ T cell is not the only type of cell subject to infection by HIV. Other cells, such as the monocyte-macrophage, express CD4 molecules and probably disseminate HIV to target organs. In addition, monocyte-macrophages serve as a reservoir for HIV and other lentiviruses. Other cells can be infected with HIV in vitro, including Langerhans cells of the skin, follicular dendritic cells, and several others, some of which do not express the CD4 antigen. For example, astrocytes, oligodendrocytes, M cells of the enteric mucosa, and epithelial cells of the intestine and vagina all express galactosylceramide or a related glycolipid receptor that may act as an alternative virus receptor for gp120env.[33,34]

latency and persistence

For any virus infection to persist, viral gene expression must be restricted to some extent. Three patterns of restricted viral expression are known; all three patterns are important for retroviral infections.[35] The first pattern, latent infection, is characterized by intermittent episodes of acute or subclinical disease; in latent infection, no virus is detectable between episodes. An example of latent infection is herpes simplex virus infection, which is characterized by episodic subclinical shedding. Latent infection may be particularly important for patients infected with HTLV or HIV-1 whose plasma levels of viral RNA have been suppressed below detectable levels through use of antiretroviral therapy. Latent infection must be differentiated from clinical latency, which occurs in the presence of ongoing viral replication.

The second pattern of restricted viral expression is chronic infection. In chronic infection, the virus is usually demonstrable but disease is absent. An example of chronic infection is cytomegalovirus infection. The chronic pattern of infection is seen in approximately one half of the patients infected with HIV-1 who are treated with antiretroviral drugs. In these patients, the plasma levels of HIV-1 RNA are persistently low as a result of potent antiretroviral therapy (HIV-1 RNA counts are greater than 50 RNA copies / ml of plasma but are less than 5,000 copies / ml). However, unlike untreated patients, these patients experience a sustained increase in $CD4^+$ T cells and improved clinical status.

The third pattern of restricted viral expression is persistent infection. This pattern is characterized by a long incubation period with slowly increasing amounts of virus, eventually leading to symptomatic disease. Examples are subacute sclerosing panencephalitis associated with measles virus infection and hepatitis C virus (HCV) infection. This pattern is often seen in HTLV infection, which is characterized by a low probability of developing clinical disease over the infected person's lifetime (the probability is from 5% to 10%) and a period lasting decades in which the patient is asymptomatic. This pattern is also seen in patients with HIV-1 infection; in these patients, the median time to the development of AIDS is approximately 10 years.

Infections with the lentiviruses, particularly HIV, have features characteristic of all three patterns but are best described as persistent and cytopathic. HTLV infections have the characteristic features of latent and persistent infections, but in addition, the infected cell may be transformed.

Both the HIV and HTLV cDNA become integrated with the genome of the infected host cell at a single random site to establish the provirus as a permanent chromosomal resident.[4] In addition, most of the HIV cDNA remains in an extrachromosomal state, either as linear cDNA fragments or as circularized forms (neither of which are replicatively competent). The degree of viral transcription and translation depends on the stage of differentiation of the infected $CD4^+$ T cell. That stage, in turn, is probably related to exogenous antigen stimulation and the action of cytokines (e.g., IL-2) and viral regulatory proteins (e.g., the vpr

protein), which promote cell differentiation and activation of viral promotors (e.g., nuclear factor–κB [NF-κB] inducible transcription factors). Integration of human retroviruses differs from that of certain animal retroviruses in that no transforming genes (oncogenes) are associated with the viral genome, and the proviral genome is not regularly inserted next to a host-transforming gene. Moreover, clinically important human retroviruses are exogenous and are not transmitted in germ cells, as are some endogenous vertebrate retroviruses and the clinically unimportant HERVs [*see Table 1*].

cytopathicity

The cytopathic destruction of lymphoid cells is a characteristic of lentivirus infection in general. In a minority of patients with HIV, an initial period of intense viral replication is followed by an acute and rapidly progressive disease; in most patients with HIV, however, this initial period of viral replication is followed by a period of persistent infection, with clinical disease developing only after a prolonged period. In some patients in whom disease progression is very slow, chronic infection can develop, and the development of such chronic infection is a viable long-term clinical objective of antiretroviral therapy.

The clinical manifestations of HIV are governed by cell and tissue tropism; the clinical signs and symptoms of infection arise directly or indirectly from viral replication within these cells and tissues. The sine qua non of HIV infection is $CD4^+$ T cell depletion, immunosuppression, and the development of opportunistic infections and malignancies. This depletion of $CD4^+$ T cells occurs not only by direct viral replication and cell lysis but also through other mechanisms. For example, HIV env-induced cell fusion may result in syncytia formation; cell surface expression of the *Fas* gene and programmed cell death (apoptosis); aberrant signaling through chemokine receptors; arrest of proliferation at the G_2 phase of the cell cycle, with cytopathic ballooning of the cells; and antibody-dependent or cell-mediated depletion induced by the binding of gp120env. In addition, the functional responses of T cells, such as signaling, are impaired both in vitro and in vivo because of the binding of gp120env with the CD4 molecule.[36]

A number of other cellular and lymphoid abnormalities are observed in persons infected with HIV, including abnormal B cell immunity and humoral immunity, monocyte-macrophage dysfunction, and immune defects in natural killer cells, among many observed immunologic defects.[36] Moreover, the follicular dendritic cells (FDCs) may play a key role in maintaining a large reservoir of protected infectious virus particles on the dendritic cell surface; although these cells do not appear to be infected, the presence of virus particles on the cell surface results in chronic immune activation and cytokine secretion, which leads to further virus replication and dissemination. Eventually, the FDCs are destroyed, which in turn leads to the destruction of the lymphoid architecture and the evolution of clinical disease.[36] In many instances, lymphoid architecture may be partially restored after prolonged antiretroviral therapy.

genomic diversity

HIV undergoes active and continuous replication in the infected person, with infected cells dying after approximately 2 days.[37,38] The level of plasma HIV particles remains relatively constant for each infected person because of the balance between rapid production and clearance of virions. To maintain this steady-state level of HIV RNA, there are an estimated one billion infectious events every day in the untreated person with HIV infection. As such, the large number of replication cycles—estimated to be 300 cycles or more a year—provide ample opportunity for the virus to develop genetic diversity as a primary defence against immune and antiretroviral therapy suppression of replication. For example, within the *env* gene, localized regions of extraordinary hypervariability are interspersed with well-conserved (i.e., nonvariable) regions. One such hypervariable region is the V3 loop, which is a target for neutralizing antibodies. The force driving this variability is probably caused by selective pressure from the host's immune system.

This variability within HIV *env* gene contrasts with the relative genetic stability of HTLV. The mutation rate in the HIV *env* gene is one million times greater than that of DNA viruses and 10 to 100 times greater than that of other retroviruses; this results in a production of so-called quasispecies and is comparable only to the variability noted for another RNA virus, HCV. This extraordinary *env* gene hypervariability is associated with amino acid changes of as much as 35% or more among divergent HIV-1 isolates. Variation arises during reverse transcription of viral RNA to cDNA, a step that is highly prone to error, that lacks proofreading (i.e., correction of transcriptional copying errors) because the RNA template is destroyed by RNase H, and that leads to substitutions and misreading, which may result in the modification of several biologic properties, including tissue tropism, virulence, replication rate, and susceptibility to antiretroviral agents. In addition, recombination between different subtypes has been shown to be an important mechanism for generating diversity. Ultimately, continued genetic diversity of HIV may allow the virus to evade containment by the immune system.[39]

Origins of Human Retroviruses

The extent to which different human and primate retroviruses are related can be determined by comparing nucleic acid sequences through a process called phylogenetic analysis. Through such analysis, the human retroviruses have been shown to be phylogenetically related to the retroviruses of Old World primates. The closest viral relative of HTLV-I is the simian T cell lymphotropic virus type I (STLV-I), which was identified as an agent of naturally occurring infection in many species of Old World monkeys and great apes. Antecedent infection of the human population probably occurred from three geographically distinct interspecies transmission events; once established, the virus followed the migratory patterns of people around the world.[40] Moreover, recent studies have convincingly shown that there have been three separate interspecies transfers of the lentivirus simian immunodeficiency virus (SIV_{cpz}) from chimpanzees (*Pan troglodytes*) to humans; these transmission events occurred within the past century and resulted in the establishment of HIV-1 groups M, N, and O.[41,42] Similarly, HIV-2 has its origin with multiple interspecies transfers of SIV_{smm} from the primate sooty mangaby (*Cerocebus atys*) to man and to primates in captivity (e.g., SIV_{mac} in the rhesus monkey *Macaca mulatta*).

Human T Cell Lymphotropic Viruses

Retroviruses cause many animal malignancies and characteristically immortalize cells in vitro. In humans, the prototype retroviruses associated with malignant transformation are

HTLV-I (and possibly HTLV-II). HTLV-I causes adult T cell leukemia (ATL); direct infection of the central nervous system results in a spastic or ataxic myelopathy termed tropical spastic paraparesis, also referred to as HTLV-I–associated myelopathy (HAM). HTLV-II was first isolated from a patient with a T cell variant of hairy-cell leukemia; it may be associated with certain neurologic, hematologic, and dermatologic diseases, but unequivocal evidence that HTLV-II is the etiologic agent is lacking.[43,44]

HTLV-I and HTLV-II have similar genomic organizations and share approximately 60% nucleotide homology[45] [*see Figure 2*]. The *gag* gene encodes for the structural proteins p19, p24, and p15. The *pol* gene encodes for the protease and the reverse transcriptase. The *env* gene encodes for the external envelope and transmembrane glycoproteins gp46 and gp21. The spliced regulatory proteins tax and rex and the other three open reading frames constitute the 9 kb genome. The gag and env proteins are most immunogenic; the antibodies to these proteins are commonly detected by enzyme immunoassay (EIA) and Western blot (WB) assay.

epidemiology

HTLV-1 has a worldwide distribution; prevalence rates range from 5% to 27%, with the higher rates occurring in certain populations in which HTLV-1 is highly endemic.[46] HTLV-II is endemic in several Native American populations in the Americas and in Pygmy tribes in central Africa; in these populations, prevalence rates range from 7% to 9%.[44] In the United States, the seroprevalence rates of HTLV-I and HTLV-II range from 7% to 49% in injection drug users and prostitutes.[46] Early serologic and epidemiologic studies are confusing, because these studies were unable to effectively differentiate between HTLV-I and HTLV-II; however, this problem has been corrected through the use of more specific recombinant peptide-based WB and nucleic acid amplification methods.[47]

classification of htlv subtypes

The HTLV genome is highly conserved, but greater nucleotide convergence in the LTRs has made possible the development of restriction fragment length polymorphism (RFLP) testing. Through such testing, it is possible to classify both HTLV-I and HTLV-II into genotypic subtypes, and valuable information on viral transmission has become available.[47] There are five major molecular and geographic subtypes of HTLV-I: cosmopolitan (worldwide), Japanese, West African, Central African, and Melanesian.[48] There are three HTLV-II subtypes that reflect population clustering rather than geographic clustering: IIa, IIb, and IIc. Subtype IIa is found in injection drug users worldwide; subtype IIb is found primarily in Native Americans; and subtype IIc is found in Brazilian tribes.[49]

overview of laboratory diagnosis of htlv

Screening of blood donors for HTLV-I and HTLV-II is now routinely used in the United States, Canada, several Caribbean countries, Europe, and Japan.[47] The primary screening assay is the EIA; WB assay is used for confirmatory testing. However, EIA cannot distinguish between HTLV-I and HTLV-II infections because of the significant protein homology between the two viruses. Importantly, antibodies to HTLV do not cross-react with HIV proteins. After repeatedly positive results on EIA, the diagnosis of HTLV infection is confirmed if antibodies to two gene products (gag and env proteins) are detected on WB assay. For example, a specimen demonstrating antibody reactivity to p24gag and to pg46env or gp61/68env, or both, is considered to be positive for HTLV-I or HTLV-II. For specimens that test positive on EIA and that react with any of the WB bands but that do not meet this criterion, results are considered indeterminate. Specimens that test positive on EIA but that display no immunoreactivity to any of the HTLV WB bands are considered to be negative for antibodies to HTLV-I and HTLV-II, and the result of the EIA is considered to be false positive. To better differentiate between HTLV-I and HTLV-II, the WB assay has been modified to contain type-specific recombinant proteins from the external glycoprotein of HTVL-I (rgp46envI) and HTLV-II (rgp46envII) as well as a truncated recombinant peptide, rp21e, from the transmembrane glycoprotein gp21env. In one study, persons with indeterminate WB assay profiles (i.e., persons who did not demonstrate antibody reactivity to p24, p19, or rp21e) who did not have risk factors for HTLV infection were shown by polymerase chain reaction amplification not to be infected with either HTLV-I or HTLV-II.[50] Such indeterminate WB assay results appear to represent antibodies to other viral and cellular antigens that cross-react with HTLV proteins. Nevertheless, blood donors with indeterminate results are deferred and their blood is excluded for transfusion purposes.

PCR has become the reference method for determining infectious status; for validating serologic assays; for distinguishing between HTLV-I and HTLV-II; for studying in vivo viral load and tissue distribution; and for further evaluating patients with risk factors for HTLV infection whose serologic status is either indeterminate or negative.[47] PCR is also an important method of testing infants for HTLV infection, because their serologic status may be unclear, owing to the presence of passively transferred maternal antibodies. In addition, PCR is important for the detection of infection in the window period between exposure, infection, and seroconversion.[47]

HTLV-I

HTLV-I is the etiologic agent of adult T cell leukemia/lymphoma (ATL) and a chronic progressive inflammatory neurologic degenerative disorder known as tropical spastic paraparesis or, more commonly, HTLV-I–associated myelopathy (HAM). However, this virus has been implicated in several other disorders, including an inflammatory arthropathy, uveitis, polymyositis, infectious dermatitis in children, pulmonary disorders, and Sjögren syndrome. There are provocative but unproven associations of HTLV-I with mycosis fungoides and Sézary syndrome. This discussion focuses on ATL and HAM because of the established etiologic linkage to HTLV-I.

epidemiology

HTLV-I is endemic in southwestern Japan and Okinawa, where more than one million persons are infected. HTLV-I infection is also prevalent in Taiwan, the Caribbean basin (including areas of South America and the southeastern United States, central Africa, Israel, and the Arctic, where seroprevalence rates range from 5% to 27% in adults.[46] In the United States, HTLV seroprevalence rates range from 0.025% in blood donors to 7% to 49% in injection drug users and prostitutes.[46] The incidence rates of seroconversion associated with HTLV are estimated to be 1.09 per 100,000 persons per year.[51] HTLV-I infection is transmitted from mother to child; perinatally; sexually; through breast milk and blood transfusions; and from contaminated

needles.[52] In the United States, where blood donors are screened for HTLV, the risk of transmitting HTLV through a unit of blood is estimated to be 1 in 641,000 (95% confidence interval, 256,000 to 2,000,000).[51]

The distribution of both ATL and HAM overlaps the distribution of HTLV-I, with more than 95% of affected persons having serologic evidence of HTLV-I infection. Although early serologic studies suggested that HTLV-I infections were common in injection drug users, confirmatory serologic assays that reliably distinguish between HTLV-I and HTLV-II have subsequently shown that the majority of HTLV infections in injection drug users are HTLV-II infections.[53] The development of ATL in persons infected by blood products is rare; however, 20% of patients with HAM acquire HTLV-I infection from contaminated blood. In ATL, there is a latent period between infection and the emergence of disease of 20 to 30 years or more; in contrast, HAM has a shorter median latency of approximately 3 years, but the latency period can be as long as 20 to 30 years.

Cross-sectional studies have suggested that coinfection with HTLV-I and HIV-1 results in an acceleration of clinical immunosuppression and shortened survival. However, prospective studies of dual infection are not available, and other factors associated with dual infection could be responsible for the clinical findings. Of interest, dual infection with HTLV-I and HIV-1 may affect the interpretation of the results of immunophenotyping because coinfection alters the relationship between $CD4^+$ T cell count and HIV-1 disease stage. As such, patients infected with HIV-1 who have a higher than expected $CD4^+$ T cell count for a given level of clinical immunosuppression should be tested for HTLV-I infection.[16]

pathogenesis

The pathophysiologic basis of HTLV-I disease is less well known than that of HIV-1. Unlike HIV-1, the cellular receptor for HTLV-I has not been identified. $CD4^+$ T cells are productively infected by HTLV-I, but some other cell types, including B cells and $CD8^+$ T cells, are infected occasionally. Like HIV-1, the reverse-transcribed viral cDNA integrates randomly into the host cell to establish the provirus, but in contrast to HIV-1, HTLV-I establishes a latent infection with infrequent expression of viral gene products. As such, HTLV-I has a very low level of disease penetrance; the transformation of an infected cell is a rare event, and the cumulative lifetime risk of developing ATL is 1% to 5% in persons infected with HTLV-I. The latent period from infection to clinical disease is estimated to be 30 to 50 years[54]; most persons with ATL appear to have acquired the infection in childhood.[55]

In contrast to many of the animal retroviruses, and in particular avian retroviruses, HTLV-I does not contain a transforming oncogene. Moreover, the integrated provirus does not locate at a unique site in the genome that would result in the expression of a cellular gene (proto-oncogene), as does, for example, the classical avian leukosis virus, which causes B cell leukemia in birds by inducing the expression of the proto-oncogene *myc*. The only viral gene product expressed in tumor cells transformed by HTLV-I in vivo is tax, a 40 kd protein with exons on either side of the *env* gene. In contrast, the infection of $CD4^+$ T cells in vitro results in transformed cells that produce complete, infectious HTLV-I virions. Tax protein induces the expression of a wide range of host cell proteins, including transcription factors and cytokines (IL-2, tumor necrosis factor [TNF], and others). However, it is not known how this induction of host cell factors leads to neoplastic transformation, and no consistent chromosomal abnormalities have been reported in ATL. The discordant observations between the in vitro and in vivo milieus are a recurrent theme in understanding the complex biology of human retroviral disease.

The pathogenesis of HAM is virus induced. Interestingly, patients with HAM generally have high proviral levels in the blood and a stronger immune response to HTLV-I, with higher antibody titers in the cerebrospinal fluid than in the serum. It has been proposed that the pathology of CNS disease may result from an autoimmune destruction of neuronal tissue by viral-specific $CD8^+$ T cells. HTLV-I has also been associated with uveitis, arthropathy, and infective dermatitis; each of these conditions probably has an autoimmune / inflammatory pathogenesis.[16]

clinical features and diagnosis

HTLV-I–Induced Adult T Cell Leukemia/Lymphoma

Four clinical presentations of ATL have been described: acute, lymphomatous, chronic, and smoldering.[54] All of these malignancies are characterized by the monoclonal expansion of $CD4^+$ T cells that contain HTLV-I provirus and rearrangements of clonal T cell receptor genes. HTLV-I virions are not recovered directly from the infected T cells, but viral tax protein is expressed in vivo. The molecular pathogenesis of this retroviral-induced neoplasm has not been fully elucidated.

Acute ATL Acute ATL accounts for approximately 60% to 80% of cases of ATL. Patients experience a short clinical prodrome, with an average of 2 weeks between the onset of symptoms and diagnosis. ATL has an aggressive natural history; median survival is 6 months. The clinical picture is characterized by rapidly progressive skin lesions (40% of cases ranging from maculopapular rashes to tumorous lesions), pulmonary infiltrates, diarrhea, hypercalcemia (seen in 50% of cases), elevated lactate dehydrogenase (LDH) and alkaline phosphatase levels, and lymphocytosis with pleomorphic mononuclear cells (termed flower cells) that contain lobulated, cloven-hoof–shaped nuclei. The skin lesions may be difficult to distinguish from those in mycosis fungoides and Sézary syndrome. The pulmonary lesions may be the result of a leukemic infiltrate or an opportunistic infection, such as *Pneumocystis carinii* infection or fungal infections. Diarrhea is almost always associated with an opportunistic infection. Hepatosplenomegaly may be present. Lytic bone lesions are common; the lesions are patchy and are composed of osteolytic cells without osteoblastic activity. Leptomeningeal involvement associated with weakness, altered mental status, paresthesias, and headache is found in approximately 10% of patients. The cerebrospinal fluid protein level is usually normal. The diagnosis is confirmed by a finding of malignant cells in the CSF.

Lymphomatous ATL Lymphomatous ATL accounts for approximately 20% of cases of ATL. Lymphomatous ATL is similar to acute ATL but differs in that lymphadenopathy is present and there is an absence of circulating, morphologically abnormal lymphocytes. The diagnosis may be suspected on the basis of the patient's geographic birthplace and the presence of skin lesions and hypercalcemia. The diagnosis is confirmed by HTLV-I serologic testing or the detection of the integrated provirus on PCR testing.

Chronic ATL Chronic ATL accounts for approximately 15% of cases of ATL. This form of ATL is characterized by normal serum levels of calcium, elevated levels of LDH, and the absence of bony involvement or involvement of the CNS or gastrointestinal tract. The median survival for these patients is 2 years. Chronic ATL may progress to acute ATL.

Smoldering ATL Smoldering ATL accounts for fewer than 5% of cases of ATL. Although fewer than 5% of the circulating lymphocytes display the morphologic abnormalities characteristic of ATL or an integrated HTLV-I provirus, there is no hypercalcemia, adenopathy, or hepatosplenomegaly. The CNS, bones, and GI tract are not involved, but typical skin lesions and pulmonary infiltrates may be present. The median survival for patients with the smoldering form of ATL is 5 years or longer.

HTLV-1–Associated Myelopathy/Tropical Spastic Paraparesis

HAM is a slowly progressive thoracic myelopathy that leaves one third of patients bedridden within 10 years of diagnosis.[56] HAM affects women disproportionately for reasons that are not understood.

The onset of symptoms in HAM is insidious; symptoms include weakness or stiffness in one or both legs, back pain, and urinary incontinence. Peripheral neuropathy is usually mild. Physical findings include spastic paraparesis or paraplegia with hyperreflexia, ankle clonus, and extensor plantar responses (Babinski reflex). Cognitive function is usually spared, and cranial nerve involvement is distinctly unusual. Demyelinating lesions are seen in the white matter and paraventricular regions of the brain and spinal cord; the clinical presentation may thus resemble multiple sclerosis or the myelopathy of HIV infection. The pathologic changes in HAM include symmetrical degeneration of the lateral columns, corticospinal tracts, and posterior columns. An inflammatory infiltrate is present on the spinal meninges, and spinal cord parenchyma shows evidence of myelin destruction, similar to that in multiple sclerosis. HTLV-I provirus is usually not found in the cells of the CNS parenchyma, but it may be detected in a few CSF-associated lymphocytes. Although a high proviral serum level of HTLV-I is an important risk factor in the development of HAM, the presence of provirus in the blood is not sufficient to cause disease, and the immunopathogenesis of HAM is probably associated with host genetic factors.

prevention and treatment

The principles of prevention of HIV infection also apply to the prevention of HTLV infection—avoidance of breast-feeding, if possible; screening of blood donors for HTLV antibody; safe sexual practice; and the avoidance of sharing or reusing of needles.

There is no proven, effective therapy for either ATL or HAM.[55,57] Unlike with HIV disease, disease progression of ATL and HAM is not associated with HTLV-I replication; as a result, antiretroviral drugs have not been effective in the treatment of these diseases. The neoplasm is responsive to combination chemotherapy that is used against other forms of lymphoma, but patients usually experience relapse within 1 year of initial remission. The combination of interferon alfa and zidovudine (AZT) is effective therapy and is associated with less toxicity than standard lymphoma regimens; however, the effectiveness of this regimen is most likely the result of the cytotoxic effects of AZT rather than its antiretroviral activity. Anecdotal cases involving the successful use of allogeneic bone marrow transplantation have been reported. Patients with chronic ATL or smoldering ATL should be treated for opportunistic infections and observed for progression to acute ATL, at which time chemotherapy should be initiated. In ATL, hypercalcemia is generally controlled with glucocorticoid therapy and cytotoxic therapy of the neoplasm. In HAM-associated inflammation, glucocorticoids reduce inflammation and may improve uveitis, but antiretroviral therapies are not effective. Danazol, an androgenic steroid, has been reported to benefit women with HAM-associated urinary and fecal incontinence.

HTLV-II

HTLV-II is endemic in certain Native American tribes of North and South America. The modes of transmission are the same as for HTLV-I, although HTLV-II is less readily transmitted sexually than HTLV-I . Because of the similarity in biologic properties between the two viruses and because of the initial inability to distinguish the two viruses serologically, the two viruses were grouped together in early studies. The seroprevalence of HTLV-II in injection drug users in several metropolitan drug treatment programs in the United States was approximately 20%.[58] Approximately 3% of these persons were infected with both HTLV-II and HIV-1. Women are significantly more likely to be infected with HTLV-II than men, a feature of the disease that may reflect the more efficient sexual transmission of HTLV-II from men to women than from women to men.

Although HTLV-II was isolated from a patient with a T cell variant of hairy-cell leukemia,[1] the virus has not been unequivocally associated with a particular disease. Nevertheless, evidence is slowly accumulating that HTLV-I may play a role in certain degenerative neurologic, hematologic, and dermatologic diseases**.** No effective therapy exists for HTLV-II infection.

HIV

The pathogenesis, epidemiology, clinical features, and treatment of HIV-1 infection are described elsewhere [*see 7:XXXIII HIV and AIDS*]. This subsection discusses the principles of laboratory diagnosis and the basis for the laboratory monitoring of HIV-1 infection. It is important that therapy be individualized on the basis of a thorough understanding of the host-virus relationship in the individual patient (see above). In this regard, an understanding of the use of the laboratory for diagnosing and monitoring HIV-1 disease is critical.[59]

laboratory diagnosis

Serologic Diagnosis

The HIV-1 testing algorithm recommended by the United States Public Health Service consists of initial screening with an EIA licensed by the Food and Drug Administration, followed by testing of repeatedly reactive specimens with an FDA-licensed supplemental test (i.e., WB assay or immunofluorescent assay).[60] Although EIAs are highly sensitive and specific, the positive predictive value of EIA is highly dependent on the seroprevalence of HIV-1 antibody in the population from which the individual is being tested. As such, use of both EIA and a supplementary test increases the likelihood of detecting HIV-1 infection. For maximum diagnostic accuracy, the laboratory HIV test results should always be interpreted by the clinician in

conjunction with the clinical and epidemiologic history of the person being tested. At this time, FDA-licensed HIV nucleic acid detection kits are not approved for diagnosis or for supplemental testing but only for disease monitoring (see below).

Enzyme immunoassays The current generation of EIAs have shortened the estimated antibody-negative window period of primary infection to approximately 1 month or less.[61] The specificities of the current commercial EIAs are over 99.5%.[62] False positive reactions arise from nonspecific cross-reacting antibodies in the serum of persons with underlying immunologic disease and of those who are gravid, who have received multiple transfusions, or who have recently received an immunization.[63] Several EIAs that may be used to screen for both HIV-1 and HIV-2 antibody are commercially available.

Immunoblot WB assay detects the serum antibodies directed against specific HIV proteins of varying molecular weights after separation of the viral proteins by gel electrophoresis and blotting onto nitrocellulose paper. WB assay detects antibodies to the following specific HIV-1 proteins: core (p17gag, p24gag, and the precursor p55gag); polymerase (p31pol, p51pol, and p66pol); and envelope (gp41env and gp120env / 160env). The reported analytic specificity of the WB assay is 97.8%.[60] A WB assay is interpreted as being negative when no antibody-antigen band is present; it is interpreted as being positive when antibodies are present to core proteins (p24gag), envelope proteins (gp41env or gp120env / 160env), and, in some cases, polymerase proteins (p31pol). Although several organizations have proposed criteria for interpreting WB assay reactivity, the Centers for Disease Control and Prevention (CDC) endorses interpretative criteria that require the presence of antibodies to two of the three following proteins: p24gag, gp41env, and gp120env / 160env.[60]

Regardless of the HIV-1 antibody seroprevalence, a reactive EIA and confirmatory WB assay together have a positive predictive value of greater than 99.99%.[64] In the blood-donor population, approximately 10 of 10,000 persons (0.1%) who are without risk for HIV-1 infection will have repeatedly reactive results on the HIV-1 EIA. Eight of those 10 low-risk persons with repeatedly reactive results on the HIV-1 EIA will have negative results on the HIV-1 WB assay, and two will have indeterminate results. False positive results for HIV-1 antibody (i.e., both EIA and WB assay are reactive for a person who is not infected with HIV-1) are extremely rare (less than one in 100,000 persons screened).[64] Therefore, an indeterminate WB assay result is more common than a false positive WB assay result.[65]

With the increased use of HIV-1 antibody screening in low-risk populations, including health care workers, it is essential that HIV-1 test results be interpreted accurately. Between 4% and 20% of serum samples that are repeatedly reactive on HIV-1 EIA are interpreted as indeterminate on WB assay.[66] Indeterminate WB assays (IWB assays) in persons infected with HIV-1 may result from early formation of antibody against viral core antigens during primary infection. IWB assays may also occur in conjunction with early detection of HIV-1 antibody by the more sensitive third-generation EIAs. IWB assays rarely occur as a result of the loss of core-specific antibody late in infection because of severe immunosuppression.[67,68] The presence of cross-reacting antibody to HIV-2 has been implicated as a cause of positive results in HIV-1 testing. False positive results on both EIA and WB assay are extremely uncommon, occurring with a frequency of fewer than one in 135,000 tests.[64]

The following recommendations have been proposed for the clinical management of patients with an IWB assay result.[63] Low-risk individuals who have a nonreactive result on repeat testing with EIAs do not need further follow-up. High-risk individuals should be followed serologically for at least 6 months; this is especially important for those with a p24gag band on WB assay. Such a result may reflect the presence of HIV-1 antibody in conjunction with early seroconversion. The early, selective use of supplemental tests for HIV-1 proviral cDNA or plasma RNA may help determine the infection status of high-risk individuals before full seroconversion occurs.[63,66,69] Seroconversion is usually identified within 3 months of primary infection through the use of appropriate supplemental testing.[61] Importantly, negative supplemental test results may help alleviate the anxiety associated with an indeterminate HIV-1 serologic result.[66]

Rapid serologic testing Rapid, reliable, and less expensive alternatives to the use of EIA with a confirmatory WB assay have been sought for use in acute care settings, emergency departments, clinics for sexually transmitted disease, medical field settings, and developing countries. Consideration should be given to the introduction of rapid screening for HIV-1 antibody in certain clinical settings, such as clinics for sexually transmitted disease; such measures would greatly enhance testing programs by preventing delays in the counseling of seronegative patients and by providing preliminary results to seropositive patients.[70] These preliminary results may encourage patients to return for confirmatory testing and to adopt risk-reducing behaviors sooner than they would if following the currently accepted testing algorithms.[71] In addition, the use of rapid screening for HIV-1 after occupational exposure to blood will reduce the duration of antiretroviral prophylaxis therapy for the exposed health care worker, thus minimizing drug-related toxicity and cost and alleviating anxiety sooner should the test result prove negative.[72,73] Rapid serologic testing will likely become the standard of diagnostic care; physicians and other health care professionals should become familiar with the indications for rapid testing.

Detection of HIV-1 subtypes HIV-1 groups and subtypes differ with regard to their diagnostic properties on both serologic and nucleic acid assays. As such, reagents in diagnostic kits have been modified to ensure optimal sensitivity and specificity for antibodies to viruses of groups M and O. Current clinical HIV-1 antibody testing does not distinguish between the various HIV-1 subtypes. However, from an epidemiologic perspective, distinguishing these subtypes by nucleic acid sequencing is very important for understanding the global spread of HIV-1.

As mentioned previously, HIV-1 strains are divided into three groups: M, O, and, most recently, N.[74] To date, in the United States, infection with group O is uncommon, and no group N infections have been reported.[75] Neutral variation in HIV-1 strains of group M has led to a further subdivision of these viruses into nine geographically distributed subtypes, or clades, designated A through K. Subtype B is the most common subtype in the United States and Europe; subtypes A and C are prominent in Africa and Asia. In addition, there are four major circulating recombinant forms: AE is prevalent in Southeast Asia; AG, in west and central Africa; AGI, in Cyprus and

Greece; and AB, in Russia. However, the circulating recombinant forms are expanding in number as more full-genome sequences of HIV-1 become available (e.g., FD, from the Democratic Republic of Congo; BC, from China; and several additional complex recombinants that combine three or more subtypes). Although there are differences in the biologic properties of these subtypes (e.g., there is a low frequency of syncytium-inducing phenotype in subtype C), the overall data are too limited to support any strong influence of subtype on either disease progression or transmission.

Because most of the primer pairs for HIV-1 cDNA PCR amplification have been optimized for group B viruses (see below), it is not surprising that HIV-1 cDNA PCR may also fail to detect HIV-1 group O and some subtypes of groups M and N. To accommodate this deficiency, primer pair modifications have been incorporated into the recent Roche Amplicor HIV-1 DNA and Roche Monitor HIV-1 RNA assays (version 1.5).[76] Because of the large number of *pol*-specific synthetic oligonucleotide target probes used by the branched-chain DNA (bDNA) assay, detection of group O and different group B subtypes has not been a problem for the bDNA assay.[77]

Detection of HIV-2 antibodies HIV-2 infection is less geographically dispersed than HIV-1 infection; the epidemic of HIV-2 is primarily focused in West Africa, and is common in the epidemic in India. In the United States, only a relatively few cases of HIV-2 have been reported. In blood donors in the United States, HIV-2 is extremely rare; only three cases of HIV-2 were detected in screening 74 million blood donations through June 1995.[78] Of the 62 persons reported with HIV-2 infection in the United States, 44 (71%) were born in, had traveled to, or had a sex partner from western Africa. Nevertheless, diagnosis of HIV-2 infection will continue to be an emerging problem in the United States and many other countries, and antibody screening for both viruses is warranted.

HIV-1 and HIV-2 genomes have about 60% homology in conserved genes, such as *gag* and *pol*, and 35% to 45% homology in the *env* gene.[79] The core proteins of HIV-1 and HIV-2 display frequent cross-reactivity, whereas the envelope proteins are more type specific. Despite this cross-reactivity, it has been estimated that the first- and second-generation EIAs used in the United States for screening of blood donors for HIV-1 detect 55% to 91% of HIV-2 infections.[80] The WB assay that is used to detect HIV-1 antibodies may yield positive, negative, or indeterminate results when used to assess sera known to be positive for HIV-2 (when the WB assay is used to confirm a positive result on EIA for HIV-2, p26gag and gp36env correspond to their HIV-1 counterparts p24gag and gp41env, respectively).

Laboratory Detection of HIV-1

The methods of direct detection of HIV-1 include the use of culture, antigen detection, and detection of nucleic acid. Each method has a specific role to play: use of culture is important in research; use of antigen detection is important to public health; and detection of nucleic acid is important for individual patient care. Near the beginning of the HIV-1 pandemic, viral culture and antigen detection were used to evaluate the effectiveness of antiretroviral therapy. However, both methods were replaced by more sensitive and precise methods involving the quantification of viral RNA in plasma through nucleic acid amplification or signal amplification. Nevertheless, both culture and antigen detection continue to have useful roles.

Viral culture Use of mixed-lymphocyte coculture for the detection of HIV-1 is a specialized procedure that has extremely high specificity but lower sensitivity in patients with high $CD4^+$ T cell counts, as compared to methods used to detect viral nucleic acid (see below).[81,82] Use of HIV-1 culture is restricted primarily to research laboratories because of its lower sensitivity than currently available nucleic acid detection methods, cost, time constraints, and highly specialized, technical nature. However, interest is being shown in the use of HIV-1 coculture for assessing viral containment after potent antiretroviral therapy[83]; HIV-1 coculture may also be useful for obtaining primary clinical HIV-1 isolates to study viral syncytium-inducing phenotype and drug-susceptibility phenotype[84] and for assessing viral fitness.[85]

Measurement of HIV-1 p24 antigen With the advent of nucleic acid amplification methods for the monitoring of HIV-1, the measurement of HIV-1 p24 antigen has a much more limited role than it once did. Currently, the primary use of p24 antigen detection is to identify patients who are in the antibody-negative window period of acute HIV-1 infection. Although antigen detection is a less expensive alternative to viral RNA detection in this setting, both the determination of viral RNA levels and the culturing of peripheral blood mononuclear cells are significantly more sensitive than detection of p24 antigenemia,[86] even with the added sensitivity of p24 antigen acid dissociation.[87] However, a tyramide signal-amplification–boosted EIA for quantification of p24 antigen has been reported to have equivalent sensitivity to viral RNA reverse transcriptase polymerase chain reaction (RT-PCR) amplification at 200 to 400 copies / ml.[87,88] Currently, the greatest use of p24 antigen testing is for screening the United States blood supply. This screening program was introduced in 1996 and has been augmented by a plasma HIV-1 RNA screening assay[89,90] to further lower the residual risk of HIV-1 infection, which is estimated to be less than one in 500,000 units (95% confidence interval, 200,000 to 2,800,000).[51]

Detection of viral nucleic acid Commercially available methods for the detection of viral nucleic acid (proviral cDNA or viral RNA) are specific and sensitive and are an effective method for identifying those persons who are infected but who have not undergone seroconversion.[86,91] These methods are also useful in identifying infected infants[92] and in resolving indeterminate HIV-1 antibody serology.[66] In addition, the quantification of plasma viral RNA has assumed a critically important clinical role in assessing disease prognosis and response to antiretroviral therapy.[93-97]

Qualitative HIV-1 DNA PCR amplification is the most commonly used assay for the diagnosis of HIV-1 infection in neonates and infants.[98,99] The Roche Amplicor HIV-1 test (Roche Diagnostic Systems, Inc.) is the only FDA-licensed commercial kit available for clinical use.

The major advantages of HIV-1 DNA PCR over culture are its increased sensitivity and more rapid reporting time (the reporting time is 1 day, as compared to 2 to 4 weeks). There is always a risk of false positive reactivity caused by contamination of the specimen with amplicons (so-called carryover product contamination) or by specimen handling errors[69,99,100-102]; carryover contamination is decreased somewhat by the use of the uracyl *N*–glycosylase enzyme in the commercial assay. False negative results can also occur because of inhibition of the PCR reaction by either hemoglobin or heparin or because there are

fewer target cells in the assay than expected. To control for the latter and improve the precision of the assay, testing for HIV-1 DNA should include concurrent amplification of a cell-associated host gene, such as *HLA-DQ* or the β-globin gene. Diagnostic laboratories should participate in a quality-assurance program to ensure that problems with sensitivity and specificity are quickly identified.[103]

RT-PCR amplification is generally more sensitive than p24 antigen EIA in detecting plasma HIV-1 RNA.[86-88,91] As such, there is much interest in using plasma HIV-1 RNA in diagnostic testing.[69,100,104] As mentioned (see above), HIV-1 RNA has augmented HIV-1 p24 antigen screening; it will likely replace HIV-1 p24 antigen screening of donor blood in the United States after its use has been validated. However, the HIV-1 RNA assays that are commercially available are not currently licensed for use in screening. To avoid incorrectly diagnosing a patient as having HIV-1, the HIV-1 RNA assay should be used diagnostically only as a supplemental test for detecting antibody-negative acute infection. In this particular diagnostic setting, a positive result on HIV-1 RNA assay (particularly one that indicates a viral RNA level of fewer than 1,000 copies / ml) should be confirmed by either another nucleic acid technology (preferably, HIV-1 DNA PCR) or HIV-1 p24 antigen EIA or HIV-1 culture, if available.[100,102,105,106] Alternatively, one can again test for the development of HIV-1–specific antibody, which should be present shortly after viral RNA reaches detectable levels.[107] The presence of HIV-1 RNA in the absence of other laboratory findings requires a correlation with the medical and epidemiologic history and a confirmatory repeat blood test for HIV-1.[100-102,106]

HIV-1 RNA Quantitative Assays

The diversity of viral subtypes of HIV-1 necessitates the use of molecular assays capable of measuring viral RNA concentrations independently of viral sequence or subtype.[108] First-generation viral RNA quantification assays were designed for optimal performance with subtype B, which predominates in Europe and North America. However, the entry of nonsubtype B virus into these areas and the discovery of intersubtype recombinant viruses complicate nucleic acid–based testing.[109] Currently, there are four commercial assays available for quantifying HIV-1 subtype B RNA in ethylenediaminetetraacetic acid (EDTA)–anticoagulated plasma. The current versions of these assays are capable of quantifying a broader range of HIV-1 subtypes than earlier tests.[108] Because these assays are not equivalent, patients should be followed clinically with repeated viral RNA testing using the same manufacturer's assay. Some of the benefits and limitations of viral RNA testing can be better appreciated if the clinician is somewhat familiar with the viral RNA assays that are currently available for clinical use.

The nucleic acid sequence–based amplification (NASBA) (NucliSens QT HIV-1 RNA assay, Organon Teknika, Advanced BioScience Laboratories) assay involves first obtaining nucleic acid through isolation by lysis and binding of the viral RNA to silica dioxide microparticles. The next step involves isothermal amplification (so-called target amplification) through use of the reverse transcriptase RNase H and T7 RNA polymerase. Three internal calibrators are added to the specimen; these are adsorbed along with the specimen before lysis. Amplification covers approximately 1,200 base-pairs in the *gag* and *pol* genes. Detection is by means of chemiluminescence. The sensitivity of the assay is approximately 100 RNA copies / ml; the quantitation limit is 500 copies / ml; and the linear dynamic range is up to 10,000,000 RNA copies / ml.

The bDNA assay (Versant HIV-1 RNA 3.0 assay, Bayer Corp.) is a nonisotopic sandwich nucleic acid hybridization assay that uses a series of target probes of the *pol* gene to hybridize the viral RNA target onto a series of capture probes on the surface of the microwell plate. The bDNA amplifier molecules are hybridized onto the captured viral RNA target. Multiple alkaline phosphatase label probes are attached to the bDNA amplifier molecules to amplify the signal after adding a specific substrate (so-called signal amplification); detection is by chemiluminescence. An external standard curve is used to calculate the HIV-1 RNA copy number. The detection and quantitation levels are approximately 50 to 100 RNA copies / ml, with a linear dynamic range up to 750,000 RNA copies / ml.[110]

The RT-PCR amplification assay (Roche Amplicor HIV-1 Monitor Test, Roche Diagnostic Systems) is the only FDA-licensed assay for assessing HIV-1 disease prognosis. The assay uses the recombinant *Thermus thermophilus* (rTth) enzyme, which serves to catalyze both reverse transcription and DNA amplification of a 142 base *gag* gene sequence in a single reaction tube. An internal quantitative standard is used to adjust for recovery and to calculate the final HIV-1 RNA copy number. The assay has an analytic sensitivity of 200 RNA copies / ml and a quantitation limit of 400 RNA copies / ml, with a dynamic range up to 750,000 RNA copies / ml. A centrifugation step (Amplicor HIV-1 Monitor Ultrasensitive specimen preparation protocol, Roche Molecular Systems) can be used to concentrate virus and thus increase the sensitivity of the assay to 50 copies / ml, and the quantitation limit is 200 copies / ml.[111]

Detection of Antiretroviral Susceptibility Genotype and Phenotype

Incomplete inhibition of HIV-1 replication in vivo may arise because of patient noncompliance with therapy, inadequate potency of the chosen regimen, poor drug absorption, drug-drug interactions, inadequate activation of the antiretroviral drug, or infection with drug-resistant virus variants[112] [*see 7:XXXIII HIV and AIDS*]. This incomplete inhibition may result in the emergence of drug-resistant HIV-1 variants and thus is an important cause of therapy failure.[113] An assessment of drug resistance may be helpful in selecting subsequent antiretroviral therapy, but this has not been rigorously proved. Nevertheless, assays for drug resistance testing in HIV-1 infection are now available, and clinical studies suggest that viral drug resistance correlates with poor virologic response to new therapy.[114] It is recommended that interpretation be made by specialists who are expert in this area, given the complexity of results and assay limitations.[115]

Antiretroviral drug susceptibility is determined either phenotypically by assessing for the susceptibility of the virus (or viral recombinant) ex vivo or genotypically by assessing for mutations that confers resistance. There are two phenotypic approaches: the first approach tests the sensitivity of the proviral population present in the peripheral blood mononuclear cells of the patient; the second approach generates recombinant fragments of the virus that contain *pol* genes obtained from the viral RNA or from the proviral DNA.[116,117] There are several genotypic approaches: DNA sequencing of the entire viral population or clones; selective PCR assay; determination of point mutations; differential probe hybridization; EIA modification of the oligoligase detection reaction assay; and a commercially available HIV-1 reverse transcription line probe assay.[118] Genotypic chang-

es may not always correlate with changes in drug susceptibility of the clinical isolate.[119] Before these techniques can be applied effectively in the clinic, much still needs to be learned about the correlation between genotype and phenotype and the effect of these phenotypic and genotypic approaches on clinical outcome in patients who receive antiretroviral therapy.[120] Nevertheless, despite the recommendation by some experts for the wider use of susceptibility testing in clinical practice,[115,121,122] most decisions to start or change therapy are based on the viral RNA level, $CD4^+$ T cell count, and previous antiretroviral drug history. In addition, the patient should be carefully educated about the importance of compliance with and adherence to the prescribed therapy regimen.[112,123]

Assessment of disease progression is discussed elsewhere [*see 7:XXXIII HIV and AIDS*].

Monitoring of Infection

In general, nadir responses in plasma viral RNA occur in most patients 4 to 12 weeks after initiation of potent antiretroviral therapy. With some potent antiretroviral regimens, plasma viral RNA levels will decrease to less than 500 RNA copies / ml by 16 weeks in 60% to 80% of patients and to less than 50 viral RNA copies / ml by 24 weeks in approximately 70%. Previous antiretroviral therapy is a factor affecting the decrease in viral RNA levels.[94,124] For patients who show a stable response, continued monitoring at intervals of 3 to 4 months seems warranted; more frequent monitoring is warranted if the plasma viral RNA level approaches a value that would cause a change in therapy. It is advisable to plot the plasma viral RNA values on a $\log_{10}$ scale; plasma viral RNA levels should be reassessed only when values exceed the upper 95% confidence interval for the expected variation in plasma viral RNA level (that is, 0.5 $\log_{10}$ RNA copies / ml above the mean nadir response value) and only if such a change in viral RNA levels would necessitate a change in therapy.[125]

By current consensus guidelines, the goal of therapy is to reduce the plasma viral RNA level to an undetectable amount, which is now fewer than 50 RNA copies / ml.[10] Other targets of therapy are a durable reduction in the plasma viral RNA level by at least threefold (0.5 $\log_{10}$) or more from pretherapy levels[125,126] and a reduction in plasma viral RNA level to below 1,000 copies / ml.[9] Although there are only limited data from controlled clinical trials that carefully delineate the decrease in risk of disease progression associated with decreases in the plasma viral RNA levels to less than 1,000 copies / ml,[9] a preliminary analysis of 1,083 patients from the AIDS Clinical Trials Group 320 Study Team showed that only seven of 126 clinical events (5.6%) were associated with a preceding plasma HIV-1 level lower than 500 copies / ml; for the remaining 119 clinical events, the plasma viral RNA level was higher than 500 copies / ml.[94] Nevertheless, many investigators believe that the target for therapy should be at least one $\log_{10}$ value lower than this (i.e., < 50 RNA copies / ml).[10] Occasional blips in detectable levels of viral RNA do not appear to adversely affect outcome. The "as low as you can go" concept in HIV treatment is an appealing virologic concept that has been repeated so often as to have been accepted as the standard. Whether this concept pertains to a chronic viral infection such as HIV-1 requires careful validation by controlled clinical trials. This is particularly important with regard to the treatment of asymptomatic patients with HIV-1 who have a $CD4^+$ T cell count greater than 500 cells / µl; in such patients, the possibility of long-term toxicity associated with the use of potent drug combinations that contain protease inhibitors needs to be weighed against the relatively small clinical benefit derived from reducing plasma viral RNA levels to the lowest level possible.

In addition to reducing plasma viral RNA levels, therapy should also lead to a stabilization of the $CD4^+$ T cell count at or above the expected level of biologic variation; the absolute number of $CD4^+$ T cells should be increased by more than 30%, or the proportion of lymphocytes that are $CD4^+$ T cells should increase by more than 3%. Interpretation of any given reduction in the level of plasma HIV-1 RNA depends on the treatment response of the $CD4^+$ T cell count. To determine clinical response to therapy, changes in both the viral RNA level and the $CD4^+$ T cell count must be considered because of the interaction between them.[127] In an analysis of several clinical studies primarily of nucleoside therapy, patients who did not experience a reduction in the plasma HIV-1 RNA level but who did experience a reduction in the $CD4^+$ T cell count had a 30% greater risk of clinical progression over 2 years than patients who had an increase in $CD4^+$ T cells above pretherapy levels.[9]

An important goal of antiretroviral therapy is to provide an improved sense of patient well-being and to minimize adverse effects. Therefore, in establishing as a target the lowest plasma viral RNA level, consideration must be given to previous antiretroviral drug exposure; in addition, therapy compliance, tolerability of the regimen, and long-term toxicity of the therapy regimen must be weighed.

Use of plasma viral RNA to define therapeutic failure A precise definition of therapeutic failure cannot be based on viral RNA level alone. Such a definition should embrace as a minimum the clinical status of the patient, the tolerability of the antiretroviral regimen, the $CD4^+$ T cell count, and the plasma viral RNA level. The failure of the plasma viral RNA level to decrease by at least 30-fold (1.5 $\log_{10}$) or more from baseline after 4 to 8 weeks of therapy is generally considered a suboptimal virologic response.[9] In addition, many clinicians consider the inability to lower plasma viral RNA to undetectable levels (< 50 RNA copies / ml) after 12 to 24 weeks of therapy to be evidence of therapeutic failure.[10] Lowering viral RNA to undetectable levels is considered a benchmark of success because of the possibility of the development of drug resistance, which can arise when viral replication occurs in the presence of selective pressure by antiretroviral drug regimens.[128] However, many patients fail to achieve undetectable viral RNA levels or experience a rebound in viral RNA after starting antiretroviral therapy.[94,124] Although the pretherapy plasma viral RNA level is itself an independent risk factor for disease progression, the relative benefit of a decline in plasma viral RNA is the same regardless of the level of viral RNA before therapy. For example, a 1 $\log_{10}$ decline in the viral RNA level from 10^5 to 10^4 RNA copies / ml represents the same relative 72% reduction in risk as a change from 10^4 to 10^3 RNA copies / ml.[9] However, these two pretherapy plasma HIV RNA levels confer different relative hazards of disease progression, after controlling for baseline $CD4^+$ T cell count and therapy assignment.[9]

Viral resistance It has been somewhat arbitrarily established that any sustainable 0.5 $\log_{10}$ (threefold) increase in plasma viral RNA level above the therapy-induced plasma viral RNA nadir that is not attributable to intercurrent infection, vaccination, incomplete adherence to the antiretroviral therapy reg-

imen, decreased absorption of antiretroviral drugs, altered drug metabolism, drug-drug interactions, or testing methodology likely represents viral failure caused by the emergence of drug-resistant HIV variants.[10,115] Although genotypic and phenotypic changes associated with drug resistance in vitro are not always synonymous with clinical drug failure in practice, retrospective and prospective clinical data on the predictive value of these tests have supported their adjunctive use in the selection of the antiretroviral regimen to employ next after virologic failure.[114,115] The correct interpretation of viral susceptibility is complicated by the complexity of the mutational patterns, the potential for undetected subpopulations of mutant virus, and residual effects of previous antiretroviral therapy. Thus, the practicing clinician should be cautious about using viral genotypic or phenotypic susceptibility analysis until definitive, prospective clinical trial data are available. Until such data are available, the clinical decision as to when to initiate or change therapy for a patient with HIV should be individualized and should depend primarily on the viral RNA level and $CD4^+$ T cell count, not antiretroviral resistance test results alone.[112]

Discordant viral RNA and $CD4^+$ T cell responses The plasma viral RNA level may increase while the $CD4^+$ T cell count remains stable or continues to rise in response to therapy.[129] This discordance occurs in approximately 14% or more of patients who receive antiretroviral therapy.[9] For many patients, the discordant response is associated with a decrease in disease progression; this raises into question the wisdom of changing antiretroviral therapy solely on the basis of plasma viral RNA response.[130] In the absence of clinical trial data, if the plasma viral RNA level increases in a sustained manner during therapy to either less than 0.5 $\log_{10}$ above the plasma viral RNA therapy nadir or 5,000 (3.7 $\log_{10}$) copies / ml, whichever is less, then it might be prudent to observe carefully for a further deterioration in $CD4^+$ T cell count or clinical progression before considering a change of therapy. A sustained increase in the plasma viral RNA level that exceeds these criteria warrants a reassessment of the antiretroviral regimen for adherence and possible therapy failure because of antiretroviral drug resistance. A more aggressive approach would be to consider a switch in therapy warranted if plasma viral RNA remains at detectable levels.[10] Neither approach, however, has received adequate validation in a controlled clinical trial.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XXXIII HIV AND AIDS

Robert D. Harrington, m.d.
David H. Spach, m.d.

The HIV/AIDS epidemic has changed dramatically over the years. The gap between AIDS cases in developed countries and those in developing countries has steadily widened as developed countries have continued to reap the tremendous benefits of combination antiretroviral therapy while developing countries have struggled with minimal resources. In response, the World Health Organization (WHO), partnering with the Joint United Nations Programme on HIV/AIDS (UNAIDS), has set an ambitious goal, detailed in their 3 by 5 Initiative, of providing effective antiretroviral therapy to 3 million HIV-infected persons in the developing world by the year 2005.[1] This effort will require an enormous commitment of funds, drugs, and human resources to create the infrastructure needed to diagnose and evaluate patients, distribute medication, and monitor treatment. In developed countries, aggressive antiretroviral therapy has already led to a remarkable decline in the rate of AIDS-related deaths and the incidence of major opportunistic infections,[2,3] but this success has ushered in a new and complicated era of HIV clinical care. This chapter provides an update of key information related to the epidemiology and pathogenesis of HIV infection and to the clinical care of HIV-infected patients. HIV serologic tests, HIV quantitative assays (viral load assays), and HIV resistance tests are described in detail elsewhere [*see 7:XXXII Human Retroviral Infections*].

Origin of HIV

HIV evolved from simian immunodeficiency virus (SIV) in chimpanzees and monkeys. Surprisingly, in its natural host, SIV does not cause disease, despite replicating to high levels in infected animals. This lack of pathogenicity may be from a lack of T cell activation in these hosts. Alternatively, these species may have developed tolerance to the infection through natural selection.[4,5]

Data suggest that humans acquired HIV type 1 (HIV-1) from *Pan troglodytes troglodytes* chimpanzees infected with SIV, and that HIV-1 was introduced into the human population (as SIV) from these chimpanzees on at least three independent occasions.[6] These conclusions arose primarily from studies that used DNA analysis of available SIV and HIV-1 strains and are based on three important findings: (1) all HIV-1 strains known to infect humans are closely related to the SIV lineage found in *P. t. troglodytes* chimpanzees; (2) the HIV-1 group is a mosaic of SIV and HIV-1–related sequences, suggesting an ancestral recombination event in a chimpanzee host; and (3) the natural geographical range of *P. t. troglodytes* corresponds with areas endemic for HIV-1 groups M, N, and O. The exact timing and the mechanism for the transmission of HIV-1 remain unknown; given the fact that some peoples in Africa hunt these chimpanzees for food, transmission may have occurred during the capture, preparation, or ingestion of these chimpanzees.

HIV-2 originated from the sooty mangabey monkey (*Cercocebus atys*). Phylogenetically, strains of SIV in sooty mangabeys are closely related (and in some cases identical) to HIV-2.[7] Moreover, the sooty mangabey's natural habitat corresponds with the epicenter of the HIV-2 epidemic. It has been proposed that at least six independent transmission events of SIV from sooty mangabeys to humans have occurred; presumably, these events occurred through the hunting of this animal or through contact with this animal as a pet.

To date, the oldest confirmed isolate of HIV is from a blood sample collected from a patient in the eastern region of Central Africa in 1959.[8] Investigators have analyzed HIV-1 phylogenetic relationships through use of maximum-likelihood phylogenetic algorithms and have concluded that HIV-1 originated in humans in Africa in 1931 or earlier.[9] Through use of these methods, it has been suggested that HIV entered the United States in approximately 1967.

One investigator has hypothesized that HIV originated in Africa as a result of contaminated polio vaccines that were widely used in Africa in the late 1950s; this theory proposes that chimpanzee kidney cells were used in preparing the vaccines. However, analysis by three independent laboratories of samples of these vaccines stored for more than 40 years failed to show even a trace of HIV or SIV; in addition, these laboratories performed mitochondrial DNA analysis and found no evidence of chimpanzee tissue in the vaccines.[10] Furthermore, the phylogenetic studies mentioned above demonstrate that HIV-1 was in the human population long before the polio vaccine program was introduced and that, by the late 1950s, there was significant diversification of HIV-1. These findings make it highly improbable that HIV was introduced through the polio vaccine.

Classification of HIV and AIDS

In 1982, the Centers for Disease Control and Prevention (CDC) established a surveillance definition of AIDS; persons were classified as having AIDS if they had defects in cell-mediated immunity (without a known cause) and if they had one or more designated opportunistic infections or malignancies. In 1985, the case definition incorporated the newly licensed HIV antibody test. In 1993, the CDC revised the AIDS case definition to include HIV-infected adults and adolescents who had an absolute $CD4^+$ T cell count of less than 200 cells/μl or in whom $CD4^+$ T cells made up less than 14% of lymphocytes.[11] Because $CD4^+$ T cell counts in children are not comparable to those in adults, the 1993 revised AIDS definition does not apply to pediatric patients. In 1993, the CDC also generated a comprehensive classification system that consists of a matrix of $CD4^+$ T cell status (levels 1, 2, and 3) and clinical manifestations (categories A, B, and C). This system became effective on January 1, 1993, and is still in use [*see Table 1*].

Epidemiology

Global epidemiology

The HIV epidemic continues to enlarge worldwide. UNAIDS and the WHO report that as of December 2003, approximately 38 million persons were living with HIV worldwide, exceeding the WHO estimates of 1991 by more than 50%. Children under 15 years of age account for 2.5 to almost 3 million of these. In 2003, a staggering 5 million new infections occurred, and 3 million people died of AIDS [*see Figure 1*].[12] Infected persons' igno-

Table 1 Centers for Disease Control and Prevention Classification System for HIV Infection[11]

CD4⁺ T Cell Categories	*Clinical Categories*		
	A (asymptomatic, first-degree HIV or progressive generalized lymphadenopathy)	*B* (symptomatic, but does not satisfy conditions in categories A or C)*	*C† (AIDS-indicator conditions)*
Category 1: ≥ 500 cells/mm³	A1	B1	C1‡
Category 2: 200–499 cells/mm³	A2	B2	C2‡
Category 3: < 200 cells/mm³	A3‡	B3‡	C3‡

*B conditions include bacterial endocarditis, meningitis, or sepsis; candidiasis (oral); candidiasis (persistent vulvovaginal); cervical dysplasia (or carcinoma in situ); constitutional illness (persistent unexplained fever, diarrhea or weight loss, or disabling weakness); herpes zoster (multidermatomal); listeriosis; myelopathy; nocardiosis; oral hairy leukoplakia; pelvic inflammatory disease; peripheral neuropathy; and thrombocytopenic purpura (idiopathic).

†C conditions include candidiasis (bronchial, esophageal, pulmonary, or tracheal); cervical cancer (invasive); coccidioidomycosis (disseminated or extrapulmonary); cryptococcosis (extrapulmonary); cryptosporidiosis (intestinal, for longer than 1 mo); cytomegalovirus (other than liver, spleen, or nodes); encephalopathy (HIV); herpes simplex virus (ulcers present for longer than 1 mo or esophagitis, bronchitis, or pneumonitis); histoplasmosis (disseminated or extrapulmonary); isosporiasis (intestinal, for longer than 1 mo); Kaposi sarcoma; lymphoma (Burkitt, immunoblastic, or primary in brain); *Mycobacterium avium* complex (disseminated or extrapulmonary), *M. kansasii* (disseminated or extrapulmonary), *M. tuberculosis*, or *Mycobacterium* of other or unidentified species (disseminated or extrapulmonary); *Pneumocystis carinii* pneumonia; recurrent pneumonia (two or more episodes in 1-yr period); progressive multifocal leukoencephalopathy; salmonellosis (recurrent septicemia); toxoplasmosis (brain); wasting syndrome (> 10% weight loss plus either chronic weakness or documented fever for at least 30 days in the absence of a concurrent illness that could explain this finding).

‡AIDS case that satisfies the surveillance definition.

rance regarding their HIV status (which may result from lack of access to testing or refusal to be tested); unsafe sexual practices; and discrimination against and stigmatization of persons who are HIV infected, who are homosexual, or who are injection drug users all promote the spread of HIV.

The global distribution of HIV infection varies widely. Sub-Saharan Africa remains the hardest-hit region, with an estimated 26.6 million persons infected, including 3.2 million who were newly infected in 2003. Injection drug use has sparked the epidemic in Vietnam, Asia, the Middle East, Eastern Europe, and Latin America. Although a few countries, such as Thailand and Uganda, have experienced success in controlling the spread of HIV, the global epidemic continues to expand; any regional stabilization of prevalence simply reflects a rising death toll.

Like the global distribution, local and regional trends in the HIV epidemic also show wide variation. In sub-Saharan Africa, the prevalence of HIV varies greatly between regions within countries (urban areas are more affected that rural areas) and between countries (with rates as low as 1% in West African countries such as Senegal to almost 40% in South African countries such as Botswana and Swaziland). Uganda stands out as the single African nation that experienced a substantial contraction in the epidemic; in the capital city, Kampala, HIV prevalence declined from 30% a decade ago to 8% in 2002. African women are more likely than men to be infected with HIV, because of earlier sexual debut and the practice of younger women having sex with older men.

The HIV epidemic continues to expand in Eastern Europe and Central Asia. The Russian Federation, Ukraine, and the Baltic States are the most affected nations in this region. In 2003 alone, an estimated 230,000 people acquired HIV in Eastern Europe and Central Asia, bringing the total number living with HIV in these areas to 1.5 million. Injection drug use is a particularly common mode for HIV infection in these regions, especially in young males. Some of the Baltic States report that up to 1% of the adult population use injection drugs, and a staggering 12% of teenage males in Moscow report having injected drugs at some time. Low rates of condom use have facilitated the spread of the epidemic from injection drug users, who are predominantly male, to women. Sexual transmission between men who have sex with men (MSM) is undoubtedly occurring as well, but few HIV-infected men admit this as a risk factor, given the stigma associated with homosexuality in these cultures.

Injection drug use also stimulated the epidemic in Cambodia and Thailand and is now the predominant reason for the spread of HIV into regions of China, Vietnam, Indonesia, and other Asian and Pacific countries. Persons using unsafe sexual practices, especially commercial sex workers (CSWs), carry the epidemic forward and spread it to men who often eventually transmit HIV to their spouses. In 2003, HIV infected more than one

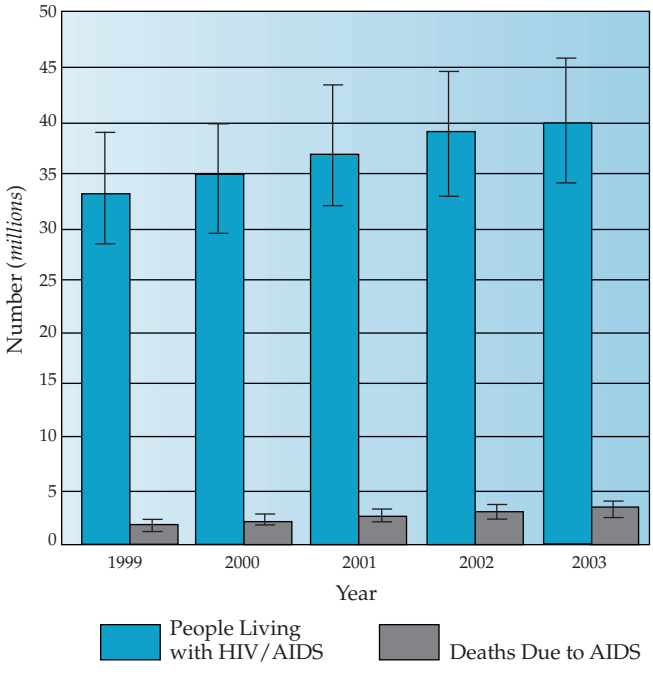

Figure 1 **Estimated number of persons living with HIV/AIDS and global AIDS deaths, 1999–2003.[12]**

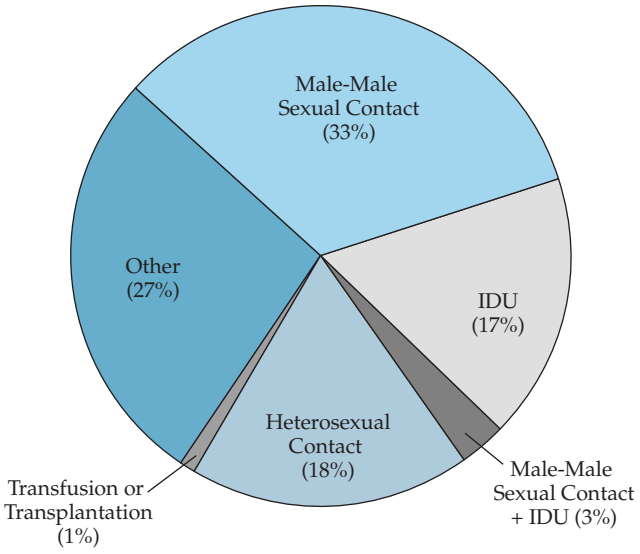

Figure 2 **The percentages of cumulative cases of AIDS of various causes in the United States through December 2002 are depicted in this illustration. These data represent both adult and adolescent AIDS patients.[2] (IDU—injection drug use)**

million persons in Asia, bringing the total number of people living with HIV in this region to 7.4 million. Although countries such as Cambodia and Thailand have posted some success in controlling the spread of HIV, primarily by vigorously promoting universal condom use by CSWs, other countries are just now experiencing the first wave of HIV infections. In these countries, the epidemic is poised to erupt, given their large, vulnerable populations, the lack of safe sex practices, and the high prevalence of contaminated injection drug equipment.

More than two million HIV-infected persons live in Latin America and the Caribbean; the prevalence in some of these countries is among the highest in the world. In Haiti, 5% to 6% of the population is HIV infected; in the Bahamas, Belize, the Dominican Republic, Guyana, and Trinidad and Tobago, the prevalence of HIV in pregnant women is 2% or greater. Different routes of infection predominate in distinct regions: in most of South America, the epidemic is driven by injection drug use; in Haiti, unsafe heterosexual sex is responsible for most infections, whereas both heterosexual and homosexual sex are important modes of transmission in Central America. In Peru and Columbia, most infections are occurring in MSM.

The Middle East and North Africa, except for southern Sudan, have been affected less than other regions of the world. Current data, however, suggest that the number of HIV-infected persons is rising because of localized outbreaks in injection drug users and emigration of HIV-infected persons from adjacent countries where the prevalence of HIV is much higher.

In developed nations other than the United States, the prevalence of HIV is rising because of declining death rates and new infections acquired within these countries or because of immigration of HIV-infected persons from other regions. Sex between men is the major mode of transmission in Germany, Greece, the Netherlands, and Australia, whereas heterosexual transmission is the rule in other Western European countries, whether the infection is imported or acquired locally. Injection drug use is responsible for 10% or less of cases in Australia and Western Europe; the exception is Portugal, where injection drug use caused roughly half of new infections in 2002.

NORTH AMERICAN EPIDEMIOLOGY

Contemporary UNAIDS and WHO estimates of the total number of HIV-infected persons (with or without AIDS) living in North America range from 750,000 to 1,200,000.[12] As of the end of 2002, the cumulative number of AIDS cases in all of the United States reported to the CDC totaled 886,575 [*see Figure 2*].[2] Of the adult patients, 81% were men and 18% were women. The majority of patients were adults or adolescents; only 1% of the patients were children younger than 13 years. Among men, 46% were white, 35% were African American, and 18% were Hispanic. Among women, 21% were white, 59% were African American, and 19% were Hispanic.

Most states have now implemented HIV (not just AIDS) surveillance programs, and many of these programs have matured to the point that the data have stabilized and trends can be monitored. The latest HIV/AIDS surveillance report summarizes cases of HIV and AIDS in the United States through 2002.[13] This report includes catalogued HIV surveillance data from 30 areas (29 states and the U.S. Virgin Islands) where confidential name-based HIV reporting has occurred since at least 1998. Within these 30 areas, several trends in the diagnoses of HIV/AIDS (which includes new diagnoses of HIV infection only, new diagnoses of HIV infection that progressed to AIDS, and concurrent diagnoses of HIV and AIDS) have occurred:

- The diagnoses of HIV/AIDS increased 3.2% from 2001 to 2002, leading to a rate of 19.1 cases per 100,000 population in 2002.
- From 1999 to 2002, increased infection rates were observed in whites, Hispanics, and Asians/Pacific Islanders, while rates in blacks remained stable. Nevertheless, most new infections continued to occur in blacks (54% in 2002).
- From 1999 to 2002, diagnoses of HIV/AIDS increased 7% in men (totaling 71% of cases in 2002), remained stable in women, and decreased in children (92 cases in 2002).
- Rates of infection increased in MSM and heterosexuals but decreased in injection drug users. In 2002, 44% of new cases of HIV/AIDS occurred in MSM and 35% resulted from heterosexual transmission.

The introduction and widespread use of aggressive antiretroviral therapy have produced a remarkable decline in the number of AIDS-related deaths.[2,3] The declining death rate has led to an increase in the prevalence of HIV-infected persons in the United States and other developed countries [*see Figure 1*]. At the end of 2002, there were an estimated 384,906 persons living with AIDS, an increase of almost 100,000 from 1998. Of these patients, approximately 141,000 were white, 162,000 black, 76,000 Hispanic, 298,000 male, 83,000 female, 282,000 between 35 and 54 years of age, and 3,900 children (younger than 13 years). The number of children with AIDS markedly declined during the 1990s, most importantly because of the rapid and widespread implementation of the use of zidovudine to prevent perinatal transmission of HIV. With the current approaches, which use more aggressive combination therapy, rates of perinatal transmission of HIV have declined even further and are currently in the range of 1%.

Approximately 40,000 new HIV infections occur annually in the United States. In recent years, nearly 50% of these new cases have involved African Americans, a group that comprises only 12% of the United States population. Approximately 75% of these infections are acquired sexually; an increasing proportion (about one third) occur through heterosexual sex. Alarming

rates of infection exist in certain demographic groups, such as African-American MSM and African-American women who partner with bisexual men. Supporting evidence for a resurgence in unsafe sexual practices includes recent outbreaks of syphilis and gonorrhea in MSM populations in San Francisco, Seattle, and elswhere.[14] Proposed explanations for this resurgence include belief in the efficacy of medication to treat HIV infection and prevent AIDS, limited exposure of younger persons to AIDS-related deaths of their peers, and the use of drugs (e.g., methamphetamine) and alcohol, which leads to impaired judgment and poor decision making about sexual behavior.

Transmission of HIV

Person-to-person transmission of HIV can occur through several routes, including sexual contact, sharing of contaminated needles used for injecting drugs, receiving a transfusion of a contaminated blood product, transmission from mother to child (during gestation, at the time of delivery, or post partum via breast-feeding), and occupational exposure. The relative risks of acquiring HIV through these routes is difficult to precisely quantitate, but available data suggest that the highest risk is through receiving contaminated blood products, followed by mother-to-child exposure (assuming the mother is not receiving treatment with antiretroviral therapy) and then by the sharing of needles when injecting drugs. Lower risks are associated with needle-stick injuries and sexual transmission.[15] The risk of sexual transmission is highly dependent on the type of encounter, with receptive anal intercourse posing the highest risk. Globally, sexual contact is by far the most common route of HIV transmission, accounting for at least 75% of HIV infections worldwide.[15]

SEXUAL CONTACT

A study from Uganda of 415 couples in which one member of the couple was free of HIV infection (HIV discordant) at the start of the study demonstrated a correlation of increased transmission with increasing HIV RNA levels.[16] Several modeling studies of MSM suggested that transmission during primary infection, which is associated with extremely high HIV RNA levels, may account for up to 50% of infections.[17-19] Longitudinal studies have clearly shown that the consistent use of condoms is highly effective in preventing transmission of HIV via heterosexual intercourse.[20] Several studies have suggested that oral-genital sex, although less risky than genital sex, poses a significant risk of HIV transmission, and a number of cases of HIV transmission have now been reported to have occurred via oral-genital sex.[21,22] Human studies have shown that the tissues in the nasopharyngeal tonsils and adenoids have abundant cells of dendritic origin; these cells can serve as an initial target for HIV and can then assist in transmitting HIV to nearby $CD4^+$ T cells.[23]

A number of factors appear to increase the risk of acquiring HIV via sexual contact; these include disruption and inflammation of the mucosal barrier of the genital tract from genital ulcer disease, urethritis, and cervicitis.[24-26] Evidence that infection with herpes simplex virus (HSV) increases the risk of HIV acquisition and transmission comes from several sources. A meta-analysis suggested that HSV enhanced the risk of HIV acquisition by 2.1-fold to 3.9-fold, depending on the type of study evaluated, although the confounding effect of sexual activity that links both infections could not be eliminated.[27] A subsequent study from India supported the meta-analysis by demonstrating that incident HSV infection increased the risk of HIV acquisition by 3.8-fold.[28] Furthermore, a reanalysis of a discordant-couples study from Uganda showed that HSV-2 seropositive persons had a fivefold increased risk of acquiring HIV per sex act, compared with HSV-2 seronegative persons.[29,30] All of these studies are consistent with reports demonstrating that HSV can increase HIV replication and that HIV is easily cultivated from active HSV lesions.[31,32] Nevertheless, to firmly establish the role of HSV in enhancing HIV transmission, prospective longitudinal studies of sexual partners discordant for both HIV and HSV would need to be performed.

INJECTION DRUG USE

Although injection drug use accounts for fewer cases of HIV transmission than sexual contact, it has played a critical role in the epidemic in certain regions of the world. When injection drug use is coupled with unsafe sexual practices, HIV can rapidly spread through a population. Although needle-exchange programs are not supported by federal funds in the United States, more than 100 exchange programs have been implemented. Multiple studies have clearly shown that needle-exchange programs decrease the incidence of HIV transmission by an estimated 33% without causing an increase in drug use.[33]

USE OF CONTAMINATED BLOOD PRODUCTS

In the United States, the American Red Cross began testing donated blood for antibodies to HIV-1 in 1985; in 1992, this program was expanded to include testing for HIV-2. In 1992 and 1993, the risk of transfusion-acquired HIV in the United States was less than one case of HIV for every 450,000 to 600,000 donations of screened blood, with almost all of the risk related to donors who were infected with HIV shortly before donating their blood and who had not yet undergone seroconversion.[34] With current enzyme immunoassay serologic tests, this so-called window period typically lasts until about day 25 after HIV infection. In 1996, HIV p24 antigen testing was mandated; this test further decreased the risk of HIV transmission. More recent attempts have used nucleic acid testing as an even more sensitive assay to detect donors during the window period. In an interesting case report, a 13-year-old boy received a blood transfusion 2 days before it was discovered that the donor had acute HIV syndrome. The boy received a three-drug antiretroviral postexposure prophylaxis regimen for 9 months and repeatedly tested negative for HIV RNA antibodies, even when tested 6 months after antiretroviral postexposure prophylaxis was discontinued.[35] In China, unsafe blood donation techniques (i.e., reuse of contaminated phlebotomy equipment) led to the infection of some Chinese communities in the 1990s.[12]

MOTHER-TO-CHILD TRANSMISSION

Mother-to-child transmission of HIV accounts for a substantial proportion of HIV cases in developing countries. Such transmission can occur during gestation, at the time of delivery, or post partum via breast-feeding. In the absence of antiretroviral therapy, mother-to-child transmission rates generally range from 20% to 30%,[36] with higher rates occurring in developing countries and in women who breast-feed. Multiple studies have clearly shown the presence of HIV RNA in the mother to be a strong predictor of transmission.[37,38] In addition, in HIV-infected mothers who were not receiving antiretroviral therapy, cesarean section decreased the risk of transmission by about 50%.[39] Although HIV transmission from mother to child can occur early in pregnancy or post partum,[40-42] available data suggest that most

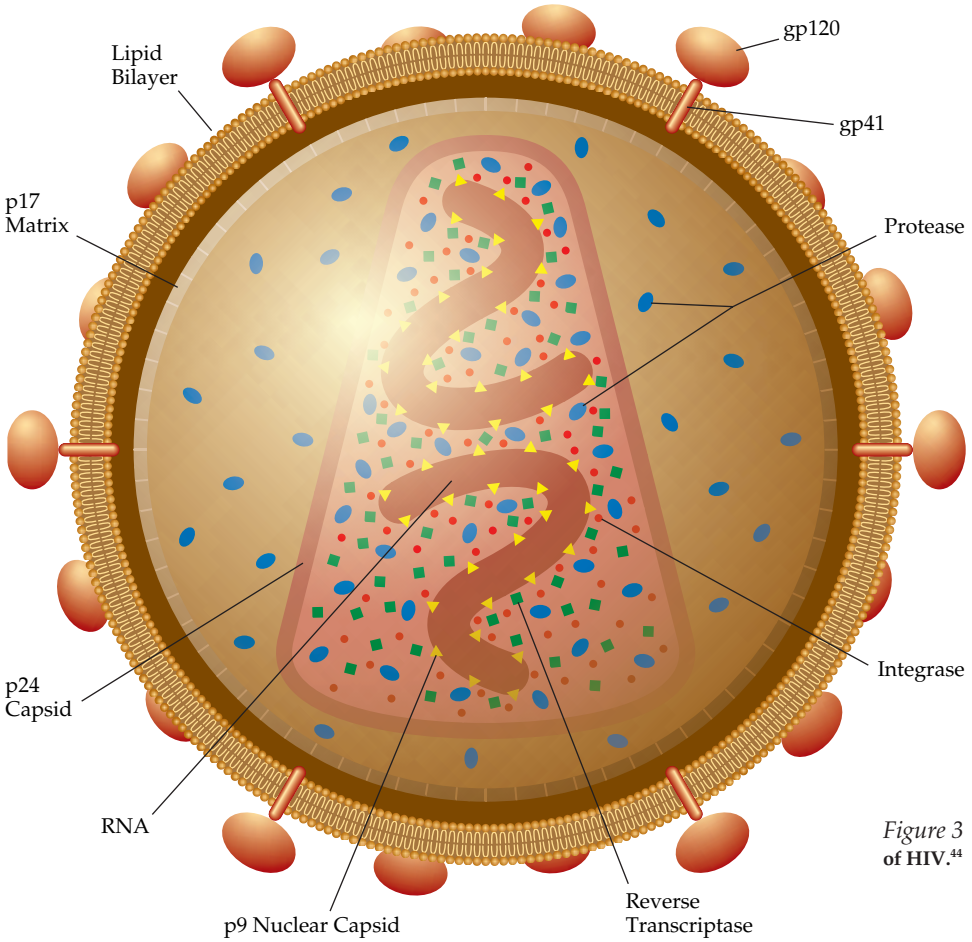

Figure 3 **The structure of HIV.**[44]

perinatal HIV transmission occurs near or at the time of delivery.[41] The widespread use of antiretroviral therapy to prevent mother-to-child HIV transmission has led to a dramatic decline in perinatal HIV transmission in developed countries.[36,41] Current recommendations for the use of antiretroviral therapy to prevent mother-to-child HIV transmission are discussed elsewhere [*see* Antiretroviral Therapy to Prevent Perinatal Transmission, *below*].

OCCUPATIONAL EXPOSURE

As of July 1, 2000, the CDC had reported 56 documented cases of occupational HIV transmission and an additional 138 cases of possible occupational HIV transmission.[2] Of the 56 documented cases, 48 (86%) involved a percutaneous exposure, five (9%) involved a mucocutaneous exposure, two (4%) involved both percutaneous and mucocutaneous exposures, and one (2%) occurred by an unknown route of exposure. In addition, 49 of the 56 cases (88%) involved exposure to blood from an HIV-infected individual. On the basis of available data, the average risk of HIV transmission to a health care worker who experiences a percutaneous exposure to HIV-infected blood but who does not receive postexposure prophylaxis is approximately 0.3%; the risk associated with a mucous membrane exposure to HIV-infected blood is approximately 0.09%.[43] There are no documented cases of HIV transmission in health care workers that resulted from exposure to intact skin. Risk factors associated with increased risk of transmission include deep needle-stick injuries, use of hollow-bore needles, use of a device visibly contaminated with blood, exposure events involving the transference of a large volume of blood, a needle-stick injury in which the needle had been placed directly in an artery or vein of an HIV-infected patient, and the source patient having advanced AIDS.[43] The relative risk of transmission in terms of the source patient's HIV RNA level has not been established for occupational HIV transmission.

Pathogenesis and Progression of Disease

HIV STRUCTURE AND LIFE CYCLE

HIV is a member of the lentivirus family of retroviruses. On electron microscopy, HIV appears as spherical particles that are approximately 110 nm in diameter, with knoblike projections on the surface of the virus and a cone-shaped viral core[44] [*see Figure 3*]. HIV particles contain two copies of an RNA genome, each of which is approximately 10,000 base pairs in length and encodes nine genes.

The genetic structure of HIV-1 is similar to that of all retroviruses. The genome is organized into three major regions (*gag*, *pol*, and *env*) that are flanked by the HIV-1 promoter or long terminal repeat. The *gag* region contains the structural genes for HIV (i.e., matrix, capsid, nucleocapsid, and two small peptides), the *pol* region contains the genes for the viral enzymes needed to carry out the life cycle (i.e., reverse transcriptase, integrase, and protease), and the *env* region encodes the genes for the viral envelope proteins (i.e., gp160, which is cleaved to gp120 and gp41).[45]

HIV-1 has six regulatory genes that are vital for its life cycle and pathogenicity: *tat* (the transactivating gene) upregulates

transcription of the genome; *rev* coordinates the expression of the regulatory and nonregulatory genes by orchestrating the transport of spliced and unspliced RNA transcripts out of the nucleus; *nef* helps the virus evade the host immune response by downregulating expression of CD4 and major histocompatibility complex (MHC) class I molecules on the cell surface and also contributes to viral virulence; *vpu* reduces host cell CD4 expression and is involved in cellular release of virions; *vpr* is important for infection of nondividing cells by facilitating nuclear localization of the viral preintegration complex and also regulates cell cycle arrest; and *vif* is important for virion assembly, infectivity, inactivation of the host cell antiviral factor APOBEC3G,[46] and gp120 membrane insertion.[47] The reverse transcriptase of HIV is very error-prone and introduces mutations at a rate of approximately 1 in 10^4, or about one mutation in every virus produced. In addition, during normal replication, the reverse transcriptase enzyme jumps from one strand of nucleic acid to another to complete the synthesis of daughter strands. This strand-jumping enables recombination between different viral strains infecting the same cell. Mutation and recombination permit the virus to respond rapidly to environmental changes such as those related to receptor availability, host immune responses, and antiretroviral drugs.

Two different HIV species have been identified: HIV-1 and HIV-2. Those isolates of HIV-1 that have been globally identified can be classified into the three major phylogenetic groups: M (main), N (neither M nor O), and O (outlier).[4,48] The M group has predominantly been responsible for the global HIV epidemic. This group can be further subdivided into 10 distinct subtypes or clades, termed subtypes A to J. Patients can be infected with more than one clade, and recombination of viruses from different clades can occur.

The life cycle of HIV is similar to that of other retroviruses. Understanding the life cycle is important for understanding both cellular pathogenesis and the targets of current and future anti-HIV therapies. The first step in the life cycle involves attachment of the virus to the host target cell. The first point of interaction consists of the binding of the HIV envelope surface protein (gp120) with the CD4 receptor on the host cell [*see Figure 4*]. For infection to proceed, cellular coreceptors must also bind gp120, causing its release and the subsequent exposure of the other HIV envelope protein, gp41. The gp41 protein mediates fusion of the virus and cell membranes by stabbing the cell membrane and undergoing a conformational change that brings the two membranes in contact, facilitating fusion and viral entry.

Although investigators have discovered numerous coreceptors that can potentially bind HIV, the coreceptors CCR5 and CXCR4 appear to play the most important role.[49] $CD4^+$ T cells express both CCR5 and CXCR4 receptors, whereas monocytes predominantly express CCR5 [*see Figure 5*]. Available data suggest that initial HIV infection predominantly involves R5 strains of HIV. There is significant genetic variation in the CCR5 coreceptor, and some individuals who are homozygous for a CCR5 deletion mutation (a 32–base-pair deletion) can be repeatedly exposed to HIV without becoming infected.[50] Individuals who are heterozygous for this Δ32 mutation are not protected against HIV infection but may initially manifest a slower rate of disease progression [*see Figure 6*].

After the fusion of the viral and cellular membranes, the viral capsid enters the cell [*see Figure 7*] and the HIV reverse transcriptase enzyme converts the single-stranded HIV RNA into a double-stranded DNA called proviral DNA. The provirus is then integrated into the host cell chromosome by the viral enzyme integrase. Subsequently, cellular enzymes transcribe the provirus into spliced and nonspliced messenger RNA (mRNA) molecules that encode the regulatory genes (*tat* and *rev*) and the structural genes and that serve as full-length genomic transcripts. This process proceeds in an organized fashion with the regulatory genes *tat* and *rev* (on spliced transcripts) expressed first, followed by the transport of full-length transcripts into the cytoplasm, which are then translated into the structural proteins or which serve as genomic RNA for progeny virus. The late stages of viral replication involve both the assembly of the viral particles, with each viral core incorporating two copies of the viral RNA genome, and the budding and release of the virus from the cell surface. The HIV protease enzyme plays an important role in this late process by cleaving the gag polyprotein into smaller functional components, which allows for the formation of mature, infectious viral particles.

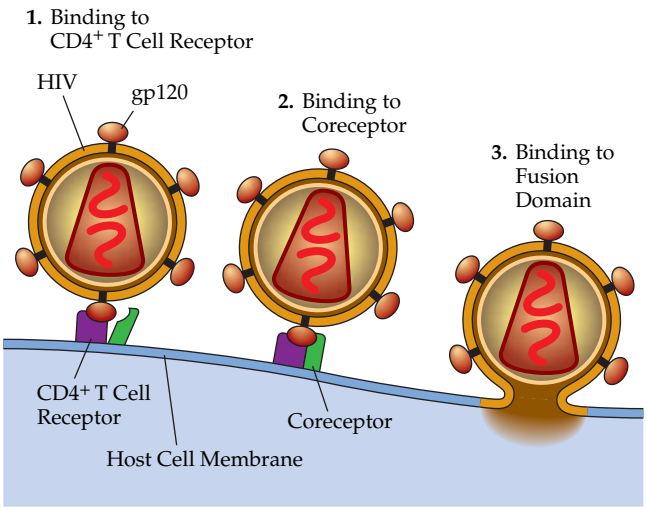

Figure 4 **This illustration shows the major steps involved in HIV binding to and entering the host cell. After binding to the fusion domain, the membranes merge.**

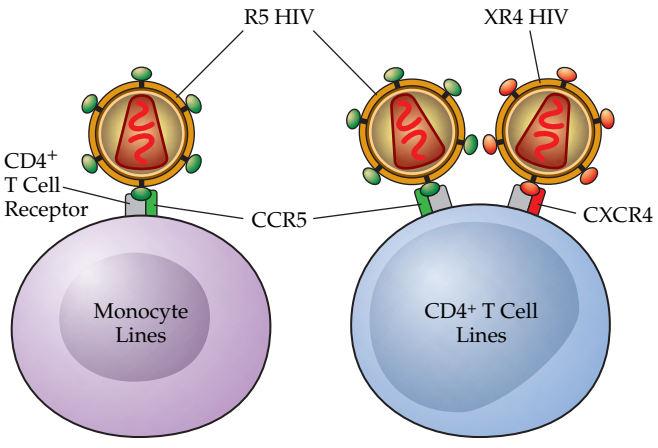

Figure 5 **R5 strains preferentially bind to CC chemokine receptor–5 (CCR5) coreceptors that are present on both monocytes and $CD4^+$ T cells. R4 strains preferentially bind to CXC chemokine receptor–4 (CXCR4) coreceptors (predominantly on $CD4^+$ T cells).**

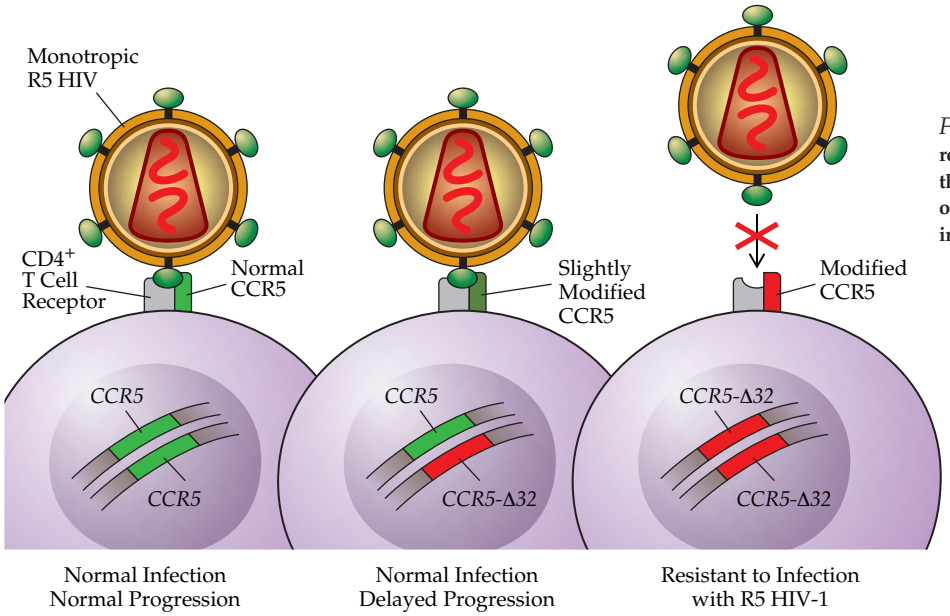

Figure 6 **This diagram shows the relationship of genetic diversity of the CCR5 coreceptor to progression of and susceptibility to HIV infection.**

EARLY EVENTS AND DISEASE PROGRESSION

Worldwide, most HIV infections occur by sexual transmission across mucosal surfaces. The R5 viruses are preferentially transferred across epithelial cell membranes,[51] where they may encounter dendritic cells, $CD4^+$ T cells, or macrophages.[52] HIV may productively infect any of these cell types or be tethered to dendritic cells by means of DC-SIGN (dendritic cell–specific ICAM [intercellular adhesion molecule]-grabbing nonintegrin) or other C-type lectin receptors (CLRs).[53,54] HIV infection of $CD4^+$ T cells is enhanced when the virus is captured and presented to the T cells by dendritic cells expressing DC-SIGN or other CLRs.[55-57] Locally infected T cells or dendritic cells coated with HIV then traffic to regional lymph nodes, where the virus propagates rapidly in the abundant $CD4^+$ T cell pool before disseminating.[58] At this point, patients may experience symptoms of an acute retroviral syndrome before mounting a cytotoxic T cell (CTL) response that partially controls viral replication.[59] However robust this CTL response may be, it never eradicates the infection, in part because the virus preferentially infects and kills the $CD4^+$ T cells that are recruited to the site of HIV replication.[60] This selective depletion of HIV-directed $CD4^+$ T cells cripples the effectiveness of HIV-directed $CD8^+$ T cells, which rely on $CD4^+$ T cell help for proper functioning. Furthermore, the high mutation rate of the virus allows it to escape the control of most potent immune responses. As a result, the infection persists, and continued rounds of replication lead to the gradual depletion of all $CD4^+$ T cells. At the same time, a subset of activated, HIV-infected $CD4^+$ T cells returns to a quiescent state, remains latently infected, and persists with a half-life of up to 44 months.[61] This latent reservoir of HIV can reactivate even after years of suppressive antiviral therapy.[62-64]

The plasma HIV RNA level is a strong independent predictor of the progression to AIDS in untreated HIV-infected persons [*see Figure 8*].[65] In essence, the higher the HIV RNA level, the more rapidly the disease will progress. For example, in patients with a $CD4^+$ T cell count greater than 500 cells/μl, about 5% of

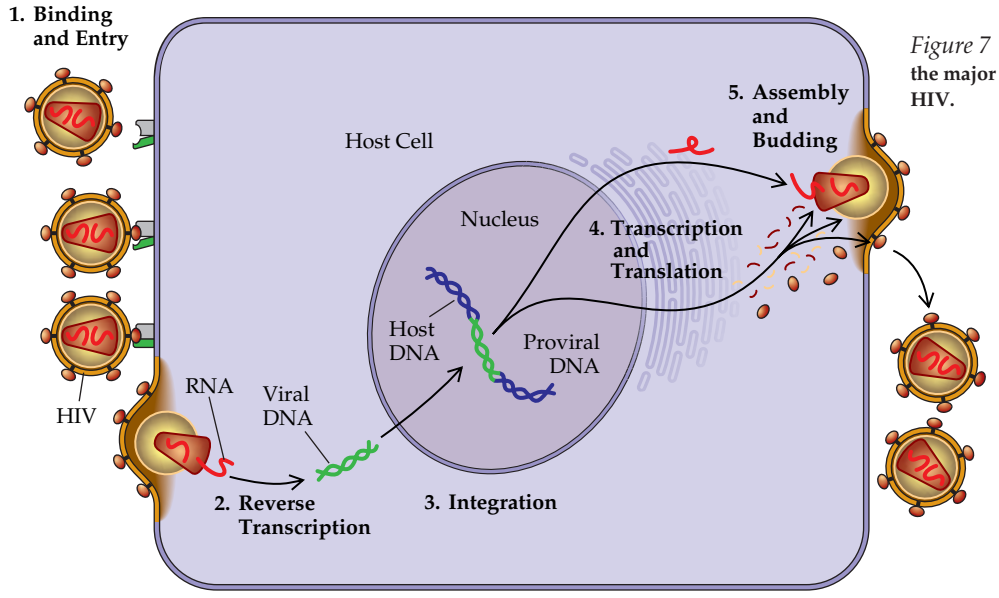

Figure 7 **This illustration depicts the major steps in the life cycle of HIV.**

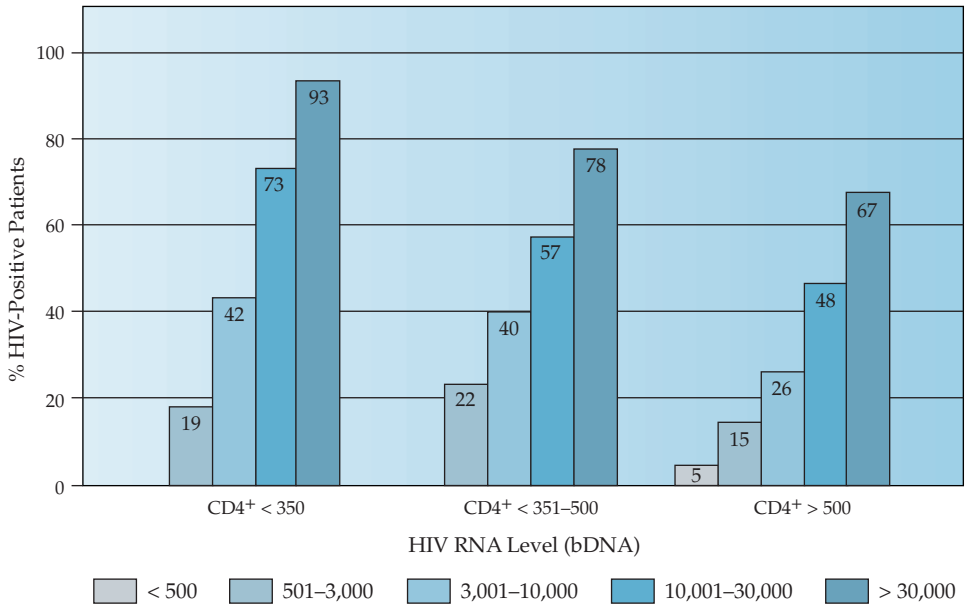

Figure 8 **This graph shows the risk of progression to AIDS at 6 years and the relationship of risk of progression to HIV RNA values and CD4$^+$ T cell counts.[65]**

those who have a baseline HIV RNA level of less than 500 copies/ml will develop AIDS within 6 years, compared with 67% of those who have a baseline HIV RNA level of greater than 30,000 copies/ml. In contrast, the CD4$^+$ T cell count provides an accurate way to assess the current immunologic status.

Within 6 months of primary HIV infection, the plasma level of HIV appears to reach a fairly constant level—a level referred to as the set point. The set point is determined by a number of host and viral factors and varies from person to person. The HIV-directed CTL response appears to be the most important factor in determining the HIV set point. Indeed, the development of the HIV CTL response coincides with the initial decline in HIV RNA levels.[66] Patients who mount a weak CTL response typically have a high set point and rapid progression of HIV disease; in contrast, patients with a strong CTL response have a low set point and slower disease progression [*see Figure 9*].[66] The strength and effectiveness of the T cell response are influenced by the human leukocyte antigen (HLA) genotype of the individual, with certain genotypes reportedly associated with different rates of disease progression; HLA-B27 and HLA-B57, in particular, have been strongly associated with long-term nonprogression.[67-69] The HIV CD8$^+$ CTL response requires a highly coordinated action of multiple cells, including CD4$^+$ helper T cells.[66]

Shortly after acute HIV infection, HIV begins to preferentially destroy HIV-directed CD4$^+$ helper T cells; this process impairs the critical interaction between host CD4$^+$ T cells and CD8$^+$ T cells and thus weakens the host CTL response.

Genetic variations in the host's HIV coreceptors also may play a significant role in the initial progression of HIV disease, most notably with regard to the CCR5-Δ32 heterozygous mutation [*see* HIV Structure and Life Cycle, *above*] and the CCR2-64I mutation.[50] Individuals with the CCR5-Δ32 or CCR2-64I mutation express coreceptors (or coreceptor levels) that are suboptimal for HIV binding, and thus, the level of HIV infection is depressed. Genetic differences between strains of HIV can also affect disease progression. HIV strains can be classified as either R5 or R4, depending on which cellular coreceptor the virus utilizes (CCR5 or CXCR4, respectively). This, in turn, influences whether the virus causes syncytia when grown in vitro.[70] Syncytia-forming HIV strains, which are predominantly R4 (CXCR4-using) viruses, destroy CD4$^+$ lymphocytes more effectively in vivo; their appearance correlates with a rate of CD4$^+$ T cell decline that may be almost three times more rapid than that seen in persons with the nonsyncytium strains.[70] Several reports have also described a small number of persons with very delayed disease progression who are infected with HIV strains containing particular sequence variations or deletions, such as absence of the regulatory gene *nef*. These genetic variations appear to render the virus less pathogenic.[71,72] Finally, individuals with persistent coinfection with the flavivirus GB virus C (GBV-C) may exhibit slower rates of HIV disease progression.[73] Proposed mechanisms for the interference of the HIV life cycle by GBV-C include a shift to a Th1 cytokine profile, downregulation of CCR5, an improved innate immune response to HIV, and decreased viral replication.[74]

Acute Infection

DIAGNOSIS

Clinical Features

After acquiring HIV, infected persons may develop a nonspecific influenzalike or mononucleosis-like illness. The exact proportion of persons with acute HIV infection whose illness reflects primary HIV infection is difficult to ascertain, but estimates range from 40% to 90%.[75] The most common route for HIV inoculation is via the genital mucosa; after genital inoculation, HIV initially infects Langerhans cells, fuses with local CD4$^+$ T cells, and then infiltrates deeper tissues. Within 48 to 72 hours after inoculation, HIV can spread to adjacent inguinal lymph nodes; systemic dissemination and viremia typically develop after about 7 days after initial infection (range, 4 to 11 days).[76] Once viremia develops, HIV extensively seeds lymphoid organs and the central nervous system. During this acute phase of infection, levels of HIV in the genital tract are apparently very high, and the person is likely to be highly infectious.

If a person with primary HIV infection develops a significant clinical illness, it typically begins from 7 to 14 days after the acquisition of the virus. In one study that followed persons considered to be at high risk for HIV, of 23 persons who became infected with HIV, 87% developed an acute HIV illness; of those who developed acute illness, 95% sought medical care, but only 25% were diagnosed as having acute HIV.[22] The correct diagnosis is often missed because of the nonspecific nature of the clinical illness—acute HIV infection may resemble influenza, mononucleosis, secondary syphilis, and more common viral illnesses. The most common signs and symptoms are fever (seen in 80% to 90% of patients), fatigue (70% to 90%), rash (40% to 80%), headache (32% to 70%), lymphadenopathy (40% to 70%), pharyngitis (50% to 70%), and myalgias or arthralgias (50% to 70%).[75] Although the clinical illness caused by acute HIV infection is often nonspecific, clinical findings of a morbilliform rash, acute meningoencephalitis, or mucocutaneous ulcerations may be particularly useful in making the diagnosis. Acute HIV illness typically persists for less than 14 days, but some patients have had illnesses that have extended for longer than 10 weeks.[22] Disease progression is generally more rapid in patients with severe and prolonged symptoms.

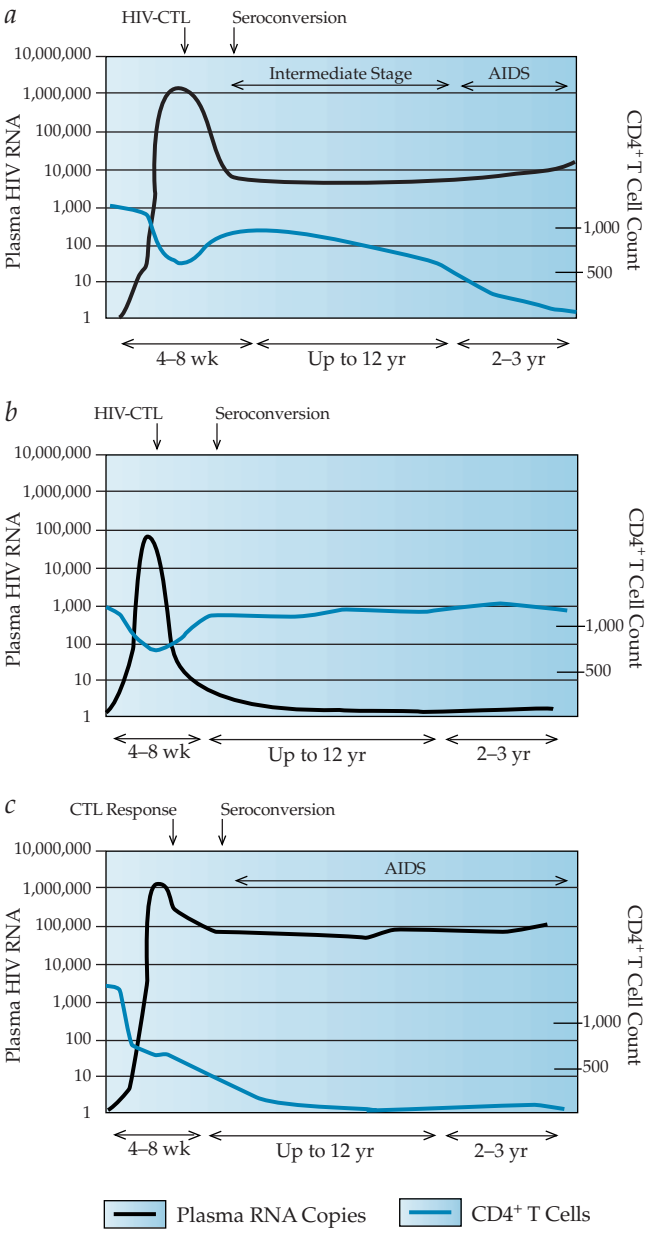

Figure 9 **Differing patterns of HIV-1 RNA and $CD4^+$ T cell levels correlate with different patterns of HIV disease progression. During acute HIV infection, plasma RNA levels rise sharply until the cytotoxic T cell (CTL) response to HIV develops; RNA levels then fall and stabilize at the viral set point. (*a*) Typical progression is marked by the death of many $CD4^+$ T cells, a fair HIV-CTL response, and fair HIV control. (*b*) Long-term nonprogression is marked by some $CD4^+$ T cell death, a good HIV-CTL response, and good HIV control. (*c*) Rapid progression is characterized by considerable $CD4^+$ T cell death, a poor HIV-CTL response, and poor HIV control.**

Laboratory Studies

Routine laboratory studies are generally nonspecific but may show varying degrees of lymphopenia or thrombocytopenia. Results of the standard recombinant enzyme-linked immunoassay (ELISA) are generally negative at the time a patient presents with acute HIV infection; these tests do not typically show a positive result until 22 to 27 days after HIV infection.[77] Although the plasma p24 antigen test is the only currently licensed test for diagnosing acute HIV infection, the HIV RNA assay yields positive results 3 to 5 days earlier than the p24 antigen test. The combination of a strongly positive HIV RNA test result and a negative HIV antibody test result confirms the laboratory diagnosis of acute HIV infection. Almost all persons with acute HIV infection have HIV RNA levels that exceed 50,000 copies/ml, and most have levels that exceed 300,000 copies/ml.[75] Persons presenting weeks or months after their acute HIV illness are likely to have significantly lower levels. A low-level positive result on the HIV RNA assay (i.e., a result of less than 10,000 copies/ml) in a person suspected of being recently infected should be viewed with great caution, as it may represent a false positive result. In this situation, if the p24 antigen test or a repeat HIV RNA test demonstrating a substantial rise cannot be obtained, the HIV serologic test should be repeated 4 to 6 weeks after the clinical illness has resolved.[75,78,79]

Implications of Early Diagnosis

Making a diagnosis of acute HIV is important for several reasons. First, persons with acute HIV are highly infectious and are more likely to transmit HIV. Second, after this initial illness, a very long interval may occur before the infected person develops HIV-related or AIDS-related symptoms, and as a result, the infection may go undiagnosed for years. Third, and most compelling, treatment of persons with acute HIV infection may present a unique opportunity to preserve HIV-directed $CD4^+$ T cells that are preferentially destroyed during acute infection. The preservation of these HIV-directed $CD4^+$ T cells may enable the development of robust $CD8^+$ T cell–mediated CTL responses that effect tight immune control of HIV. This could theoretically alter the natural course of the infection and delay disease progression even if antiretroviral therapy is withdrawn.

TREATMENT

At present, there are limited data on the treatment of patients with acute HIV infection. In the only randomized, placebo-controlled trial that has been performed, patients recently infected with HIV received either zidovudine or placebo. After 6 months, those who received zidovudine experienced a mean

increase in their CD4+ T cell count of 173 cells/μl; those receiving placebo had a mean increase of 6 cells/μl.[80]

Several observational studies have demonstrated that treatment of early or acute HIV infection helps preserve HIV-directed CD4+ and CD8+ T cells.[81-84] However, there are only limited data to suggest that these favorable immunologic profiles translate into long-term clinical benefits. In one study, opportunistic and nonopportunistic infections and progression to AIDS occurred less frequently in 20 patients with early HIV infection who received treatment than in 47 largely untreated historical control patients.[85] A large, randomized, placebo-controlled study has not been performed, however.

The 2004 Department of Health and Human Services (DHHS) guidelines note that certain authorities endorse treatment of acute HIV infection on the basis of the theoretical rationale and limited but supportive clinical trial data. In addition, these guidelines recommend considering therapy for patients who underwent seroconversion within the previous 6 months.[86] However, several questions remain unanswered: (1) How early after infection does treatment have to be initiated? (2) What is the optimal therapeutic regimen? and (3) When and how should HIV therapy be stopped?

Structured Treatment Interruption

One promising strategy for the treatment of primary infection has been the use of structured treatment interruptions. This is a process of scheduled starting and stopping of antiretroviral medications that is intended to enhance CTL responses and thus provide better immunologic control of HIV. The interest in structured treatment interruptions arose from studies that showed the importance of CTL responses in controlling HIV[87] and the observation that CTL responses became very weak in persons who achieved long-term control of HIV with antiretroviral therapy.[88] The goal of structured treatment interruptions is to intermittently expose the immune system to HIV-1 antigen in an attempt to upregulate HIV-specific CTL activity, thus leading to better immunologic control of HIV [*see Figure 10*].

Clinical interest in structured treatment interruption was sparked by a case report of a single patient, known as the Berlin patient, who received early aggressive antiretroviral therapy and then experienced several treatment interruptions; the Berlin patient achieved excellent control of HIV when not receiving antiretroviral therapy and showed excellent HIV-specific CTL responses.[89] A subsequent report showed initially promising results with structured treatment interruption in a carefully selected group of eight patients identified and treated during acute HIV infection. All eight received antiretroviral therapy for longer than 1 year, and all had HIV RNA levels that were consistently lower than 50 copies/ml.[90] With structured treatment interruptions, five of the eight patients were eventually able to maintain HIV RNA levels below 500 copies/ml without treatment. However, expansion of the group to 14 patients with longer follow-up yielded less encouraging results: by intention-to-treat analysis, control of HIV was maintained in only three of the 14 patients without antiretroviral therapy after 2 years.[91] The concept of structured treatment interruptions needs to be evaluated in larger, prospective, randomized studies before it can be recommended.

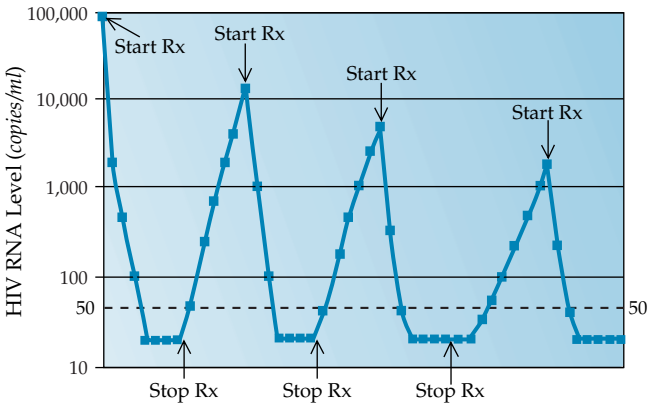

Figure 10 **Conceptual diagram of structured treatment interruption. Medications are started and stopped on several cycles. HIV RNA levels are measured in copies per milliliter. (Rx—therapy)**

Chronic (Established) Infection

INITIAL EVALUATION

The initial evaluation of a patient with HIV who is establishing routine care should include a thorough health history, physical examination, disease screens, vaccinations, and extensive laboratory studies. This initial evaluation process usually requires multiple visits. In the first visit, the health history is obtained, a complete physical examination is performed, and appropriate laboratory studies are ordered. During follow-up visits, which are conducted several weeks after the first, pertinent laboratory data are reviewed; the patient's disease stage and prognosis are discussed; necessary vaccinations are administered; the need for prophylaxis against opportunistic infection is reviewed; and, if appropriate, antiretroviral therapy is discussed.

Medical History

Particular aspects of the HIV-related medical history that should be emphasized are the risk factors for HIV infection, the approximate date of acquisition of HIV, results of the first HIV test that indicated the patient had HIV, a history of an acute seroconversion illness, prior CD4+ T cell and HIV RNA studies, prior HIV-related illnesses, prior and current antiretroviral therapy, and history of other infectious diseases, such as syphilis or hepatitis. Obtaining information regarding the patient's past and current sexual activity and drug use provides insight into both the original acquisition of HIV and current behaviors that may place contacts at risk for HIV infection. In addition to obtaining a complete medical history, it is important to assess the patient's social and psychiatric situation, because social and psychiatric issues can have a critical impact on the patient's adherence to antiretroviral therapy.

Laboratory Studies

The recommended laboratory studies that should be performed at the initial office visit are listed [*see Table 2*].[92]

OVERVIEW OF MANAGEMENT

Prevention Strategies

Recommendations regarding the incorporation of HIV prevention strategies into the care of HIV-infected patients have been developed by the CDC, the Health Resources and Services Administration, the National Institutes of Health, and the HIV

Table 2 Laboratory Studies for the Initial Routine Evaluation of an HIV-Infected Adult

Test	*Comment*
HIV antibody test	Need to firmly establish diagnosis; this test can be omitted if HIV RNA test is convincing
$CD4^+$ T cell count	Critical for staging disease and determining need for antiretroviral therapy
HIV RNA level	Critical for predicting progression of disease and determining need for antiretroviral therapy
Complete blood count	Hematologic problems are more common in HIV-infected persons; baseline value is useful because the number of medications used has effects on marrow
Serum chemistries	Useful to have routine serum chemistries as a baseline
Liver function tests	Useful to have as a baseline, considering potential hepatotoxicity of some antiretroviral medications; useful in patients with active hepatitis B virus (HBV) or hepatitis C virus (HCV) infection
Cholesterol panel	Useful as baseline; significant alterations in lipids can occur with antiretroviral therapy
Serologic testing for syphilis	Important with known higher rates of syphilis among HIV-infected persons
Toxoplasma IgG antibody	Useful in determining whether patient is at risk for developing toxoplasmosis; if negative, patient can receive counseling on preventing acquisition of *T. gondii*
Hepatitis A, B, or C antibody; hepatitis B antigen	Useful for identifying patients coinfected with HIV and either HBV or HCV; useful for identifying patients who are seronegative for hepatitis A virus or HBV and who should therefore receive vaccination; if HCV antibody is positive, testing should be performed to determine whether patient has a positive HCV viral load
Cytomegalovirus serology	IgG levels useful for determining past exposure and risk of reactivation
Urinalysis	Useful as a baseline screen
Purified protein derivative	Considered positive if ≥ 5 mm induration; controls are no longer recommended
Chest x-ray	Useful as a baseline; some specialists obtain a chest x-ray only in patients with a history of pulmonary disease

Medical Association of the Infectious Diseases Society of America.[93] These recommendations are made with the understanding that prevention strategies directed toward persons with known HIV infection can reduce the transmission of HIV and may be particularly effective because they are targeted to a specific group of persons rather than the entire at-risk population. The recommendations include the following: (1) screening patients for risky behaviors, (2) discussing behaviors that are associated with HIV transmission, (3) reinforcing practices that reduce HIV transmission, (4) referring patients with substance abuse problems to appropriate programs, (5) facilitating partner notification and HIV counseling and testing, and (6) regular testing for and treatment of sexually transmitted diseases. These recommendations are particularly important when caring for acutely infected persons, given the high viral loads and high infectivity associated with primary infection.

Vaccination

Asymptomatic HIV-infected patients who have a $CD4^+$ T cell count greater than 500 cells/μl generally produce good antibody responses to vaccines. Responses are frequently poor in patients with lower $CD4^+$ T cell counts, particularly those with AIDS. Persons with more advanced immune suppression may respond better to vaccines administered after immune reconstitution through antiretroviral therapy. Preliminary studies raised concerns that vaccines given to HIV-infected persons could cause significant increases in HIV RNA levels. Further study has shown that although some patients do have a mild to moderate increase in HIV RNA levels after immunization, these increases generally are transient and do not have permanent adverse consequences. Nevertheless, concerns remain regarding the use of live-virus vaccine in HIV-infected patients, particularly those with advanced immune suppression. Vaccines for HIV-infected adults are listed [*see Table 3*].

Routine Follow-up

How often a patient should return for routine follow-up visits depends on the immune status, the clinical status, concomitant medical problems, and whether or not the patient is receiving antiretroviral therapy. In general, patients should have visits at least every 3 months for monitoring of $CD4^+$ T cell counts, HIV RNA levels, and clinical status. More frequent visits are often needed in patients with significant ongoing HIV-related problems or ongoing concomitant medical problems and in those who have recently begun antiretroviral therapy. Visits every 6 months would be appropriate for patients whose disease will probably not progress in the interim, who have a $CD4^+$ T cell count greater than 500 cells/μl, and whose HIV RNA level is less than 10,000 copies/ml.

Antiretroviral Therapy

Before starting antiretroviral therapy, the physician must give careful consideration to the patient's social and medical conditions. In general, the patient should be both interested in and able to take antiretroviral medications consistently. Active social problems (e.g., ongoing drug use, homelessness, or unstable emotional states) can be major barriers to successful antiretroviral therapy. In addition, if a patient has an active severe medical problem, every attempt should be made to defer antiretroviral therapy until that problem is stabilized. Medical indications for antiretroviral therapy are based on the patient's clinical status, the $CD4^+$ T cell count, and the HIV RNA level [*see* Principles for Antiretroviral Therapy, *below*]. There is a wide array of possible antiretroviral drug combinations; in choosing a specific regimen, the clinician should take into account the dosing schedule, possible adverse effects, and underlying patient preferences.

Agents Currently, four different classes of medications, comprising a total of 20 drugs, target HIV: (1) nucleoside reverse transcriptase inhibitors (NRTIs)—abacavir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir disoproxil fumarate (tenofovir-DF), zalcitabine, and zidovudine; (2) nonnucleoside reverse transcriptase inhibitors (NNRTIs)—delavirdine, efavirenz, and nevirapine; (3) protease inhibitors—atazanavir, fosamprenavir, indinavir, lopinavir plus ritonavir, nelfinavir, ritonavir,

Table 3 Vaccinations for HIV-Infected Adults

Vaccine	*Comment*
Haemophilus influenzae type B vaccine	Not generally recommended for adults
Hepatitis A virus vaccine (Havrix, VAQTA)	Recommended for men who have sex with men, injection-drug users, and persons with chronic liver disease; dosage is 1.0 ml given intramuscularly and repeated 6–12 mo later
Hepatitis B virus (HBV) vaccine (Recombivax HB, Engerix-B)	Recommended; regimen for vaccination is 10–20 µg of recombinant HBV vaccine given in the deltoid muscle at 0, 1, and 6 mo; responses are often suboptimal, particularly in those with more advanced immune suppression
Influenza virus vaccine	Recommended; the dosage is 0.5 ml I.M. and should be administered during the period from late October through late December; the goal is to prevent influenza and secondary bacterial pneumonias
Mumps, measles, and rubella vaccine	Recommended, with exceptions; the dosage is 0.5 ml S.C.; patients with severe immunodeficiency should not receive this live vaccine; this vaccine is generally recommended for persons born after 1956 who do not have a documented history of measles or measles vaccination and persons who received the killed vaccine (1963 to 1967) and do not have a documented history of measles or live measles vaccination
Pneumococcal vaccine (polysaccharide 23-valent vaccine)	Recommended if $CD4^+$ T cell count is > 200 cells/µl; the dosage is 0.5 ml I.M. repeated every 5 years; consider repeating vaccine if $CD4^+$ T cell count was less than 200 cells/µl but has increased to greater than 200 cells/µl; there are insufficient data in HIV-infected persons to recommend conjugated 7-valent vaccine
Polio vaccine	Recommended; inactivated vaccine only; live oral polio vaccine is contraindicated in HIV-infected patients; patients who have not been immunized should receive inactivated polio vaccine (trivalent killed poliovirus), 0.5 ml S.C. at 0, 1, and 6 mo
Tetanus-diphtheria toxoid	Recommended; patients previously immunized should receive a booster every 10 years; those never immunized should receive primary vaccination, 0.5 ml I.M. at 0, 1, and 6 mo
Varicella vaccine	Insufficient data to recommend for adults

and saquinavir; and (4) fusion inhibitors—enfuvirtide [*see Figure 11 and Table 4*].[91] The NRTIs—also known as nucleoside analogues (or nucleotide analogues, in the case of tenofovir-DF)—structurally resemble the human nucleosides that HIV uses to make viral DNA. The HIV reverse transcriptase enzyme can mistakenly incorporate the synthetic nucleoside analogue into the elongating strand of viral DNA during the reverse transcriptase process; once incorporated into viral DNA, the nucleoside analogues act as chain terminators because they lack the 3′ hydroxyl group required for chain elongation. The NNRTIs do not act as chain terminators; rather, they directly inhibit the proper functioning of the reverse transcriptase enzyme. The HIV protease inhibitors selectively bind to HIV protease and prevent this enzyme from performing its normal function of cleaving viral polyprotein precursors into individual functional proteins. Successful inhibition of HIV protease causes the formation of deformed HIV particles that generally do not replicate. The fusion inhibitor enfuvirtide represents the newest class of antiretroviral agents. It works by binding to the gp41 envelope protein of HIV to prevent it from mediating fusion of the viral and cell membranes.

Dosing schedules Practical considerations have led to the increasing use of antiretroviral regimens that have infrequent dosing schedules, minimal meal restrictions, and the least possible adverse effects. Most of the NRTIs can be taken twice daily without regard to food consumption; the exceptions are zalcitabine, which is taken three times daily, and didanosine, which is taken a half hour before a meal or 1 hour after a meal. Although the new enteric-coated didanosine capsule is taken once daily, it should not be taken with meals. Alcohol significantly increases the plasma levels of abacavir. The NNRTIs can be taken without regard to food consumption, with the caveat that efavirenz should not be taken after a meal high in fats, because this will increase the plasma level of efavirenz by approximately 50%. Dosing schedules and food restrictions are more complicated with the protease inhibitors. Atazanavir, nelfinavir, saquinavir, and ritonavir should be taken with food; fosamprenavir can be taken with or without meals. Indinavir should be taken 1 hour before or 2 hours after a meal, or it can be taken with a low-fat meal.

Combination therapy Increasingly, pharmacologic boosting of protease inhibitor levels is being used to simplify the dosing schedule, decrease the pill burden, and improve the efficacy of several of the protease inhibitors. Most often, this technique has involved the use of low-dose ritonavir in combination with another protease inhibitor, also at a reduced dosage. Ritonavir significantly increases the trough level of the other protease inhibitor, usually without causing a major increase in the peak levels [*see Figure 12 and Table 5*]. Long-term data from studies on the combination of ritonavir and saquinavir have shown this combination to be highly effective.[94] The fixed combination of ritonavir and lopinavir (Kaletra) is highly effective and is preferred by many providers. Ritonavir is now also commonly used with atazanavir, fosamprenavir, or indinavir to boost the blood level of coadministered drug, simplify the dosing schedule, and reduce the pill burden. Two other fixed combinations are now available: emtricitabine and tenofovir-DF (Truvada) and abacavir and lamivudine (Epzicom).

Principles of Antiretroviral Therapy

An expert panel convened by the DHSS and the Henry J. Kaiser Family Foundation has issued antiretroviral therapy recommendations for medical providers in the United States. These guidelines, which are based on data from clinical trials, basic virologic principles, and clinical experience, were last updated March 23, 2004, and will continue to be modified as needed.[91] A second set of published guidelines was issued by the International AIDS Society[95]; these guidelines had more international input than the DHHS guidelines. As described in the DHHS guidelines, the goal of antiretroviral therapy is to obtain maximal and durable suppression of HIV, restore and preserve im-

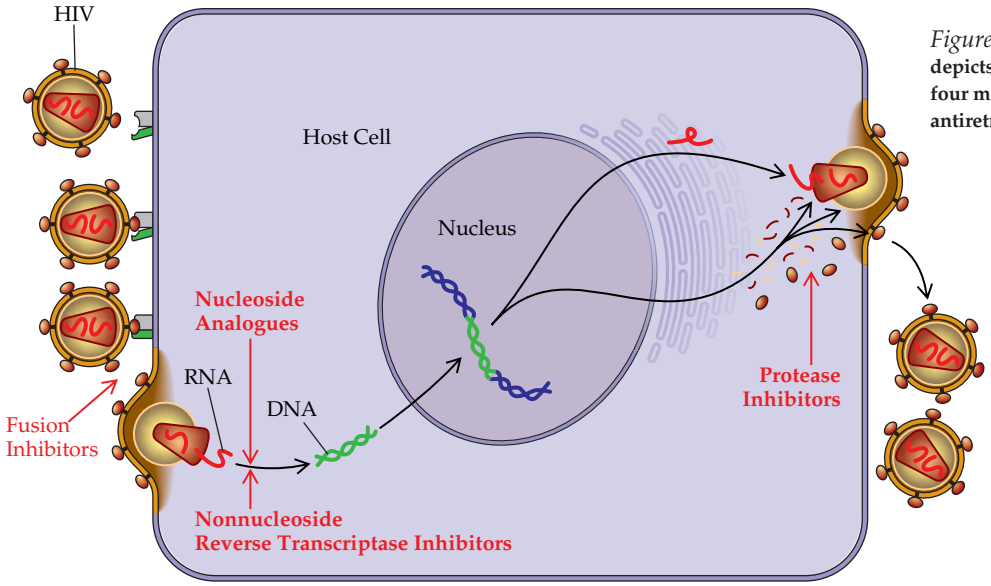

Figure 11 **This illustration depicts the site of action of four major classes of antiretroviral medications.**

mune function, improve quality of life, and reduce HIV-related mortality.

INITIATION OF THERAPY

The DHHS guidelines recommend that antiretroviral therapy be offered to chronically infected patients who have severe HIV-related symptoms or AIDS or who are asymptomatic but meet certain immunologic or virologic thresholds. Asymptomatic patients with $CD4^+$ T cell counts below 200/μl should be offered therapy because of the significant risk of opportunistic infection and death without treatment. Asymptomatic patients with $CD4^+$ T cell counts between 200 and 350/μl should generally be offered treatment unless their plasma HIV RNA level is low, in which case their short-term risk of disease progression and death is also low. Asymptomatic patients with $CD4^+$ T cells above 350/μl can generally be followed without treatment unless their HIV RNA level is high (> 55,000 copies/ml by reverse transcriptase polymerase chain reaction [RT-PCR] or branched DNA [bDNA] assay), in which case some providers recommend treatment because of the risk of more rapid disease progression. Patients who are diagnosed during acute infection or within 6 months of infection may have the unique opportunity to modify their disease history with treatment (see above). Theoretically, early treatment may lower the viral set point, preserve HIV-directed $CD4^+$ T cells, relieve symptoms of acute infection, and prevent transmission. These benefits, however, must be weighed against the toxicity of therapy, the possible promotion of drug-resistant HIV strains, and the lack of long-term clinical data demonstrating a clear benefit of early therapy.

REGIMEN SELECTION

Antiretroviral therapy should consist of a potent regimen that includes a combination of three or more medications [*see Table 6*]. The combination regimens typically consist of (1) two NRTIs plus a protease inhibitor, (2) two NRTIs plus an NNRTI, or (3) two NRTIs plus ritonavir plus a second protease inhibitor. In the last case, ritonavir's potent inhibition of the cytochrome P-450 elimination pathway is used to boost the blood level of the second protease inhibitor. Preferred regimens for antiretroviral-naive patients have been identified in the DHHS guidelines [*see Table 6*].

Enfuvirtide is most effective in patients with $CD4^+$ T cell

Table 4 Antiretroviral Medications

Generic Name	*Trade Name*	*Dosage*
Nucleoside RTIs		
Abacavir (ABC)	Ziagen	300 mg p.o., b.i.d.
Didanosine (ddI)	Videx	400 mg p.o., q.d. (250 mg q.d. if < 60 kg)
Emtricitabine (FTC)	Emtriva	200 mg p.o., q.d.
Lamivudine (3TC)	Epivir	150 mg p.o., b.i.d.
Stavudine (d4T)	Zerit	40 mg p.o., b.i.d. (30 mg p.o., b.i.d., if < 60 kg)
Zalcitabine (ddC)	Hivid	0.75 mg p.o., t.i.d.
Zidovudine (AZT)	Retrovir	300 mg p.o., b.i.d.; or 200 mg t.i.d.
Zidovudine + lamivudine*	Combivir	One tablet p.o., b.i.d.
Zidovudine + lamivudine + abacavir*	Trizivir	One tablet p.o., b.i.d.
Nucleotide RTI		
Tenofovir	Viread	300 mg p.o., q.d.
Nonnucleoside RTIs		
Delavirdine	Rescriptor	400 mg p.o., t.i.d.
Efavirenz	Sustiva	600 mg p.o., q.d. (dose can be split and given 200 mg in A.M. and 400 mg in P.M.)
Nevirapine	Viramune	200 mg p.o., q.d. × 14 days, then 200 mg p.o., b.i.d.
Protease inhibitors		
Atazanavir	Reyataz	400 mg p.o., q.d.
Fosamprenavir	Lexiva	1,400 mg q.d. or 700 mg b.i.d.
Indinavir	Crixivan	800 mg p.o., q. 8 hr
Lopinavir + ritonavir	Kaletra	3 p.o., b.i.d. (lopinavir, 400 mg b.i.d. + ritonavir, 100 mg b.i.d.)
Nelfinavir	Viracept	1,250 mg p.o., b.i.d., or 750 mg p.o., t.i.d.
Ritonavir	Norvir	600 mg p.o., b.i.d. (dose escalation†)
Saquinavir	Fortovase	1,200 mg p.o., t.i.d.

*Standard dosages are used in fixed combinations.
†Ritonavir dose escalation: 300 mg p.o., b.i.d. × 2 days; 400 mg p.o., b.i.d. × 3 days; 500 mg p.o., b.i.d. × 8 days; 600 mg p.o., b.i.d.
RTI — reverse transcriptase inhibitor

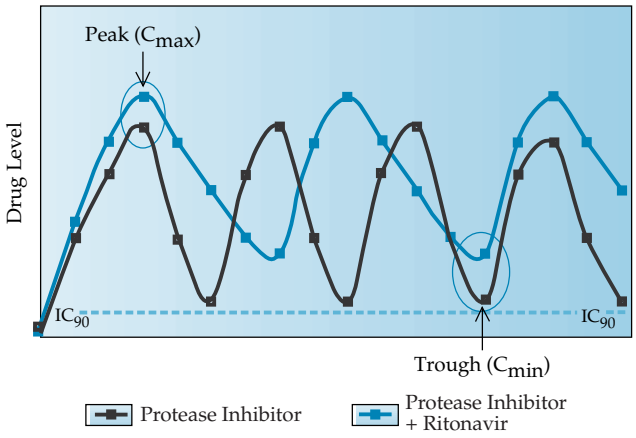

Figure 12 **In this illustration, the drug levels of a protease inhibitor are compared with boosted levels of ritonavir. (IC_{90}—concentration of drug required to inhibit 90% of viral replication)**

counts above 100 cells/μl; in these cases, enfuvirtide is combined with a standard regimen of drugs that includes one or two agents to which the patient's virus is sensitive. However, patients who do not meet these criteria may still experience a virologic response and some immunologic benefit from enfuvirtide. These benefits must be weighed against the cost, difficulty of administration (twice-daily subcutaneous injections), and adverse effects (e.g., injection-site reactions, hypersensitivity, and possible pneumonia).[96]

DRUG SELECTION

Adverse Effects of Drugs

Potential adverse effects can greatly influence the choice of antiretroviral medications and a patient's ability and willingness to stay on long-term antiretroviral therapy [*see Table 7*]. Possible acute life-threatening reactions include didanosine-induced pancreatitis, abacavir-related hypersensitivity syndrome, lactic acidosis secondary to the use of any of the NRTIs but more closely associated with stavudine, Stevens-Johnson syndrome secondary to the use of any of the NNRTIs, and nevirapine-associated liver failure.[97] Several older reports have described fatalities in patients taking hydroxyurea in combination with didanosine and with didanosine plus stavudine, so the use of hydroxyurea as adjuvant treatment with NRTIs is no longer recommended. Unfortunately, the pancreatitis associated with didanosine can occur without warning at any time during therapy.

A number of metabolic abnormalities have been reported in HIV-infected persons, some of which are linked to treatment with antiretroviral agents. Reported metabolic derangements include lactic acidosis, insulin resistance, hyperlipidemia, body-fat redistribution (lipodystrophy), osteonecrosis, and osteopenia.[98]

Hypersensitivity syndrome The abacavir hypersensitivity syndrome occurs in approximately 2% to 3% of patients receiving that drug and is strongly associated with a particular HLA haplotype (HLA-B*5701, HLA-DR7, and HLA-DQ3).[99] It typically develops within the first 3 to 4 weeks after abacavir is started. Symptoms of abacavir hypersensitivity syndrome most often consist of rash, fever, nausea, oral lesions, and cough. Patients often describe an accentuation of these symptoms shortly after taking each dose of abacavir. Patients who begin to develop the hypersensitivity syndrome and then stop taking abacavir can have an acute, potentially fatal reaction on resuming abacavir therapy. Treatment of a patient with mild symptoms that are suggestive of abacavir hypersensitivity should be conducted in consultation with an expert on this matter.

Lactic acidemia Lactic acidemia is defined as an elevated venous lactate level (> 2 mmol/L) and a normal arterial pH. Lactic acidosis is present when the arterial pH is below 7.3. Mild, usually asymptomatic lactic acidemia occurs in 8% to 21% of patients on antiretroviral therapy,[100,101] whereas symptomatic acidemia occurs in less than 2.5%. The leading proposed mechanism is NRTI inhibition of the mitochondrial DNA gamma polymerase. Risk factors for the development of lactic acidemia include longer duration of NRTI exposure (especially with stavudine[102]), female gender, and pregnancy. Symptoms associated with increased serum lactate levels are generally vague and may include nausea, malaise, and anorexia and weight loss, which may go on for months. Symptoms of more severe disease in-

Table 5 Ritonavir Boosted Protease Inhibitor Regimens

Ritonavir Dose	*Other Protease Inhibitor*	*Comment*
100 mg b.i.d.	Lopinavir, 400 mg b.i.d.	FDA-approved fixed combination with excellent potency
400 mg b.i.d.	Saquinavir, 400 mg b.i.d.	Combination with best long-term data; highly effective combination, but intolerance to ritonavir common at this dosage Can use with hard-gel (Invirase) or soft-gel (Fortovase) formulations
100 mg b.i.d.	Saquinavir, 1,000 mg b.i.d.	Can use with hard-gel (Invirase) or soft-gel (Fortovase) formulations, but better pharmacokinetic profile with hard-gel formulation
100 mg b.id. *or* 200 mg b.i.d.	Indinavir, 800 mg b.i.d.	Moderate amount of data suggest regimen very potent; can be taken with meals; increased indinavir toxicity at this dosage
400 mg b.i.d.	Indinavir, 400 mg b.i.d.	Moderate amount of data suggest regimen very potent; ideal pharmacokinetics, but intolerance to ritonavir common at this dosage
200 mg q.d.	Fosamprenavir, 1,400 mg q.d.	Once-daily dosing of fosamprenavir not recommended for protease inhibitor–experienced patients
100 mg b.i.d.	Fosamprenavir, 700 mg b.i.d.	—

Table 6 DHHS Recommendations for Antiretroviral Regimens for the Treatment of Established HIV in Adults and Adolescents[87*]

Regimen Type	*Drugs*	*No. of Pills per Day*
NNRTI based	**Efavirenz + lamivudine + (zidovudine or tenofovir DF or stavudine*)[†]**	**3–5**
	Efavirenz + emtricitabine + (zidovudine or tenofovir DF or stavudine*)[†]	3–4
	Favirenz + (lamivudine or emtricitabine) + (didanosine or abacavir)	3–5
	Nevirapine[‡] + (lamivudine or emtricitabine) + (zidovudine or stavudine* or didanosine or abacavir)	4–5
PI based	**Lopinavir/ritonavir (Kaletra) + lamivudine + (zidovudine or stavudine*)**	**8–10**
	Atazanavir + (lamivudine or emtricitabine) + (zidovudine or stavudine* or abacavir)[†]	4–5
	Fosamprenavir + (lamivudine or emtricitabine) + (zidovudine or stavudine* or abacavir)	6–8
	Fosamprenavir/ritonavir[§] + (lamivudine or emtricitabine) + (zidovudine or stavudine* or abacavir)	6–8
	Indinavir/ritonavir[§] + (lamivudine or emtricitabine) + (zidovudine or stavudine* or abacavir)	8–11
	Lopinavir/ritonavir (Kaletra) + emitricitabine + (zidovudine or stavudine* or abacavir)	8–9
	Lopinavir/ritonavir (Kaletra) + lamivudine + abacavir	8–9
	Nelfinavir[‖] + (lamivudine or emtricitabine) + (zidovudine or stavudine* or abacavir)	12–14
	Saquinavir (SGC or HGC)/ritonavir[§] + (lamivudine or emtricitabine) + (zidovudine or stavudine* or abacavir)	14–16
Triple NRTI[¶]	Abacavir + lamivudine + (zidovudine or stavudine*)	2–6

Note: Preferred regimens, drugs, and doses are in bold type: regimens are designated as preferred for use in treatment-naive patients when clinical trial data suggest optimal and durable efficacy with acceptable tolerability and ease of use. Alternative regimens are those for which clinical trial data show efficacy, but the preferred agent has better antiviral activity or demonstrated durable effect, tolerability, or ease of use. In some cases, a regimen listed as an alternative regimen in the table may actually be the preferred regimen because of individual patient characteristics.

*Higher incidences of lipoatrophy, hyperlipidemia, and mitochondrial toxicities are reported with stavudine than with other NRTIs.

†Regimen not to be used in women with childbearing potential (i.e., women who want to conceive or who are not using effective contraception).

‡A high incidence of symptomatic hepatic events has been observed in women with pre-nevirapine CD4+ T cell counts > 250 cells/μl (11%) and in men with counts > 400 cells/μl (6.3%). Use with caution in these patients, with close clinical and laboratory monitoring, especially during the first 18 wk of therapy.

§Low-dose (100–200 mg) ritonavir.

‖Nelfinavir is available in a 250 mg or 625 mg tablet.

¶A triple-NRTI regimen is to be used only when an NNRTI-based or a PI-based regimen cannot or should not be used as first-line therapy.

HGC—hard gel capsule NRTI—nucleoside reverse transcriptase inhibitor NNRTI—nonnucleoside reverse transcriptase inhibitor PI—protease inhibitor SGC—soft gel capsule

clude abdominal pain, dyspnea, and encephalopathy. Although severe lactic acidosis is unusual, patients with serum lactate levels greater than 10 mmol/L have a mortality of approximately 80%.[97] Treatment of symptomatic lactic acidemia should include discontinuance of NRTIs and supportive care. Most patients can be successfully rechallenged with other NRTIs after the acidemia has resolved.[103]

Insulin resistance Protease inhibitor–based regimens are associated with significant increases in insulin resistance (i.e., increased insulin concentrations and increased C-peptide levels)[104-106]; in one historical cohort study of 221 patients, the reported incidence of new-onset hyperglycemia was 5%.[107] Other retrospective studies have reported hyperglycemia in 3% to 17% of patients. Postulated mechanisms include a direct effect of HIV therapy on glucose uptake, drug-induced body-fat redistribution (lipodystrophy) (see below) that is associated with increased insulin resistance, and, in the case of indinavir,[108] inhibition of peroxisome proliferator-activated receptor gamma. Reported treatment strategies include substitution of the protease inhibitor with an NNRTI or abacavir.[109-111] Otherwise, treatment should be as recommended for non–HIV-infected patients with diabetes and should include diet and exercise, followed by insulin-sensitizing agents and insulin, if necessary.

Hyperlipidemia Before the widespread use of antiretroviral therapy, reduced levels of high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, and total cholesterol and elevated levels of triglycerides were reported in HIV-infected patients.[112-114] The use of protease inhibitors has been associated with a return of LDL cholesterol levels to normal or with high LDL cholesterol levels in conjunction with marked hypertriglyceridemia.[115-118] Ritonavir has been associated with the greatest increases in triglyceride levels,[117] whereas other protease inhibitors, such as atazanavir and nelfinavir, are less closely linked to this effect. The evidence of an association between NNRTIs and hyperlipidemia is mixed. Improvements in hyperlipidemia are more marked in patients changing from a protease inhibitor to nevirapine than to efavirenz.[110,119,120] Except for one study showing higher lipid levels with stavudine than with tenofovir-DF, the NRTIs have not been associated with hyperlipidemia.[121]

The important clinical question is whether these abnormal lipid values translate into an increased risk of cardiovascular and cerebrovascular disease. Two very large studies reached different conclusions regarding this issue. A study that retrospectively abstracted coded data from records of 36,000 HIV-infected Veterans Affairs patients followed between 1995 and 2001 found a reduction in the rate of hospital admission for cardiovascular or cerebrovascular disease and a reduction in death from all causes that was associated with antiretroviral therapy.[122] In contrast, a study of 23,000 HIV-infected patients enrolled in the multinational Data Collection on Adverse Events of Anti-HIV Drugs (DAD) study demonstrated a 26% increase in the risk of myocardial infarction for each year of antiretroviral treatment.[123] Neither study had the long follow-up periods usually needed to assess cardiovascular disease outcomes, and neither study included an HIV-negative control group. Nevertheless, it is likely that the hyperlipidemia seen in antiretroviral-treated HIV-infected patients is one of several factors that does increase the risk of development of cardiovascular and cerebrovascular disease. However, this potentially adverse effect is far outweighed by the benefits of antiretroviral therapy.

Table 7 Adverse Effects Associated with Antiretroviral Medications

Generic Name	*Trade Name*	*Toxicity*
Nucleoside RTIs		All nucleoside RTIs may be associated with mitochondrial toxicity, lactic acidemia, and lipodystrophy (atrophy)
Abacavir (ABC)	Ziagen	Hypersensitivity reaction in 3% of patients; characterized by fever, rash, nausea, vomiting, or malaise; may be fatal; lactic acidosis (rare)
Didanosine (ddI)	Videx	Peripheral neuropathy, pancreatitis, nausea, lactic acidosis, lipoatrophy
Emtricitabine (FTC)	Emtriva	Few side effects; lactic acidosis (rare)
Lamivudine (3TC)	Epivir	Few side effects; lactic acidosis (rare)
Stavudine (d4T)	Zerit	Peripheral neuropathy; lactic acidosis (rare)
Zalcitabine (ddC)	Hivid	Peripheral neuropathy, stomatitis, lactic acidosis (rare)
Zidovudine (AZT)	Retrovir	Anemia, neutropenia, gastrointestinal problems, headache, lactic acidosis (rare), lipoatrophy
Nucleotide RTIs		
Tenofovir	Viread	Renal dysfunction (unusual)
Nonnucleoside RTIs		
Delavirdine	Rescriptor	Rash (4%); increased transaminase levels; headache
Efavirenz	Sustiva	Rash seen in 2% of patients; central nervous system side effects (confusion, abnormal dreams, agitation, etc.)
Nevirapine	Viramune	Rash seen in 7% of patients; increased transaminase levels; hepatitis (can be fatal)
Protease inhibitors		Most protease inhibitors are associated with lipid abnormalities, lipodystrophy (central fat accumulation) and gastrointestinal side effects
Fosamprenavir	Lexiva	Gastrointestinal intolerance; lipid abnormalities; perioral paresthesias; fat redistribution
Atazanavir	Reyataz	Gastrointestinal intolerance, elevated bilirubin levels
Indinavir	Crixivan	Gastrointestinal intolerance; nephrolithiasis; increase of indirect bilirubin; headache; lipid abnormalities; fat redistribution
Lopinavir + ritonavir	Kaletra	Gastrointestinal intolerance; lipid abnormalities, including increased triglyceride levels; fat redistribution
Nelfinavir	Viracept	Diarrhea; lipid abnormalities; major drug–drug interactions; fat redistribution
Ritonavir	Norvir	Gastrointestinal intolerance; perioral and extremity paresthesias; taste perversions; asthenia; hepatitis; major drug–drug interactions; lipid abnormalities, including increased triglyceride levels; fat redistribution
Saquinavir	Fortovase, Invirase	Gastrointestinal intolerance; headache; lipid abnormalities; fat redistribution

RTI — reverse transcriptase inhibitor

Current recommendations from an International AIDS Society–USA panel for treatment of hyperlipidemia include the following: (1) a possible change to protease inhibitor–sparing antiretroviral regimens, (2) adherence to diet and exercise guidelines, and (3) use of lipid-lowering agents.[98] Specific recommendations for the use of lipid-lowering agents follow those of the United States National Cholesterol Education Program guidelines.[124] Of the statins, pravastatin has the least severe drug interactions with protease inhibitors and is often used as a first-line agent. Although atorvastatin has more interactions with protease inhibitors than does pravastatin, few adverse events have been reported with atorvastatin. In addition, atorvastatin has greater potency than pravastatin, and it has a favorable impact on triglyceride levels.[125] Patients with marked hypertriglyceridemia often require treatment with a fibric acid analogue (e.g., fenofibrate or gemfibrozil).

Lipodystrophy The lipodystrophy syndrome, also known as the fat-redistribution syndrome, has become a problematic long-term complication of antiretroviral therapy. The lipodystrophy syndrome typically presents as central fat accumulation (i.e., accumulation of fat in the abdomen, breasts, or posterior neck) or peripheral fat wasting (i.e., wasting in the face, buttocks, and limbs), or both[126] [*see Figure 13*]. Lipodystrophy is reported in 25% to 75% of HIV-infected patients.[112,113,127-129]

Several mechanisms have been proposed for the lipodystrophy syndrome, but none are proven. Protease inhibitors, because of their role in inducing insulin resistance, have been blamed for the central lipoaccumulation.[112,130] Fat accumulation has also been reported in HIV-infected patients who were not exposed to protease inhibitors, however.[127,131] Lipoatrophy is more closely tied to exposure to NRTIs,[126,132,133] particularly stavudine. In this setting, NRTI-induced mitochondrial poisoning (as occurs in NRTI-induced lactic acidemia) may be responsible for adipocyte death and loss of subcutaneous fat. Other possible risk factors for the syndrome include older age, low body weight before starting antiretroviral therapy, duration of HIV infection, duration and effectiveness of antiretroviral therapy, and white race.[97,107,134-136]

A number of drugs and interventions have been tried as treatment for lipodystrophy, with only modest success. Switching from stavudine to other NRTIs has reversed limb-fat atrophy in some patients,[137] but substitution of protease inhibitors to reverse fat accumulation has not been successful. Exercise may have only a limited benefit in reducing fat accumulation,[138] but it does have other obvious health advantages. Growth hormone has been shown to benefit a small number of patients with fat accumulation,[139] but this approach is not considered practical, given the extreme cost, adverse effects, and the need for continued use to sustain benefit. Promising results in the treatment of lipodystrophy have been reported from preliminary studies of the insulin-sensitizing agent metformin. In a randomized, double-blind, placebo-controlled trial, use of metformin at a dosage of 500 mg twice daily for 3 months was associated with decreased

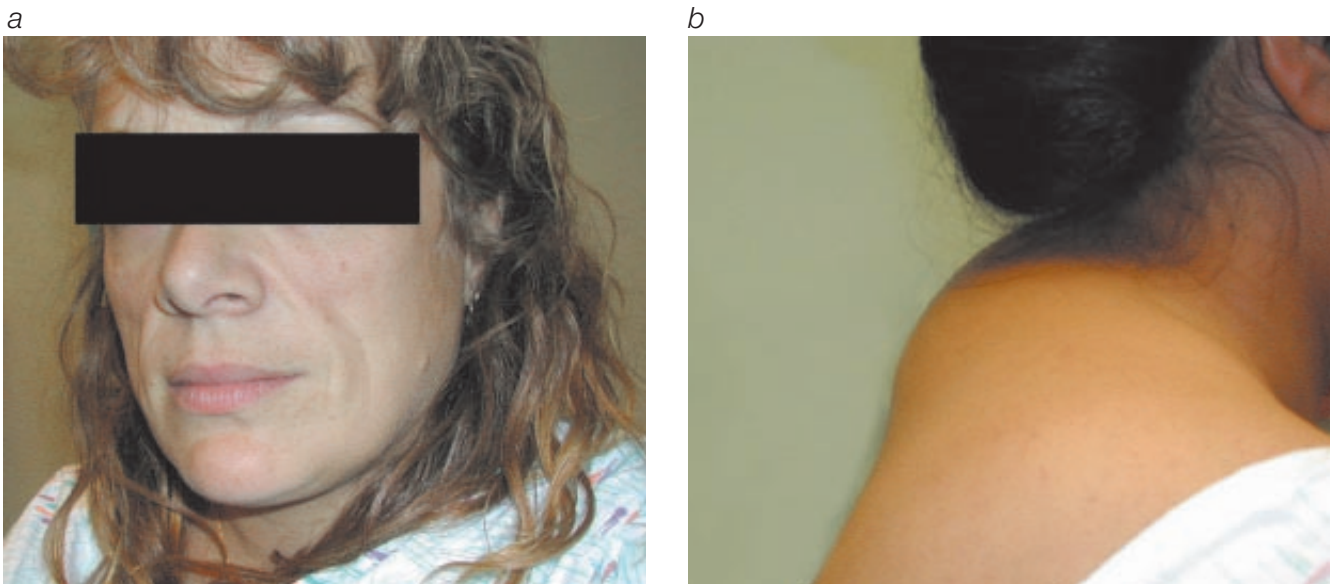

Figure 13 **Typical presentations of the lipodystrophy syndrome include (*a*) wasting of facial fat and (*b*) accumulation of fat in the posterior neck.**

insulin levels, decreased weight, decreased visceral abdominal fat, and decreased subcutaneous abdominal fat.[140] In this study, patients taking metformin did not experience an increase in serum lactate levels or hepatic transaminase levels. Similarly, a study of the insulin sensitizer rosiglitazone showed that this agent can improve insulin sensitivity, reduce free fatty acid levels, and increase subcutaneous leg fat in patients with lipodystrophy.[141] No change was seen in subcutaneous abdominal or visceral fat. The study was small (28 patients) and of short duration (3 months) but was randomized, double blind, and placebo controlled and will hopefully be confirmed by larger studies with longer follow-up. These reports provide further indirect evidence that insulin resistance plays a central role in the pathogenesis of HIV-associated lipodystrophy. Further study is needed to better predict which patients will develop fat-redistribution syndrome and to identify preventive measures.

Bone abnormalities Avascular necrosis (AVN), osteopenia, and osteoporosis are becoming prominent complications of HIV infection and may be linked to antiretroviral therapy. AVN is still an unusual clinical diagnosis, although one study using magnetic resonance imaging scanning documented occult AVN of the femoral head in 5% of HIV-infected patients.[142] Traditional risk factors for AVN include trauma, systemic lupus erythematosus, corticosteroid use, hemoglobinopathies, hypercoagulable states, hyperlipidemia, and alcohol abuse, whereas case-control studies involving HIV-infected patients have demonstrated links only to steroid use and hyperlipidemia.[142-144] HIV-associated AVN occurs more frequently in the hips and knees and is often bilateral, distinguishing it from AVN in HIV-negative persons, which is usually not multifocal. Treatment options for AVN are limited to pain control and, in severe cases, surgery.

Reports of decreased bone mineral density in HIV-infected patients predate the use of potent antiretroviral therapy.[145] However, studies have demonstrated an association between protease inhibitors, osteopenia, and lipodystrophy.[146,147] The pathogenesis of HIV-associated bone abnormalities is unknown. Regular screening for osteopenia in HIV-infected patients is not currently recommended. If patients are discovered to have decreased bone mineral density, treatment should include calcium and vitamin D supplementation. Frank osteoporosis may merit the addition of bisphosphonates, calcitonin, or estrogen receptor modulators.[91]

MONITORING OF RNA LEVELS AND CD4$^+$ T CELL COUNTS

The HIV RNA level should be measured before antiretroviral therapy is started, 2 to 8 weeks after starting therapy, and then at 3 to 4 months after starting treatment to document control of HIV replication. Subsequently, the HIV RNA level and CD4$^+$ T cell count should be monitored approximately every 3 months. In most patients, the HIV RNA level should decrease by at least 1 $\log_{10}$ by week 8 and then to less than 50 copies/ml by weeks 16 to 20. Suppressing HIV levels to less than 50 copies/ml diminishes the number of new HIV virions and thus significantly decreases the chance that resistant strains will emerge.

The CD4$^+$ T cell counts of patients on antiretroviral therapy should be monitored every 3 to 4 months to assess the impact of antiretroviral therapy on immune function. Despite earlier hopes that treatment with an aggressive antiretroviral regimen for 2 to 3 years could eradicate HIV, subsequent studies have shown that HIV eradication is not a realistic goal of antiretroviral therapy. Although potent antiretroviral therapy does have tremendous impact on the total burden of HIV on the body, several cellular and anatomic reservoirs of virus contribute to the long-term persistence of HIV.[148] Resting CD4$^+$ memory T cells that contain latently integrated HIV DNA are the most important cellular reservoirs; the CNS and the male urogenital tract are important anatomic reservoirs. Novel strategies to eliminate the latent HIV reservoirs need to be developed before eradication of HIV becomes a realistic goal.

ADHERENCE TO THERAPY

The degree of adherence to antiretroviral therapy clearly predicts whether or not a patient will sustain long-term viral suppression.[149] Other factors that may affect long-term viral suppression are the inherent potency of the regimen, whether the

patient has previously received antiretroviral therapy, the patient's immune status, absorption of the antiretroviral medications, and drug-drug interactions that may decrease the concentration of the antiretroviral medications. In patients who achieve an HIV RNA level of less than 50 copies/ml, a change in therapy should be considered if there is a significant increase in the HIV RNA level, if there is a persistent decline in the $CD4^+$ T cell count, or if there is evidence of clinical deterioration. The choice of a salvage regimen should take into consideration the patient's prior antiretroviral therapy, resistance testing, the likelihood of adherence with complex salvage regimens, and the stage of the patient's HIV disease. The choice of a salvage regimen should be made in consultation with an expert in antiretroviral therapy.

DRUG RESISTANCE AND RESISTANCE TESTING

Antiretroviral therapy can lead to the emergence of resistant strains of HIV, which can render antiretroviral therapy less effective. Indeed, multiple studies have shown that in cases in which HIV suppression fails, there is usually evidence of HIV drug resistance.

Types of Resistance Assays

Two types of resistance assays are now commercially available to test for HIV resistance: genotype and phenotype assays. The genotype assays identify specific codon mutations associated with resistance, either by amplifying and then sequencing the reverse transcriptase and protease genes of plasma virus or by using standardized probes to detect mutations known to be associated with resistance. The genotype assays can be performed in 1 to 2 weeks, but interpretation of the results requires expertise and review of current and prior antiretroviral therapy.

Phenotype assays measure growth, in the presence of specific antiretroviral medications, of chimeric HIV strains that contain the patient's virus reverse transcriptase and protease genes; the results are reported as the concentration of drug required to inhibit 50% or 90% of viral replication (IC_{50} and IC_{90}, respectively). Chimeric HIV strains are constructed by splicing the amplified reverse transcriptase and protease genes of the patient's virus into a standard HIV backbone that contains an indicator gene, then transfecting these chimeric constructs into cells expressing viral envelope proteins to generate viral stocks. As with genotype results, the phenotype results require expertise to interpret and must be interpreted in the context of current and prior antiretroviral therapy. The strains of HIV identified in the patient are compared with reference strains and reported as the "fold" resistance in IC_{50}. In general, phenotype assays require longer periods than genotype assays and are more expensive.

Both testing techniques have inherent problems: the tests may sample only a minority of the HIV strains; the sampled strains from the blood may not adequately represent strains from other body regions (compartments); resistance to medications taken in the past may not be evident; and for resistance to be determined, plasma HIV RNA levels typically must be in the range of at least 500 to 1,000 copies/ml. Nevertheless, several studies have shown that patients who undergo resistance testing in the setting of virologic failure have better virologic outcomes than those who do not undergo resistance testing.[150,151]

To date, no randomized trials have compared genotypic tests with phenotypic tests. Thus, there is no basis for recommending one over the other. Because the tests will not detect any nonreplicating archived viruses that may contain resistance mutations, they cannot predict with certainty which drugs will work. However, test results indicating the presence of resistance to particular drugs do predict failure if those drugs are used.

Indications for Resistance Testing

The DHHS guidelines recommend resistance testing for patients who experience virologic failure with an antiretroviral regimen, for patients in whom HIV remains at detectable levels after starting therapy, and for patients with acute HIV infection who are considering treatment.[91] Virologic failure is constituted by any one of the following three events: (1) a decrease in HIV RNA of less than 0.75 $\log_{10}$ by week 4 of antiretroviral therapy or of less than 1.0 $\log_{10}$ by week 8; (2) a failure to suppress the level of HIV RNA to less than 50 copies/ml within 6 months of starting or changing therapy; or (3) repeated detection of a high level of HIV RNA (> 5,000 copies/ml) in plasma after initial suppression to less than 50 copies/ml.[91] In addition, some experts consider utilizing resistance testing for those patients with low-level breakthrough viremia (50 to 5,000 copies/ml). The level in such patients must be greater than 1,000 copies/ml to obtain a reliable resistance assay, however. Resistance testing is recommended for patients with acute infection who are considering therapy, because of the known transmission of drug-resistant HIV variants and the demonstration that a significant proportion of persons newly infected with HIV harbor drug-resistant strains.[152]

Drug-resistance testing in chronically infected persons who are not on therapy is controversial. Resistant viruses can persist in the circulation for months or years in the absence of selective drug pressure, so resistance testing may be of value.[153-155] Theoretically, transmitted drug-resistant viruses with mutations that significantly decrease fitness should disappear from the circulating pool (but will be archived) in the absence of drug pressure. However, mutations with limited effects on replication will persist and can be detected by resistance tests. Resistance testing in these individuals may be of benefit, but this has not been formally evaluated in clinical trials. It is reasonable to offer resistance testing to antiretroviral-naive patients who have been infected for less than 2 years and who are contemplating treatment. Resistance testing should be performed for pregnant women starting therapy.[92]

STRUCTURED TREATMENT INTERRUPTIONS

Structured treatment interruptions have been used in an attempt to autoimmunize patients with rebounding HIV viremia in the hope of eliciting better HIV-directed immune responses that will help control HIV replication over the long term. Although this approach held some initial promise in the treatment of acutely infected patients, there is little evidence that it is a viable strategy in chronically infected patients.[156] The desired immunologic responses have not been consistently observed, and patients have not had sufficient CTL responses to permit simplifying or stopping antiretroviral therapy. In addition, stopping and starting antiretroviral therapy in chronically infected patients could have several negative effects. First, drug resistance could develop when the virus rebounds or when the patient resumes therapy. The risk of resistance developing during viral rebound would be of particular concern in persons on regimens that include drugs with long elimination half-lives, such as nevirapine or efavirenz. Second, one study has shown that patients who have long-term viral suppression and quiescent lymph nodes will develop hyperplastic and activated lymph nodes within 1 to 2 months after stopping antiretroviral treatment.[157]

Third, several reports have now described persons with well-controlled HIV who developed an acute retroviral syndrome after stopping antiretroviral therapy.[158,159]

Structured treatment interruption has been suggested for use in patients with uncontrolled HIV replication despite therapy, as a means for allowing repopulation with drug-sensitive virus that would then be killed when treatment was restarted.[160] This tactic, however, is associated with marked reductions in $CD4^+$ T cell counts during the phase of regrowth of wild-type virus, and the archived drug-resistant strains reemerge when treatment is restarted.[161] Consequently, structured treatment interruptions are currently not recommended in patients chronically infected with HIV.

Prophylactic Therapy

ANTIRETROVIRAL THERAPY AFTER OCCUPATIONAL EXPOSURE

Despite widespread efforts to implement universal precautions, health care workers still occasionally suffer accidental exposures to HIV. Current recommendations for postexposure prophylaxis are based on previous retrospective human data, data from animal studies, and extrapolation of experience with antiretroviral therapy in HIV-infected patients. One retrospective case-control study found that use of zidovudine monotherapy for postexposure prophylaxis in health care workers reduced the risk of HIV transmission by approximately 81%.[162] In addition, animal studies have suggested that postexposure prophylaxis decreases the risk of transmission.[43]

Recommendations

A health care worker who has incurred a recognized risk of occupational HIV transmission should first adequately clean the site of exposure and then start postexposure antiretroviral therapy as soon as possible. Combination therapy is recommended for postexposure prophylaxis, because extrapolations from treatment data in HIV-infected patients indicate that two- or three-drug regimens are likely to be more effective than zidovudine alone for preventing transmission of HIV; their superiority is not proven, however. The basic prophylactic regimen contains two drugs; an expanded three-drug regimen is recommended for HIV exposures that pose an increased risk of transmission, such as those involving larger volumes of blood or those in which the source patient has advanced AIDS.

Three basic regimens are recommended by the United States Public Health Service for use in adults: (1) zidovudine (300 mg b.i.d. or 200 mg t.i.d.) plus lamivudine (150 mg b.i.d.); (2) stavudine (40 mg b.i.d.) plus lamivudine (150 mg b.i.d.); and (3) stavudine (40 mg b.i.d.) plus didanosine (400 mg q.d.).[43] For persons who weigh less than 60 kg, the dosage of stavudine should be reduced to 30 mg twice a day, and the dosage of didanosine should be reduced to 300 mg daily. The expanded three-drug regimen consists of a basic regimen plus either nelfinavir (750 mg t.i.d.) or indinavir (800 mg every 8 hours). Newer protease inhibitors, such as lopinavir-ritonavir, atazanavir, or fosamprenavir, are attractive alternatives for use as a third drug. In addition, tenofovir-DF is an excellent option for patients who cannot tolerate zidovudine, especially because it is well tolerated and requires only once-daily administration. Life-threatening hepatotoxicity has been reported in two health care workers who were taking nevirapine for postexposure prophylaxis[163]; accordingly, nevirapine should not be used for this purpose.

The United States Public Health Service guidelines note several special circumstances that warrant consultation with local experts or the National Clinicians' Post-Exposure Prophylaxis Hotline ([PEPline] 1-888-448-4911). These circumstances include cases in which there is a delayed report of exposure; the source person is unknown; the exposed person is pregnant; the source virus is resistant to antiretroviral agents; or the health care worker experiences a toxic reaction to the prophylactic regimen.[43]

Regardless of whether the basic regimen or the expanded regimen is used, it is recommended that the prophylaxis be taken for 28 days. Unfortunately, health care workers frequently have adverse effects with postexposure antiretroviral prophylaxis, even to the extent that many cannot complete their 28-day course.[164]

Health care workers receiving postexposure prophylaxis should undergo drug-toxicity monitoring at baseline and again 2 weeks after therapy is started. In addition, health care workers with occupational exposure to HIV should undergo serologic testing for HIV on first exposure and at 6 weeks, 3 months, and 6 months after exposure. Because three health care providers experienced seroconversion between months 6 and 12 after exposure, some experts recommend also performing follow-up HIV serologic testing at 12 months. In general, health care workers should use safe-sex practices and avoid breast-feeding for at least the first 12 weeks after exposure to HIV.

ANTIRETROVIRAL THERAPY TO PREVENT PERINATAL TRANSMISSION

The Pediatric AIDS Clinical Trials Group Protocol 076 study generated the initial enthusiasm for using antiretroviral therapy to prevent perinatal HIV transmission.[36] In this trial, HIV-infected pregnant women received either placebo or a regimen that consisted of oral zidovudine administered after week 14 of gestation and intravenous zidovudine administered during labor and delivery; in addition, oral zidovudine was given to the newborn until the infant reached 6 weeks of age. The HIV transmission rate in those who received zidovudine was 8.3%, compared with 25.5% in placebo recipients. Longer-term complete results of this study showed transmission rates of 7.6% in the zidovudine group and 22.6% in the placebo group.[165] As perinatal prophylaxis regimens became incorporated into clinical practice, HIV perinatal transmission rates in the United States dramatically declined.[41] Available data have shown no significant differences with regard to congenital abnormalities, growth rates, or neurologic development, nor have the data uncovered other evidence of long-term toxicity in children exposed to zidovudine, either in utero or post partum, compared with children in the general population.[41]

Subsequent international studies have also shown the benefit of antiretroviral therapy in preventing mother-to-child transmission of HIV. In one study in Thailand in which mothers received zidovudine for 4 weeks before and during labor, perinatal transmission was 9% in the zidovudine group and 19% in the placebo group.[166] A study from Uganda found nevirapine to be more effective than zidovudine in the prevention of perinatal HIV transmission.[167] In one arm of the study, a single 200 mg dose of nevirapine was given to the mother at the onset of labor and a single 2 mg/kg dose was given to the infant 48 to 72 hours after birth. In the second arm of the study, a short course of oral zidovudine was given to the mother during labor, and oral zidovudine was given to the infant for 1 week after birth. The HIV infection rate for the newborns at 6 weeks after birth was 12% in

Table 8 Prophylactic Measures Strongly Recommended as Standard of Care for the Prevention of First Episodes of Opportunistic Disease in Adults and Adolescents Infected with HIV[188]

Pathogen	*Indication*	*First Choice**	*Alternatives**
Pneumocystis jiroveci†	$CD4^+$ T cell count < 200/μl *or* Oropharyngeal candidiasis	TMP-SMX, 1 DS q.d. TMP-SMX, 1 SS q.d.	Dapsone, 50 mg b.i.d. or 100 mg q.d. Dapsone, 50 mg q.d. + pyrimethamine, 50 mg q. wk + leucovorin, 25 mg q. wk Dapsone, 200 mg + pyrimethamine, 75 mg + leucovorin, 25 mg q. wk Aerosolized pentamidine, 300 mg q. mo via Respirgard II nebulizer Atovaquone, 1,500 mg q.d. TMP-SMX, 1 DS t.i.w.
Mycobacterium tuberculosis			
Isoniazid-sensitive‡	TST reaction ≥ 5 mm or previous positive TST result without treatment or contact with case of active tuberculosis	Isoniazid, 300 mg + pyridoxine, 50 mg q.d. × 9 mo Isoniazid, 900 mg + pyridoxine, 100 mg b.i.w. × 9 mo	Rifampin, 600 mg q.d. × 4 mo Rifabutin, 300 mg q.d. Pyrazinamide, 15–20 mg/kg q.d. × 2 mo + rifampin, 600 mg q.d. × 2 mo *or* rifabutin, 300 mg q.d. × 2 mo
Isoniazid-resistant	Same; high probability of exposure to isoniazid-resistant tuberculosis	Rifampin, 600 mg × 4 mo Rifabutin, 300 mg q.d. × 4 mo	Pyrazinamide, 15–20 mg/kg q.d. × 2 mo + rifampin, 600 mg q.d. × 2 mo *or* rifabutin, 300 mg q.d. × 2 mo
Multidrug (isoniazid and rifampin)-resistant	Same; high probability of exposure to multidrug-resistant tuberculosis	Choice of drugs requires consultation with public health authorities	None
Toxoplasma gondii§	IgG antibody to *Toxoplasma* and $CD4^+$ T cell count < 100/μl	TMP-SMX, 1 DS q.d.	TMP-SMX, 1 SS q.d. Dapsone, 50 mg q.d. + pyrimethamine, 50 mg q. wk + leucovorin, 25 mg q. wk Dapsone, 200 mg q.d. + pyrimethamine, 75 mg q. wk + leucovorin, 25 mg q. wk Atovaquone, 1,500 mg q.d. ± pyrimethamine, 25 mg q.d. + leucovorin, 10 mg q.d.
Mycobacterium avium complex‖	$CD4^+$ T cell count < 50/μl	Azithromycin, 1,200 mg q. wk Clarithromycin, 500 mg b.i.d.	Rifabutin, 300 mg q.d. Azithromycin, 1,200 mg q. wk + rifabutin, 300 mg q.d.
VZV	Significant exposure to chickenpox or shingles for patients who have no history of either condition or, if available, have negative antibody to VZV	Varicella-zoster immune globulin (VZIG), 5 vials (1.25 ml each) I.M., administered ≤ 96 hr after exposure, ideally within 48 hr	

*All regimens are oral unless indicated otherwise.

†Prophylaxis should also be considered for persons whose $CD4^+$ cells constitute less than 14% of total lymphocytes, for persons with a history of an AIDS-defining illness, and possibly for those with $CD4^+$ T cell counts greater than 200 cells/μl but less than 250 cells/μl. TMP-SMX also reduces the frequency of toxoplasmosis and some bacterial infections. Patients receiving dapsone should be tested for glucose-6-phosphate dehydrogenase deficiency. A dosage of 50 mg q.d. is probably less effective than that of 100 mg q.d. Patients who are being given sulfadiazine-pyrimethamine for toxoplasmosis are protected against *Pneumocystis jiroveci* pneumonia and do not need additional prophylaxis against that illness.

‡It is recommended that patients receiving isoniazid, 900 mg b.i.w., remain under observation during therapy. Isoniazid regimens should include pyridoxine to prevent peripheral neuropathy. Rifampin should not be administered concurrently with protease inhibitors or nonnucleoside reverse transcriptase inhibitors. Rifabutin should not be given with hard-gel saquinavir or delavirdine; caution is also advised when the drug is coadministered with soft-gel saquinavir. Rifabutin may be administered at a reduced dosage (150 mg q.d.) when combined with indinavir, nelfinavir, or amprenavir; at a reduced dosage (150 mg q.o.d. or 150 mg three times weekly) when combined with ritonavir; or at an increased dosage (450 mg q.d.) when combined with efavirenz. Information is lacking regarding coadministration of rifabutin with nevirapine. Exposure to multidrug-resistant tuberculosis might require prophylaxis with two drugs; public health authorities should be consulted. Possible regimens include pyrazinamide plus either ethambutol or a fluoroquinolone.

§Protection against toxoplasmosis is provided by TMP-SMX, dapsone plus pyrimethamine, and possibly atovaquone.

‖As noted in the first footnote above, rifabutin may be administered at a reduced dosage when used in combination with the protease inhibitors indinavir (rifabutin dosage, 150 mg q.d.), nelfinavir (150 mg q.d.), amprenavir (150 mg q.d.), and ritonavir (150 mg q.o.d. or 150 mg three times weekly). It may be administered at an increased dosage with the nonnucleoside reverse transcriptase inhibitor efavirenz (rifabutin dosage, 450 mg q.d.). Information is lacking regarding coadministration of rifabutin with nevirapine.

DS — double-strength tablet SS — single-strength tablet TMP-SMX — trimethoprim-sulfamethoxazole TST — tuberculin skin test VZV — varicella-zoster virus

the nevirapine group and 21% in the zidovudine group.[167] The enthusiasm for these excellent results with short-course nevirapine was tempered by the discovery of high rates of resistance associated with this therapy: in tests conducted 6 weeks after the conclusion of therapy, resistance to nevirapine was found to have developed in 20% of the women.[168] This high rate of resistance after receiving only one dose of nevirapine presumably relates to the very long elimination half-life of this drug. Nevirapine is also associated with severe hypersensitivity reactions involving the skin and liver; these reactions may be more common in pregnant women. These adverse effects have not been reported in women taking only one or two doses of nevirapine to prevent HIV transmission, but they have occurred in women taking nevirapine as part of a potent antiretroviral regimen. The risk of severe hypersensitivity and hepatic failure is increased in persons with $CD4^+$ T cell counts greater than 250 cells/μl and those

with preexisting liver disease.[169,170] Nevirapine should be used with extreme caution in pregnancy; it requires close laboratory and clinical monitoring, and it should be discontinued if the patient shows any clinical or laboratory evidence of hepatitis.

Recommendations

In its recommendations for reducing perinatal HIV transmission, the Public Health Service Task Force stated that pregnancy should influence the decisions regarding timing and choice of antiretroviral therapy but that antiretroviral therapy should not be deferred on the grounds that the patient is pregnant.[41] Several of the unique and important factors to consider with the use of antiretroviral therapy in pregnancy include the physiologic changes associated with pregnancy, which may require altering medication dosages; the potential short-term or long-term adverse effects on the fetus and newborn; and the effectiveness of the regimen in reducing the risk of perinatal transmission. In addition, the efficacy of the regimen for treatment of the mother's HIV infection needs to be taken into consideration. Unfortunately, data regarding combination antiretroviral therapy in pregnancy are insufficient to clarify the safety and efficacy of these regimens. Accordingly, medical providers who offer antiretroviral therapy to HIV-1–infected women during pregnancy need to extensively discuss issues related to the potential short-term and long-term risks and benefits of therapy during pregnancy.

If antiretroviral therapy is given during pregnancy, the three-part zidovudine regimen should be used. In general, clinicians are likely to encounter one of four scenarios: (1) the HIV-infected pregnant woman has not received prior antiretroviral therapy; (2) the HIV-infected woman is receiving antiretroviral therapy at the time the pregnancy is discovered; (3) the HIV-infected woman is in labor and has not been receiving antiretroviral therapy during her pregnancy; or (4) the infant is born of an HIV-infected mother who did not receive antiretroviral therapy during pregnancy or labor. Specific considerations and recommendations for each of these scenarios are discussed in detail in the Public Health Service Task Force recommendations.[41] In addition, these recommendations address issues regarding the mode of delivery, with particular consideration to the performance of cesarean section in women who have HIV RNA levels greater than 1,000 copies/ml near the time of delivery. Women who have HIV RNA levels less than 1,000 copies/ml have a very low rate of HIV transmission, and thus, their child would be unlikely to receive substantial benefit from cesarean section.

VACCINES AGAINST HIV

The development of an effective HIV vaccine has eluded investigators for years. Recently, two large placebo-controlled phase III trials of bivalent recombinant gp120 vaccines (B/B and B/E) demonstrated no benefit from either vaccine.[171,172] Although neutralizing antibodies are produced during natural HIV infection, viral escape develops rapidly because of the high mutation rate of HIV,[173,174] so the failure of these trials is not surprising. Most recent vaccine work has focused on the development of vaccines that elicit potent $CD4^+$ and $CD8^+$ T cell–mediated responses. Theoretically, these vaccines would not prevent infection but might be able to eradicate infection by eliminating HIV-infected cells, or at least they might be able to tightly control the virus and delay or halt disease progression. A variety of vaccines (e.g., killed virus, DNA, viral and bacterial vector) and vaccine strategies (e.g., vaccination, prime-boost with combinations of vaccines) have been tried in animal models and humans, with mixed success.[175-184] Major hurdles are to identify antigens or epitopes that elicit protective responses across a wide variety of HIV types and from which the virus cannot escape. The ideal vaccine would be one that stimulates production of broadly valent neutralizing antibodies that may prevent infection with primary isolates and that elicits potent T cell responses that eliminate or control any infection that is not prevented.[185] Unfortunately, such a vaccine does not currently exist.

Prevention and Management of Opportunistic Infections

With the widespread use of antiretroviral therapy in developed countries, the incidence of serious opportunistic infections has dramatically declined.[3,186] In the United States, the incidence of *Pneumocystis jiroveci* (formerly *P. carinii)* pneumonia, *Mycobacterium avium* complex disease, or cytomegalovirus (CMV) retinitis in HIV-infected patients declined from 21.9 per 100 person-years in 1994 to 3.7 per 100 person-years in mid-1997.[3] In addition, a separate study examined the incidence of the most common opportunistic infections in the United States from 1992 to 1998 and found profound declines during that period; the most pronounced reductions occurred from 1996 to 1998, reflecting the widespread use of aggressive antiretroviral therapy.[186] The incidence of Kaposi sarcoma has also markedly declined, with an estimated 50% reduction occurring in persons receiving potent antiretroviral therapy.[187] Despite these advances, major opportunistic infections continue to cause significant morbidity and mortality in HIV-infected persons. Indeed, prevention of major opportunistic infections remains a critical aspect of HIV care.

PRIMARY PREVENTION OF OPPORTUNISTIC INFECTIONS

The U.S. Public Health Service, in conjunction with the Infectious Diseases Society of America, has issued guidelines for preventing opportunistic infections [*see Table 8*].[188] As the standard of care, these guidelines strongly recommend measures to prevent the first episode of opportunistic disease caused by *M. tuberculosis, P. jiroveci, Toxoplasma gondii,* and *M. avium* complex. Primary prophylaxis against a particular pathogen is recommended when disease from the organism is likely to occur and prophylaxis for that disease is simple, effective, and relatively nontoxic; these four pathogens meet those criteria. The guidelines do not recommend the routine use of prophylaxis to prevent a first episode of *Cryptococcus neoformans, Histoplasma capsulatum,* or CMV infection.

The latest version of the guidelines also addresses discontinuance of primary prophylaxis in patients who have a sustained immunologic response to antiretroviral therapy. The risk of developing *Pneumocystis* pneumonia is extremely small in persons who discontinue primary prophylaxis once they have maintained $CD4^+$ T cell counts of greater than 200 cells/μl for at least 3 months.[189] Similarly, patients can safely discontinue primary prophylaxis for *M. avium* complex when their $CD4^+$ T cell counts have stayed above 100 cells/μl for 3 months or more, and they can discontinue primary prophylaxis for *T. gondii* when their $CD4^+$ T cell counts have stayed above 200 cells/μl for that length of time.[190-192]

MANAGEMENT OF OPPORTUNISTIC INFECTIONS

Tuberculosis

Although tuberculosis can occur in HIV-infected patients regardless of their $CD4^+$ T cell count, the clinical presentation usually varies with the $CD4^+$ T cell count. The clinical picture of

Table 9 Treatment of Acute Opportunistic Infections

Pathogen	*First Choice**	*Alternatives**	*Comment*
Cryptococcal meningitis	Amphotericin B, 0.7–1.0 mg/kg/day I.V. ± flucytosine, 100 mg/kg/day p.o. × 14 days, followed by fluconazole, 400 mg/day for a minimum of 10 wk	Amphotericin B, 0.7–1 mg/kg/day I.V. *or* Fluconazole, 800 mg/day I.V. or p.o. ± flucytosine, 100 mg/kg/day p.o.	Amphotericin is preferred as initial therapy; fluconazole is reasonable as initial therapy only in persons with normal mental status; management of increased intracranial pressure is essential; lumbar punctures should be performed to keep CSF pressure < 200 mm Hg
Cytomegalovirus retinitis	Ganciclovir, 5 mg/kg I.V., b.i.d. × 14–21 days, then 5–6 mg/kg/day I.V. *or* valganciclovir, 900 mg b.i.d. with food × 14–21 days, then 900 mg q.d.	Foscarnet, 60 mg/kg q. 8 hr I.V. × 14–21 days, then 90–120 mg/kg/day Intraocular ganciclovir pellet + ganciclovir, 1,000 mg p.o. t.i.d. Cidofovir, 5 mg/kg I.V. q. wk × 2, then 5 mg/kg every 14 days	Ganciclovir is much easier to administer than foscarnet; intraocular ganciclovir pellets are very effective, but there is risk involved in administering them and they do not provide protection against disease outside the eye
Mycobacterium avium complex	Clarithromycin, 500 mg b.i.d. + ethambutol, 15 mg/kg/day ± rifabutin, 300 mg/day	Azithromycin, 600 mg q.d., can be substituted for clarithromycin Ciprofloxacin, 500 mg b.i.d., can be substituted for rifabutin	Benefit of adding third drug is unclear; clarithromycin and rifabutin can have significant interactions with antiretroviral medications
Mycobacterium tuberculosis	Isoniazid, 300 mg q.d. + rifampin, 600 mg q.d. + pyrazinamide, 25 mg/kg (maximum, 2 g) q.d. + ethambutol, 15–25 mg/kg (maximum, 2.5 g) q.d. × 9 mo	Rifabutin, 150–450 mg q.d., should be substituted for rifampin and the dose adjusted, depending on drug interactions	If the isolate is not drug resistant, then pyrazinamide and ethambutol should be discontinued after 2 mo; if the isolate is drug resistant, the regimen should be chosen in consultation with a tuberculosis expert
Pneumocystis jiroveci	Trimethoprim-sulfamethoxazole, 15–20 mg/kg/day, p.o. or I.V. in three or four divided doses × 21 days	Trimethoprim, 15–20 mg/kg/day in three or four divided doses + dapsone, 100 mg q.d. × 21 days Pentamidine, 3–4 mg/kg I.V. q.d. × 21 days Atovaquone, 750 mg q.d. × 21 days Clindamycin, 450 mg q.i.d. + primaquine, 15 mg base q.d. Trimetrexate, 45 mg/m^2 I.V. q.d. + folinic acid, 20 mg/m^2 q.i.d.	Patients with P_{O_2} < 70 mm Hg or A-a gradient > 35 mm Hg should receive corticosteroids (prednisone, 40 mg b.i.d. × 5 days, then 40 mg q.d. × 5 days, then 20 mg q.d. × 11 days); I.V. pentamidine has been associated with major toxicity
Toxoplasma gondii	Pyrimethamine, 100–200 mg loading dose, then 50–100 mg q.d. + sulfadiazine, 1.5–2.0 g q.i.d. + leucovorin, 10–25 mg q.d.	Clindamycin, 600–900 mg q.i.d., can be substituted for sulfadiazine Other agents that could be substituted for sulfadiazine include azithromycin, 1,200 mg q.d.; clarithromycin, 1.0 g b.i.d.; or atovaquone, 750 mg b.i.d.	After approximately 6–8 wk, patients can change to suppressive regimens that use lower dosages of medications

*All regimens are oral unless noted otherwise.
CSF — cerebrospinal fluid P_{O_2} — oxygen tension

HIV-infected patients with active tuberculosis whose CD4$^+$ T cell count is greater than 350 cells/μl is similar to that of persons not infected with HIV—the illness is characterized by gradual onset of weight loss, cough, fever, upper lobe infiltrates, and cavitary lesions. In contrast, patients with advanced AIDS who develop active tuberculosis often have an atypical presentation that may include diffuse pulmonary lesions, lymph node involvement, blood cultures that are positive for *M. tuberculosis*, and an absence of cavitary lesions. A diagnosis is made by isolating *M. tuberculosis* from any body site; most often, the diagnosis is made on sputum staining or from bronchoscopy. It is critical that drug susceptibility testing be performed on the *M. tuberculosis* isolate.

Initial therapy for *M. tuberculosis* consists of a minimum of three drugs (isoniazid, rifampin, and pyrazinamide); most experts recommend adding ethambutol until susceptibility results become available [*see Table 9*]. Recommendations for the treatment of tuberculosis in HIV-infected patients were published in 2003.[193] These recommendations review the drug interactions between antiretroviral agents and the rifamycins (rifampin and rifabutin), the evidence for and against particular antituberculous regimens in HIV-infected patients, and the importance of directly observed therapy for the treatment of patients who have both HIV infection and tuberculosis.

Pneumocystis *Pneumonia*

Patients with *P. jiroveci* pneumonia generally have a CD4$^+$ T cell count of less than 200 cells/μl; the clinical presentation is characterized by a nonproductive cough of gradual onset, dyspnea, fever, and fatigue. Chest radiographs most often show a diffuse, reticulonodular pattern, predominantly in the perihilar region, but up to 30% of patients have a normal chest radiograph early in the course of their disease. A definitive diagnosis should be established by induced sputum stain or bronchoscopy. For patients with suspected *P. jiroveci* pneumonia, therapy should not be delayed while the patient undergoes a diagnostic workup. First-line therapy consists of trimethoprim-sulfamethoxazole. Patients whose arterial oxygen tension (P_aO_2)

Table 10 USPHS/IDSA Guidelines for the Prevention of Recurrence of Opportunistic Infections in Adults and Adolescents Infected with HIV after Chemotherapy for Acute Disease[188]

Pathogen or Condition	*Indication*	*First Choice*	*Alternatives*
Cryptococcus neoformans	Documented disease	Fluconazole, 200 mg p.o., q.d.	Amphotericin B, 0.6 mg/kg I.V., q.w. to t.i.w. Itraconazole, 200 mg p.o., q.d.
Cytomegalovirus retinitis	Prior end-organ disease	Volganciclovir, 900 mg p.o., q.d. Ganciclovir, 5–6 mg/kg/day I.V., 5–7 days/wk Foscarnet, 90–120 mg/kg I.V. q.d. For retinitis, sustained-release intraocular ganciclovir pellet, q. 6–9 mo + ganciclovir, 1,000 mg t.i.d.	Cidofovir, 5 mg/kg I.V. every 14 days Fomiversen, 1 vial (330 μg) injected into the vitreous, then repeated every 2–4 wk
Pneumocystis jiroveci	Prior *Pneumocystis jiroveci* pneumonia	TMP-SMX, 1 DS p.o., q.d. TMP-SMX, 1 SS p.o., q.d.	Dapsone, 50 mg b.i.d. or 100 mg q.d. Dapsone, 50 mg q.d. + pyrimethamine, 50 mg q.w. + leucovorin, 25 mg q.w. Dapsone, 200 mg + pyrimethamine, 75 mg + leucovorin 25 mg q.w. Aerosolized pentamidine, 300 mg q. mo via Respirgard II nebulizer Atovaquone, 1,500 mg q.d. TMP-SMX, 1 DS t.i.w.
Toxoplasma gondii	Prior *Toxoplasma* encephalitis	Pyrimethamine, 25–75 mg q.d. + sulfadiazine, 0.5–1.0 g q.i.d. + leucovorin, 10–25 mg q.d.	Pyrimethamine, 25–75 mg q.d. + clindamycin 300–450 mg q.i.d. + leucovorin, 10–25 mg q.d. Atovaquone, 750 mg b.i.d. to q.i.d. ± pyrimethamine, 25 mg q.d. + leucovorin, 10 mg q.d.

DS — double-strength tablet IDSA — Infectious Diseases Society of America SS — single-strength tablet TMP-SMX — trimethoprim-sulfamethoxazole
USPHS — U.S. Public Health Service

measurement is less than 70 mm Hg or whose alveolar-arterial difference in oxygen (A-aDO_2) is greater than 35 mm Hg should also receive corticosteroids as part of their initial therapy.

CNS Toxoplasmosis

CNS toxoplasmosis typically develops only in patients who have a $CD4^+$ T cell count of less than 100 cells/μl; it is characterized by fever, headache, altered thought processes, and, in some instances, seizures. The diagnosis is strengthened by serologic evidence of *Toxoplasma* and findings of multiple enhancing lesions on either computed tomography or MRI. At 14 days, nearly all patients with *Toxoplasma* encephalitis show some radiologic improvement in response to therapy. Brain biopsy is rarely performed at the onset of therapy but may be considered in patients who do not show a clinical and radiographic response to therapy.

Cryptococcal Meningitis

Cryptococcal meningitis most often occurs in patients with a $CD4^+$ T cell count of less than 100 cells/μl; the clinical presentation may be similar to that of *Toxoplasma* encephalitis. Fewer than 25% of patients with cryptococcal meningitis have overt symptoms of meningeal irritation, such as photophobia and neck stiffness. More typically, patients have fever, personality changes, and diminished memory. More than 98% of patients with cryptococcal meningitis have a positive result on serum cryptococcal antigen testing; the definitive diagnosis of cryptococcal meningitis is made by isolating *Cryptococcus neoformans* from the cerebrospinal fluid. Current guidelines recommend amphotericin B plus flucytosine as initial therapy for the first 14 days, followed by high-dose fluconazole for a minimum of 10 weeks, followed by lower-dose fluconazole.[194] A pretreatment opening CSF pressure of 250 mm H_2O or greater is generally as-

Table 11 Criteria for Discontinuance of Secondary Prophylaxis for Opportunistic Infections

Disease	*Disease-Specific Treatment Response*	*$CD4^+$ T Cell Counts*
Pneumocystis jiroveci pneumonia	Completion of initial therapy and absence of signs or symptoms of active infection	> 200 cells/μl for at least 6 mo
Mycoplasma avium complex	Absence of symptoms suggestive of ongoing infection after 12 mo of treatment	≥ 100 cells/μl for at least 6 mo
Cytomegalovirus retinitis*	Quiescent disease with treatment	≥ 100–150 cells/μl for at least 6 mo
Toxoplasma gondii encephalitis	Completion of initial therapy and absence of signs or symptoms of active infection	> 200 cells/μl for at least 6 mo
Cryptococcal meningitis	Completion of initial therapy and absence of signs or symptoms of active infection	> 100–200 cells/μl for at least 6 mo

*In patients with extensive or sight-threatening lesions from cytomegalovirus (CMV) infection, the decision to discontinue anti-CMV treatment should be made with an ophthalmologist, because of the risk of vision loss should reactivation of CMV occur.

sociated with a higher titer of cerebrospinal cryptococcal antigen, increased abnormal focal neurologic findings, and decreased survival.[195] In addition, outcomes are worse in patients whose CSF pressure increases by at least 10 mm H_2O after therapy is started. Accordingly, CSF opening pressure should be measured in all patients with suspected cryptococcal meningitis; those patients whose CSF opening pressure is 250 mm H_2O or greater should undergo large-volume CSF drainage by lumbar puncture. Such drainage should be repeated as often as necessary.

Disseminated Mycobacterium avium *Complex Infection*

Disseminated *M. avium* complex infection is a frequent complication in patients who have a $CD4^+$ T cell count of less than 50 cells/μl. This disease is characterized by vague constitutional symptoms, such as fever, night sweats, fatigue, weight loss, abdominal pain, and diarrhea. The preferred method of diagnosis is blood culture, which has a sensitivity of at least 90%; detection by culture, however, often takes longer than 7 days. Empirical therapy should generally be discouraged. Therapy for disseminated *M. avium* complex infection consists of clarithromycin (or azithromycin) plus ethambutol; many experts recommend adding either a fluoroquinolone or rifabutin as a third medication, particularly for the first 2 to 3 months of initial therapy.

Cytomegalovirus Retinitis

CMV infection is another common opportunistic infection in patients who have a $CD4^+$ T cell count of less than 50 cells/μl. CMV most often causes a retinitis that generates visual symptoms such as floaters, flashing lights, or visual-field deficits. The diagnosis is established by characteristic findings on ophthalmologic examination; in general, the patient should be referred to an ophthalmologist for diagnosis. Prompt diagnosis and prompt initiation of therapy are essential to minimize permanent visual loss. Initial therapy should consist of an induction course of either intravenous ganciclovir or intravenous foscarnet, followed by long-term maintenance therapy. Most clinicians prefer ganciclovir as initial therapy because it has fewer adverse effects than foscarnet. Newer therapies include long-term suppression with oral ganciclovir, oral valganciclovir (a ganciclovir prodrug), and implantation of ganciclovir pellets in the affected eye. CMV infection can also occur in the upper or lower gastrointestinal tract, as well as in the CNS.

Immune Reconstitution Syndromes

Immune reconstitution syndromes are the clinical manifestation of inflammatory responses directed against known or occult pathogens that develop after patients are started on antiretroviral therapy. These reactions coincide with improvements in immune function as measured by rising $CD4^+$ T cell counts and have been reported to occur with opportunistic and nonopportunistic infections, as well as malignancies.[196] These inflammatory syndromes often involve mycobacterial infections (*M. avium* complex and *M. tuberculosis*) and typically develop within weeks after initiating antiretroviral treatment. The clinical presentations are often atypical and present diagnostic challenges; other possible causes include adverse drug reactions and progressive disease from resistant pathogens or cancers. Reported findings with *M. avium* complex infection include fever, adenitis, organomegaly, and granulomatous masses. Immune reconstitution syndromes with *M. tuberculosis* may present as fever, new lung infiltrates, pleural and pericardial effusions, tuberculomas, and skin findings.[197] Other reported syndromes include the following: (1) vitreitis with CMV infection, (2) neurologic deficits and enhancing MRI lesions with progressive multifocal leukoencephalopathy, (3) inflammatory meningitis with *Cryptococcus,* (4) hepatitis flares with hepatitis B and C infections, (5) adenitis with histoplasmosis, and (6) inflammatory reactions to Kaposi sarcoma. In most cases, treatment of the involved pathogen and antiretroviral therapy can be continued, and the inflammatory response can be managed with anti-inflammatory medications, including steroids. In severe and life-threatening cases, antiretroviral therapy should be discontinued.

SECONDARY PREVENTION OF OPPORTUNISTIC INFECTIONS

The U.S. Public Health Service guidelines include recommendations for preventing recurrent disease after patients have received therapy for acute disease [*see Table 10*]. As with primary prophylaxis, discontinuance of secondary prophylaxis for a number of opportunistic infections is safe for patients who have completed a set length of therapy for the infection and who have had a robust immunologic response to antiretroviral therapy.

HIV/AIDS Telephone Consultation Services

WARMLINE

National HIV Telephone Consultation Service

Available from 7:30 AM to 5:00 PM PST; detailed information on the service can be obtained at the following URL: http://www.ucsf.edu/hivcntr

Telephone: 1-800-933-3413

PEPline

National Clinicians' Post-Exposure Prophylaxis Hotline

Available 24 hrs; detailed information on the service can be obtained at the following URL: http://www.ucsf.edu/hivcntr/PEPline/index.html

Telephone: 1-888-448-4911

Specific criteria have been determined for *P. jiroveci* pneumonia,[198] *M. avium* complex infection,[199,200] CMV retinitis,[201-203] *T. gondii* encephalitis,[204,205] and cryptococcal meningitis[206] [*see Table 11*]. Discontinuance of secondary prophylaxis (or maintenance therapy) for other opportunistic infections may be possible, but there is too little evidence to permit recommendations at this time.

Additional Resources

Because the field of HIV and AIDS continues to change at a very rapid pace, clinicians need easy access to updated material. The resources available in the current electronic era are outstanding, but they are often overwhelming. Several excellent Web sites that provide current information on treatment guidelines, conference summaries, drug-safety warnings, and summaries of articles are listed [*see Sidebar* Internet Resources for Information on HIV and AIDS]. In addition, national consultation services provide expert clinical advice and state-of-the-art information [*see Sidebar* HIV/AIDS Telephone Consultation Services]. These Internet and telephone resources can provide critical information to help practicing physicians optimally manage HIV infection.

XXXIV PROTOZOAN INFECTIONS

Wesley C. Van Voorhis, m.d., ph.d.
Peter F. Weller, m.d.

Definitions

Parasites are generally subdivided into three categories: protozoans, or single-celled nucleated organisms; helminths, which are metazoan wormlike organisms; and arthropods such as ticks and insects. This chapter focuses on protozoan pathogens [*see Figure 1*]; helminths are discussed elsewhere [*see 7:XXXV Helminthic Infections*].

Parasitism can lead to four different host-parasite states: (1) symbiosis, which is the association of two organisms that cannot exist independently; (2) mutualism, an association in which both organisms benefit; (3) commensalism, in which the parasite benefits and the host is unaffected; and (4) disease, in which the parasite benefits and the host is harmed.

Parasites can be ectoparasites that live on the outside of the host, where they cause an infestation, or endoparasites that live within the host, where they cause an infection. Hosts are classified by the forms of parasites found in them. There are five categories of hosts: definitive, reservoir, incidental, intermediate, and carrier. A definitive host harbors the adult or sexual form of the parasite. Definitive hosts can be reservoir hosts (animals that harbor the same parasite species as humans) or incidental hosts (unnecessary for the maintenance of the parasite in nature). Intermediate hosts harbor a developing larval or asexual form of the parasite. Carrier hosts harbor larval or asexual forms of the parasite without development.

Vectors are objects or organisms responsible for transmitting parasites between hosts. A vector may be biologic, in which the parasite multiplies or develops, or mechanical, which transmits the unchanged parasite from host to host.

In general, protozoa are classified by their organelles of locomotion [*see Figure 1*]. Sporozoa, including *Plasmodium, Toxoplasma*, and *Cryptosporidium*, have no evident organelles of locomotion. Microsporidia also lack evident organelles of locomotion. Ciliates, such as balantidia, move with cilia; flagellates, such as the trypanosomes *Giardia, Leishmania,* and *Trichomonas*, move with flagella; and *Sarcodina*, or amebae, move by means of pseudopodia extension of the cytoplasm.

Only the sporozoa have a clearly identified sexual phase. Other protozoa appear to divide simply by binary mitosis.

Malaria

Four *Plasmodium* species cause human malaria: *P. falciparum, P. vivax*, *P. ovale,* and *P. malariae* [*see Table 1*]. *P. vivax* and *P. falciparum* are the most prevalent worldwide, and falciparum malaria is the one responsible for most deaths. Malaria is transmitted by anopheline mosquitoes. Although malaria transmission in the United States is uncommon, about 300 to 500 million malaria cases, with one to three million deaths, are estimated to occur annually worldwide.[1,2] Malaria is resurgent because of multiple factors, including mosquito vector resistance to insecticides, inability of governmental programs to control mosquito vector populations, increased opportunities for breeding of vector mosquitoes, and increasing resistance of *Plasmodium* to chemotherapeutic agents.

etiology and epidemiology

Malaria is endemic in many countries [*see CE:VII Health Advice for International Travelers*]. Most malaria in the United States is imported. In 2001, 1,383 cases of malaria—11 of them fatal—were reported to the Centers for Disease Control and Prevention (CDC). Of these cases, 891 occurred in United States civilians, 316 in foreign civilians, and 18 in United States military personnel.[1] *P. falciparum* accounted for 50% of cases; *P. vivax,* for 28% . Along with infections acquired abroad, less common means of transmission are by blood transfusion, by sharing of contaminated needles, by organ transplantation, and congenitally in infants who are born of infected mothers.[1,3] In addition, because species of *Anopheles* mosquitoes that can transmit malaria are endemic in the United States, isolated cases of autochthonous malaria have developed in persons in the United States who have been bitten by local mosquitoes that fed on persons with imported malaria.[4] A final means of introduction of malaria into the United States is so-called airport malaria, which arises when an infected mosquito enters the country on an aircraft from a malarious area and transmits the infection in the area around the airport.[5]

pathogenesis

Malaria is normally acquired through the bite of an infected female *Anopheles* mosquito [*see Figure 2*]. Sporozoites inoculated into the bloodstream during the blood meal travel to the liver and infect hepatocytes; this is the preerythrocytic stage of infection. Notably, only two species of *Plasmodium*—*P. vivax* and *P. ovale*—cause persistent infections within the liver; the dormant intrahepatic sporozoites are termed hypnozoites. Within the he-

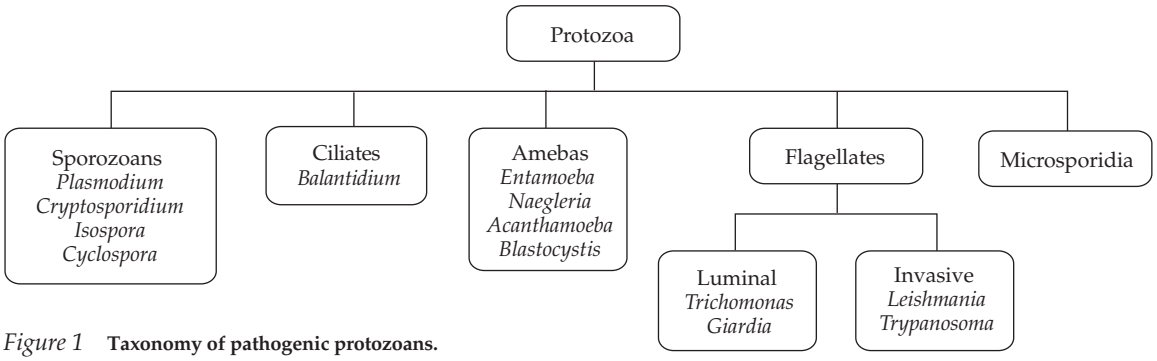

Figure 1 **Taxonomy of pathogenic protozoans.**

Table 1 Differentiating Features of Malaria Species

Species	*Global Prevalence*	*Mortality*	*Clinical Manifestations*	*Length of Erythrocytic Cycle*	*Persistence in Liver*	*Chloroquine Resistance*
P. falciparum	Common	Common (especially if untreated in nonimmune hosts)	Fever, anemia Microvascular blockade with local anoxia Brain (cerebral malaria) Lungs (pulmonary edema) Kidneys (acute renal failure) Intestines (diarrhea) Liver (tenderness, anoxia) Blood (thrombocytopenia)	36–48 hr	No	Common
P. vivax	Common	Uncommon	Fever, anemia Splenic rupture (uncommon)	48 hr	Yes	Uncommon
P. ovale	Uncommon	Rare	Fever, anemia	48 hr	Yes	No
P. malariae	Uncommon	Rare	Mild, chronic parasitemia, often with no symptoms Immune complexes (nephrotic syndrome)	72 hr	No	Rare

patocytes, the sporozoites transform into merozoites. In the erythrocytic stage of malarial infection, merozoites released from infected hepatocytes and later from infected erythrocytes interact with specific erythrocyte membrane proteins and invade the red blood cells. (The Duffy blood group antigen is the requisite erythrocyte receptor for *P. vivax*. Absence of the Duffy blood group—a genetic trait found in many West Africans and their descendants—confers resistance to that species of *Plasmodium*.) Within the infected cells, malarial parasites undergo schizogony to form new merozoites, which are then released to reinfect other erythrocytes. A few parasites differentiate into sexual stages (gametocytes) capable of infecting mosquitoes [*see Figure 3*]. Male and female gametocytes transform and reproduce in the midgut of the mosquito, leading to the production of new sporozoites that localize in the mosquito's salivary glands.

Because malarial parasites can multiply in an infected human, intense infections can develop from minimal inocula of sporozoites. Travelers have developed malaria after being bitten by mosquitoes during brief layovers at airports in malarious areas and during flights on airplanes that have stopped in malarious regions. Consequently, malaria prophylaxis is warranted for even the most limited exposures to mosquitoes in malarious regions.

Infected persons remain asymptomatic during the time between the infecting mosquito bite and the erythrocytic stage of infection, a period that may range from about 1 to 4 weeks for deadly *P. falciparum* infection. Because malaria chemoprophylaxis does not actually prevent malaria but, rather, treats erythrocytic-stage infection, chemoprophylactic medication must be continued for the full 4 weeks after a return from a malarious area. Failure to do so permits the development of *P. falciparum* infection. An exception to this is with so-called causal prophylactic medication, such as atovaquone-proguanil, which also kills liver-stage parasites. This form of prophylaxis can be discontinued a week after leaving a malarious area. Prophylaxis generally does not prevent late emergence of *P. vivax* or *P. ovale* from incubating liver hypnozoites.

Immune responses develop to malarial infections. Development of antibodies to the most indolent and chronic malarial species, *P. malariae*, may lead over years to the onset of immune complex–mediated nephrotic syndrome. Repeated infections with other *Plasmodium* species can elicit a partially protective immunity that will limit the severity of infection but not prevent it. Of note, residents of malarious areas may lose their relative immunity after staying several years in a nonmalarious region; such persons may be fully susceptible to malarial infection upon their return.

DIAGNOSIS

Malaria should be considered as a cause of any febrile illness in immigrants from malarious areas and in persons who have traveled or worked in malarious areas. Febrile illness in recipients of transfused blood or transplanted organs and in neonates of potentially infected mothers should be considered as possible acquired malaria. Finally, even in United States residents, the diagnosis of malaria may need to be considered in febrile patients with compatible illnesses that may have developed from the uncommon autochthonous transmission of malaria.

Infections with the four human malarial species of *Plasmodium* produce distinct clinical syndromes, based in part on the interactions of each species with erythrocytes. The four species of malaria can be distinguished by their characteristics on blood smears [*see Figure 3*]. *P. vivax* and *P. ovale* infect young red cells only, which helps limit the intensity of infection. It also explains why enlarged red cells are characteristic of *P. vivax* and *P. ovale* infections in speciation of malaria on blood films. In contrast, *P. falciparum* infects erythrocytes of all ages. This capacity of falciparum malaria, the greater numbers of merozoites produced by this species, and especially the great propensity of falciparum-infected erythrocytes to adhere to the microvascular endothelium help make falciparum malaria distinctly more severe than other forms of malaria. Erythrocytes infected with *P. falciparum* develop unique surface knobs that mediate binding and adherence to endothelial cells in capillaries and venules. Sequestration of infected erythrocytes in these small vessels results in local anoxia and can lead to severe complications, including cerebral malaria and pulmonary edema [*see Table 1*].

Clinical Features

Symptoms of malaria develop about 1 to 4 weeks after infection and typically include fever and chills. Virtually all patients with acute malaria have episodes of fever. At the outset, fever may occur daily; over time, the paroxysms may take on the typ-

ical pattern of fevers every other day (*P. vivax*, *P. ovale*, *P. falciparum*) or every third day (*P. malariae*) [*see Table 1*]. The paroxysms of fever, which may reach as high as 41.5° C [106.7° F], and chills (with or without rigors) may be irregular, however—especially in falciparum malaria. Other possible symptoms are headache, increased sweating, back pain, myalgias, diarrhea, nausea, vomiting, and cough. The constellations of symptoms are nonspecific and may suggest diagnoses other than malaria.[6] With time, anemia and splenomegaly develop.

Because of the distinct capacity of falciparum-infected erythrocytes to cause microvascular blockade, potentially fatal organ involvement can develop rapidly in falciparum malaria. Cerebral involvement may lead to delirium, focal disorders (e.g., seizures), and coma.[7] Pregnant women are at special risk for death and fetal loss from falciparum infections. Splanchnic involvement may cause protracted nausea, vomiting, diarrhea, melena, and abdominal pain; this syndrome can be readily mistaken for traveler's diarrhea. Lung involvement may cause pulmonary edema and acute respiratory distress syndrome. There may be severe hypoglycemia. A rare syndrome known as blackwater fever reflects hemoglobinuria and acute renal failure from massive intravascular hemolysis.

P. malariae organisms can persist in the blood as an indolent, even asymptomatic, infection for years or even decades.[8]

Laboratory Findings

The white blood cell count is usually in the normal range in malaria patients. Anemia develops but may not be prominent on presentation, especially if the patient is dehydrated. Thrombocytopenia may develop; disseminated intravascular coagula-

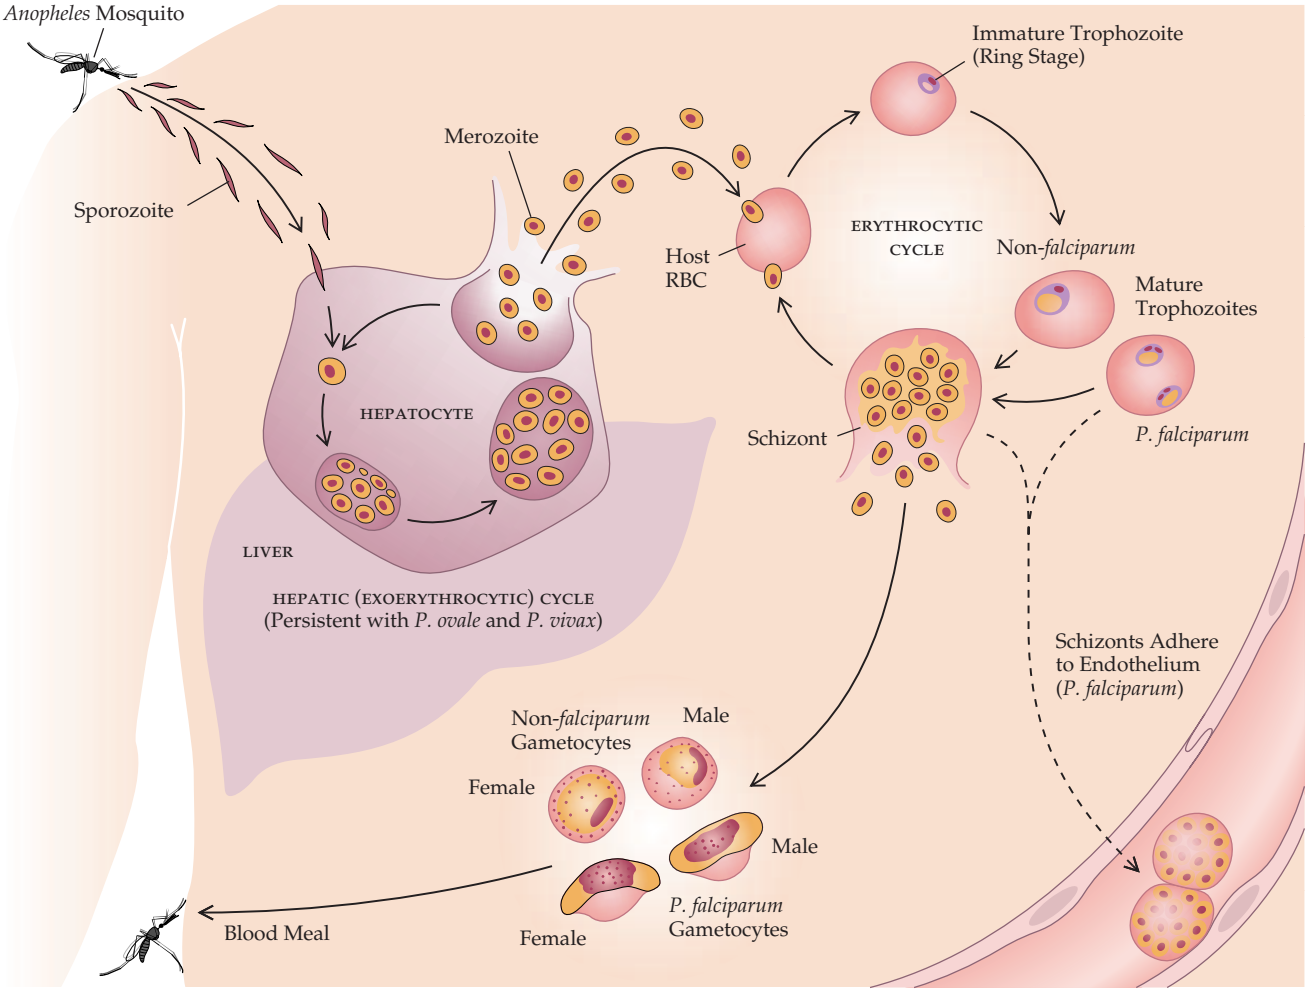

Figure 2 **The life cycle of malaria.[110] All four human malaria species—*Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*—may be transmitted by *Anopheles* mosquito bites or, rarely, introduced by blood (e.g., congenitally, through transfusion, and by sharing of needles). Once in the bloodstream, *Plasmodium* sporozoites travel to the liver and infect hepatocytes. This is the preerythrocytic stage of infection. Only two species of *Plasmodium*, *P. vivax* and *P. ovale*, cause persistent infections within the liver, which can lead to later recrudescence of malaria. Within the hepatocytes, the sporozoites transform into merozoites. In the erythrocytic stage of malarial infection, merozoites released from infected hepatocytes and later from infected erythrocytes interact with specific erythrocyte membrane proteins and invade the red blood cells. Within the infected cells, malarial parasites undergo schizogony to form new merozoites, which are then released to reinfect other erythrocytes. A few parasites differentiate into sexual stages (gametocytes) capable of infecting mosquitoes. Symptoms develop with infection of erythrocytes (erythrocytic cycle), about 1 or more weeks after a mosquito bite; malaria therapy is directed toward the erythrocytic stage. *P. falciparum* causes more severe disease because it is able to invade all stages of red blood cells (RBCs); thus, the parasitemia is higher. In addition, late trophozoites and schizonts of *P. falciparum* adhere to endothelia, causing end-organ damage such as cerebral malaria or placental malaria in pregnancy.**

tion sometimes occurs in falciparum malaria. Liver enzyme levels may be elevated.

The specific diagnosis and speciation of malaria depends on the recognition of parasites in properly stained smears of peripheral blood [*see Figure 3*]. Thick smears are more sensitive than thin smears, but the layering of cells necessitates greater expertise in examining morphology. Smears should be taken repeatedly for several days because of the cyclic nature of the parasitemia. This is especially important in suspected *P. falciparum* infections, in which infected cells may be sequestered in the microvasculature and in which late trophozoites and schizonts are generally not seen. The morphologic features of the parasites (and the infected host erythrocytes) are useful in species identification and in distinguishing *Plasmodium* species from the morphologically similar *Babesia microti*, which causes babesiosis. It is very important to identify and treat *P. falciparum* infection rapidly because of its potential for swift progression if left untreated or if treated improperly. In the absence of a skilled microscopist, the clinician is advised to presumptively treat for falciparum malaria when malarial forms are identified on a blood smear.

The quantitative buffy coat (QBC) technique is sensitive in identifying plasmodial parasitemia, but it does not identify the species. Dipstick antigen-capture assays are available and have the potential to help clinicians detect falciparum infections, particularly where no specialized laboratories are available.[9] DNA probes, polymerase chain reaction (PCR) tests, and serologic tests exist, but these are not usually immediately available for diagnosis of acute malaria at presentation. Thus, examination of blood smears is still the standard in assessing, first, whether a patient has malaria and, second, whether the malaria is caused by *P. falciparum*.

TREATMENT

Treatment of patients with acute malaria requires consideration of the *Plasmodium* species involved and, in cases of falciparum malaria, the likelihood of resistance to antimalarial med-

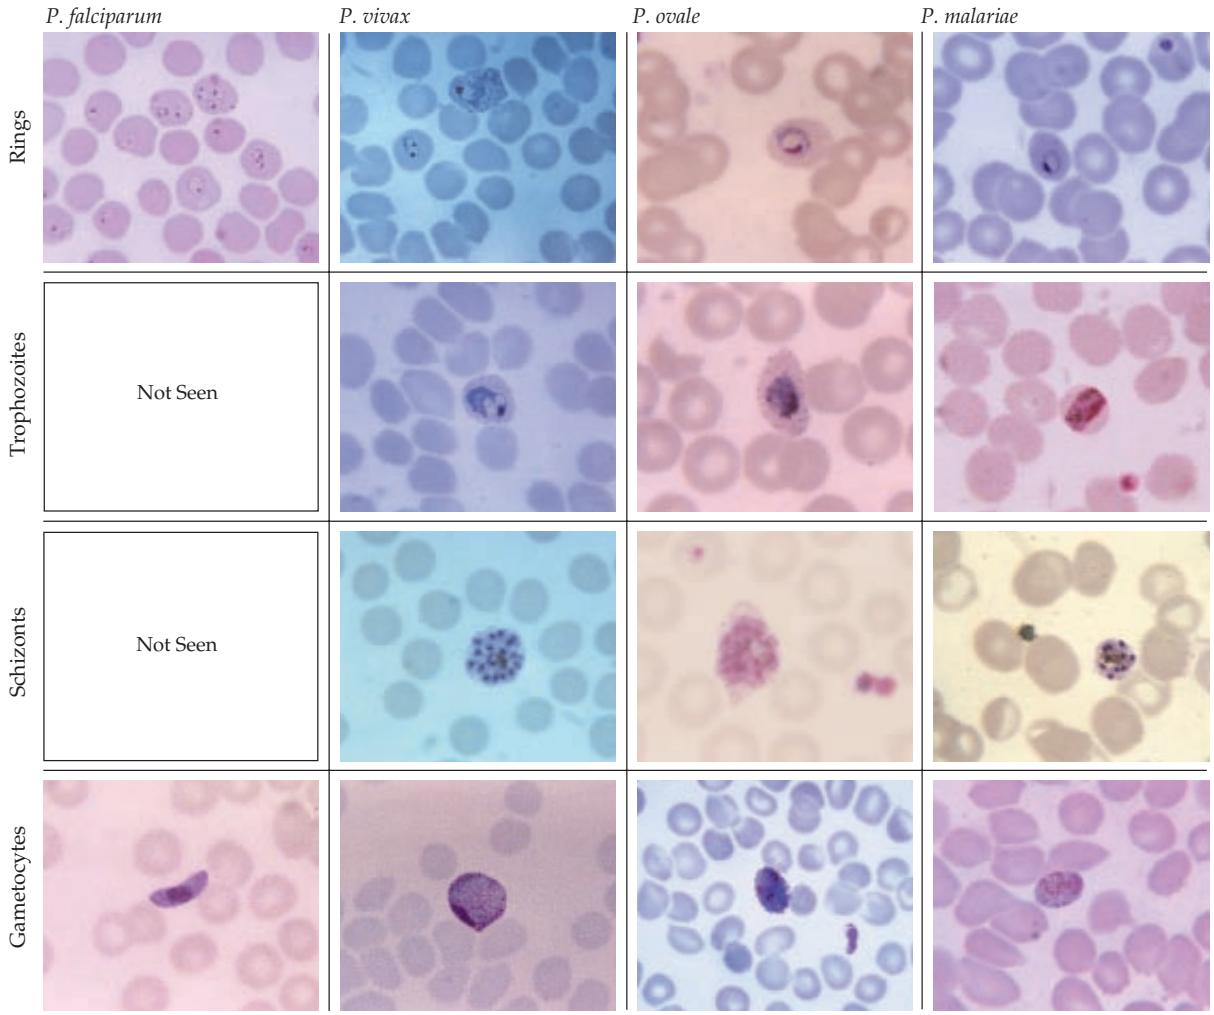

Figure 3 **Identification of species of malaria based on forms seen on blood smears. During the ring stage, multiple parasites are more likely to be seen within the red blood cell in *Plasmodium falciparum* infection. The late trophozoites and schizonts of *P. falciparum* are not usually seen on smears because of their propensity to adhere to the endothelia of the peripheral organs. *P. falciparum* infects mature red blood cells, whereas *P. vivax* and *P. ovale* commonly infect only reticulocytes, which are larger and slightly bluish when stained. Schizonts of *P. vivax* often have more than 14 nuclei, which distinguishes them from other malarial species. The trophozoites of *P. malariae* often have a bandlike appearance across the red blood cell. The spots in late trophozoites are hemozoin deposits; these cells can sometimes be mistaken for granulocytes. Banana-shaped gametocytes are pathognomonic for *P. falciparum* infection, but they are seen only after 10 to 14 days of erythrocytic infection.**

Table 2 Antimalarial Drugs[10]

Category	*Drug (Trade Name)*	*Dosage*	*Cost of Treatment ($)**	*Principal Side Effects*	*Main Limitations*
Quinine derivatives	Chloroquine phosphate	1,000 mg, then 500 mg at 6, 24, and 48 hr	29	Headache, nausea, vomiting, blurred vision, dizziness, fatigue, and confusion	Resistance
	Quinine	650 mg q. 8 hr × 3–7 days	17	Tinnitus, temporary hearing loss, headache, dysphoria, nausea, vomiting, and mild visual disturbances	Compliance, safety, and resistance
	Amodiaquine	—	—	Neutropenia, hepatoxicity	Safety and resistance
	Mefloquine (Lariam)	750 mg, then 500 mg at 12 hr	89	Nausea, dizziness, vivid dreams, and neuropsychiatric disturbances	Safety, resistance, and cost
Artemisinins†	Artemether†	—	—	Infrequent and mild decreases in reticulocyte and neutrophil counts, elevated liver transaminases, abdominal pain, diarrhea, and drug fever	Compliance, safety, and cost
	Artesunate†	4 mg/kg/day × 3 days	—	Same as for artemether (see above)	Compliance, safety, and cost
Antibiotics‡	Tetracycline Doxycycline Clindamycin	500 mg q.i.d × 7 days 100 mg b.i.d. × 7 days 900 mg t.i.d. × 5 days	8 9 40	GI disturbance, photosensitivity, diarrhea, and *Candida* vaginitis	Slowly effective if used alone
Combinations	Sulfadoxine-pyrimethamine (Fansidar)	1,500/75 mg p.o., single dose	4	Rash, fever, and marrow suppression	Resistance
	Atovaquone-proguanil (Malarone)	500/200 mg b.i.d. × 3 days	38	Rash, nausea, and diarrhea	Resistance potential and cost
	Artemether-lumefantrine (Coartem)†	1–4 tablets (by patient weight) at 0, 8, 24, 36, 48, and 60 hr	—	Possible mild CNS disturbances	Compliance, resistance potential, and cost

*Costs are derived from online pharmaceutical sources and are intended to indicate relative costs of available therapies.
†Not available in the United States; artemisinins should be given with another antimalarial.
‡Antibiotics are usually used in combination with quinine or other rapidly killing antimalarials.

ications. Chloroquine is the mainstay of treatment for all malarial species except those strains of *P. falciparum* that are resistant to the drug [*see Table 2*]. Notably, chloroquine-resistant *P. falciparum* (CRPF) malaria is now widespread in all countries where *P. falciparum* is endemic, except Haiti, the Dominican Republic, areas of Central America west of the Panama Canal, and parts of the Middle East [*see CE:VII Health Advice for International Travelers*]. For *P. falciparum* infections acquired in countries with chloroquine-resistant strains, alternative therapies must be utilized [*see Table 2*]; the typical regimen in such cases remains quinine or quinidine combined with a tetracycline. Mefloquine-resistant strains of *P. falciparum* have been identified at the Thailand-Myanmar border. Isolated strains of *P. vivax* resistant to chloroquine have been reported in Africa, Central and South America, Oceania, and Asia. Isolates of *P. malariae* resistant to chloroquine have now been reported, as well.

Acute attacks caused by all species except CRPF are treated with oral chloroquine phosphate at an initial dose of 1 g (600 mg base), followed by 500 mg (300 mg base) at 6 hours and again at 24 and 48 hours.[10] For suspected CRPF malaria, several alternative regimens are available.[10] Quinine sulfate (650 mg every 8 hours for 3 to 7 days) is combined with doxycycline (100 mg b.i.d. for 7 days), sulfadoxine-pyrimethamine (Fansidar) (three 500/25 mg tablets as a single dose on the last day of quinine treatment), or clindamycin (900 mg t.i.d. for 5 days). Alternative therapies for CRPF malaria include mefloquine (750 mg followed by a dose of 500 mg 12 hours later) and atovaquone in combination with proguanil (500 mg and 200 mg b.i.d. within 45 minutes of meals for 3 days).[10]

For patients who are too ill to take oral therapies, intravenous quinidine gluconate and quinine dihydrochloride are the drugs of choice for any species of malaria.[10] Quinidine is effective and well tolerated when appropriate precautions, including hemodynamic and electrocardiographic monitoring, are used. A loading dose of 10 mg/kg (maximum, 600 mg) of quinidine in normal saline is infused slowly over 1 to 2 hours, followed by continuous infusion of 0.02 mg/kg/min. Parenteral therapy should be continued until oral therapy can be tolerated; in most cases, oral therapy can be substituted within 48 to 72 hours. For fulminant falciparum malaria, exchange transfusion can be an adjunct to chemotherapy, but it has not been convincingly shown to decrease mortality.[11] Patients with moderate to severe falciparum malaria should be hospitalized and monitored for hypoglycemia and other complications, as well as response to therapy.

With the exception of atovaquone-proguanil, each of the chemotherapeutic agents above is active only in the erythrocytic stage of infection. Because *P. vivax* and *P. ovale* have persisting hepatic stages that may cause relapses of malaria after chloroquine use, an agent that is active against the exoerythrocytic cycle should be administered after a course of chloroquine. Primaquine is the sole agent used to eradicate hepatic involvement; the dosage is 26.3 mg (15 mg base) orally every day for 2 weeks.

P. vivax from Oceania and Tanzania has been reported to be primaquine tolerant, and 1.5 to 2 times the normal dose is given for 2 to 3 weeks if primaquine-tolerant strains are suspected.[10] Because primaquine may induce hemolysis in persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency, patients should be screened for the disorder before treatment. If only mild G6PD deficiency is found, primaquine may be given at a dosage of 79 mg (45 mg base) orally once a week for 8 weeks.

Advice for Travelers

Most United States residents lack immunity to malaria and are at risk for the morbidity and mortality associated with the disease, especially the falciparum form, if they visit countries where malaria transmission occurs. Of the 891 United States civilians who acquired malaria abroad in 2001, only 20.2% had followed a CDC-recommended chemoprophylactic drug regimen.[1] It is imperative that travelers receive appropriate advice on reducing their risk of acquiring malaria, including the use of appropriate chemoprophylactic regimens [*see CE:VII Health Advice for International Travelers*]; up-to-date information can be found on the CDC Web site (http://www.cdc.gov/travel). Current alternatives, depending on the area of travel and the traveler, include chloroquine, mefloquine, doxycycline, atovaquone-proguanil, and primaquine.

Babesiosis

Babesia organisms are intraerythrocytic protozoan parasites that produce a malarialike illness. Most cases of babesiosis have been reported in the northeastern United States, but cases have also occurred in the upper Midwest, the West Coast, and other regions of the United States, as well as in Europe and elsewhere.[12]

ETIOLOGY AND EPIDEMIOLOGY

Several species of *Babesia* have been recognized as causes of human disease. The first to be recognized was *B. divergens*, a parasite of cattle that has caused several fatal infections in splenectomized persons. Most of these cases have occurred in Europe, although a related species, designated MO1, has caused a fatal case in a splenectomized man in Missouri.[13]

B. microti is the principal cause of babesiosis in the eastern and central United States. This parasite of white-footed mice is transmitted by deer ticks and is prevalent on the islands off Massachusetts, New York, and Rhode Island and in focal areas in Connecticut, Wisconsin, and Minnesota. Risk of *Babesia* infection is not increased by splenectomy, but the disease is more serious in persons who have undergone splenectomy, have HIV infection, or have other immunocompromising conditions.[12,14] Many infected persons have subclinical infections, as evidenced by serologic surveys in endemic areas. Because nymphal ticks are the most efficient at transmitting infection, most cases develop between May and August, when nymphal ticks are most abundant.[12]

Another form of babesiosis develops from infection with an organism found in states along the Pacific coast and designated as WA1.[15] The vector and the reservoir of this emerging *Babesia* species are not yet known. Infections have been recognized in asplenic persons and less commonly in normal hosts; serologic surveys in rural and semirural California indicate that subclinical infection with WA1 may have developed in up to 20% of the population.[12]

Babesiosis may also be acquired perinatally and through blood transfusions.[12,15]

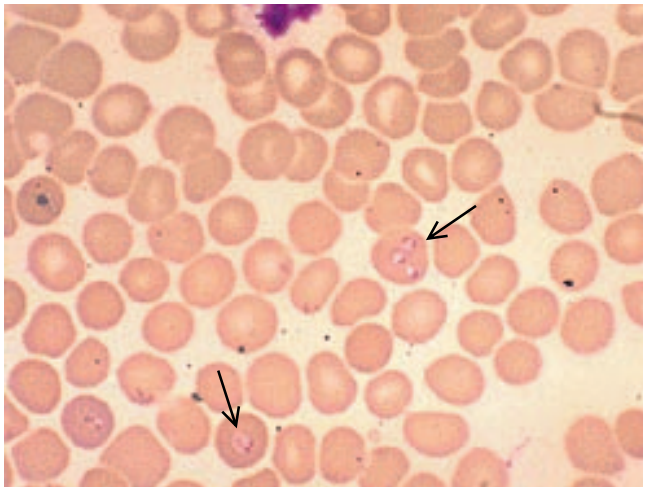

Figure 4 **Blood smear showing *Babesia* parasites in erythrocytes (arrows).**

DIAGNOSIS

Clinical Features

Many persons infected with *B. microti* or WA1 remain asymptomatic. In those who have symptoms, illness develops gradually in the weeks after tick bites or blood transfusions. Malaise, anorexia, and fatigue are followed by the onset of myalgias, fevers, and sweats. Emotional lability, depression, nausea, vomiting, and headache are common. Symptoms tend to abate over several weeks, although fatigue and malaise may persist for months. Splenomegaly is occasionally present. Infections may become more fulminant and persistent in asplenic patients, elderly patients, and patients with HIV infection or other immunocompromising conditions. Intravascular hemolysis, hemoglobinuria, and renal failure may develop. On blood smears, parasitemia is usually less than 1%, but parasites may be present in as many as 85% of red blood cells; this level of parasitemia can be fatal, especially in asplenic persons.

Laboratory Findings

Laboratory findings may include hemolytic anemia, normal to low leukocyte counts, and abnormal liver function test results. The diagnosis is based on the finding of ring forms and pleomorphic intraerythrocytic organisms on Giemsa-stained blood smears [*see Figure 4*]. Occasionally, extracellular merozoites are seen. Unlike malarial parasites, *Babesia* organisms do not produce pigment in red blood cells. In some patients, a parasitemia level of 5% or higher and the presence of several ring forms in a single red cell might suggest *P. falciparum* infection; the absence of gametocytes and intracellular pigmentation will help distinguish babesiosis from malaria. Serologic testing is of value for diagnosing chronic infections with *B. microti* and WA1 when parasites are not detectable on blood smears.

TREATMENT

The treatment of choice for babesiosis is a combination of clindamycin (1.2 g b.i.d. I.V. or 600 mg t.i.d., p.o., for 7 to 10 days) and quinine (650 mg t.i.d., p.o., for 7 days).[10] An alternative is atovaquone (750 mg p.o., b.i.d., for 7 to 10 days) plus azithromycin (600 mg p.o. daily for 7 to 10 days).[10] In a minority of patients who improve symptomatically, parasitemia may nevertheless persist.[16] Occasionally, pulmonary edema may de-

velop after initiation of therapy for babesiosis, as also may occur with malaria. Exchange transfusion can be an adjunct to chemotherapy in cases of fulminant babesiosis.

The tick vector of babesiosis may simultaneously transmit *Borrelia burgdorferi*, the agent of Lyme disease [*see 7:VII Leptospirosis, Relapsing Fever, Rat-Bite Fever, and Lyme Disease*], and *Ehrlichia* (*Anaplasma*) species, the agents of ehrlichiosis [*see 7:XVII Infections Due to Rickettsia, Ehrlichia, and Coxiella*]. Those coinfections may make clinical illness more severe and warrant special therapy.[17]

Toxoplasmosis

Toxoplasma gondii, the cause of toxoplasmosis, is an intracellular protozoan parasite of worldwide distribution. *T. gondii* can infect nearly all animals and birds, making it one of the most widely distributed parasites.[18] Cats are the definitive hosts of *T. gondii*, because only felines harbor the sexual forms; however, humans can develop toxoplasmosis in ways other than exposure to cats.

Humans acquire *T. gondii* infections by the oral and transplacental routes and, less commonly, from blood transfusion and organ transplantation. Infection via the oral route is caused by the ingestion of *T. gondii* tissue cysts in undercooked food or the ingestion of *T. gondii* oocysts, which are found in cat feces [*see Figure 5*]. After ingestion, bradyzoites (from tissue cysts) or sporozoites (from oocysts) invade surrounding cells and develop into tachyzoites, a rapidly dividing form that may disseminate and invade any nucleated cell type. With time and the development of immunity, the parasite will form tissue cysts containing many bradyzoites. Tissue cysts may remain viable for decades without causing disease. Loss of immunity, however, allows reactivation from the latent tissue cysts and the generation of many invasive tachyzoites.

Although toxoplasmosis is extremely common, most acquired and congenital infections are subclinical and are revealed only by the presence of antibodies. The prevalence of infection varies greatly in different population groups and geographic regions. In the United States, serologic evidence of *Toxoplasma* infection varies regionally in prevalence from 3% to 30%.

CLINICAL SYNDROMES

Toxoplasmosis can be divided into five major clinical syndromes: primary toxoplasmosis, toxoplasmosis in immunosup-

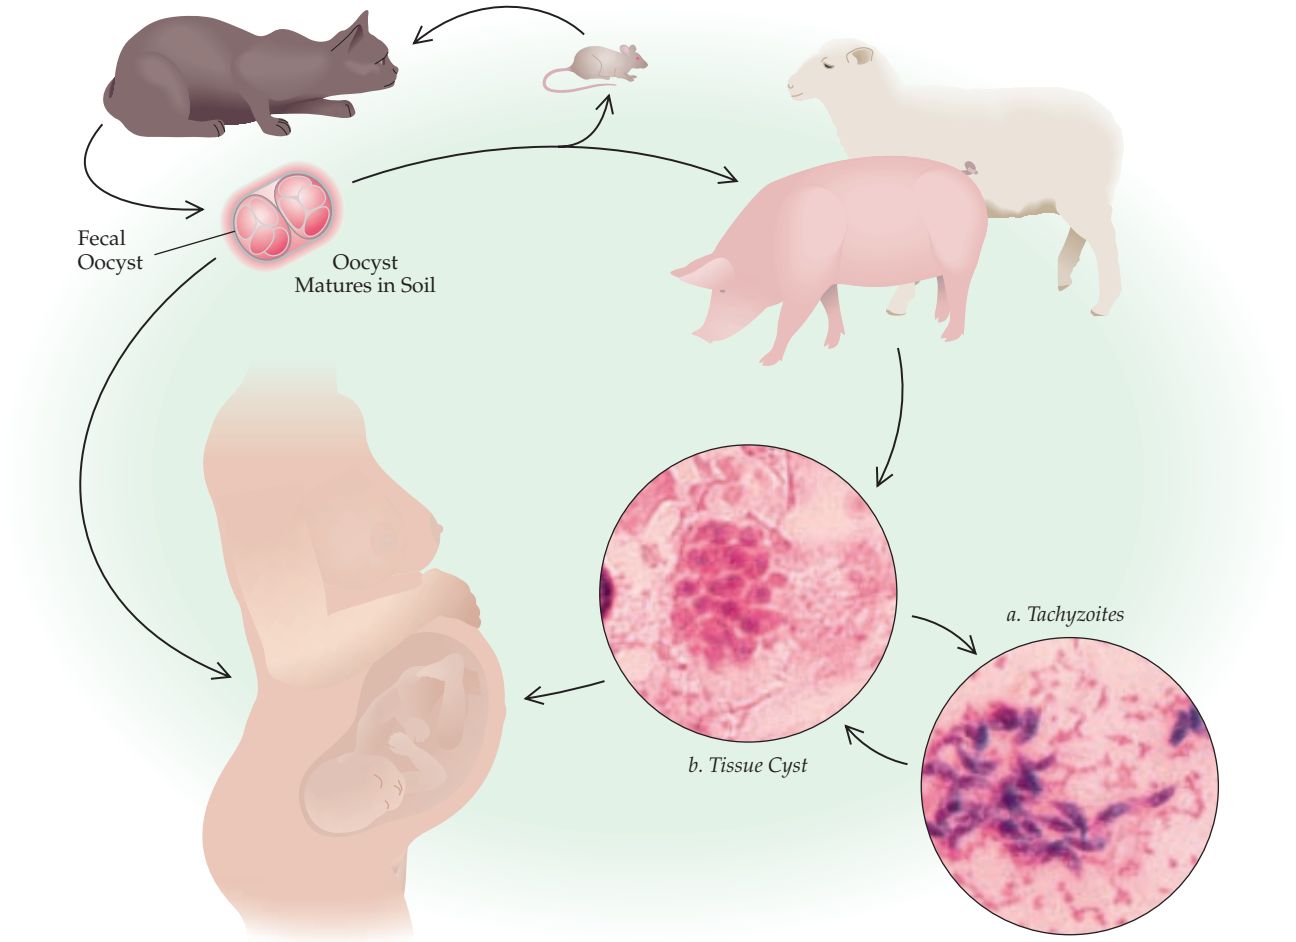

Figure 5 **Life cycle of *Toxoplasma gondii*. Felines, which acquire infection by carnivorism, are the definitive hosts; they are the only species supporting the sexual cycle that leads to oocyst excretion in feces. The oocysts must mature in the environment for at least several days to become infectious to intermediate hosts such as humans. Humans and other carnivores become infected by ingestion of mature oocysts or by ingestion of tissue cysts in undercooked meat. Within the host, both oocysts and tissue cysts convert to rapidly proliferating tachyzoites (*a*); tachyzoites can invade and grow in almost any cell. They form tissue cysts (*b*), which persist in a latent form and can reactivate to proliferate and cause clinical disease if the host becomes immunosuppressed. Reactivation can occur even decades after infection.**

pression, toxoplasmosis in AIDS, congenital toxoplasmosis, and ocular toxoplasmosis.

Primary Toxoplasmosis

An immunocompetent person usually experiences subclinical illness after acquisition of a primary toxoplasmosis infection. Painless lymphadenopathy is the most common symptom. Lymphadenopathy may be localized or generalized and may persist for many months. Isolated cervical lymphadenopathy is the most frequent finding.[19] Enlarged nodes may be the only manifestation; less often, fever, malaise, myalgias, and sore throat are also present. Fatigue and weakness may be pronounced. In addition to lymphadenopathy, physical findings may include pharyngitis, maculopapular rash,[20] and, in a minority of patients, hepatosplenomegaly. Atypical lymphocytosis may be present. The major differential diagnosis includes infectious mononucleosis, cytomegalovirus infection, and lymphoma; less often, sarcoidosis, cat-scratch disease, and other infectious processes may resemble toxoplasmosis. Serologic testing is the key to diagnosis.[21]

Although symptoms of acquired lymphadenopathic toxoplasmosis can persist for weeks or months, the process is almost always self-limited and does not require specific therapy. In severe or protracted cases, pyrimethamine and sulfonamides may be helpful. Chemotherapy should also be used for the rare complications that can occur in the normal host, including chorioretinitis, pericarditis, myocarditis, pneumonitis, myositis, and meningoencephalitis.

Toxoplasmosis in Immunosuppression

In an immunosuppressed person with defective cell-mediated immunity, *T. gondii* can cause devastating neurologic or disseminated disease. Usually, this process develops from reactivation of latent infection and not from a primary infection. Seronegative recipients of organs (especially hearts) transplanted from seropositive donors are at particular risk,[22,23] as are patients with Hodgkin disease, hairy-cell leukemia, and other malignant disorders.[24]

Neurologic abnormalities predominate in at least 50% of these patients. The clinical picture is highly variable and may take the form of a diffuse encephalitis, a meningoencephalitis, or a cerebral mass lesion.[25] The cerebrospinal fluid often shows a mild lymphocytic pleocytosis and an elevation of protein levels; glucose levels, however, remain normal. Pneumonitis may occur in immunosuppressed patients with toxoplasmosis.[26] Fever and dyspnea are present, but cough is absent and no sputum is produced. Chest radiographs typically reveal diffuse bilateral pulmonary infiltrates. In a few cases, the diagnosis has been established by the presence of organisms in the fluid obtained from bronchoalveolar lavage. Other manifestations of disseminated toxoplasmosis in immunosuppressed patients include myocarditis, pericarditis, peritonitis, and lymphadenitis. Many of these immunosuppressed patients have simultaneous infections with other opportunistic pathogens, especially herpesvirus and cytomegalovirus.

Appropriate serologic titers will support the diagnosis of toxoplasmosis; however, antibody levels may be low in these patients, and therefore, brain, lung, or lymph node biopsy may be required for diagnosis. An aggressive diagnostic approach is warranted because pyrimethamine and sulfonamides can be effective in these infections, which are usually fatal if left untreated.

Toxoplasmosis in AIDS

Toxoplasmosis is a particularly severe problem in patients with AIDS; clinically apparent toxoplasmosis develops in 3% to 40% of these patients.[27] Although any of the manifestations of disseminated toxoplasmosis may occur in patients with AIDS,[28] central nervous system abnormalities predominate. Most cases of toxoplasmosis in patients with AIDS result from reactivation of latent *Toxoplasma* cysts acquired before infection with HIV; reactivation is particularly likely when the $CD4^+$ T cell count falls below 100 cells/mm^3.[27] All HIV-infected persons should be tested for antibodies to *T. gondii.* Those who are *Toxoplasma* negative should be cautioned to minimize exposure by cooking meat to an internal temperature of 150° F, washing their hands after contact with raw meat or soil, washing fruits and vegetables before eating them, and avoiding contact with cat feces or contaminated litter (or wearing gloves if these materials must be handled).[29]

In AIDS patients, toxoplasmosis most often presents as necrotizing encephalitis. Symptoms include focal abnormalities (e.g., hemiparesis, sensory loss, visual abnormalities, tremor, cranial nerve palsies, and focal seizures) and generalized neurologic abnormalities (e.g., headache, personality changes, confusion, stupor or coma, and seizures). Although a CSF lymphocytic pleocytosis is consistent with the diagnosis of cerebral toxoplasmosis, computed tomographic or magnetic resonance imaging scans are the crucial diagnostic tests in most cases. Typical findings include single or multiple rounded mass lesions; when a contrast agent is administered, more than 90% of these lesions display ring or nodular enhancement. MRI scans may reveal lesions that were not visualized by CT scanning.[30] Positron emission tomography (PET) may prove useful for distinguishing lesions of toxoplasmosis (which are hypometabolic) from lymphomas (which are hypermetabolic).[31]

Serum antibody tests are useful for screening AIDS patients for cerebral toxoplasmosis; such tests are usually positive because most cases of cerebral toxoplasmosis in patients with AIDS arise from reactivation of latent infection. Although negative antibody tests suggest a diagnosis other than toxoplasmosis, a few seronegative cases have been reported. However, serum antibody tests cannot be relied on in the diagnosis of primary toxoplasmosis in patients with AIDS; antibody titers do not reach the high levels typical of immunocompetent patients with toxoplasmosis, nor are IgM antibodies always present in patients with AIDS.[27] Antibodies against *Toxoplasma* are present in the CSF in nearly two thirds of AIDS patients with cerebral toxoplasmosis, and their detection may assist in the diagnosis [*see* Diagnosis, *below*].[32]

In addition to toxoplasmosis, CNS lesions caused by fungi, mycobacteria, lymphomas, Kaposi sarcoma, metastatic tumors, multifocal leukoencephalopathy, or HIV itself may develop in patients with AIDS. Despite this broad differential diagnosis, empirical treatment of toxoplasmosis is often preferable to early brain biopsy if the clinical and radiologic picture is compatible with the diagnosis and if serum anti-*Toxoplasma* antibodies are present.[33] Because toxoplasmosis is the most common and most treatable cause of cerebral lesions in patients with AIDS, empirical therapy using a combination of sulfonamides and pyrimethamine or the combination of clindamycin and pyrimethamine can be initiated; if the diagnosis is correct, clinical and radiologic improvement is often observed within 1 to 2 weeks. If patients respond poorly to treatment and are seronegative or belong to population groups with a high risk of tuberculosis (e.g., Haitians, Africans, or intravenous drug abusers), biopsy should be strongly considered.[33]

Congenital Toxoplasmosis

Congenital toxoplasmosis arises almost exclusively when the mother develops a primary infection during gestation. Congenital infection almost never develops from latent toxoplasmosis acquired before pregnancy, and the few recognized cases have developed mainly in pregnant women with reactivation of toxoplasmosis secondary to immunosuppressive therapy or HIV infection.[34] The risk of fetal infection depends on when maternal infection occurs, rising from 10% during the first trimester to 60% during the third trimester.[35] The consequences of fetal infection also depend on when infection occurs: fetal infections early in gestation are most likely to result in severe damage.

The clinical spectrum of congenital toxoplasmosis varies widely. About 85% of infected babies appear normal at birth; without treatment, however, about 85% of these infants will experience chorioretinitis, hearing loss, or developmental delay.[35,36] The clinical spectrum of symptomatic congenital toxoplasmosis includes fetal death, neurologic damage (cerebral calcification, seizures, retardation, hydrocephalus, or microcephaly), chorioretinitis, fever, hepatosplenomegaly, and rash. The differential diagnosis includes congenital infection with cytomegalovirus, herpes simplex, rubella, or syphilis. Congenital toxoplasmosis can be diagnosed by serologic methods, by a PCR test performed on amniotic fluid,[37] or by identification of the organism in the placenta or fetal tissues. Infants with congenital toxoplasmosis may benefit from prolonged treatment with pyrimethamine and sulfonamides.[38]

The prevention of congenital toxoplasmosis is of major importance. Pregnant women should minimize contact with cats, especially strays or cats who eat raw meat; they should wash their hands after contact with cats and should have another person empty the litter box daily. In addition, pregnant women should wash all fruits and vegetables before eating them and should not eat undercooked meat. Serologic screening of pregnant women is advisable.

Ocular Toxoplasmosis

Toxoplasmosis may account for about 30% of cases of retinochoroiditis.[39] Many cases result from the reactivation of congenital infection; hence, ocular toxoplasmosis is most common in older children and young adults. Retinochoroiditis may also develop as a manifestation of primary infection.[40] Impairment of vision is the most common symptom, but pain and photophobia may accompany intense inflammation. Typical lesions appear as yellow-white fluffy exudates clustered in the posterior pole. Although a positive *Toxoplasma* serology is needed for the diagnosis of ocular toxoplasmosis, most patients have relatively low titers because the initial infection was acquired years earlier. In most cases, therefore, ocular toxoplasmosis is a clinical diagnosis that depends on the morphology of the lesions. Other conditions considered in the differential diagnosis include tuberculosis, sarcoidosis, syphilis, histoplasmosis, and candidiasis.

DIAGNOSIS

Serologic testing is important in evaluating patients with potential toxoplasmosis. Many tests are available; the most widely used are the indirect fluorescent antibody test and the Sabin-Feldman dye test. Many other tests are utilized by reference laboratories. Tests that measure IgG antibodies show positive results 1 to 3 weeks after infection and continue to show positive results for many years after infection. Diagnoses of recently acquired toxoplasmosis, especially pertinent during pregnancy, and of congenital toxoplasmosis in the newborn require assays of IgM anti-*Toxoplasma* antibodies. Some commercial IgM assays have been noted to generate false positive results and to detect IgM antibodies persisting for over 1 year, potentially confounding the reliability of these assays to detect only recent infections.[41] Positive IgM test results may necessitate confirmation by alternative testing assays, such as avidity testing; IgM, IgG, and IgG Western blot testing to detect new bands bound by infant but not maternal antibodies; and PCR.[42]

Because tissue cysts may be present in tissues for years, definitive evidence of active toxoplasmosis within biopsied tissues requires the detection of tachyzoites. These forms are not readily seen with conventional pathologic stains. Application of immunofluorescent or peroxidase–antiperoxidase antibody staining is needed. Tachyzoites are not usually detectable in biopsied lymph nodes, although characteristic histopathologic features can support the diagnosis.[43] PCR methods are highly sensitive for detecting the organism in amniotic fluid in congenital infections,[37] but neither PCR nor direct culturing of the organisms from blood or tissues has been widely used in diagnosing other forms of toxoplasmosis.

TREATMENT

Primary and AIDS-Associated Toxoplasmosis

Although the majority of patients with primary lymphadenopathic toxoplasmosis do not require treatment, chemotherapy should be considered for patients with unusually prolonged or severe illness. Patients with active chorioretinitis, CNS involvement, or disseminated toxoplasmosis should also be treated, as should immunosuppressed patients with toxoplasmosis, including patients with AIDS.

Combined administration of pyrimethamine and sulfonamides (sulfadiazine or trisulfapyrimidines) is the treatment of choice.[10] Other sulfonamides are less active against *T. gondii* and therefore should be avoided. In adults, a loading dose of 200 mg of pyrimethamine is given on the first day of treatment, followed by the usual dosage of 50 to 75 mg/day. Sulfadiazine or trisulfapyrimidines are usually given to adults in a loading dose of 4 g, followed by 1 to 2 g four times daily. The most common toxic effect of pyrimethamine is marrow suppression; leukocyte, red cell, and platelet counts should be monitored twice weekly, and 10 to 15 mg of folinic acid should be administered daily. Combined pyrimethamine and sulfonamide therapy is usually given for 3 to 6 weeks.

For AIDS patients who are intolerant of sulfonamides, clindamycin at a dosage of 600 mg orally or intravenously four times a day in combination with pyrimethamine has been effective in treating CNS toxoplasmosis.[44] Atovaquone plus pyrimethamine is also effective for sulfa-intolerant patients.[45]

Patients with AIDS who have been treated for toxoplasmosis and those who have not experienced active toxoplasmosis infection but have positive *Toxoplasma* serologies and $CD4^+$ T cell counts below $100/mm^3$ are at risk for reactivation of toxoplasmosis and require prolonged suppressive therapy. A variety of regimens are available for toxoplasmosis prevention in AIDS patients. A regimen consisting of sulfadiazine (500 to 1,000 mg four times a day) and pyrimethamine (25 to 50 mg/day) plus folinic acid (5 mg/day) is most effective.[46] Dapsone-pyrimethamine is also effective for patients intolerant of sulfonamides.[47] Some regimens used for the prevention of *Pneumocystis* pneumonia also provide primary prophylaxis for toxoplasmosis; ex-

amples include trimethoprim-sulfamethoxazole, dapsone-pyrimethamine, and, for sulfa-intolerant patients, atovaquone.[47] If the $CD4^+$ T cell count rises above 200/mm^3 for 3 months, secondary prophylaxis for toxoplasmosis can be stopped.[47]

Congenital Toxoplasmosis

Newly acquired toxoplasmosis documented during pregnancy presents difficult choices. Pyrimethamine is teratogenic and should be avoided in the first trimester. Spiramycin—available in the United States only directly from the manufacturer, Rhône-Poulenc Rorer—given at 3 to 4 g/day, can diminish the risk of transplacental infection.[10] If in utero infection is documented, therapy with pyrimethamine and sulfadiazine should be initiated. Therapeutic abortion might be considered if infection is acquired early in pregnancy; ultrasonography can be used to detect hydrocephalus, intracranial calcifications, and other signs of fetal damage. Children who are born with serologic or clinical evidence of congenital toxoplasmosis should be treated for a year with pyrimethamine and sulfadiazine.[36]

Ocular Toxoplasmosis

Pyrimethamine and sulfonamides are the mainstays of therapy for ocular toxoplasmosis, but results are unpredictable and relapses commonly occur. When there is a threat of visual loss, the patient should receive corticosteroids in combination with antimicrobials.

Intestinal Protozoan Infections

The human intestinal tract may serve as a host for several protozoan parasites. The intestinal protozoa *Entamoeba coli*, *E. hartmanni*, *Endolimax nana*, and *Iodamoeba bütschlii* are nonpathogenic and do not require therapy. Pathogenic intestinal protozoan parasites include five groups: (1) the flagellates (*Giardia lamblia* and *Dientamoeba fragilis*); (2) the amebae, or *Sarcodina* (*Entamoeba histolytica* and, possibly, *Blastocystis hominis*); (3) coccidia (*Cryptosporidium, Isospora, Cyclospora*); (4) a ciliate (*Balantidium coli*); and (5) microsporidia.

GIARDIASIS

G. lamblia inhabits the proximal small intestine; manifestations of *G. lamblia* infections can vary from no symptoms to profound malabsorption. *G. lamblia* and *Cryptosporidium* are the most common pathogenic intestinal protozoan parasites in the United States.[48]

Etiology and Epidemiology

G. lamblia exists in two morphologic forms: the trophozoite and the cyst [*see Figure 6*]. The trophozoite is a pear-shaped, multiflagellated organism that measures 9 to 15 µm long, 5 to 15 µm wide, and 2 to 4 µm thick. It is bilaterally symmetrical and contains two prominent nuclei. On the ventral surface is an adhesive disk with which the trophozoite attaches to the mucosal surface of the duodenum and jejunum. During passage in the bowel, the trophozoite usually encysts. The cysts measure 8 to 12 µm long by 7 to 10 µm wide, have a well-defined outer wall, and contain four nuclei when mature [*see Figure 6*].

Trophozoites may be seen in duodenojejunal fluid and in loose stools but generally are not found in formed stools [*see* Diagnosis, *below*]. Trophozoites are not resistant to external environmental stresses. In contrast, cysts are hardier and may survive in water for at least several months; decreased water temperature enhances their survival. Although infection can occur if trophozoites are ingested in quantities of food that are sufficient to buffer their transit through the stomach, the cyst stage is principally responsible for human infections. In studies, ingestion of as few as 10 cysts has resulted in human infection.

Infection derives from fecally excreted organisms and is spread by direct fecal-oral passage or by foodborne or waterborne transmission. Direct person-to-person transmission accounts for a heightened prevalence of giardiasis in several settings. In institutions where there is fecal incontinence and poor hygiene, giardiasis may be hyperendemic. Particularly in child day care centers, giardiasis can be a cause of intestinal disease.[49] The risk of acquisition and transmission is greatest for young children not yet toilet trained, who may be a source of additional secondary cases within their families.[49] Person-to-person transmission is also responsible for the prevalence of giardiasis in promiscuous male homosexuals. Sexual practices, including anilingus, can allow direct transfer of infectious cysts.

Waterborne transmission is a major source of giardiasis. Because filtration of water through soil removes *Giardia* cysts, deep well water is usually safe. In contrast, surface water, such as mountain streams and reservoirs, can harbor *Giardia* cysts, which are hardy in water and resistant to routine levels of chlorination. Coliform counts are not a reliable measure of giardial contamination. In addition, water-dwelling mammals, such as beavers, can become infected and then serve as continuing sources of water contamination, though whether giardiasis is a zoonotic disease is currently controversial.[50] It may be difficult to recognize a water supply as the common source of giardiasis, because the resultant infection is often asymptomatic.

G. lamblia is widely distributed throughout the world. Travelers to many countries, including those in developed areas, may acquire giardiasis.

Pathogenesis

After *G. lamblia* cysts have been ingested and have passed through the stomach, they liberate trophozoites that proliferate by binary fission. Trophozoites, which localize in the duodenum and the proximal jejunum, may attach to the microvillous border of intestinal epithelial cells by means of their ventral adhesive suckers. They may also reside in the unstirred layer above the epithelium, move around in the luminal contents, or, uncommonly, invade the space between the epithelial cells. Functional changes in the absorptive capabilities of the small bowel may develop. The activities of epithelial brush-border enzymes are diminished, leading to deficiencies in disaccharidases, including lactase deficiency. Jejunal biopsies of patients with giardiasis usually reveal no pathologic findings.[51] The pathogenetic mechanisms of these functional alterations in the small bowel remain uncertain. Both types of alterations return to normal with specific antigiardial therapy, albeit slowly in some patients. Hypochlorhydria predisposes persons to infection. Giardiasis often occurs with greater severity in patients with cystic fibrosis and in those with immunoglobulin deficiencies, possibly because of deficiencies in secretory IgA.[52]

Diagnosis

Clinical features The clinical manifestations of giardiasis may be quite varied. A significant number of persons with giardiasis are asymptomatic. Indeed, in one well-studied outbreak of waterborne giardiasis, two thirds of those infected were asymptomatic. In contrast, others with the infection experience typical acute giar-

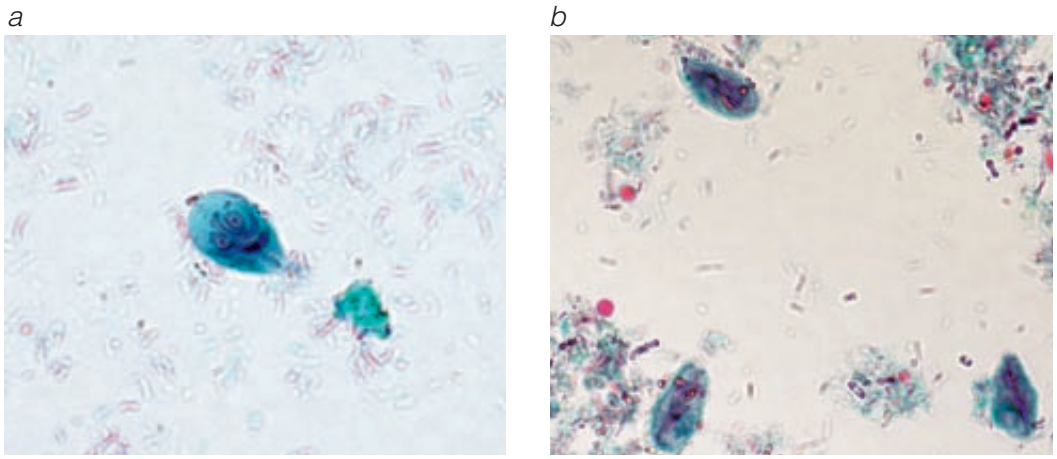

Figure 6 ***Giardia lamblia*** **trophozoites (*a*) and cysts (*b*).**

diasis. After a 1- to 3-week incubation period, the acute onset of the illness is marked by watery diarrhea; abdominal cramping (and other, frequently epigastric, discomfort); nausea (less commonly, vomiting); and systemic symptoms. Fever has been reported but is extremely unusual. Increased intestinal gas production leads to malodorous flatulence and sulfurous eructation. Impaired fat absorption and steatorrhea are common in symptomatic giardiasis. Stools are usually greasy and malodorous and float in water. Blood and mucus in stool are uncommon. These symptoms may be prominent for more than a week, diminishing in intensity over the ensuing weeks. Clinical findings that have helped identify cases of giardiasis in epidemiologic studies include a duration of illness lasting 7 or more days, with at least two of the following six symptoms: diarrhea, flatulence, foul-smelling stools, nausea, abdominal cramps, and excessive fatigue.[53]

A chronic phase of giardiasis may follow the acute phase or may become manifest without an antecedent acute illness. This chronic phase is characterized by loose, but usually not diarrheic, stools that are soft and greasy. Increased abdominal gassiness with cramping, borborygmi, flatulence, and burping occurs. Fever is uncommon, but malaise, fatigue, and depression may ensue. Lactose intolerance can develop with the infection and augment intestinal symptoms after ingestion of milk products. The course can be remitting; asymptomatic periods may alternate with exacerbations of symptoms. For a small number of patients, particularly children, the persistence of infection is associated with moderate to marked malabsorption and weight loss.[54]

Uncommonly, *G. lamblia* spreads from the duodenum to the biliary and pancreatic ducts. Cases of cholecystitis, cholangitis, and granulomatous hepatitis have been reported. Impaired exocrine pancreatic function, manifested by diminished secretion of trypsin and lipase, has been noted.

Laboratory findings Leukocytosis and eosinophilia do not occur in giardiasis. Fecal fat excretion is increased (see above), and the results of other laboratory tests of malabsorption may also be abnormal. An upper GI series usually shows no significant radiologic changes.

Definitive diagnosis of giardiasis requires the morphologic identification of the cyst or trophozoite forms of the parasite [*see Figure 6*]. Fecal examinations are usually positive in acute giardiasis, and evaluation of three sequential daily fecal samples can detect more than 90% of infections. Cysts, which may be present in either loose or formed stools, are hardy, so the search for them does not necessitate prompt analysis of stools. In contrast, examinations to detect trophozoites should be performed on fresh stools or stools preserved in polyvinyl alcohol or merthiolate-iodine-formaldehyde (MIF). Substances that interfere with fecal microscopic evaluations, such as barium, antacids, and mineral oil, should be avoided before stool examinations. Immunologic assays detect giardial antigens in stool with greater sensitivity than a single stool examination.[55]

In chronic giardiasis, the frequency of detection of giardial forms on stool examination diminishes. If three or more stool examinations are unrevealing, the upper intestinal contents should be sampled by duodenojejunal aspiration. Alternatively, a biopsy of the small bowel can be performed. Recognition of trophozoites in biopsied material may require diligent searching of processed tissue; direct examination of mucosal imprint smears from a biopsy can increase detection.

Differential Diagnosis

Other infectious agents that cause gastroenteritis must be considered early in the course of acute giardiasis. Because most of these agents produce illness of short duration, the persistence of symptoms after a week and the prominence of symptoms of malabsorption (flatulence, lactose intolerance, burping) suggest a giardial etiology. However, chronic giardiasis is difficult to distinguish from other chronic small bowel infections, such as *Cyclospora* or *Cryptosporidium*. Chronic giardiasis may resemble other diseases associated with malabsorption.[56]

Treatment

Metronidazole, although not approved by the Food and Drug Administration for giardiasis, is the principal agent used to treat this infection[10,57,58] because quinacrine, the first effective drug for giardiasis, is no longer distributed in the United States. The usual dosage of metronidazole is 250 mg orally three times a day for 5 days, though this may lead to recurrences in up to 40%, or 500 to 750 mg orally three times a day for 10 days, which is 60% to 95% effective.[58] Administration of 2 g of metronidazole once daily for 3 consecutive days is associated with the highest cure rates, yielding 93% to 100% efficacy.[58] Refractory cases can be cured by a combination of quinacrine (available through compounding pharmacies) and metronidazole.[57] Side effects of metronidazole include nausea, headache, and a metallic taste in the mouth; less commonly, dark urine, paresthesias, and dizziness occur. Metronidazole may have a disulfiram-like effect, so

alcohol consumption should be avoided when metronidazole is used. Although not available in the United States, tinidazole (given as a single 2 g oral dose) is highly effective.[58] Another alternative is nitazoxanide (in adults, 500 mg b.i.d.; in children 4 to 11 years of age, 250 mg b.i.d; and in children 1 to 3 years of age, 150 mg b.i.d. for 3 days). A randomized trial showed that for the treatment of symptomatic giardiasis in children, nitazoxanide has an efficacy comparable to that of metronidazole.[59]

For children, furazolidone, available as a suspension, is effective and tolerated.[10] Treatment of giardiasis in pregnancy can be difficult. Metronidazole is often avoided, although studies have not documented teratogenic risks of metronidazole during pregnancy.[60] If symptoms of giardiasis are minimal, therapy can be withheld until delivery. If symptoms are bothersome, one approach is to administer a nonabsorbable aminoglycoside, paromomycin, 25 to 35 mg/kg/day orally in three divided doses for 7 days.[10] This regimen may provide at least symptomatic relief. If giardiasis in pregnancy is associated with dehydration, malabsorption, or severe symptoms, therapy with metronidazole is warranted. In any patient, resolution of malabsorptive symptoms may require months for regeneration of functioning intestinal mucosa after effective antiparasitic therapy, and lactose intolerance may remain indefinitely.

Attention to hygiene is necessary to prevent person-to-person transmission of giardiasis. The risks and benefits of treating asymptomatic infected children in day care centers have not been fully defined; however, treatment of asymptomatic persons who pass cysts is indicated to prevent the spread of infection. Boiling water or heating it to at least 70º C (158º F) for 10 minutes renders water noninfectious. For hikers and campers, iodine-based water treatments are more effective than chlorine-based treatments; iodine disinfection must be carried out for at least 8 hours to be 99.9% effective. High-quality water-filtration units are effective for *Giardia* cyst removal.

DIENTAMOEBA FRAGILIS INFECTION

The large-intestine parasite *D. fragilis* has only a trophozoite stage and no cyst stage [*see Figure 7*]. Although previously grouped with the amebae, histologic and antigenic examination and ribosomal RNA homology have demonstrated that it is closely related to the trichomonad flagellates.[61,62] Because the trophozoite is not resistant to gastric acid, it is not clear how humans acquire infection. The eggs of the pinworm, *Enterobius vermicularis,* might transmit *D. fragilis* trophozoites because the two infections frequently coincide. *D. fragilis* can cause an illness characterized by abdominal pain, anorexia, and loose stools. As with *Isospora* infections, but not other protozoan infections, eosinophilia may accompany infection with *D. fragilis*.[63] The trophozoite stage is not hardy and is difficult to detect; to ensure detection, stool samples must be preserved in polyvinyl alcohol fixative, sodium acetate–acetic acid–formalin fixative, or Schaudinn fluid and must be examined after permanent staining. *D. fragilis* infection can be treated with tetracycline (500 mg q.i.d. for 10 days), paromomycin (25 to 30 mg/kg/day in three doses for 7 days), or iodoquinol (650 mg t.i.d. for 20 days).[10]

AMEBIASIS

Infection with the ameba *E. histolytica* is responsible for human amebiasis. These infections may be limited primarily to the colon. Infections range in severity from asymptomatic to markedly dysenteric and may involve extraintestinal sites, of which the liver is the most common.

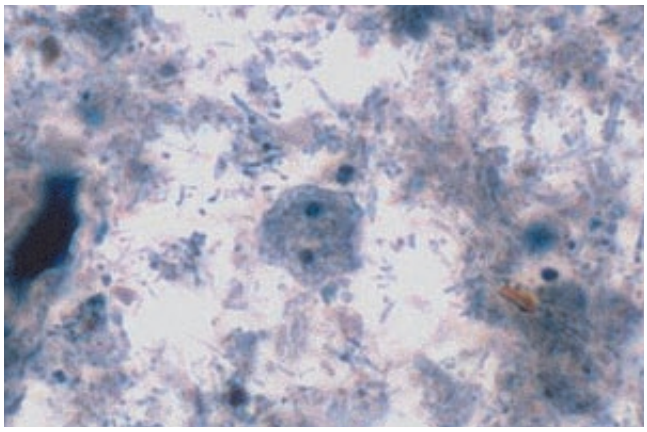

Figure 7 ***Dientamoeba fragilis* trophozoite. Note double nuclei.**

Etiology and Epidemiology

E. histolytica is distinguishable morphologically from the other nonpathogenic intestinal amebae, including *E. coli* and *E. hartmanni* [*see Figure 8*]. *E. histolytica* exists in two forms: as a trophozoite and a cyst. The trophozoite, which usually measures 10 to 20 µm in diameter but may be larger in dysenteric stools, is motile and possesses a single nucleus and a granular cytoplasm [*see Figure 9*]. Trophozoites are passed in loose stool, but this form is not hardy and does not survive outside the body. In contrast, the cyst stage, which arises within the colon from the trophozoite, can survive environmental stresses as well as passage through the acid of the stomach. Cysts measure 10 to 20 µm in diameter and contain one to four nuclei, which have small, centric karyosomes and a pattern of fine peripheral chromatin.

It has long been recognized that not all strains of *E. histolytica* are pathogenic. Nonpathogenic strains can be isolated from asymptomatic patients and have been prevalent in promiscuous male homosexuals in the United States and England. Pathogenic and nonpathogenic strains cannot be distinguished by microscopy, except that pathogenic trophozoites often phagocytose erythrocytes. On the basis of biochemical, immunologic, and genetic data, *E. histolytica* has been redescribed. A new spe-

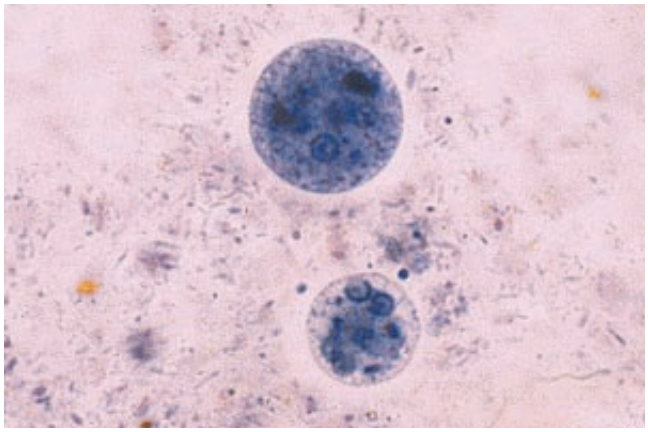

Figure 8 ***Entamoeba histolytica*, which causes amebiasis, is distinguishable morphologically from nonpathogenic intestinal amebae such as *E. coli;* on this photomicrograph, the cyst of *Entamoeba histolytica* is visibly larger than the cyst of *E. coli.***

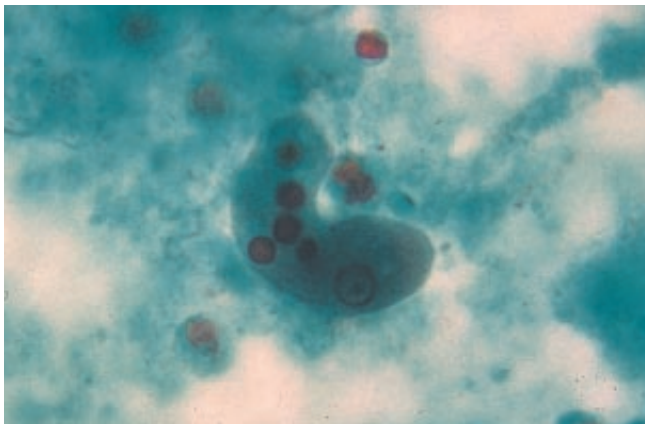

Figure 9 **Trophozoite form of *Entamoeba histolytica*.**

cies, *E. dispar*, now represents the nonpathogenic isolates and is apparently never invasive in humans, whereas *E. histolytica* includes only the potentially pathogenic strains.[64] Because not all potentially pathogenic *E. histolytica* strains invariably produce disease, other processes undoubtedly influence amebic virulence.

An immunoassay to distinguish *E. histolytica* from *E. dispar* has been developed, based on the *E. histolytica*–specific *N*-acetyl-D-galactosamine lectin.[65] There is currently no other method available for a commercial diagnostic laboratory to readily distinguish one organism from the other [*see* Diagnosis, *below*], though these organisms can be distinguished by differences in isoenzymes, restriction fragment patterns, repetitive DNA, and riboprinting.[66]

Cysts passed in human feces are primarily responsible for human infections. Acquisition of infection represents fecal-oral contamination and may occur by waterborne or foodborne transmission, as well as by person-to-person transmission. The latter accounts for the heightened prevalence of *E. histolytica* infection among promiscuous male homosexuals and in institutions where there is fecal incontinence and poor hygiene. Amebiasis is more common in lower socioeconomic groups than in the general population because of poor sanitation and overcrowding. In the United States, cases are seen in persons who have returned from international travel or have immigrated from areas where amebiasis is endemic.

Pathogenesis

Ingested cysts are carried into the intestine, where they excyst to liberate trophozoites that proliferate by binary fission within the colon [*see Figure 9*]. Trophozoites are cytolytic and may invade the bowel wall to produce local necrosis. The resultant ulcers are flask shaped, with a narrow neck through the mucosa and a broader submucosal base. Unless colonic involvement is extensive, intervening areas of bowel are normal. The areas most frequently affected are the cecum and the ascending colon, followed in frequency by the rectosigmoid, the appendix, the descending and transverse colon, and the terminal ileum [*see Figure 10*].

The severity of colonic involvement in patients with amebiasis is quite varied and may range from mild or negligible disease to diffuse and extensive tissue invasion and necrosis. Most persons who harbor *E. histolytica* experience no significant colonic invasion. The determinants of severity are not well understood but may include the inoculum size of *E. histolytica,* the coexistent colonic microbial flora, and the nutritional and physiologic state of the host. Corticosteroid use and pregnancy both diminish host resistance. Complications of colonic involvement include hemorrhage and peritonitis, the latter developing more commonly from transmural leakage across involved colonic tissue than from frank perforation. With chronicity, a granulomatous tissue response can develop at a site of infection (most commonly in the cecum) and can produce a mass lesion termed an ameboma. Colonic strictures may also develop.

Amebiasis may spread hematogenously from the bowel to involve any organ in the body. The liver is most commonly affected, followed in frequency by the lungs, which are principally affected as a result of transdiaphragmatic spread from the liver [*see Figure 10*]. Trophozoites carried via the portal venous system produce necrosis in the liver and cause abscess formation.

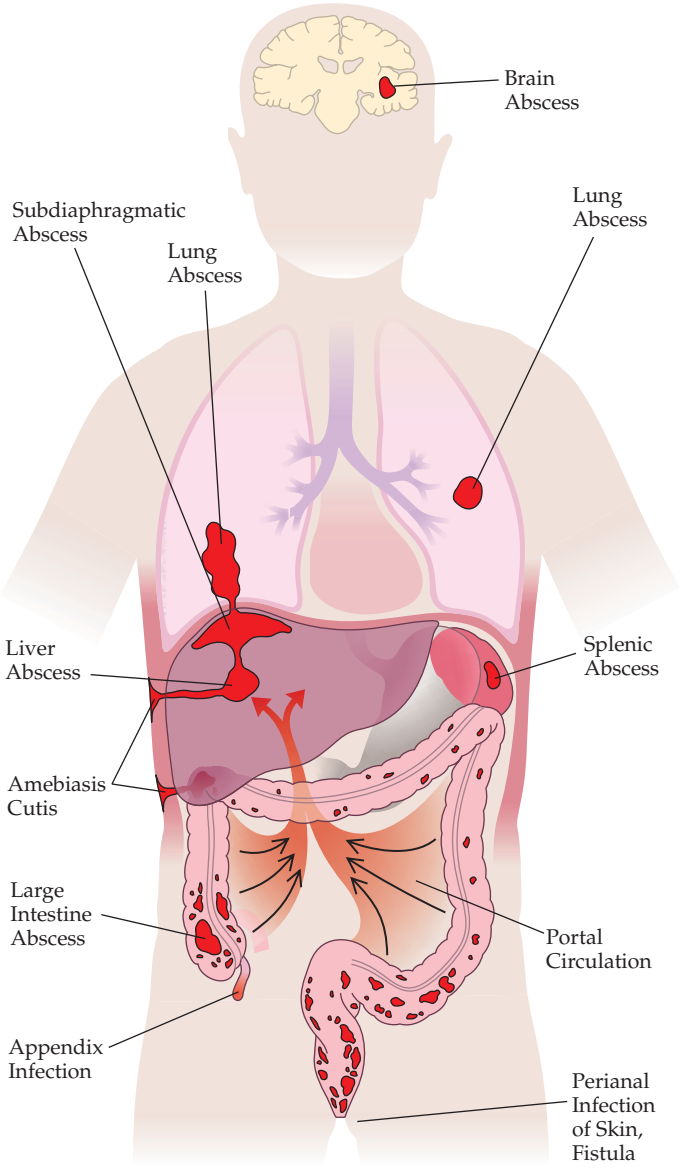

Figure 10 **Amebiasis from *Entamoeba histolytica* may be limited to the colon—most often, the proximal or terminal portions—or may spread by direct extension or hematogenously to any organ in the body. The liver is most commonly affected, followed by the lungs, but brain or spleen abscess may also occur, as may cutaneous involvement.**

About 90% of abscesses are in the right lobe, especially in the superior and anterior aspects. Although multiple abscesses can occur, a solitary abscess ranging in size from a few centimeters to 20 cm in diameter is more common. Amebic liver abscesses are seven to nine times more common in males than in females, although in children, the sex distribution is equal. Uncommonly, an abscess may develop concomitantly with amebic colitis. Depending on the reported series, 50% to 70% of patients with amebic-hepatic abscesses have no history of amebic colitis. Rupture of a right lobe abscess may result in extension into the chest, producing an amebic empyema, pneumonia, or a bronchopleural fistula. Extension into the peritoneal cavity is less common. Rupture from a left lobe abscess can extend into the pericardium, frequently with fatal consequences.

The role of immunity in protection of disease from *E. histolytica* has been controversial, but studies in children in endemic regions suggest that development of intestinal IgA antibodies to an *E. histolytica N*-acetyl-D-galactosamine lectin is highly associated with the development of acquired immunity.[67] This lectin appears essential for cell binding and pathogenesis by *E. histolytica,* and presumably, blocking its function in vivo leads to protection.

Diagnosis

Clinical features Most persons with colonic amebiasis experience no symptoms. Fecal cyst excretion in these asymptomatic individuals is detected only by serendipity. In persons who do experience symptoms, the illness may range from mild diarrhea to fulminant dysentery. The former presentation is common, and most patients are able to continue daily activities as they experience mild diarrhea that may alternate with constipation. The course of illness can be remitting, with subsequent symptomatic relapses. Abdominal discomfort, tenesmus, dull sacral pain, and flatulence are common, but systemic symptoms and fever are less prominent than what is common with bacterial colitis. Blood and mucus are frequently noted in stools. Abdominal findings reflect the severity of the colonic involvement. Tenderness may be absent or mild over the involved areas. In some cases, however, prominent abdominal tenderness, together with high fever and systemic toxicity, is a consequence of extensive colonic disease.[68] Amebomas may be palpable as tender abdominal masses.

In patients with amebic liver abscess, presenting symptoms usually include malaise, fatigue, anorexia, abdominal pain, fever, and weight loss; the duration is usually 1 week to several weeks or, less commonly, many months. The abdominal pain is usually dull and aching and localized over the right upper quadrant or right chest. At times, there is referred pain to the right shoulder. A presentation with pleuritic chest pain, cough, and dyspnea may mistakenly suggest an intrapulmonary infection. An abscess in the left lobe may produce midepigastric or left upper quadrant pain. On examination, hepatomegaly and hepatic punch tenderness or focal tenderness over the abscess are frequent. Frank jaundice is rare. On chest examination, dullness at the right lung base as a result of diaphragmatic elevation and pleural effusion formation can be appreciable. Rales may be heard.

Cutaneous amebiasis, resulting in ulcerative or fungating lesions, most commonly develops on the perineum and genitalia. Lesions arise from invasion by trophozoites derived from fecal contamination or sexual transmission. The lesions can be distinguished from neoplastic, tuberculous, and syphilitic processes by the presence of trophozoites in exudate or biopsied tissue.

Laboratory findings In symptomatic amebic colitis, a mild to moderate leukocytosis may develop. Mild anemia and mild elevations of liver enzyme levels (which are not usually indicative of incipient abscess formation) may occur. Feces usually will contain frank or occult blood.

Leukocytosis, anemia, and an elevated erythrocyte sedimentation rate are common with an amebic liver abscess. In more than two thirds of patients, alkaline phosphatase levels are one to four times higher than normal. Elevated aminotransferase levels occur in fewer than 50% of patients. Bilirubin levels may be elevated, but usually to no more than 2.5 mg/dl. Chest x-ray often shows elevation of the right diaphragm and may reveal a pleural effusion. An isotopic liver scan will reveal a space-occupying lesion; an ultrasound scan will show a round to ovoid hypoechoic lesion and can detect transdiaphragmatic pleural involvement. CT or MRI also can document the abscess and any local extension.

For intestinal amebiasis, definitive diagnosis requires morphologic or antigenic identification of the cysts or trophozoites of *E. histolytica* [*see Figures 8 and 9*]. Unformed stool should be examined immediately for motile trophozoites. Formed stools may be examined directly or after application of concentration techniques for cysts. Stools may also be preserved in polyvinyl alcohol or MIF for subsequent examination. Fecal leukocytes and nonpathogenic amebae are easily confused with *E. histolytica*, and thus, definitive speciation should be performed on stained samples by experienced personnel. Antimicrobial agents, cathartics, antacids, and barium interfere with microscopic detection. Testing of a single stool has only 33% to 50% sensitivity, so multiple stools should be examined when the diagnostic suspicion is high. Because the excretion rate of cysts varies daily, three or more stool samples from different days should be examined. About half of patients with symptomatic amebic colitis have rectosigmoid involvement; thus, aspirates, scrapings, or biopsies of mucosal lesions obtained at sigmoidoscopy can be examined for trophozoites. A fecal antigen detection test for *E. histolytica* has been introduced that is based on a monoclonal antibody to a specific lectin on this organism.[65]

Serologic tests for amebiasis are infrequently positive in asymptomatic cyst passers, but rates of seropositivity rise with increasing extent and duration of amebic colonic involvement. Such tests can be an adjunct to the diagnosis of acute amebic disease and can be especially helpful in the etiologic assessment of chronic colitis. Serologic tests, performed by a variety of methods, may remain positive for months to years after infection; this fact should be considered when interpreting a positive test result.

Serologic tests are positive in 90% to 95% of patients with extraintestinal amebiasis; titers increase with the duration of the disease. A positive titer, together with compatible clinical findings and tests demonstrating a cystic hepatic lesion, allows for the diagnosis of amebic hepatic abscess. Results of stool examinations, either negative or positive, are not etiologically pertinent in such cases. Trophozoites are rarely demonstrable in aspirated abscess fluid, which usually has an anchovy-sauce or chocolate-brown appearance.

Differential Diagnosis

In cases of mild intestinal amebiasis, the diagnosis of irritable bowel syndrome, diverticulitis, or regional enteritis may be suggested by the duration and symptoms of the infection. For more severe intestinal amebiasis with an acute presentation, infections

with *Shigella*, *Salmonella*, *Escherichia coli* O157:H7, and *Campylobacter* can be distinguished by positive stool cultures and by the presence of large numbers of fecal leukocytes, which are not found in amebic colitis. Ulcerative colitis and Crohn disease are to be considered in the differential diagnosis for chronic amebic colitis [*see 4:IV Inflammatory Bowel Diseases*]. Lesions on sigmoidoscopy and barium enema findings may be identical in amebic colitis and ulcerative colitis. It is critical to distinguish between these two conditions because corticosteroid therapy, which may be indicated for ulcerative colitis, would aggravate amebic colitis; therefore, amebic serologic tests and examinations of feces and mucosal lesions for amebae are of cardinal importance. A therapeutic trial of metronidazole cannot be relied on to identify the etiology, because metronidazole may have a salutary effect on inflammatory bowel disease as well as on amebic colitis.

An ameboma may simulate an adenocarcinoma or another granulomatous process. A positive amebic serology and resolution of the mass with metronidazole therapy support the diagnosis of an ameboma. If resolution is not complete, a biopsy is indicated to exclude a coincidental lesion of nonamebic cause.

The differential diagnosis of amebic hepatic abscess is guided by two observations: (1) an isotopic liver scan that shows a space-occupying lesion and (2) an ultrasound, CT, or MRI scan that shows a cystic lesion. Although hepatic cysts and echinococcal cysts are usually not associated with fever and the other symptoms of an amebic lesion, they should be considered in the differential diagnosis. Pyogenic abscesses should be considered as well. A positive amebic serology supports an amebic etiology. In contrast to echinococcal cysts, amebic abscesses calcify very rarely. Imaging studies of echinococcal cysts often demonstrate complicated cysts with internal daughter cysts, which are not seen in amebic abscesses. An amebic abscess and a pyogenic abscess may respond alike to metronidazole therapy. Amebic abscesses are uncommonly infected secondarily. If uncertainty persists about the bacterial or amebic etiology of an abscess, diagnostic aspiration of abscess fluid for bacterial cultures and Gram stain may be necessary.

Treatment

For symptomatic intestinal disease or extraintestinal disease, oral metronidazole (750 mg t.i.d. for 10 days) is usually highly effective and is the preferred therapy.[10] Alternatively, oral tinidazole (800 mg t.i.d. for 3 to 5 days) can be given. Information about the side effects of metronidazole and precautions about its use have been presented in the discussion of giardiasis (see above). Occasional failures in the treatment of hepatic abscesses with metronidazole have been noted. Because relapses of intestinal disease may infrequently occur in the absence of reinfection, follow-up is indicated for a number of months.

Chemotherapy may be unnecessary for many asymptomatic cyst passers because they often harbor nonpathogenic *E. dispar*. If speciation of *Entamoeba* is not available, asymptomatic cyst passers should be treated if they handle food or if they are receiving corticosteroids; they should also be treated in the setting of an amebiasis outbreak.[64] In asymptomatic patients, concentrations of metronidazole in the colonic lumen may be inadequate to eradicate amebae, and one of two luminal amebicides should be used.[10] Paromomycin (25 to 35 mg/kg/day for 7 days) can be used. An alternative is iodoquinol (650 mg t.i.d. for 20 days); it is important not to exceed this dosage because of the potential for causing optic neuritis. Iodoquinol is contraindicated for patients with optic neuropathy or thyroid disease. The administration of a course of iodoquinol is recommended for patients treated for symptomatic intestinal or extraintestinal amebiasis.[10] Another alternative is nitazoxanide, which in one study showed 96% efficacy for elimination of cyst passage[69]; controlled studies have not yet shown efficacy for *E. histolytica* infections.

Therapeutic aspiration is usually not necessary for amebic hepatic abscess, although diagnostic aspiration may be useful in certain cases [*see* Differential Diagnosis, *above*]. Drainage, which can be achieved by percutaneous aspiration, is indicated for those lesions that fail to respond to initial medical therapy or that are in imminent danger of rupturing.

Prevention of amebiasis relies on personal hygiene to prevent person-to-person transmission. In areas where amebiasis is endemic, the provision and use of adequate toilet facilities can decrease the spread of disease. Avoidance of vegetables that grow close to the ground (e.g., lettuce) is advisable because of potential contamination by human feces. Water can be rendered safe by boiling or by use of iodine-based water-treatment tablets.

BLASTOCYSTIS HOMINIS INFECTION

Although *B. hominis* was previously considered to be a nonpathogenic yeast, most investigators now consider this organism to be a protozoan distantly related to ameba or perhaps in its own phylogenetic group.[70] Whether *B. hominis* is capable of causing intestinal illness is controversial.[70] Support for the belief that this organism may be pathogenic stems from the finding of large numbers of *B. hominis* organisms in the feces of patients with diarrhea for which no other cause has been identified. Other investigators, however, have failed to confirm this finding.[70] They have found no concordance between numbers of fecal organisms and extent of the diarrhea and have seen no resolution of symptoms after therapy for *Blastocystis* infection. Until the issue of the pathogenicity of *B. hominis* is settled, patients with a diarrheal illness who are excreting this organism in their feces should be studied for other parasitic, bacterial, or viral infections or other reasons for illness, such as irritable bowel syndrome or inflammatory bowel disease. Stool samples typically reveal the vacuolated form of *B. hominis,* though several other forms can be seen as well [*see Figure 11*]. If diarrheal symptoms are sufficient to warrant therapy and other causes for diarrhea have been ruled out, iodoquinol, 650 mg three times a day for 20 days, or metronidazole, 750 mg three times a day for 10 days, can be used.[10]

COCCIDIOSIS

Coccidia, which are found in the intestines of many domestic and wild animals, are unicellular parasites that reproduce by asexual and sexual cycles in gut epithelium. Three coccidial organisms—*Isospora belli*, *Cryptosporidium*, and *Cyclospora cayetanensis*—have documented pathogenicity as enteric parasites for humans; humans serve as the definitive host and pass infectious cysts in stool [*see Figure 12*]. Contact with infected cattle may result in infection with *Cryptosporidium*, and contaminated water or food sources transmit *I. belli*, *Cryptosporidium,* and *C. cayetanensis*.[71] All three coccidial parasites have been identified as opportunistic pathogens in patients infected with HIV.[72]

Isosporiasis

Diagnosis Infections with *I. belli* usually begin abruptly. Fever and malaise appear first, followed by abdominal pain, diarrhea, and weight loss. In most cases, the illness is self-limited, although chronic infections may last several weeks to several months. Severe diarrhea, steatorrhea, and hepatic involvement

may ensue; in rare instances, severe disease results in death. In patients with AIDS, infection with *I. belli* causes a clinical picture of chronic watery diarrhea and weight loss that is indistinguishable from that produced by *Cryptosporidium*.

Histologic examination of mucosal lesions in patients who have isosporiasis shows shortened villi, crypt hypertrophy, and infiltration with eosinophils, neutrophils, lymphocytes, and plasma cells. Blood eosinophilia, which is not seen with other protozoan infections except *D. fragilis*, may develop with *I. belli* infections. The presence of oocysts in the stool establishes the diagnosis. Although routine stool examinations may fail to detect oocysts, they can be demonstrated with acid-fast staining. If oocysts in the feces are few, incubation of stool at room temperature for 24 to 48 hours can encourage oocyst maturation and the zinc sulfate concentration technique can be used before examining the stool. Parasite forms may also be detected in biopsied intestinal tissue and in intestinal contents.

Treatment *I. belli* infections are treated with double-strength trimethoprim-sulfamethoxazole (160 mg of trimethoprim and 800 mg of sulfamethoxazole) given orally four times a day for 10 days and then twice a day for 3 weeks.[10] Because recurrences of infection are likely in patients who have AIDS, the initial 10-day course of trimethoprim-sulfamethoxazole should be followed by long-term maintenance therapy with either one double-strength tablet of trimethoprim-sulfamethoxazole three times a week or the combination of 25 mg of pyrimethamine and 500 mg of sulfadoxine once a week in those patients. In patients who are intolerant of sulfa drugs, pyrimethamine (75 mg/day) or ciprofloxacin (500 mg b.i.d for 7 days) therapy has been successful; a maintenance dosage of 50 to 75 mg/day of pyrimethamine or 500 mg orally three times a week of ciprofloxacin has prevented relapses of *I. belli* infections.[72,73]

Cryptosporidiosis

Cryptosporidium inhabits the brush border of the small intestine mucosa and can cause enterocolitis in both normal and immunocompromised hosts. Infection may be acquired by ingestion of fewer than 100 oocysts.[74] A common means of transmission is by water, including municipal drinking water supplies[75] and recreational water (pools and water slides).[48,76,77] Cryptosporidiosis has caused outbreaks of diarrheal disease in day care centers and may be acquired by international travelers. Cryptosporidial infection and cryptosporidial disease have their highest incidences in children of the developing world.[76] Because fecal oocysts are infectious, infection can spread nosocomially, via food handlers, and within households.[76,78]

Diagnosis In normal hosts, illness begins after a mean incubation period of about a week. It consists of watery, nonbloody diarrhea that is accompanied at times by such clinical manifestations as abdominal pain, nausea, fever, anorexia, and weight loss. The diarrhea is generally noninflammatory in nature, though children in the developing world and small numbers of infected adults have white blood cells and lactoferrin in the stool. Symptoms may persist for 1 to 2 weeks and are usually self-limited. By contrast, in immunocompromised patients, cryptosporidiosis can be persistent and severe. In HIV-infected patients with $CD4^+$ T cell levels greater than 180/mm^3, cryptosporidiosis can be self-limited. With more profound immunocompromise, however, the secretory diarrhea, which is chronic and profuse, is usually unremitting. In these persons, *Cryptosporidium* organisms may also cause hepatobiliary disease, including cholecystitis, cholangitis, and papillary stenosis.

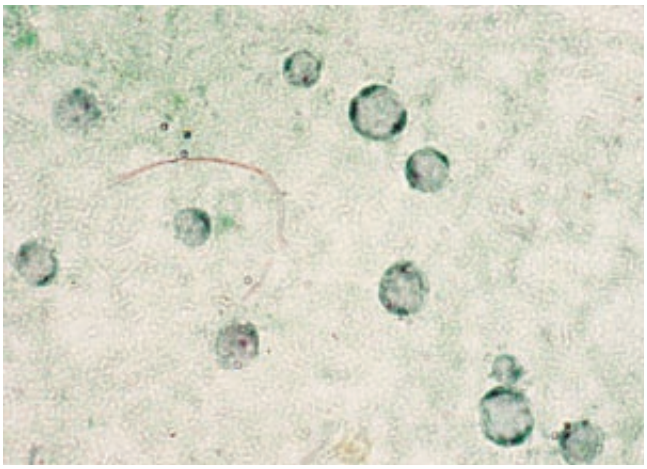

Figure 11 ***Blastocystis hominis*** **on a trichrome stain.**

Cryptosporidium oocysts, which are 4 μm in size, can be detected in fecal smears examined microscopically, either as an iodine wet mount or after staining with a monoclonal antibody or the modified Kinyoun acid-fast reagent [*see Figure 12*]. In addition, direct fluorescent stains and immunoassays of fecal samples can enhance diagnostic yields of *Cryptosporidium*.

Treatment In immunocompetent patients, cryptosporidiosis is a self-limited illness and usually requires only supportive therapy. Chemotherapy would be valuable in immunocompromised patients, but an effective regimen for cryptosporidiosis has not been established.[26] If the patient is receiving immunosuppressive drugs, cessation of these agents may lead to resolution of the diarrhea. Similarly, improvement of $CD4^+$ T cell levels in HIV-infected patients by highly active antiretroviral therapy has led to the cessation of life-threatening cryptosporidial diarrhea.[79] For some HIV-infected patients, paromomycin may be at least partially beneficial in treating cryptosporidiosis, although small controlled trials were unable to show a difference between paromomycin and placebo.[26] Perhaps a better alternative, nitazoxanide (in adults, 500 mg b.i.d.; in children 4 to 11 years of age, 250 mg b.i.d; in children 1 to 3 years of age, 150 mg b.i.d.), is approved by the FDA for the treatment of cryptosporidiosis and giardiasis, albeit in children only. Three randomized trials have shown efficacy in cryptosporidiosis.[80]

Cyclosporiasis

Cyclospora appears to be widely distributed geographically; illness attributable to this protozoan has been described in the United States, Latin America, Africa, Europe, and Asia.[81] Epidemiologic studies indicate that contaminated water[71] and contaminated produce such as raspberries, blackberries, mesclun, and basil[82] have been sources of infection. The oocysts that are passed in stool require days to weeks outside the host in the right environmental conditions to sporulate and become infectious. This implies that person-to-person transmission is unlikely. The median incubation period after ingestion of the infectious sporocyst is about 1 week but is possibly as short as 1 to 2 days.[82,83]

Diagnosis Many patients infected with *Cyclospora* experience prodromal flulike symptoms, diarrhea, and symptoms

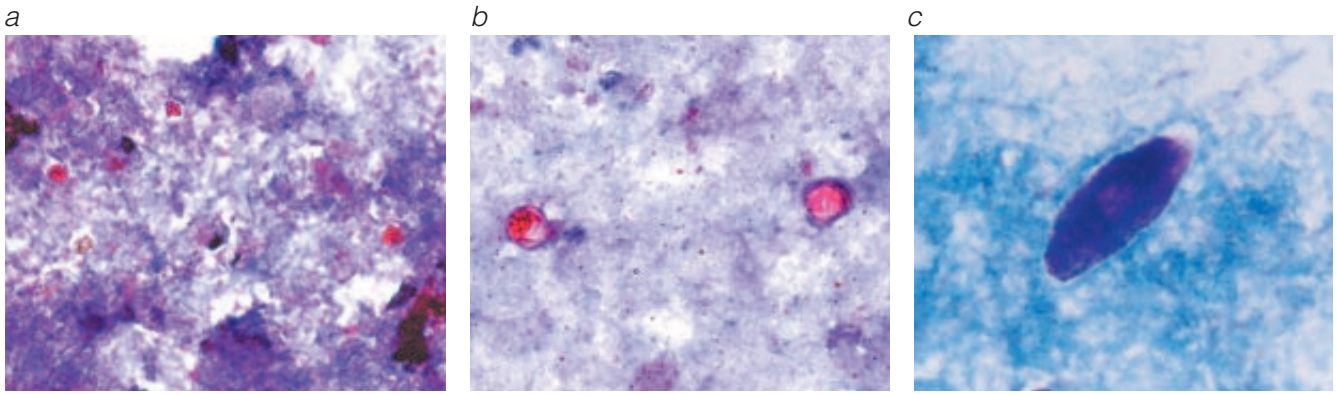

Figure 12 **Cysts of the three coccidial organisms—(*a*) *Cryptosporidium*, (*b*) *Cyclospora*, and (*c*) *Isospora*—with documented pathogenicity as enteral parasites. All are stained with modified Kinyoun (acid-fast) stain. Note that cysts of *Cryptosporidium* and *Cyclospora* can be distinguished only by their size (*Cryptosporidium* is 4 μm in diameter, and *Cyclospora* is 8 μm), whereas *Isospora* cysts are 25 × 15 μm and ovoid in shape.**

common to other small bowel pathogens, including nausea, vomiting, flatulence, and burping.[82] The illness may be confined to a single self-limited episode or may wax and wane, but prolonged diarrhea, anorexia, and upper GI symptoms often occur. Prolonged fatigue and weight loss also frequently occur.

Small-bowel biopsies can detect the parasite in epithelial cells and can detect jejunal inflammation, which is associated with increased numbers of intraepithelial lymphocytes and increased degrees of villous atrophy and crypt hyperplasia. Fecal leukocytes and blood are absent, suggesting that disease involves a noninvasive mechanism. The diagnosis can be made by detection of oocysts in the stool, which, like *Cryptosporidium* oocysts, are apparent in acid-fast stains. Although *Cyclospora* oocysts, which measure 8 to 10 μm in diameter, are larger than *Cryptosporidium* oocysts, caution is needed so that diagnostic testing does not confuse the two distinct protozoan organisms [*see Figure 12*]. Fluorescence microscopy is a rapid and sensitive means to detect oocysts, which are autofluorescent.[84] *Cyclospora* oocysts have been found in patients infected with HIV, and infection in these patients can range from asymptomatic to severe.[72,82]

Treatment Double-strength trimethoprim-sulfamethoxazole (160 mg/800 mg) tablets twice daily for 7 days has proved to be effective therapy for cyclosporiasis.[10] HIV-infected patients, however, may require a higher dosage (four times a day for 7 days) and may need long-term maintenance treatment (three times a week).[10,82] Ciprofloxacin (500 mg b.i.d. for 7 days, then 500 mg three times a week) has been shown to be less effective than trimethoprim-sulfamethoxazole in HIV-infected persons but can be used in patients who are sulfa intolerant.[73] Like cryptosporidiosis, *Cyclospora* infection must be considered in any patient with prolonged diarrhea, anorexia, and upper GI symptoms.

BALANTIDIUM COLI INFECTION

Balantidium coli is the only ciliate that causes human disease. *B. coli* is a rare cause of diarrhea and inflammatory colitis. Humans are incidental hosts. Large mammals, such as pigs, and contaminated food or water are the main sources of human infection. The ciliated trophozoite is found in diarrheal stools and is usually 60 to 70 μm and ovoid in shape; cysts may also be found [*see Figure 13*]. Clinical symptoms usually consist of chronic intermittent diarrhea and weight loss, but acute dysentery occurs in about 5% of cases.[61] In these latter cases, superficial and, rarely, deep colonic ulcerations have been observed. Treatment with tetracycline (500 mg q.i.d for 10 days) or, possibly, metronidazole (750 mg t.i.d. for 5 days) or iodoquinol (650 mg t.i.d. for 20 days) is effective.[10]

MICROSPORIDIOSIS

Microsporidia, which are obligate intracellular, spore-forming organisms, belong to a distinct phylum of protozoans that includes many genera capable of infecting diverse vertebrate and invertebrate hosts. They are most closely related to fungi, although their exact phylogenetic relationship to other eukaryotes remains unclear.[85] Human microsporidial infections have been recognized in recent years, and to date, seven genera of microsporidia—*Enterocytozoon*, *Encephalitozoon* (including *Septata*), *Vittaforma*, *Trachipleistophora*, *Pleistophora*, *Nosema*, and *Brachiola*—have been identified as causes of human disease, especially in persons infected with HIV.[86-88] These microsporidia are differentiated by their size, nuclear morphology, and mode of division, as well as by the intracellular site of proliferation (microsporidia multiply either freely in the cytoplasm or within membrane-bound vacuoles). Despite the ubiquity of microsporidia in other host species, how humans become infected is not known. Because almost all microsporidial infections in humans have been identified in immunocompromised hosts, it is

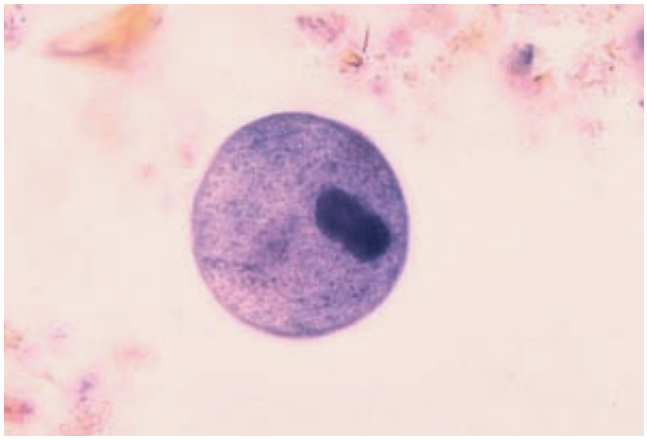

Figure 13 ***Balantidium coli* cyst.**

not clear how frequently immunocompetent hosts are infected or whether infections that develop in immunocompetent hosts are symptomatic or self-limited.

The spectrum of disease attributable to microsporidia is broad, with the disease state apparently depending on the infecting species and the immune status of the host. The most commonly recognized microsporidial infections are *Enterocytozoon bieneusi* infections in HIV-infected patients, usually those with $CD4^+$ T cell levels below $100/mm^3$. In HIV-infected patients, intestinal *E. bieneusi* and *Encephalitozoon intestinalis* (formerly *Septata intestinalis)* infections are causes of chronic diarrhea,[86,88,89] and *E. bieneusi* and *E. intestinalis* may infect the biliary tract, causing cholangitis. *Encephalitozoon* species have caused keratoconjunctivitis marked by a coarse punctate epithelial keratopathy in HIV-infected patients, whereas *Vittaforma* and *Nosema* species have caused stromal keratitis in a few HIV-seronegative patients. *Encephalitozoon* microsporidia have also been associated with peritonitis and hepatitis, as well as nasal and sinus infections and infections in other diverse sites in HIV-infected patients. *Trachipleistophora*, *Pleistophora,* and *Brachiola*[90] species have caused myositis.

The small size of microsporidia, which are gram-positive organisms with mature spores that measure 0.5 to 2 µm by 1 to 4 µm, hinders detection of the parasite. Many microsporidial infections have required electron microscopic tissue evaluation for diagnosis [*see Figure 14*]. Intracellular spores can also be recognized by light microscopy if tissues are stained with hematoxylin-eosin, Giemsa, Gram stain, or modified acid-fast stains. Intestinal microsporidia appear to be spottily distributed and may not be detected on examination of biopsied tissues. Chromotrope-based and fluorochrome (Uvitex 2B and Calcofluor) staining methods facilitate detection of microsporidial spores in smears of either feces or duodenal aspirates.[86]

For intestinal infections with *E. intestinalis*, oral albendazole (400 mg b.i.d. for 21 days) has been beneficial or curative; *E. bieneusi* infections are less responsive, although patients may experience symptomatic improvement without eradication of the infection.[88,89] Oral albendazole has also been used for systemic infections with *E. hellum, E. cuniculi, E. intestinalis, Pleistophora, Trachipleistophora,* and *Brachiola vesicularum.*[10] Oral fumagillin (60 mg daily for 14 days) has been effective in treating *E. bieneusi* infections.[10] For keratoconjunctivitis caused by *Encephalitozoon hellem*, topical therapy with fumagillin suspension combined with oral albendazole (400 mg b.i.d.) has been beneficial.[10]

Infections from Free-Living Amebae

Although amebae such as *E. histolytica* cannot survive and replicate outside of animal hosts, most amebae are free-living in soil or water. Amebae of the genera *Naegleria, Acanthamoeba, Balamuthia,* and *Sappinia* can cause acute meningitis, acute meningoencephalitis, or chronic granulomatous meningoencephalitis [*see Figures 15 and 16*].[91-93] *Naegleria* species, notably *N. fowleri*, cause acute meningoencephalitis in immunocompetent hosts; infection has been reported after trauma in warm freshwater in the southeastern United States. Progression of disease is typically rapid and inexorable, although effective therapy has been reported with amphotericin B, miconazole, and rifampin.[94]

In addition to chronic granulomatous meningoencephalitis, *Acanthamoeba* species have been recognized as a cause of keratitis[95] and, in a small number of HIV-infected patients, of disseminated disease with cutaneous manifestations.[96] *Acanthamoeba* organisms have been isolated from water, airborne dust, hot tubs, and saline solutions used to clean contact lenses. Factors associated with the development of amebic keratitis include the lack of effective disinfection of contact lenses, a history of minor corneal trauma, and exposure to soil or standing water. The lesions, which are usually chronic and severely painful, consist of variable anterior uveitis, epithelial erosion, scleritis, and an infiltrative stromal keratitis that is often ring shaped. Lesions are refractory to the usual antimicrobial medications and must be distinguished from keratitis caused by herpes simplex virus [*see 7:XXVI Herpesvirus Infections*]. The diagnosis can be made by microscopic examination of Giemsa- or trichrome-stained corneal scrapings and by the use of indirect immunofluorescent antibody staining of corneal scrapings. The amebae can be cultured by inoculating corneal tissue into nonnutrient agar seeded with *Escherichia coli.* Acanthamebic keratitis has been treated with topical regimens using chlorhexidine (bis-biguanide) and propamidine or the polymeric equivalent polyhexamethylene biguanide (PHMB). PHMB was originally combined with propamidine but is now combined with hexamidine.[95] This topical therapy is usually effective for patients presenting within 8 weeks, and cure can be achieved in 4 weeks of therapy.[95]

Trichomoniasis

Trichomonas vaginalis is a flagellated protozoan that causes an estimated three million vaginal infections a year.[97] It is a venereal disease, with the highest incidence in women who have multiple sexual partners; thus, persons with *Trichomonas* infection should be screened for other sexually transmitted pathogens, such as *Chlamydia*, *Neisseria gonorrhoeae*, and HIV. *Trichomonas* infection can be passed to neonates, and 2% to 17% of infected women transmit it to their female offspring during birth. It does not have a cyst form but, rather, only the trophozoite form, so that human-to-human transmission is the norm, although *T. vaginalis* can exist outside of the host for several hours if it is in a moist environment. Trichomonads appear to damage genital epithelium by direct contact, and this results in microulcerations

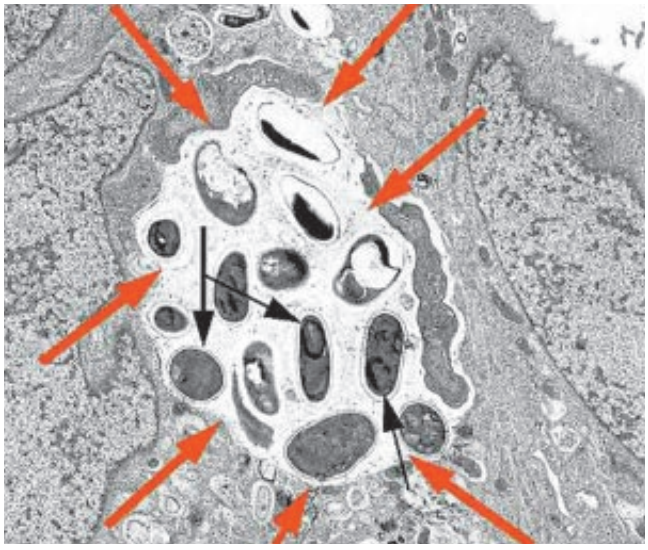

Figure 14 **A transmission electron micrograph shows developing forms of *Encephalitozoon intestinalis* inside a parasitophorous vacuole (red arrows) with mature spores (black arrows).**

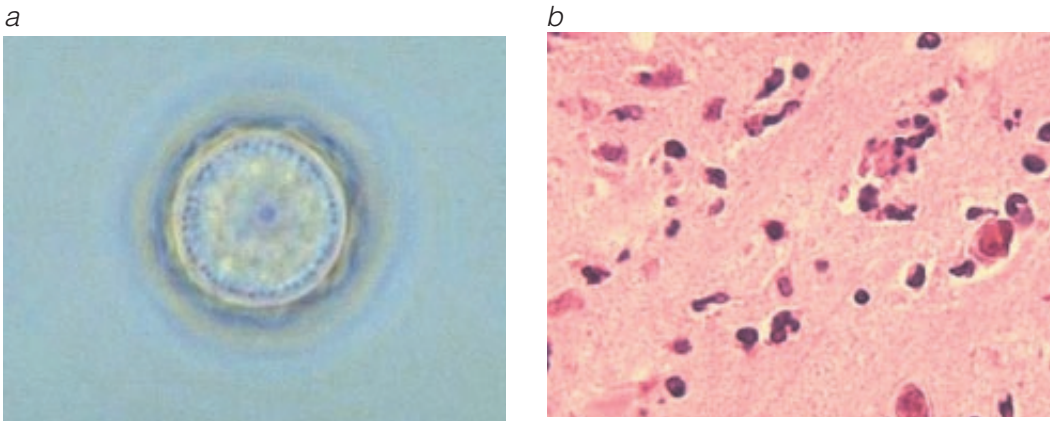

Figure 15 **(*a*) *Acanthamoeba polyphaga* cyst. (*b*) A histopathologic slide shows *A. polyphaga* infection in a mouse brain. Similar histopathologic features are seen in *Acanthamoeba* meningoencephalitis, which generally occurs in immunocompromised persons.**

and inflammation. Management of trichomonal infection is discussed in detail elsewhere [*see 7:XXII Vaginitis and Sexually Transmitted Diseases*].

Leishmaniasis

Leishmania organisms are protozoan hemoflagellates that are obligate intracellular parasites in humans. *Leishmania* species produce a wide spectrum of disease, ranging from generalized visceral involvement to diffuse or circumscribed cutaneous or mucocutaneous lesions. Four species complexes of *Leishmania* may infect humans: *L. donovani*, *L. tropica*, *L. mexicana*, and *L.* (subgenus *Viannia*) *braziliensis*. The resulting patterns of illness arise from the tissue tropism of the leishmanial species and the host's immune response, principally the cell-mediated component of immunity.

VISCERAL LEISHMANIASIS

Etiology and Epidemiology

The *L. donovani* species complex includes several species (e.g., *L. infantum* and *L. chagasi*). These species cause visceral leishmaniasis, or kala-azar, which is endemic in areas of India, China, Central and South America, East and West Africa, and the countries surrounding the Mediterranean. *L. tropica* can also cause a viscerotrophic disease involving bone marrow cells.[98] Sandflies of the genus *Phlebotomus* are the insect vectors that spread *L. donovani*; the species vary in the different areas. In India, no extrahuman reservoirs are known, but in other regions, infection may involve several mammalian species, including dogs, foxes, and wild rodents.

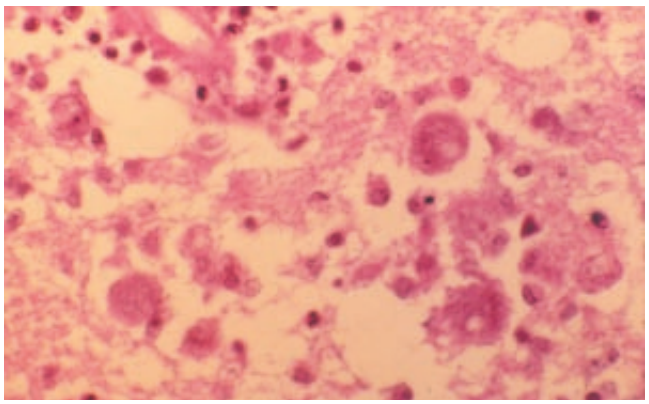

Figure 16 ***Naeglaria* meningoencephalitis in a human brain, on hematoxylin-eosin stain.**

Pathogenesis

The flagellated promastigotes of *L. donovani* are introduced by an insect bite. After entering macrophages of the reticuloendothelial system, these forms change into amastigotes, which multiply in phagocytic cells. Released amastigotes disseminate hematogenously and invade reticuloendothelial cells in the spleen, liver, lymph nodes, bone marrow, and skin. Prospective studies have demonstrated that the ratio of inapparent infection to disease ranges from greater than 6.5:1 in children younger than 5 years, the most susceptible group, to greater than 18:1 in older children and adults.[99] Cell-mediated immunity controls *Leishmania* infection, and compromise of cell-mediated immunity, such as from young age or malnutrition, contributes to susceptibility.

Diagnosis

Clinical features Symptoms of visceral leishmaniasis usually have a gradual onset several months after infection and include weakness, dizziness, weight loss, diarrhea, and constipation. Fever, which almost always develops, may spike twice daily and is sometimes accompanied by chills and sweating. As the disease progresses, the liver and spleen enlarge, the latter often expanding into the iliac fossa. When bone marrow macrophages are parasitized, anemia and leukopenia ensue. The thrombocytopenic patient may bleed from the gingivae, nose, or GI tract, and ecchymoses and petechiae may appear on the skin. Death can result from secondary bacterial infections, severe anemia, or uncontrolled bleeding. Latent infection can become manifest and progressive during immunosuppression, and visceral leishmaniasis can develop as an opportunistic infection in HIV-infected patients. Two thirds of patients with visceral leishmaniasis have typical infections, but leishmanial parasites may localize in unusual sites, including the larynx and throughout the GI tract, and hepatosplenomegaly may be absent.

Laboratory findings Anemia, leukopenia, thrombocytope-

nia, hyperglobulinemia, and hypoalbuminemia suggest visceral leishmaniasis when they are observed in a patient with fever, hepatosplenomegaly, and a history of exposure in endemic areas. The differential diagnosis is wide, including hepatosplenic schistosomiasis, malarial hypersplenism, myeloproliferative diseases, typhoidal *Salmonella* infections, miliary tuberculosis, brucellosis, histoplasmosis, subacute bacterial endocarditis, and infectious mononucleosis. Definitive diagnosis of visceral leishmaniasis requires demonstration of the organism in host tissues cultured on a Novy-MacNeal-Nicolle (NNN) or other medium or detection of Leishman-Donovan bodies (amastigotes) in stained tissue samples. Alternatively, PCR can be performed using genus- or species-specific oligonucleotides. In most cases, the diagnosis can be established by examining bone marrow aspirates. Splenic aspirates have the highest yields but may be risky. Liver biopsy or aspiration of enlarged lymph nodes can also provide diagnostic material.

Treatment

Sodium stibogluconate (pentavalent antimony, 20 mg/kg daily I.M. or I.V. for 20 to 28 days) is the therapy of choice for treating most cases of leishmaniasis and is available as Pentostam through the CDC Drug Service (404-639-3670, days; 404-639-2888, nights and weekends) [*see Sidebar,* Protozoan Infection Information on the Internet].[10] Miltefosine has been shown to be effective in India for treatment of visceral leishmaniasis.[100] The dose of miltefosine is 2.5 mg/kg/day, preferably in two divided doses or a single dose, orally for 28 days. When initial treatment of kala-azar with sodium stibogluconate fails, amphotericin B or pentamidine may be used.[10] Kala-azar that is resistant to sodium stibogluconate may respond to liposomal amphotericin B.[101]

CUTANEOUS AND MUCOCUTANEOUS LEISHMANIASIS

Etiology and Epidemiology

Old World cutaneous leishmaniasis is caused by three species of *Leishmania* that belong to the *L. tropica* complex: *L. tropica* is present in the Middle East and the Mediterranean littoral; *L. major* is found in the Middle East, Arabia, the former Soviet Union, India, and sub-Saharan Africa; and *L. aethiopica* is found principally in Ethiopia and Kenya. *Phlebotomus* sandflies are the principal vectors, although direct contact with an ill person may, in rare cases, result in infection. Infections that are caused by *Leishmania* can be acquired by travelers, as well as by military and other personnel residing in endemic areas. Military personnel in the Middle East have acquired cutaneous leishmaniasis with *L. major* and viscerotropic infections with *L. tropica*.[98]

New World cutaneous leishmaniasis arises from infection with parasites belonging to the *L. mexicana* group or the *L. braziliensis (Viannia* subgenus) group. The *Viannia* subgenus is distinguished from the *Leishmania* subgenus by the differences in development in the sandfly gut. The patterns of illness vary with the nature of the infecting leishmanial organisms, which are found in different regions of North, Central, and South America [*see Table 3*]. In areas of Central and South America, infection with organisms of the *L. mexicana* group produces cutaneous leishmaniasis. A few autochthonous cases have been found in Texas. Infections with strains of *L. viannia*, which are endemic in various areas of South America, cause cutaneous leishmaniasis and, in a small percentage of those infected, result in the later development of mucocutaneous leishmaniasis. Such mucocutaneous disease (espundia) involves the nasal or oropharyngeal mucosa, or both, and may prove fatal. All of these New World leishmanial parasites are transmitted principally by sandfly vectors, although direct human contact may also bring about infection. Various mammals are naturally infected reservoirs of the organisms.

Pathogenesis

Both Old World and New World forms of leishmaniasis are initiated when the bite of an infected sandfly injects promastigotes into the human host. The organisms enter tissue macrophages and capillary endothelial cells, become amastigotes, and multiply. A granulomatous inflammatory response develops at the bite site. With local ischemia, the lesion ulcerates [*see Figure 17*]; a bacterial infection of the necrotic area may extend the ulceration. Resolution of clinical infection is associated with $CD4^+$ T helper type 1 cells that secrete interferon gamma in response to *Leishmania*. Progression of disease appears to be associated with an immune response dominated by interleukin-10, a cytokine that suppresses other cytokine responses.

Diagnosis

Clinical features In Old World cutaneous leishmaniasis, after an incubation period of weeks to months, a papule develops at the inoculation site. This area may resolve spontaneously. More frequently, it ulcerates and a shallow circular lesion appears that is several centimeters in diameter and has a raised margin. Bacterial superinfection may lead to regional lym-

Table 3 New World Cutaneous Leishmaniasis[97]

Parasite	*Disease in Humans*	*Geographic Areas*
Leishmania viannia group		
L. viannia braziliensis	Usually a single or few lesions but frequently very large, persistent, and disfiguring; later nasopharyngeal involvement (espundia) in a small percentage	Brazil, Peru, Ecuador, Bolivia, Venezuela, Paraguay, Colombia, northern Argentina, Belize, Guatemala
L. viannia colombiensis	Usually a single lesion	Colombia, Panama
L. viannia guyanensis	Pian bois (bush yaws); multiple skin lesions, frequently with metastatic spread along lymphatics	Guyana, Suriname, Belize, northern Brazil
L. viannia panamensis	Usually a single lesion but occasional spread via lymphatics; nasopharyngeal involvement rare	Panama, Costa Rica, Colombia
L. viannia peruviana	Uta; a single or few self-healing skin lesions; no nasopharyngeal involvement	Western slopes of the Peruvian Andes, the Argentinian highlands
L. mexicana group		
L. mexicana mexicana	Frequent involvement of ear pinna (chiclero's ear, bay sore); a single or few skin lesions; no nasopharyngeal lesions; diffuse cutaneous leishmaniasis rare	Mexico, Central America, Texas
L. mexicana amazonensis	Rare human infection; a single or few skin lesions; diffuse cutaneous leishmaniasis	Amazon basin and neighboring areas, Brazil
L. mexicana pifanoi	Simple and diffuse cutaneous leishmaniasis	Venezuela
L. mexicana venezuelensis	Simple cutaneous leishmaniasis	Venezuelan Andes
L. mexicana species	Simple and diffuse cutaneous leishmaniasis	Dominican Republic

phadenopathy. The lesions are often solitary, but multiple bites can produce several concurrent lesions. Healing of the lesions is slow, sometimes requiring more than a year.

L. mexicana infections produce a single lesion or a few lesions on exposed surfaces of the body such as the face and ear.[102] The ulcer usually heals spontaneously over 6 months. An ulcer involving the ear, however, may cause extensive destruction of the pinna. *L. viannia* infection is associated with lesions on the skin or mucous membranes, which may be multiple and may become very large, especially when bacterial superinfection develops. Cutaneous lesions caused by *L. braziliensis* are much less likely to heal spontaneously than those caused by *L. mexicana*.[102] *L. viannia braziliensis* species can invade regional lymph nodes and cause progressive ulcerations along the lymphatics or extend locally and involve mucous membranes. Often, the infection metastasizes to the nasal or oral mucosa after an intervening period of months to years. Metastatic lesions can erode the nasal septum or the hard palate or soft palate. Some patients die of malnutrition or bacterial infection.

Diffuse cutaneous leishmaniasis occurs in parts of Ethiopia, Venezuela, Brazil, and the Dominican Republic. The initial nodule does not ulcerate; instead, multiple nodules evolve on the body. Leishmanial organisms abound in the lesions. Patients with this form of leishmaniasis have a deficiency of cell-mediated immunity, which is similar to the defective immunity that occurs in patients with lepromatous leprosy.

Laboratory findings Definitive diagnosis is made by demonstrating amastigotes on stained smears [*see Figure 18*] of a biopsy or of scrapings from the border of an ulcer. Alternatively, the diagnosis can be made by culturing amastigotes on NNN medium inoculated with lesion material. Use of PCR targeting parasite kinetoplast DNA has allowed detection of organisms that might be missed on histologic section or culturing. Moreover, this technique serves as a rapid method for speciating *L. mexicana* and *L. viannia*. In contrast to *L. tropica* and *L. mexicana* amastigotes, which can be readily cultured and are abundant in lesions, *L. viannia* amastigotes are difficult to culture and are sparse in lesions, especially those of mucocutaneous leishmaniasis. Organisms of these species cannot be distinguished morphologically, and specialized immunologic, enzymatic, or nucleic acid studies may be needed for definitive speciation. Except in diffuse cutaneous leishmaniasis, the leishmanin skin test is usually positive.

Treatment

Although the pentavalent antimonial compounds, sodium stibogluconate (20 mg/kg/day I.V. or I.M. of pentavalent antimonial for 20 days) and meglumine antimoniate, are the general treatments of choice for both Old World and New World cutaneous leishmaniasis,[10] optimal therapeutic regimens with these or alternative agents have not been rigorously defined. Individual species and geographic strains of *Leishmania* respond differently to treatment and have different capacities to cause mucosal

Figure 17 **An ulcerative lesion of *L. (Viannia) braziliensis* acquired in the jungles of Belize.**

disease or to heal spontaneously. Furthermore, it is difficult to distinguish infective species solely on clinical grounds. Therefore, progress in developing rational plans for appropriate treatment has been impeded. Advice on treatment of leishmaniasis is available from the CDC's Division of Parasitic Diseases [*see Sidebar,* Protozoan Infection Information on the Internet]. *Leishmania* organisms have ergosterol in their membrane and are sensitive to amphotericin-containing preparations and azole 14-demethylase inhibitors. Amphotericin B and lipid preparations of amphotericin have been shown to be effective for mucosal leishmaniasis resistant to antimonial compounds. For Old World cutaneous disease with *L. major*, treatment with fluconazole (200 mg daily for 6 weeks) has been shown to be effective.[103] Pentamidine and topical paromomycin have been used as alternatives for treatment of cutaneous disease.[10]

Trypanosomiasis

AMERICAN TRYPANOSOMIASIS (CHAGAS DISEASE)

Infection with the protozoan hemoflagellate *Trypanosoma cruzi* produces American trypanosomiasis, or Chagas disease, which has acute and chronic forms.[104]

Etiology and Epidemiology

Two forms of *T. cruzi* infect mammals: trypanosomes, which are carried in the blood, and amastigotes, which are found in infected cells. The parasite is transmitted by several genera of reduviid or triatomid bugs, commonly called assassin bugs because they prey on other insects or called kissing bugs because of their predilection for biting the face [*see Figure 19*]. Nonhuman reservoirs include cats, dogs, rats and other rodents, raccoons, opossums, and armadillos. The local pattern of transmission of *T. cruzi* infections depends on the species of reduviid bug, the sylvatic and domestic mammalian reservoirs, and housing conditions. Infected animals living around dwellings, usually in rural areas, are likely to transmit the organism to reduviid bugs. These infected bugs inhabit niches in walls and ceilings of poorly constructed houses. At night, they come out and feed on the blood of sleeping humans by biting exposed skin areas such as the face. During their meal, the insects excrete feces containing infective-stage metacyclic trypanosomes, which enter the host through the bite wound, cutaneous abrasions, or mucous membranes of the conjunctiva or lips.

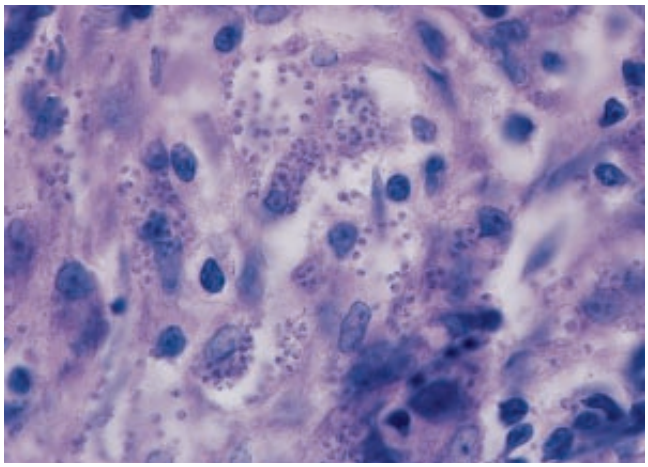

Figure 18 **Amastigotes are demonstrated on Giemsa-stained biopsy tissue from an ulcer in a patient with Old World cutaneous leishmaniasis.**

Although reduviid vectors are present in the United States and infected mammals have been found in several states, the opportunity for transmission of infections seems limited. Only five autochthonous cases of Chagas disease have been reported in the United States.[105] In rural areas of Central and South America, human infections are common where conditions favor access of infected bugs to persons.[104] In addition, infections may be transmitted by blood transfusions, across the placenta, to laboratory workers, and, in rare instances, by ingestion of foodstuffs contaminated with the excreta of infected reduviid bugs.

Pathogenesis

Both acute and chronic forms of Chagas disease are recognized. The acute form, which develops soon after infection, principally affects children in endemic areas.[104] Within several days of infection, an indurated erythematous lesion termed a chagoma appears at the inoculation site. When the inoculation site is the conjunctiva, unilateral periorbital edema develops, called the Romaña sign [*see Figure 20*]. After about 2 weeks, trypanosomes appear in the blood and invade cells, generally those of mesenchymal origin, where they multiply as intracellular amastigote forms. They are even able to proliferate in macrophages, unless the macrophages have been activated by interferon gamma. The resultant intracellular pseudocysts rupture, releasing both trypanosomal and amastigote forms. Both of these forms are infectious to mammalian cells. A combination of humoral and cell-mediated immunity controls high-level parasitemia, but despite this relative immunity, the host remains parasitemic at low levels for life. The reasons *T. cruzi* is able to establish lifelong infection are incompletely understood, but contributors include the following: evasion of complement-mediated cytolysis, intracellular growth in phagocytes, and the display of thousands of antigenically distinct surface proteins that appear to disrupt an effective cell-mediated immune response. Only 10% to 30% of infected persons develop chronic forms of Chagas disease. The reasons some persons develop disease and others don't is poorly understood and may involve the initial parasite burden, continuous inflammation in critical areas, induction of autoimmunity by the chronic infection, or some combination thereof.

Diagnosis

Clinical features During the acute phase, the patient may experience intermittent or continuous fever, malaise, an evanescent rubelliform or petechial rash, hepatosplenomegaly, lymphadenopathy, nonpitting edema of the face or extremities, tender subcutaneous nodules termed hematogenous chagomas, and, in infants, diarrhea. In severe cases, fatal myocarditis or meningoencephalitis can develop. The acute phase is usually self-limited: patients eventually become asymptomatic, and parasites can no longer be detected in the bloodstream except by PCR or by feeding reduviid bugs on the patient's blood and examining them for infection later.

The chronic form of Chagas disease may become manifest either after an acute infection or, more commonly, after a clinically inapparent infection. It usually arises in the second or third decade of life and progresses over subsequent decades. Chronic complications of Chagas disease result from the destruction of autonomic ganglia and from myositis; the pathogenesis of these

Figure 19 ***Triatoma infestans,* commonly known as assassin bugs or kissing bugs, are vectors for Chagas disease.**

lesions is not understood. The organ most frequently involved is the heart,[104] which develops biventricular hypertrophy and a mononuclear cell infiltrative myocarditis. Conduction disorders often include right bundle branch block, partial or complete atrioventricular block, and premature ventricular contractions. Sudden death has occurred in patients with Chagas disease, and fatalities have also resulted from complications of heart failure.

The GI tract is the second most frequently involved organ system.[104] The disease causes denervation leading to impaired motility and dilatation, which results in megaesophagus and megacolon. Neurologic disease is the third most frequently observed complication of chronic Chagas disease and manifests primarily as peripheral neuropathies.[106]

Congenital infections are usually responsible for premature births. Such premature infants may have hepatosplenomegaly, abdominal distention, cardiomegaly, megaesophagus, and meningoencephalitis.

In HIV-infected patients, reactivation of Chagas disease can produce cerebral masses and, in patients with acute infections, necrotizing encephalitis. These CNS infections cannot be distinguished radiographically from toxoplasmosis, and biopsy must be performed in patients with risk factors for both infections.

Laboratory findings In acute Chagas disease, the total leukocyte count often exceeds 18,000 cells/mm^3 (70% to 90% lymphocytes), and parasites are often demonstrable in the blood or in specimens from bone marrow, lymph nodes, CSF, pericardial fluid, or other involved areas. On unstained blood smears, motile trypanosomes may be seen; on Giemsa-stained smears, the organisms appear as C-shaped forms [*see Figure 21*]. If smears do not reveal the organisms, trypanosomes may be found in stained sediment obtained by centrifuging several milliliters of blood after lysing the erythrocytes. Organisms may be cultured from blood on NNN medium or in blood broth. Alternatively, blood may be injected into a laboratory rodent, whose blood is then monitored for evidence of parasitemia. Xenodiagnosis, which is not readily available, is one of the most sensitive diagnostic techniques to detect parasites. In this procedure, laboratory-reared reduviid insects are allowed to feed on a patient. If the blood ingested by the insects contains trypanosomes, the insects will become infected, and such infection can be detected by subsequent examinations of the insects' feces for excreted parasites. PCR to detect circulating parasites is becoming available in clinical labs, is as sensitive as xenodiagnosis, and is easier to implement than xenodiagnosis. Blood containing trypanosomes is infectious and should be handled with care.

In chronic Chagas disease, a chest x-ray may reveal biventricular cardiomegaly and congestive heart failure. Electrocardiographic abnormalities are commonly seen, particularly right bundle branch block. Barium swallow or enema exams may demonstrate megaesophagus or megacolon disease. Methods other than PCR or xenodiagnosis are rarely capable of detecting organisms in the blood. Similarly, it is difficult to demonstrate parasites in affected tissues; commonly, only mononuclear inflammatory cells or fibrosis is seen in pathologic specimens. Indirect fluorescent antibody and enzyme immunoassay *T. cruzi* serology tests are performed by the CDC. Both of these tests rely on crude antigens derived from cultured insect forms of *T. cruzi,* and individuals infected with *Leishmania* may have cross-reactive antibodies that give a false positive result on these tests. Although these serology tests may be positive, their results may only reflect past infection and fail to establish a link between clinical findings and active Chagas disease.

Figure 20 **Periorbital edema of the right eye (Romaña sign) is evident in a child from Panama with acute Chagas disease.**

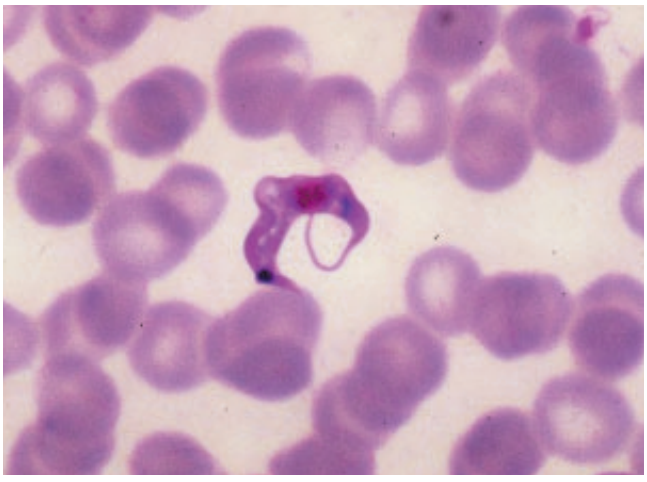

Figure 21 **A trypanosomal form of *Trypanosoma cruzi* is visible on this Giemsa-stained blood smear.**

Treatment

Optimal therapy for *T. cruzi* infections remains to be established. Nifurtimox (available from the CDC Drug Service) eliminates parasitemia [*see Sidebar,* Protozoan Infection Information on the Internet]. It should be administered to patients with acute disease and to patients with chronic disease and demonstrated parasitemia.[10] Side effects are frequent and include hemolytic anemia in patients with G6PD deficiency, peripheral neuritis, and psychosis. Anecdotal evidence suggests that interferon gamma combined with nifurtimox may shorten the duration of acute disease. Some authors believe that benznidazole is the drug of choice for treating *T. cruzi* infection, but it is not available in the United States and has a variety of toxicities, including granulocytopenia, rash, and peripheral neuropathy.[104] Itraconazole and other azoles have activity in blocking the ergosterol synthesis of *T. cruzi,* and itraconazole has some efficacy against chronic disease.[107] Though some small studies have shown benefit of benznidazole or nifurtimox treatment of early chronic Chagas cardiac disease, most experts agree that the cardiovascular and GI complications of chronic Chagas disease should be managed medically. Surgical treatment may be required for megacolon, and balloon dilatation of the lower esophageal sphincter may be needed for megaesophagus. If cardiac transplantation is contemplated, preparations to provide antitrypanosomal therapy should be made because reactivation of latent parasitemia can occur as a complication of the immunosuppressive drugs.

AFRICAN TRYPANOSOMIASIS

Etiology and Epidemiology

African trypanosomiasis, or sleeping sickness, is an acute or chronic parasitic disease caused by protozoan hemoflagellates of two *Trypanosoma brucei* subspecies. The disease is prevalent in a broad periequatorial belt across Africa. Two forms occur in humans: West African and East African, or Rhodesian, sleeping sickness. West African trypanosomiasis is present in the tropical forests of West and Central Africa and is caused by *T. brucei gambiense*, a parasite not carried in any major animal reservoir. In contrast, *T. brucei rhodesiense*, which produces East African sleeping sickness, is prevalent in the savanna and woodlands of tropical East Africa and exists in wild animal reservoirs. Visitors to game parks are at risk for acquiring East African trypanosomiasis.[108] Both types of African trypanosomiasis are transmitted by species of tsetse flies (genus *Glossina*), with the riverine *G. palpalis* group transmitting *T. brucei gambiense* and the savanna *G. morsitans* group transmitting *T. brucei rhodesiense*. *T. brucei* species are able to exist as chronic infections in the bloodstream and, later, in the CNS, partly because of their ability to undergo sequential antigenic variation of the major variant surface glycoprotein (VSG) that covers the trypanosome. As antibodies develop to a given VSG, most of the trypanosomes are eliminated from the circulation, but variants expressing an antigenically distinct VSG grow out and continue the infection. The combination of thousands of genes and pseudogenes for VSGs, plus an ability to create new VSG genes by recombination, allows the trypanosome to stay ahead of the immune response.

Diagnosis

Clinical features Within a few days to a couple of weeks after inoculation of organisms by a tsetse fly, a trypanosomal chancre may develop at the site of the insect bite, which is usually on exposed skin.[109] The chancre initially appears as a papule and, within 2 weeks, evolves into an inflamed, painful nodule that subsequently resolves spontaneously. Trypanosomal chancres commonly occur in non-African patients but usually do not develop in African patients.

During the next phase of African trypanosomiasis, the hemolymphatic phase, trypanosomes invade the bloodstream and lymph nodes. In Africans, the development of symptoms in this phase occurs slowly, over several months, and presenting symptoms include fever, lymphadenopathy, headache, and debility. In non-Africans, however, the onset is abrupt and early, often concomitant with the development of the chancre. In non-Africans, episodes of high fever that last 1 to 7 days and recur after afebrile periods are prominent. Associated symptoms include chills, headache, malaise, and anorexia. Soft, nontender lymphadenopathy develops more prominently with West African trypanosomiasis and may include enlargement of posterior cervical nodes (Winterbottom sign). A characteristic rash, which can be observed on light-skinned individuals, occurs about 6 to 8 weeks after infection and may appear as evanescent, circinate, erythematous patches, usually located on the trunk.

The next phase in the evolution of African trypanosomiasis is CNS invasion leading to diffuse meningoencephalitis or meningomyelitis. In West African trypanosomiasis, which is a slowly evolving illness, the symptoms of sleeping sickness may not develop until years after infection. Increasing lassitude and indifference are complicated by progressive neurologic compromise leading to coma and death by inanition or intercurrent infection. In contrast, the pace of East African trypanosomiasis is much more rapid, and CNS involvement may develop earlier. Even before CNS involvement, such manifestations as somnolence, personality changes, and an inability to concentrate may appear. Pancarditis often complicates acute East African trypanosomiasis and may cause death before the onset of CNS disease. Because East African trypanosomiasis may be acquired by visitors to game preserves and is an acute febrile illness, it may be mistaken for malaria and must be considered in the differential diagnosis of a febrile patient returning from an endemic area.[77]

Laboratory findings The total leukocyte count is usually normal, but the differential may show mononucleosis of 50% to 70%. Serum IgM levels rise 1 to 2 weeks after parasites appear in

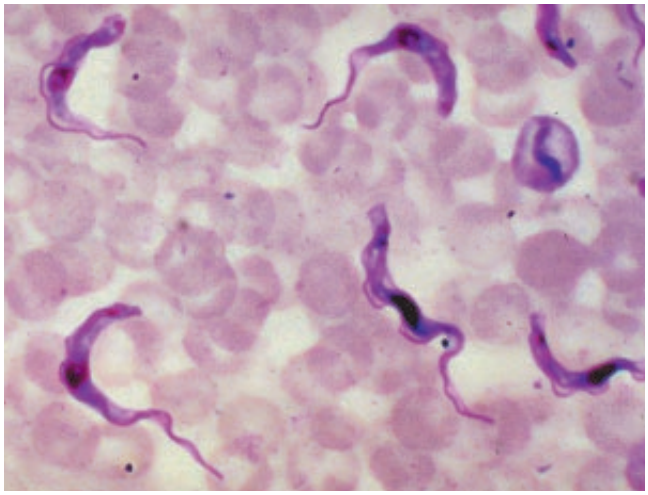

Figure 22 ***Trypanosoma brucei* parasites, the cause of African sleeping sickness, are evident on this Giemsa-stained blood smear.**

the blood and may shoot up to more than seven times the normal level. The definitive diagnosis is made by detecting trypanosomal organisms in blood, bone marrow, fluid from enlarged lymph nodes, or centrifuged CSF [*see Figure 22*]. Trypanosomes may be seen moving rapidly on wet mounts of blood or other aspirates. Organisms stained with Wright, Giemsa, or Leishman stain may be found in a chancre 48 hours before they appear in the blood. If examination of peripheral blood is unrevealing, trypanosomes may be found in fluid aspirated from involved lymph nodes or among buffy coat cells. Even in cases in which neurologic symptoms are absent, CNS disease must be excluded by performing a lumbar puncture. Even if trypanosomes are not seen in centrifuged CSF, CNS involvement may still exist, as indicated by elevations of the cell count or of protein or IgM concentrations. Serologic tests for African trypanosomiasis exist, but treatment is generally reserved for parasitologically confirmed cases because the therapy is so toxic.

Treatment

Eflornithine is effective therapy for *T. brucei gambiense* infections,[10,109] even those refractory to the arsenical agent melarsoprol. Eflornithine is the treatment of choice for both the early hemolymphatic and the later CNS stages of West African trypanosomiasis. Because eflornithine can cause anemia, leukopenia, and thrombocytopenia, blood cell counts should be monitored twice a week during therapy. Eflornithine has not been effective with *T. brucei rhodesiense* infections. The early stage of East African trypanosomiasis is treated with suramin, and the CNS stage is treated with melarsoprol.[10] Both of these drugs are available from the CDC Drug Service [*see Sidebar*, Protozoan Infection Information on the Internet] but have a variety of toxicities; notably, melarsoprol treatment is itself fatal in 4% to 6% of patients.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XXXV HELMINTHIC INFECTIONS

Wesley C. Van Voorhis, m.d., ph.d., f.a.c.p.
Peter F. Weller, m.d., f.a.c.p

General Considerations

Parasites are generally subdivided into three categories: protozoans, helminths, and arthropods such as ticks and insects. This chapter focuses on helminthic pathogens; protozoans are discussed elsewhere, as are general characteristics of parasite-host relationships [*see 7:XXXIV Protozoan Infections*].

Helminthic parasites are divided into three major groups: nematodes (roundworms), cestodes (tapeworms), and trematodes (flukes) [*see Figure 1*]. Helminthic parasites differ from protozoan parasites in several respects. First, protozoan parasites are unicellular organisms, whereas helminthic parasites are metazoan (multicellular) worms that possess differentiated organ systems. Second, most helminthic parasites do not replicate within the human host; rather, they develop to a certain stage within the human body and mature further outside the human body. During their extrahuman life cycle, helminths exist either as free-living organisms or as parasites within another host species and mature into new developmental stages capable of reinfecting humans. Thus, with only a few exceptions (i.e., those parasites capable of internal reinfection, notably, *Strongyloides stercoralis* and *Capillaria philippinensis*), augmentation of the number of adult helminthic parasites that reside within the human host requires exogenous reinfection.

A third attribute of helminthic parasites but not of protozoan parasites is their tendency to elicit eosinophilia within the tissues and blood of infected humans. The magnitude of eosinophilia tends to correlate with the extent of tissue invasion by larvae or adult helminths. For example, in several helminthic infections, such as paragonimiasis, acute schistosomiasis, and *Ascaris* and hookworm infections, the elicited eosinophilia is greatest during the early phases of infection, when migrations of infecting larvae and the progression of subsequent developmental stages through the tissues are greatest. In established infections, local-tissue eosinophil infiltration is often present around helminths within tissues, but blood eosinophilia may be intermittent, mild, or absent. There may be no eosinophilia in established infections that are well contained within tissues (e.g., intact echinococcal cysts) or confined within the lumen of the intestinal tract (e.g., *Ascaris* and tapeworms). For some established infections, increases in blood eosinophilia may be episodic. Intermittent leakage of fluids from echinococcal cysts can elicit transient increases in blood eosinophil levels, as well as symptoms attributable to allergic or anaphylactic reactions (e.g., urticaria and bronchospasm).[1] With tissue-dwelling helminths, increased eosinophilia may be associated with the migration of adult parasites, as in loiasis and gnathostomiasis.

Certain established infections—including trichinellosis, anisakiasis, gnathostomiasis, visceral larva migrans, echinococcosis, and the several forms of filariasis—are capable of inducing eosinophilia but cannot be diagnosed on the basis of stool examination. In addition, some intestinal helminths may not be readily detectable on routine stool examination. The intestinal nematode that is most likely to cause persistent eosinophilia and that may not be detected on initial stool examination is *S. stercoralis*.[2]

Intestinal Nematode Infections

The major intestinal nematodes are roundworms, hookworms, whipworms, pinworms, and *S. stercoralis* [*see Table 1*]. Infection with these parasites occurs in many hundreds of millions of persons worldwide, especially in tropical areas. Children are particularly affected.

roundworm, hookworm, and whipworm

Roundworms, hookworms, and whipworms are geohelminths, requiring a soil phase for the fecally expelled eggs to develop into their infective stages. Thus, infections from these parasites usually occur in rural areas with poor sanitation. In these areas, highly prevalent infections with these intestinal nematodes are major contributors to malnutrition in children.[3]

Epidemiology, Pathogenesis, and Clinical Features

Hookworm The World Health Organization (WHO) estimates that 700 million persons are infected with *Ancylostoma duodenale* or *Necator americanus.* Hookworm infection is more likely where the following conditions coexist: sanitary practices that permit human fecal contamination of the soil; soil that is damp enough for larval survival; and human contact with contaminated soil. Persons at risk include children, gardeners, plumbers or electricians in contact with soil, and infantry personnel.

Hookworm eggs excreted in feces hatch in the soil, releasing larvae that develop into infective larvae [*see Figure 2*]. Percutaneous larval penetration is the principal mode of human infection, but infections with *A. duodenale* may also be acquired by oral ingestion. Larval penetration of the skin often produces a pruritic, maculopapular eruption at each site of entry. In persons previously infected, serpiginous tracts of intracutaneous larval migration, as in cutaneous larva migrans, can occur. From the skin, hookworm larvae travel via the bloodstream to the lungs. The hookworm larvae enter the alveoli, ascend the tracheobronchial tree to the pharynx, and are swallowed. The development of *A. duodenale* larvae can be arrested for many months before the larvae proceed to the lungs for subsequent maturation. Although transpulmonary larval passage may elicit a transient eosinophilic pneumonitis, this phenomenon is much less common with hookworm infections than with roundworm infections.[4] Larvae and young adult worms in the intestinal tract may cause gastrointestinal symptoms, including nausea, diarrhea, vomiting, abdominal pain (often with postprandial accentuation), and flatulence.

A major health impact of hookworm infection is iron loss resulting from the 0.1 to 0.4 ml of blood ingested daily by each adult worm [*see Figure 3*]. In malnourished hosts, such blood loss can lead to severe iron-deficiency anemia. The number of parasites necessary to cause anemia varies with host iron and protein stores, but hookworm burdens of 40 to 160 worms are associated with hemoglobin levels below 11 g/dl. Severe anemia from the interaction of malnutrition, malaria, and hookworm infection is a major contributor to childhood mortality in areas of the world where these conditions coexist.

Roundworm *Ascaris lumbricoides* is the most prevalent intestinal helminthic parasite, infecting well over one billion people worldwide. Each adult female can produce up to 200,000 eggs a day. Passed in feces, these eggs are remarkably resistant

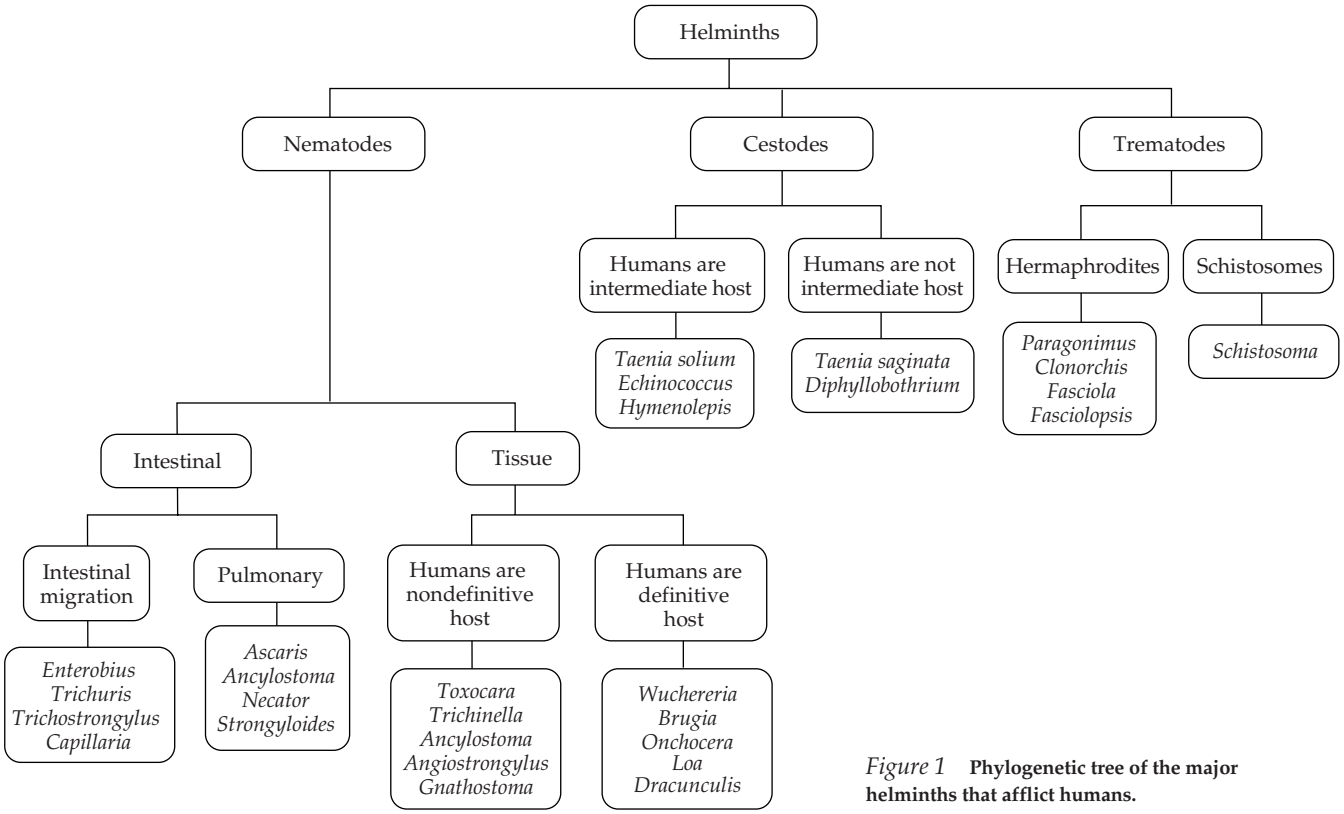

Figure 1 **Phylogenetic tree of the major helminths that afflict humans.**

to environmental stresses and are capable of remaining viable for up to 6 years. With exposure to warm, humid soil, fertilized eggs become embryonated and infectious. Most transmission occurs by ingestion of fertilized eggs on dirty hands, in fecally contaminated agricultural products or other foodstuffs, or through geophagia (the life cycle of *Ascaris* is illustrated in the Centers for Disease Control and Prevention Public Health Image Library [CDC PHIL], at http://phil.cdc.gov/Phil; photograph 5231). Infection is more common in areas with poor sanitation. In regions with large concentrations of *Ascaris* eggs in the soil, eggs may be disseminated in the air, where they are inhaled and swallowed later with respiratory secretions.

From swallowed *Ascaris* eggs, larvae hatch in the intestine within 1 to 2 days and molt into second-stage larvae, which are carried hematogenously to the liver and lungs. Roughly 1 to 2 weeks after infection, larvae penetrate alveoli from the capillary bed and molt into third-stage larvae, which ascend the tracheobronchial tree, are swallowed, and return to the intestine. These larvae mature into adult male and female worms, measuring 10 to 30 cm in length [*see Figure 4*]. The fertilized adult females begin producing eggs 2 to 3 months after the initial infection.

The clinical manifestations of ascariasis occur during early larval migration or with established intestinal infections. During the phase of transpulmonary migration, eosinophilic, often migratory, pulmonary infiltrates (Löffler syndrome) can develop, especially in previously sensitized hosts.[4] The large adult worms in the intestine usually elicit no symptoms, although they may contribute to malnutrition.

Infrequently, adult *Ascaris* worms cause serious complications. In heavy infections, especially in children, the mass of entangled adult worms may cause partial or complete intestinal obstruction.[5,6] A second type of complication can develop even when only a single adult worm migrates from its normal location within the intestinal lumen. Migration into the appendix can precipitate acute appendicitis. Acute or recurrent migrations of one or more adult worms into the biliary tract can cause obstruction leading to acalculous cholecystitis, pyogenic cholangitis, pancreatitis, or liver abscesses.[7] If the bowel wall is thinned or ulcerated by typhoid enteritis or other diseases, adult *Ascaris* worms may penetrate and perforate the intestine.

Heavy worm burden is more frequently seen in children younger than 10 years. Worm burden tends to decrease with increasing age, in correlation with increased secretion of cytokines by type 2 helper T cells (Th2) in response to *Ascaris* antigens.[8] Thus, Th2 cytokine responses may protect against heavy infections.

Whipworm Infection with *Trichuris trichiura* is widespread in tropical regions throughout the world and also occurs in rural areas of the southern United States. Whipworm infection results from ingestion of eggs that have embryonated in the soil for 15 to 30 days (the life cycle of *Trichuris* is illustrated in the CDC PHIL [http://phil.cdc.gov/Phil], photograph 5231; a whipworm is shown in photograph 414).

Moderate whipworm infection provokes gastrointestinal complaints; heavy infections (> 200 worms) in children cause the *Trichuris* dysentery syndrome, characterized by chronic diarrhea, anemia, growth retardation, and, occasionally, rectal prolapse.[9]

Laboratory Findings and Imaging Studies

Intestinal infections with roundworm, hookworm, or whipworm are usually easily diagnosed by finding the eggs of the responsible parasite on stool examination. During the pulmonary phase of *Ascaris* or hookworm infections, the diagnosis is made by finding larvae in respiratory secretions. Results of stool examinations are usually negative during the pulmonary phase be-

Table 1 Intestinal Nematodes

	Roundworm (Ascaris lumbricoides)	*Pinworm* (Enterobius vermicularis)	*Hookworm* (Necator americanus *or* Ancylostoma duodenale)	*Whipworm* (Trichuris trichiura)	Strongyloides stercoralis
Infective stage	Egg	Egg	Larva	Egg	Filariform larva
Route of infection	Oral	Oral	Percutaneous Oral (*A. duodenale)*	Oral	Percutaneous or internally with ongoing auto-infection
Extraintestinal penetration					
Larval stage	After egg ingestion	None	During initial infection	None	During initial infection and during ongoing autoinfection
Adult stage	With aberrant migration	Rarely via female genital tract	None	None	None
Adult length	10–30 cm	~ 1 cm	0.6–1.2 cm	3–5 cm	~ 0.2 cm
Principal symptoms	Usually none; occasionally, GI or biliary tract obstruction by adult worms	Perianal pruritus or none	Usually none; iron deficiency anemia in heavy infection	Usually none; GI symptoms or iron deficiency anemia in heavy infection	In uncomplicated infection, none or GI symptoms and skin lesions; in disseminated disease, symptoms related to involvement of GI tract, lungs, or other organs, with possible bacteremia
Diagnostic stage	Eggs in stool	Eggs from perianal skin on cellulose acetate tape	Eggs in fresh stool; larvae in old stool	Eggs in stool	Rhabditiform larvae in stool; filariform larvae in duodenal aspirate, in pulmonary secretions, in stool, or in other fluids or tissues; serology helpful in low-grade infections
Indications for therapy	Presence of adult worms	Symptoms	Heavy worm burden; iron deficiency anemia	Symptoms with heavy infection	Presence of parasite
Therapy (adult dose)	Albendazole (400 mg p.o. once) *or* Mebendazole (100 mg p.o., b.i.d., for 3 days or 500 mg p.o. once) *or* Ivermectin (150–200 μg/kg p.o. once) *or* Nitazoxanide (500 mg p.o., b.i.d., for 3 days)	Pyrantel pamoate (11 mg/kg p.o. in a single dose; maximum: 1 g/day) *or* Mebendazole (100 mg p.o. in a single dose) *or* Albendazole (400 mg p.o. once) For each agent, repeat course after 2 wk	Albendazole (400 mg p.o. once) *or* Mebendazole (100 mg p.o., b.i.d., for 3 days or 500 mg p.o. once) *or* Pyrantel pamoate (11 mg/kg p.o. in a single dose; maximum: 1 g/day)	Mebendazole (100 mg p.o., b.i.d., for 3 days or 500 mg p.o. once) *or* Albendazole (400 mg p.o. for 3 days) *or* Ivermectin (200 μg/kg p.o. daily for 3 days) *or* Nitazoxanide (500 mg p.o. daily for 3 days)	Ivermectin (200 μg/kg p.o., q.d., for 1–2 days) *or* Albendazole (400 mg p.o., b.i.d., for 2 days) *or* Thiabendazole (25 mg/kg p.o., b.i.d.; maximum dose, 3 g/day for 2 days or, in cases of disseminated disease, for 5 days) Immunocompromised persons may require prolonged therapy

cause this phase occurs early in infection, weeks or months before adult worms have matured sufficiently to liberate eggs into the feces. Positive stool samples during the respiratory phase indicate earlier long-standing infection. Thus, in eosinophilic pneumonitis, negative stool examination results do not exclude a parasitic etiology.

Adult *Ascaris* worms can be readily detected in upper GI series; the large worms are outlined by contrast material, and in late follow-up films, the parasite's alimentary tract may be defined by a thin line of ingested contrast medium. Ultrasonography can detect adult worms in the small intestine, facilitating diagnosis of *Ascaris* as the cause of abdominal symptoms.[10] Worms in the biliary tract can be detected by ultrasonography[11] or endoscopic cholangiopancreatography.[12] At times, patients may note the passage of the large, smooth adult *Ascaris* worms in the stool or may cough up an adult worm.

Adult whipworms, which are 3 to 5 cm in length, may be visualized by anoscopy or colonoscopy. Adult hookworms, which are 0.6 to 1.2 cm in length, may be visualized by endoscopy of the proximal small intestine.

Treatment

Therapy for roundworm, hookworm, and whipworm infections utilizes the well-tolerated broad-spectrum anthelmintic agents mebendazole, albendazole, and, in some cases, pyrantel pamoate, ivermectin, and nitazoxanide [*see Table 1*]. Several caveats apply, however. Pyrantel is not used for whipworm or roundworm; ivermectin and nitazoxanide are not used for hookworm. Because mebendazole and albendazole may be teratogenic, they are contraindicated during pregnancy. Albendazole, ivermectin, and nitazoxanide are not yet approved by the Food and Drug Administration for these indications.

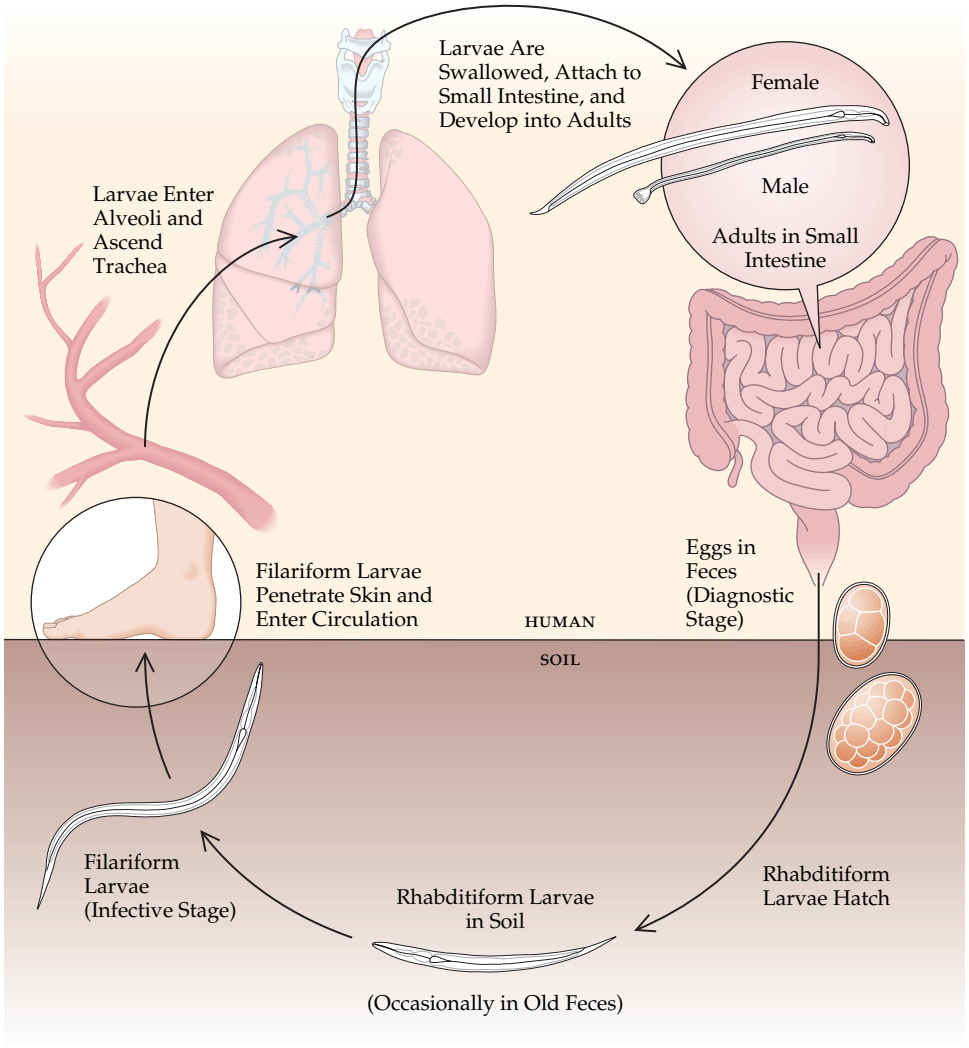

Figure 2 **Hookworm infection typically begins when filariform larvae in soil penetrate the skin and enter the circulation. The larvae travel via the bloodstream to the lungs, where they cross into the alveolar air space and ascend the tracheobronchial tree. They are then swallowed and attach to the small intestine. There they develop into adults, which feed on blood. Adult females lay eggs that are excreted in feces and hatch in the soil, releasing rhabditiform larvae that develop into infective filariform larvae. The hookworm *Ancylostoma duodenale* may also be acquired by oral ingestion of larvae.**

Therapy for *Ascaris* is mandatory to prevent unusual complications resulting from aberrant migration of the large adult worms. Adult *Ascaris* worms causing biliary and pancreatic obstruction may be removed at endoscopy.[12]

Anemia caused by hookworm responds to iron supplementation. Several animal models have shown that vaccination with recombinant hookworm antigens shows great promise in reducing the worm burden in humans and alleviating anemia.[13]

PINWORMS

Pinworms (*Enterobius vermicularis*) often affect groups of children, such as in schools or families, because the eggs are infectious when passed and can be transmitted from person to person and by fomites in the environment (the life cycle of *Enterobius* is illustrated in the CDC PHIL [http://phil.cdc.gov/Phil]; photograph 5228). The cardinal symptom of pinworm infection is perianal pruritus, but some infected patients remain asymptomatic. The pruritus often worsens at night, when the worms tend to migrate. Occasionally, migration of adult worms into or through the female genital tract results in vaginitis or peritoneal inflammation associated with granuloma formation.[14] Pinworm larvae may also cause eosinophilic enterocolitis or appendicitis.[15,16]

Diagnosis

Because pinworm eggs are deposited by female worms on the perianal skin, stool examinations usually are not revealing. Pinworm infections are diagnosed by applying cellulose acetate tape to the perianal skin in the morning and microscopically examining the tape on a slide to detect the eggs (a photograph of pinworm eggs is available in the CDC PHIL [http://phil.cdc.gov/Phil]; photograph 4818). Adult pinworms, which are about 1 cm in length, may be visualized by anoscopy or colonoscopy.

Treatment

Pinworm infection is treated with mebendazole, pyrantel pamoate, or albendazole (not yet FDA approved for this indication) [*see Table 1*]. Because mebendazole and albendazole may be teratogenic, they are contraindicated during pregnancy. A second treatment should be given 2 weeks after the initial course. Even with repeat treatment, however, reinfection is common. Before treatment, hygienic measures such as frequent baths, the clipping of fingernails, and cleaning of the egg-contaminated household environment should be instituted to reduce the opportunity for reinfection. Because household members are often infected and can provide a source for reinfection, simultaneous treatment of all household members is indicated.

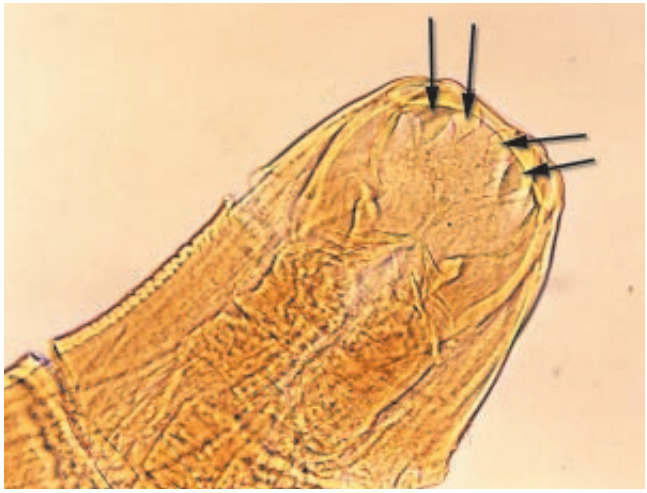

Figure 3 **The mouthparts (arrows) of an *Ancylostoma duodenale* hookworm are visible on an unstained micrograph.**

STRONGYLOIDIASIS

Although *S. stercoralis* is the least prevalent of the intestinal nematodes in the United States, it is widely distributed within the tropics and subtropics. In the United States, *Strongyloides* infection is more prevalent in persons residing in the southern states[17]; in persons living in institutions with poor sanitation[18]; and in immigrants, military veterans, and other persons who have traveled or resided in locales where *Strongyloides* is endemic. *Strongyloides* is one of the few helminths capable of internal reinfection; it can multiply in the human host without reinfection by soil-dwelling larvae. As a result of ongoing internal reinfection, strongyloidiasis may persist for decades, as has been documented in some World War II and Vietnam War veterans. If host immunity is suppressed, the internal reinfection cycle may become unbridled, leading to hyperinfection that can result in an overwhelming and frequently fatal illness.[18]

Pathogenesis and Clinical Features

Eggs of *S. stercoralis* hatch in the intestine into rhabditiform larvae, which develop further by one of three routes [*see Figure 5*]. Two of the routes occur after stool passage: the larvae may develop in the soil into infective filariform larvae either immediately or after an intervening stage as free-living adults. The filariform larvae penetrate the skin and travel via the bloodstream to the lungs, where they enter the alveoli, ascend the trachea, and are swallowed; adult worms subsequently develop in the small intestine.

The third route is the autoinfection cycle, in which the rhabditiform larvae mature directly within the intestine into filariform larvae, which penetrate the colon or the perianal skin to enter the circulation and complete the cycle of maturation into adult worms. This last route can increase the parasitic burden and permit the infection to become chronic.

Invasion of the small intestine wall by adult *S. stercoralis* worms may produce abdominal pain that is often localized to the midepigastrium; the pain is similar to that of peptic ulcer but is aggravated by food consumption. Diarrhea, nausea, and vomiting often occur; less commonly, urticaria, asthma, and weight loss may occur. Patients with heavy infection may experience malabsorption, gastrointestinal bleeding, and a protein-losing enteropathy. In cases of chronic infection, symptoms may be absent or may be mild and intermittent; symptoms include diarrhea, abdominal pain, and recurring episodes of urticaria, especially on the buttocks and the wrists. Less commonly, larva currens, which is a pathognomonic serpiginous, pruritic, elevated eruption, evolves along the tract of larval migration in the skin of the perianal, gluteal, or other body areas.

Disseminated strongyloidiasis may occur, especially in patients who have a malignant disorder or who are immunocompromised as a result of malnutrition or the administration of corticosteroids or other immunosuppressive medications.[18] Disseminated strongyloidiasis occurs but is uncommon in patients with AIDS, although strongyloidiasis is encountered in patients who are infected with human T cell lymphotropic virus type I.[18] In immunocompromised patients, the autoinfection cycle produces large numbers of filariform larvae that may disseminate from the colon and invade any organ system. Colonic leakage or carriage of intestinal bacteria by larvae into the bloodstream often produces concomitant bacterial infection and pneumonia. This progression of events frequently results in a fatal hyperinfection syndrome in the immunocompromised host.

Laboratory Findings

Eosinophilia is elicited in strongyloidiasis but may be minimal or only episodic in chronic infection and absent in the hyperinfection syndrome, especially if the patient has taken corticosteroids. Midepigastric discomfort or unexplained eosinophilia in a patient about to receive immunosuppressive therapy should prompt a diagnostic search for the larvae of *Strongyloides*. Serial stool samples should be examined with the use of concentration techniques. Stool examinations are repeatedly negative in about 25% of patients with strongyloidiasis. An enzyme-linked immunosorbent assay (ELISA) is an especially useful diagnostic test. When hyperinfection is present, *Strongyloides* larvae may be found in other fluids, such as surgical drainage fluid and sputum, and the stool may contain filariform and rhabditiform larvae.

Treatment

Strongyloidiasis must be treated because of the potential for subsequent fatal hyperinfection. The anthelmintic agents used are ivermectin, thiabendazole, and albendazole [*see Table 1*]. Ivermectin, approved in the United States for uncomplicated infection, is safe and effective. Thiabendazole can be used for uncomplicated infection or for disseminated disease.[19] However, thiabendazole often causes unpleasant side effects, and treatment is

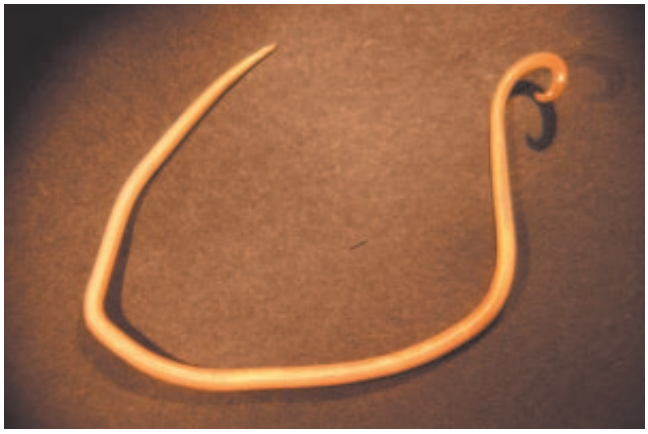

Figure 4 **Adult *Ascaris lumbricoides* roundworms are 10 to 30 cm in length.**

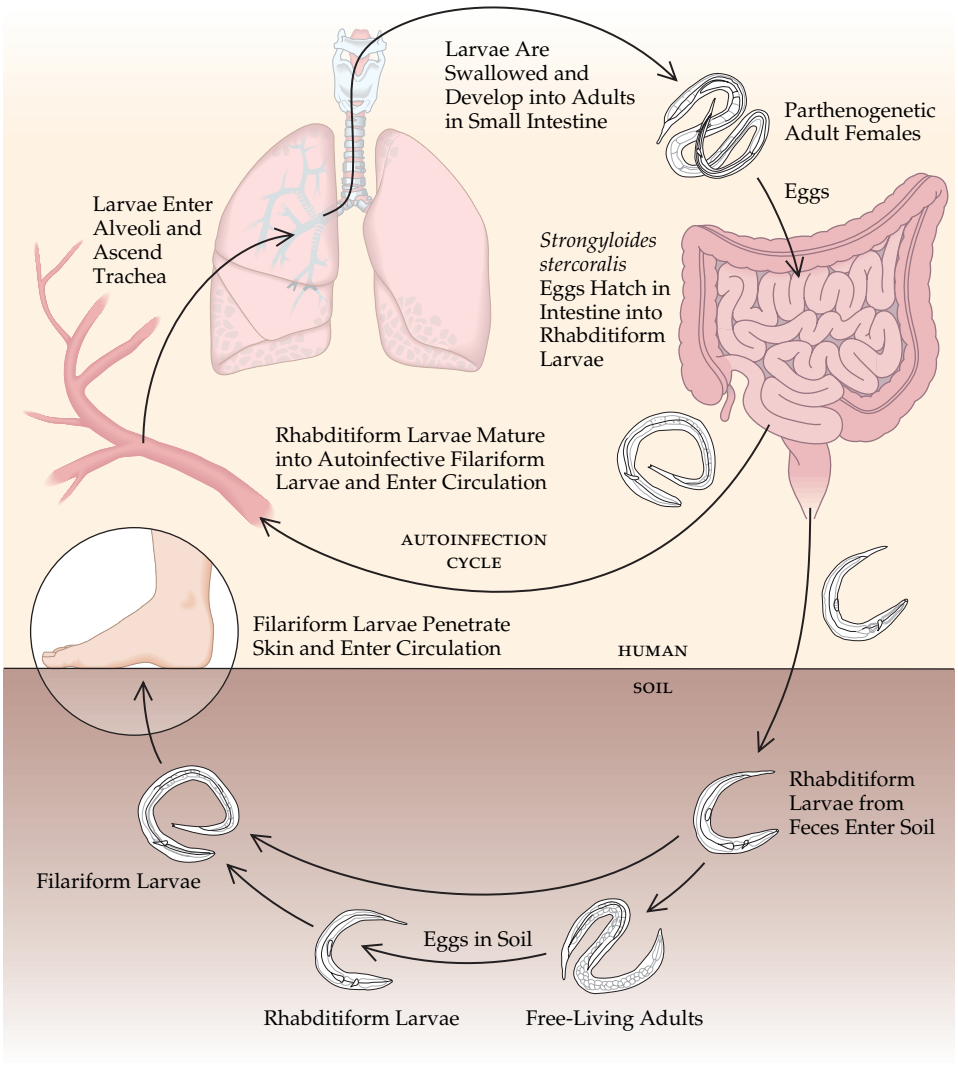

Figure 5 **Filariform larvae of the intestinal nematode *Strongyloides stercoralis* penetrate the skin or mucous membranes and enter the circulation. Larvae travel to the lungs, where they cross into the alveolar air space and ascend the tracheobronchial tree. They are then swallowed and develop into adults, which may mate or undergo parthenogenetic fertilization, penetrate the mucosa of the proximal small bowel, and lay eggs. The eggs hatch within the small intestine and develop into rhabditiform larvae, which then follow one of two paths: a soil phase or an autoinfection cycle. In the soil phase, larvae are passed in the feces and contaminate the soil, where they either transform directly into infectious filariform larvae or develop into free-living adults that generate new infectious larvae. In the autoinfection cycle, rhabditiform larvae penetrate the colonic wall or perianal skin and enter the circulation.**

not uniformly successful. Many experts believe that ivermectin will completely supplant thiabendazole. Although not approved for the treatment of strongyloidiasis in the United States, albendazole is an effective agent but is less effective than ivermectin in clearing larvae from stools.[18] Serial stool examinations should be obtained in the weeks and months after therapy to confirm eradication of the parasite. Immunocompromised hosts may require prolonged anthelmintic therapy.

TRICHOSTRONGYLIASIS

Although *Trichostrongylus* are usually intestinal pathogens of herbivores, several species may infect humans. Infection is most common in Asia and is acquired by consuming food that harbors infectious larvae. Adult worms attach to the proximal small bowel and in most cases do not produce symptoms, but mild GI distress and eosinophilia have been reported. The eggs of *Trichostrongylus* are somewhat larger and have less rounded ends than hookworm eggs. Trichostrongyliasis is treated with pyrantel pamoate (a single oral 11 mg/kg dose, to a maximum of 1 g), mebendazole (100 mg p.o., b.i.d., for 3 days), or albendazole (400 mg p.o., once).[19]

CAPILLARIASIS

Most human infection with *Capillaria* is caused by *C. philippinensis,* which is found primarily in the northern Philippines, Thailand, and Egypt. Humans acquire the infection by eating raw freshwater fish, but birds that eat fish are the major host. The small (3 to 4 mm long) adult worms dwell in the small intestine. Females produce unembryonated eggs that mature in the environment. However, a small percentage of these eggs embryonate and hatch in the intestine, leading to an internal autoinfection similar to that seen in strongyloidiasis. Symptomatic intestinal capillariasis is marked by diarrhea and abdominal pain. When infection is severe, edema, muscle wasting, fat and sugar malabsorption, and a protein-losing enteropathy may ensue.[14] Because of the autoinfection cycle, untreated severe infection may result in death after several months.

Hepatic and pulmonary capillariasis are rare diseases that are found worldwide. Hepatic capillariasis, from *C. hepatica,* manifests as acute or subacute hepatitis; pulmonary capillariasis, from *C. aerophila,* manifests as fever, cough, asthma, and pneumonia. Capillariasis is treated with mebendazole (200 mg orally twice daily for 20 days) or albendazole (400 mg orally daily for 10 days).[19]

CANINE HOOKWORMS

Two canine hookworms, *Ancylostoma ceylanicum* and *A. caninum,* can cause human intestinal infections; a third canine hook-

worm, *A. braziliense,* can cause cutaneous larva migrans [*see* Larva Migrans, *below*]. *A. ceylanicum* is a widely distributed canine and feline parasite of the tropics and subtropics. Like human hookworm parasites, the sexually mature, egg-laying adult worms of this species can cause blood loss and consequent iron deficiency.

Most cases of *A. caninum* infection in humans have been recognized in Australia and Egypt.[20,21] Reported clinical features have been variable, ranging from acute intestinal obstruction to subclinical infections. Eosinophilic enteritis is common, and some patients have experienced acute or recurrent abdominal pain, rectal bleeding, or diarrhea. Worms—often a single worm—have been recovered at surgery or colonoscopy in many patients. The immature worms do not produce eggs and hence are not detectable by stool examinations. An ELISA serologic test has helped with diagnosis. As in human hookworm infections [*see Table 1*], mebendazole or albendazole has been effective.

Tissue Nematode Infections

TRICHINELLOSIS

Trichinella are nematodes whose larvae typically become encysted in striated muscle. Transmission of *Trichinella* occurs via ingestion of infected meat, usually pork or the meat of certain carnivores. Mild to moderate trichinellosis is usually asymptomatic or mildly symptomatic; heavy infection can cause myalgias, periorbital edema, eosinophilia, and, in rare cases, death.

Etiology and Epidemiology

Five species of *Trichinella* are now recognized to infect humans. *T. spiralis,* found in many carnivorous and omnivorous animals, and *T. pseudospiralis,* found in mammals and birds, are distributed throughout the world. *T. nativa* is present in arctic regions and infects bears and arctic mammals; *T. nelsoni* is present in equatorial Africa, where it is common in felid predators and scavenger animals (e.g., hyenas and bush pigs); and *T. bitovi* is present in temperate areas of Europe and western Asia, where it is found in carnivores but not domestic swine.[22,23]

Trichinella is transmitted by the consumption of meat containing encysted larvae [*see Figure 6*]. In its sylvatic life cycle, the parasite is ingested by wild animals that eat trichinous carcasses; in its domestic life cycle, the parasite is ingested by pigs that eat contaminated meat in garbage. Worldwide, most human trichinellosis is caused by ingestion of infected pork products; in the United States, however, ingestion of wild carnivores has surpassed pork in transmitting the infection.[24] Although cattle are

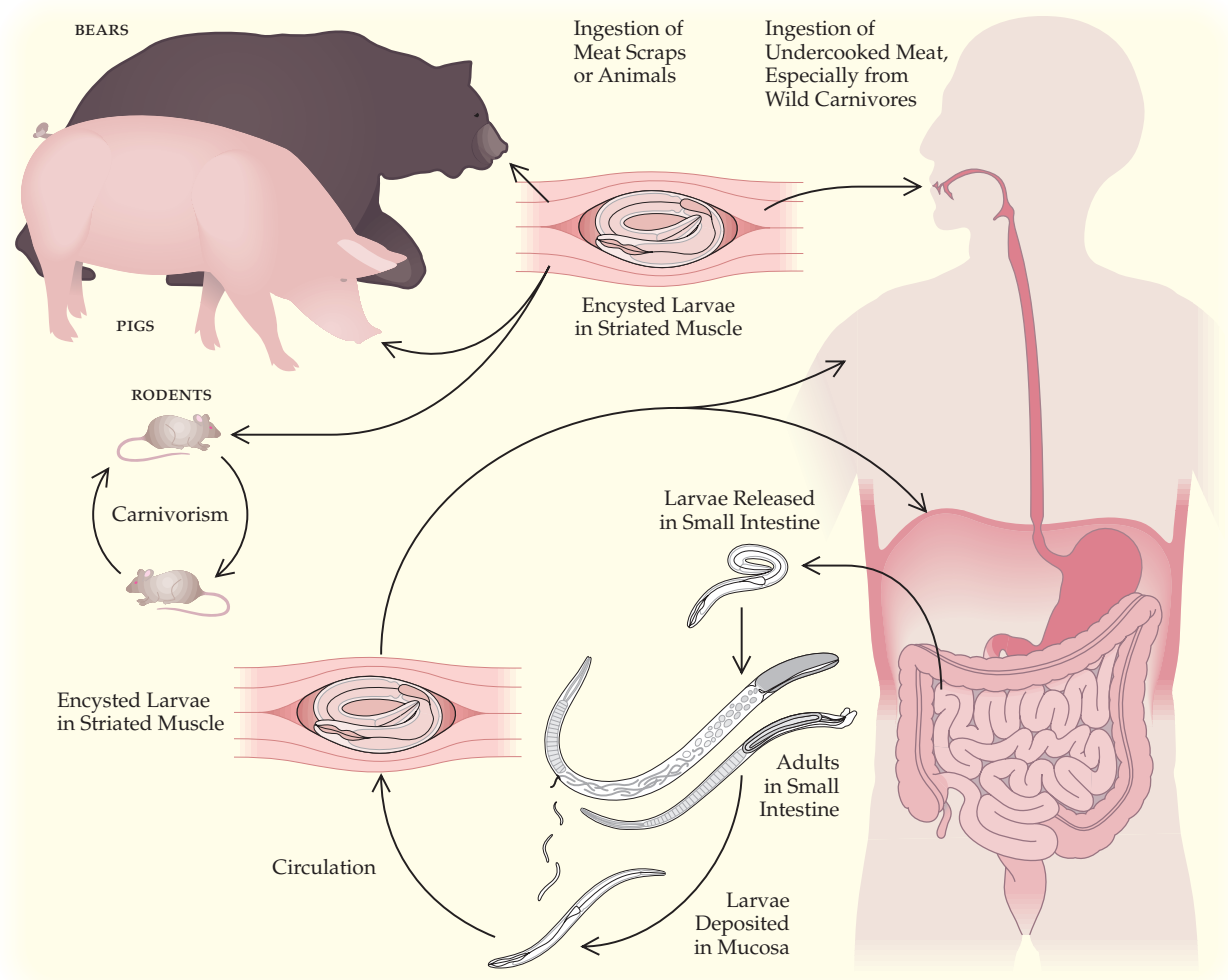

Figure 6 ***Trichinella* infection is acquired by the consumption of meat containing encysted larvae. Digestion liberates the larvae, which penetrate into the small intestine, mature into adult worms, and mate. Adult females produce larvae, which enter the circulation and spread to striated muscle, where they become encysted.**

not natural hosts of the parasite, beef may be implicated in outbreaks because of adulteration with pork, either intentional or incidental, through the common use of a meat grinder. Human trichinellosis can also be acquired from horse meat or the meat of wild animals such as bears, walrus, boars, and cougars.[24,25]

Although meat in the United States is not inspected for *Trichinella* larvae, laws proscribing the feeding of uncooked garbage to pigs have reduced the transmission of the disease.[24] Most cases in the United States are attributable to noncommercial pork, bear, and cougar meat. About 15 cases of trichinellosis, occasionally leading to death, are reported annually in the United States, but more cases, especially mild ones, probably remain undiagnosed.[24]

Larvae in pork may be rendered noninfective by heating to a temperature of 77° C. Freezing at –15° C for 3 weeks, as in a home freezer, will generally kill larvae in meat; however, arctic species of the parasite, which may be present in walrus or bear meat, are more resistant to freezing and thus may remain viable.

Pathogenesis and Clinical Features

The severity of clinical illness in trichinellosis usually correlates with the number of ingested larvae. In most infections, there are only one to 10 larvae per gram of muscle, and prominent symptoms are absent; however, in some infections, there are more than 50 larvae per gram of muscle. The symptoms of these heavier infections may reflect the two phases of the parasite's development (i.e., the intestinal phase and the muscle phase).

Intestinal phase Encysted larvae are liberated from infected meat by the action of gastric acid and peptic enzymes. The larvae burrow into the villi of the small intestine and mature into adult worms. Within 4 to 5 days, the adult worms produce larvae, which enter the circulation. During this enteric phase, which usually lasts from 1 to 7 days, patients may be asymptomatic or may experience nausea, vomiting, constipation, or abdominal aches. Prolonged diarrhea that lasts for weeks, as noted in patients with arctic trichinellosis, may be the result of secondary infections in previously infected and sensitized patients.[26]

Muscle phase After the intestinal phase, larvae are carried by the bloodstream to various organs. In the early muscle phase, periorbital and facial edema, subconjunctival and retinal hemorrhages, and subungual splinter hemorrhages commonly develop.

After about 3 weeks of infection, larval encystment in muscles begins. Patients experience myalgias, muscle edema and weakness, fever, and eosinophilia. Headache, cough, dyspnea, dysphagia, and macular or urticarial skin lesions develop less commonly. Although larvae only become encysted in striated muscle, inflammatory lesions may develop in the heart, lungs, and central nervous system. Deaths usually result from myocarditis. Symptoms generally abate slowly after the third week of infection. Infections with *T. pseudospiralis* may be associated with years of myositis.[27]

Laboratory Findings

Eosinophilia develops in more than 85% of patients with symptomatic trichinellosis.[24] Elevations of muscle enzymes (i.e., serum aspartate aminotransferase and creatine kinase) often accompany symptomatic muscle involvement. Serologic tests are positive in most patients with acute infection, but diagnostic antibody titers may not be detectable until the third week of infection.

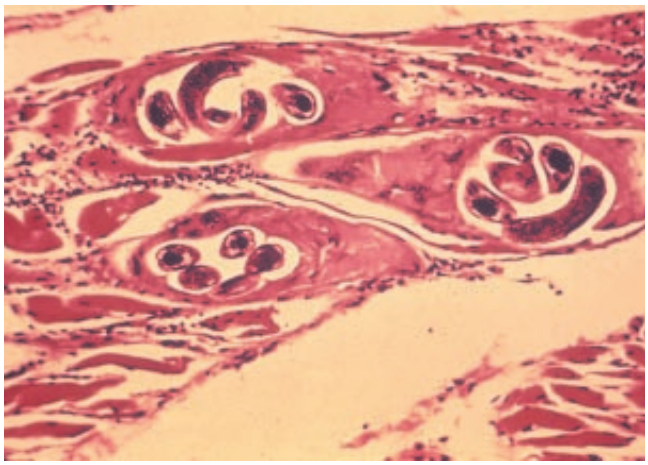

Figure 7 **A micrograph shows developing *Trichinella* cysts in human muscle tissue.**

Definitive diagnosis requires demonstration of larvae in muscle [*see Figure 7*]. The likelihood of obtaining a positive muscle biopsy specimen increases if the specimen is taken from a clinically involved muscle; if it is taken near a tendinous insertion, where the density of larvae is greatest; and if it is obtained after the third week of infection, when larvae are more numerous, larger, and more resistant to digestion. A portion of the muscle biopsy specimen should be submitted for histopathologic examination. In addition, another portion should be compressed between glass slides and examined microscopically for larvae. Because a larger volume of muscle can be examined by this technique, it is more sensitive than histopathologic examination for detecting larvae. Differentiation of *Trichinella* species can be based on the absence of larval encystment with *T. pseudospiralis* and on DNA-based molecular biologic techniques.[23]

Differential Diagnosis

The triad of periorbital edema, myalgias, and eosinophilia strongly suggests the diagnosis of trichinellosis. Most patients with trichinellosis have a history of consuming pork products or the meat of wild mammals. The development of symptomatic infection or eosinophilia in other persons who have eaten the meat incriminated in a case of trichinellosis provides epidemiologic confirmation of the diagnosis. Persons with light infections may have minimal symptoms, or the symptoms may suggest diagnoses other than trichinellosis, such as diarrheal or influenzal syndromes or polymyositis. In rare instances, CNS involvement may suggest aseptic meningitis or encephalitis.[28]

Treatment

Specific therapy for trichinellosis is unsatisfactory. Most infections, however, are not life threatening and are self-limited; bed rest, analgesics, and antipyretics suffice to alleviate myalgias and fever. If serious cardiac, neurologic, or pulmonary involvement occurs, corticosteroid therapy with prednisone (40 to 60 mg daily) is indicated. Prednisone is often given with oral mebendazole (200 to 400 mg t.i.d. for 3 days, then 400 to 500 mg t.i.d. for 10 days) or oral albendazole (400 mg b.i.d. for 8 to 14 days).[19] Limited experience suggests that *T. nativa* and *T. pseudospiralis* infection may respond to albendazole.[27,29]

ANISAKIASIS

Anisakiasis is a zoonotic infection that develops in persons who consume fish infected with anisakine or related parasites.[30] *Anisakis* species are present in the muscle of mackerel, herring, and salmon. In a study in the Pacific Northwest of the United States, all salmon caught in the wild had *A. simplex* larvae, and 87% of the fish had larvae in their edible musculature.[31] Infection caused by *Pseudoterranova* (previously termed *Phocanema*) species is referred to as codworm anisakiasis. *Pseudoterranova* parasites are found most frequently in cod, but they have also been detected in the muscle of pollack, halibut, flatfish, greenling, Pacific rockfish (Pacific red snapper), and squid. Infective third-stage larvae in fish are killed by heating to 60° C, by commercial blast freezing, or by freezing at –20° C for 3 days. Salting, cold smoking, and marinating do not normally kill either *Anisakis* or *Pseudoterranova* larvae.

The number of cases of anisakiasis recognized in the United States, Japan, Europe, and other countries has increased in recent years, probably as a result of three developments.[30] First, raw fish dishes, including sushi, sashimi, and lomi lomi salmon, have become increasingly popular. Second, the population of marine mammals, including sea lions and seals, has increased as a result of legal protection; these marine mammals are the definitive hosts for anisakine nematodes that in a later stage of their life cycle infect fish. Third, there has been an increase in awareness of anisakiasis and, especially in Japan, greater use of endoscopy as a diagnostic modality.

In addition to anisakine nematodes, other parasites, including *Diphyllobothrium latum* [*see* Cestode Infections, Fish Tapeworm, *below*], the intestinal fluke *Nanophyetus salmincola,* and larval *Eustrongylides* nematodes, can be acquired by eating raw fish.[30]

Pathogenesis and Clinical Features

The clinical manifestations of infection after the ingestion of fish containing live anisakine larvae depend in part on the genus of the infecting parasite and on the anatomic localization of the larvae. Typically, in the United States, infection with *Pseudoterranova* species becomes apparent when a patient coughs up a live worm, often within 48 hours after eating raw or undercooked fish. Some patients have experienced mild epigastric pain and a tingling throat and have sensed the worm in the oropharynx or proximal esophagus. In the United States, the infection has only infrequently been associated with serious illness.[32] In Japan, by contrast, codworm anisakiasis has been associated with gastric, but usually not intestinal, invasion. Within several hours after infected fish have been consumed, the larvae can invade the stomach mucosa and produce severe epigastric pain that recurs every 5 to 10 minutes. Patients may experience nausea, vomiting, urticaria, and a tingling throat. Endoscopy at this time will reveal the invading larvae at a site that is swollen and hemorrhagic; often, the site is the posterior wall of the stomach.

Infections with *Anisakis* species can cause either gastric or intestinal involvement. Invasion of the gastric mucosa produces the same clinical syndrome that occurs in gastric codworm anisakiasis but without the tingling throat; the pathologic findings on endoscopy are also the same.[33] Larval invasion of the intestinal mucosa can produce abdominal pain, fever, nausea, vomiting, and diarrhea. Larvae can elicit an eosinophil-rich granulomatous reaction in the submucosa and infrequently penetrate the peritoneum. The clinical presentation of intestinal anisakiasis often mimics that of acute appendicitis, but it can also be confused with gastrointestinal ulcers or neoplasms, acute Crohn disease, or ischemic ileitis. In addition to causing invasive disease, *Anisakis* parasites may elicit allergic reactions.[30] Patients may develop IgE-mediated reactions to *Anisakis* proteins and experience urticaria, angioedema, and anaphylactic reactions after ingesting even adequately cooked infected fish.[30]

Laboratory Findings and Imaging Studies

In gastric anisakiasis, eosinophilia is often present, and occult blood is frequently detectable in gastric fluid or stool. In intestinal anisakiasis, eosinophilia may be absent, and a leukocytosis may develop. In either form of anisakiasis, a history of recent raw fish ingestion before the onset of symptoms can strongly suggest the diagnosis. The definitive diagnosis of anisakiasis involving the stomach or proximal intestine can be made with endoscopy, which will reveal the invading larva.[32,33] The codworm larva resembles a thick piece of yellowish string, whereas the *Anisakis* larva is fine and whitish. *Eustrongylides* larvae, which have infrequently been reported to cause intestinal perforation in humans, have a distinctive bright-red coloration.[34]

Radiographic studies can help identify gastric anisakiasis.[33] In intestinal anisakiasis, such studies may show thickening of the involved bowel area and may detect the larva.[35]

Treatment

Endoscopic or surgical removal of the larva is the only proven treatment. Although surgery for presumed appendicitis is often performed in patients with intestinal anisakiasis, surgical resection may not be needed if the correct diagnosis is considered in time. With conservative care, the illness may be self-limited, and patients may recover without surgical treatment.[35] The efficacy of anthelmintic medications against human anisakiasis has not been properly evaluated. Animal studies suggest that ivermectin and albendazole have activity against *A. simplex,* and there are anecdotal reports of successful treatment of human anisakiasis with albendazole; because anisakiasis is often self-limited, however, the true utility of albendazole therapy is unknown.[19,36]

LARVA MIGRANS

Humans may occasionally act as the nondefinitive host for nematode parasites that normally infect animals. In such cases, the parasites usually do not mature completely, but the introduced larvae may persist and induce an inflammatory reaction in the skin, viscera, or eyes.

Cutaneous Larva Migrans

The syndrome of cutaneous larva migrans (creeping eruption) develops when the larvae of various parasites, including the dog or cat hookworm *A. braziliense,* penetrate human skin. Pruritic, serpiginous cutaneous lesions form along the migratory tracts of the larvae [*see Figure 8*].[37,38] These lesions can be treated with oral albendazole (400 mg daily for 3 days), oral ivermectin (200 μg/kg daily for 1 to 2 days), or topical thiabendazole.[19,37]

Visceral and Ocular Larva Migrans

The syndrome of visceral larva migrans develops when nematode larvae of animal parasites migrate in human tissues. Visceral larva migrans with fatal eosinophilic meningoencephalitis has been caused by the raccoon ascarid *Baylisascaris procyonis,*[39] but visceral larva migrans is most commonly caused by dog or cat ascarids.

Toxocara canis, the canine roundworm, is common in North American dogs. Although fewer than 20% of adult dogs are in-

Figure 8 **Cutaneous larva migrans in a person who had recently been on a beach vacation in Haiti is evident as a serpiginous tract that moves over time.**

fected, transplacental migration of larvae from infected females results in an incidence of infection that may exceed 80% in their puppies at 2 to 6 months of age.[40] Both the puppies and the lactating mother shed large numbers of *T. canis* eggs in their stools within a month after parturition. The prevalence of *T. cati* in cats is generally lower than that of *T. canis* in dogs; kittens do not become infected before birth.

After *Toxocara* eggs are shed in the feces, about 3 weeks must elapse before the eggs develop sufficiently to become infectious; thereafter, they may remain viable for several months. Humans acquire infection principally by ingesting eggs in soil; public playgrounds have been implicated [*see Figure 9*]. Direct contact with infected animals is not a major source of infection because of the time required for eggs to become infectious. A history of eating soil is strongly associated with the risk of acquiring infection. Thus, visceral larva migrans is most likely to develop in children with geophagia.

Pathogenesis and clinical features After infectious *Toxocara* eggs are ingested, the larvae hatch and penetrate the gastrointestinal mucosa. They are carried to the liver in the portal circulation; from there, they move into the systemic circulation. When the larvae enter vessels too small to allow their passage, they exit and migrate into the surrounding tissues. The manifestations of visceral larva migrans are a consequence of both the damage done by the migrating *Toxocara* larvae and the induced eosinophilic granulomatous inflammatory reaction.

Many infections are mild and subclinical. Clinically apparent infections may present in one of two distinct patterns: visceral and ocular.[41] In the visceral form of infection, patients are usually 1 to 5 years of age and generally have a history of geophagia. Malaise, irritability, weight loss, wheezing, cough, fever, hepatomegaly, and pruritic cutaneous eruptions are common. Neurologic involvement may produce seizures and behavioral disorders. In rare instances, death results from severe neurologic or myocardial involvement.

In the ocular form of larva migrans, patients are older: the mean age is 7.5 years, and the range includes young adults. A history of geophagia is unusual; a history of an antecedent symptomatic visceral form of the disease is rare. Common symptoms of ocular larva migrans are strabismus and failing vision. The characteristic ocular lesion is a whitish elevated granuloma measuring one to two disk diameters that is located in the posterior pole of the retina; however, the disease may also present as endophthalmitis or uveitis. The ocular lesions may be mistaken for a retinoblastoma, which can lead to unnecessary surgical enucleation of the eye.

Laboratory findings and imaging studies Usual findings in the visceral form of larva migrans are leukocytosis, prominent blood eosinophilia (generally in excess of 1,000/μl), and hypergammaglobulinemia (increased levels of IgG, IgM, and IgE). On chest x-ray, transient pulmonary infiltrates are found in about half of the patients with pulmonary symptoms. All these findings are uncommon, however, in the ocular form of larva migrans.

An ELISA serologic test has proved to be a sensitive, specific diagnostic test for both the visceral and the ocular forms; it can detect subclinical cases that may present only as an unexplained eosinophilia.[40,41]

Treatment The visceral form of larva migrans is often self-limited. However, anthelmintic and anti-inflammatory therapy have been shown to be beneficial. Albendazole (400 mg p.o., b.i.d., for 5 days), though not licensed by the FDA for this indication, is the drug of choice for toxocariasis and has been shown to be superior to thiabendazole.[41] Corticosteroids are used to treat patients with severe respiratory, myocardial, or CNS involvement or, in the ocular form, to suppress active inflammation.

ANGIOSTRONGYLIASIS

Infection of humans with the parasite *Angiostrongylus cantonensis* may produce eosinophilic meningitis.[39] The rat is the definitive host of *A. cantonensis,* but the larval stages develop in mollusks, which serve as intermediate hosts. Humans acquire the infection either by ingesting infected mollusks (i.e., land snails or slugs) or by consuming inadequately cooked carrier hosts (i.e., freshwater shrimp, aquatic and amphibious crabs, and certain marine fish) that have previously ingested infected mollusks. In the United States, *A. cantonensis* is endemic to the Hawaiian Islands, and the parasite has been found in rats in New Orleans. *A. cantonensis* is found throughout the Pacific Basin and in Southeast Asia, Australia, and the Caribbean. Eosinophilic meningitis from this parasite occurs in all these areas. An outbreak causing eosinophilic meningitis in 12 travelers on a cruise ship in Jamaica has been described; ingestion of Caesar salad was highly associated with acquisition of disease.[42]

Pathogenesis and Clinical Features

After *A. cantonensis* larvae are ingested, they migrate to the CNS. There the parasites die, but their passage into the CNS induces an eosinophilic inflammatory reaction. The most common symptom of *A. cantonensis* infection is a severe frontal or bitemporal headache, which is usually the reason patients seek medical attention. More than half of patients experience stiff neck, vomiting, or paresthesias. Extraocular muscle palsies, seizures, and significant fever are uncommon. Although some deaths have been recorded, symptoms generally resolve in 1 to 2 weeks; however, paresthesias may persist for months.[39]

Laboratory Findings

Peripheral blood eosinophilia usually accompanies eosinophilic meningitis caused by *A. cantonensis;* however, the eosinophilia may be mild, and eosinophil levels may not be elevated ini-

tially. In the cerebrospinal fluid, the white blood cell counts ordinarily range from 150 to 1,500 μl, with eosinophils accounting for more than 20% of the leukocytes. CSF protein levels are usually elevated, and glucose levels are at the low end of the normal range. On rare occasions, larvae of *A. cantonensis* are found in the CSF. No serologic tests are available for identifying the organism, so diagnosis is based on a compatible epidemiologic history and clinical course together with eosinophilic pleocytosis in the CSF. Eosinophils in the CSF, which are also found in other diseases,[39] may be misidentified if they are not specifically stained.

Treatment

There is no specific treatment for eosinophilic meningitis caused by *A. cantonensis;* anthelmintic agents have no effect. Corticosteroids have been shown to provide symptomatic relief of headaches caused by eosinophilic meningitis, as has removal of cerebrospinal fluid in patients with increased intracranial pressure.[19,43] For most patients, the illness is self-limited and the prognosis is good. In one report, treatment with the combination of mebendazole and corticosteroids appeared to shorten the duration of illness.[19,39,44]

MAMMOMONOGAMOSIS (SYNGAMOSIS)

Nematodes of the genus *Mammomonogamus* (*Syngamus*) inhabit the trachea of cattle and other herbivores. Although the life cycle of the parasite is unknown, human infection is believed to result from the ingestion of foodstuffs that contain some intermediate host of the parasite. Of the several dozen cases recognized in humans, most have been acquired in the Caribbean area. A chronic, nonproductive cough is characteristic in such patients.[45] No blood eosinophilia is elicited, and no parenchymal lesions are seen on chest x-ray. The diagnosis is made when an

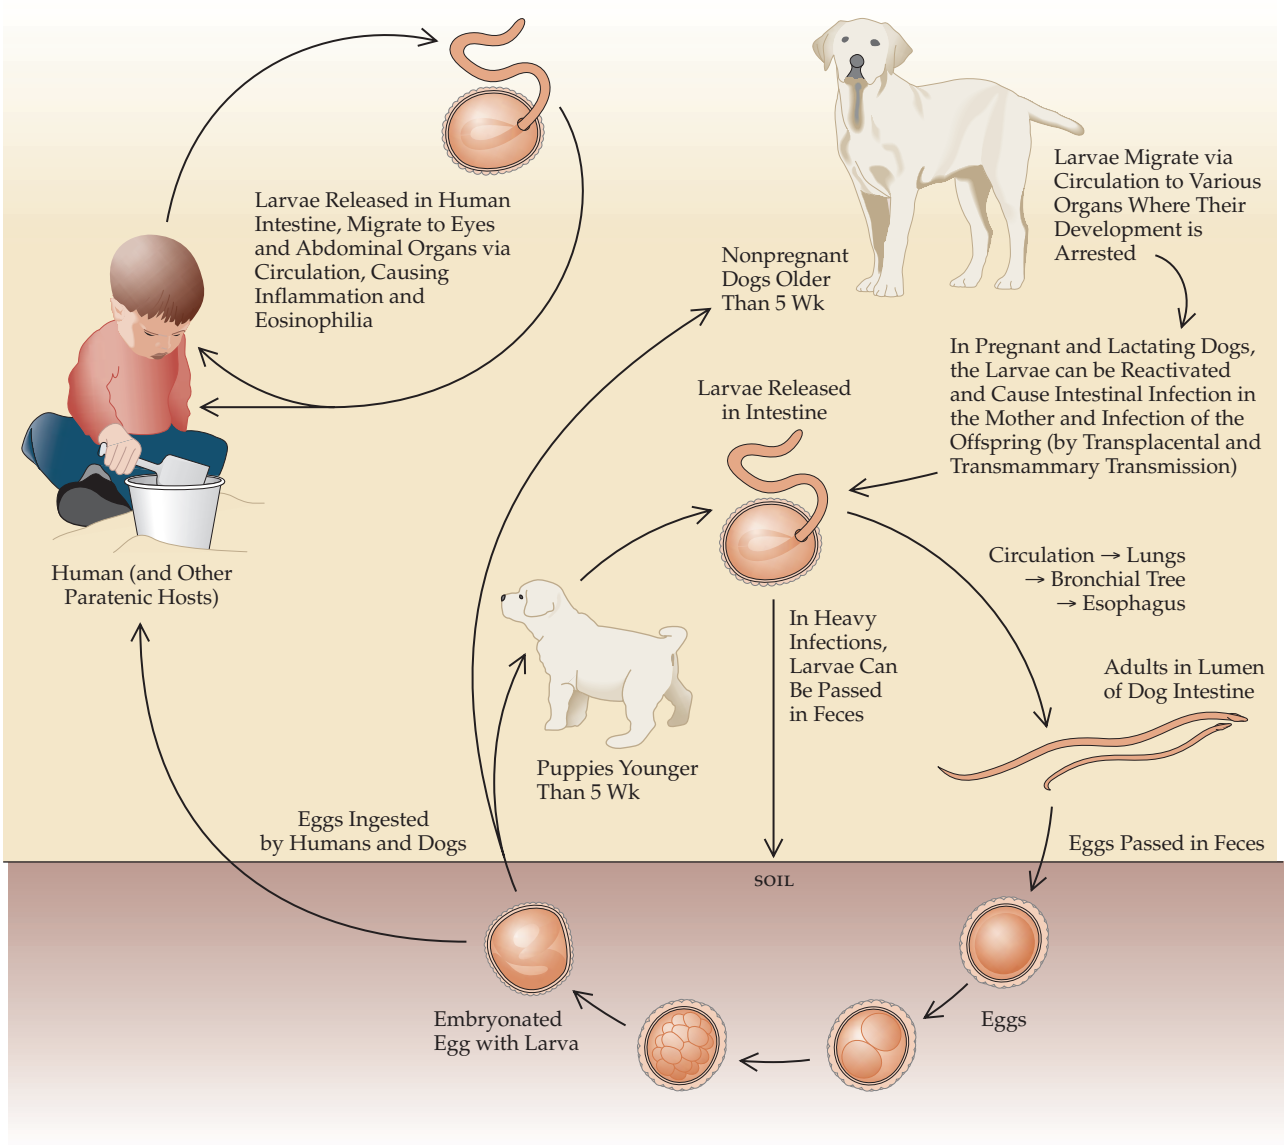

Figure 9 **Life cycle of *Toxocara canis*, one of the principal agents of visceral larva migrans. Humans are nondefinitive hosts for *Toxocara;* after infectious eggs are ingested, the larvae hatch and penetrate the gastrointestinal mucosa. They are carried to the liver in the portal circulation; from there, they move into the systemic circulation. When the larvae enter vessels too small to allow their passage, they exit and migrate into the surrounding tissues, where they may cause an inflammatory reaction.**

Table 2 Filarial Parasites of Humans

	Distribution	*Vector*	*Pathology*	*Localization of Adult Worms*	*Localization of Microfilariae*
Wuchereria bancrofti	Tropics worldwide	Mosquito	Lymphatic, pulmonary	Lymphatic tissues and vessels	Blood
Brugia malayi	Southeast Asia	Mosquito	Lymphatic, pulmonary	Lymphatic tissues and vessels	Blood
Brugia timori	Indonesia	Mosquito	Lymphatic	Lymphatic tissues and vessels	Blood
Onchocerca volvulus	Africa, Central and South America	Blackfly	Cutaneous, ocular	Nodules in subcutaneous tissues	Skin, subcutaneous tissues
Loa loa	Central West Africa	Deerfly	Subcutaneous	Subcutaneous and subconjunctival tissues	Blood
Mansonella perstans	Africa, South America	Midge	Uncertain, possibly allergic	Body cavities	Blood
Mansonella ozzardi	Central and South America	Midge, blackfly	Uncertain	Body cavities	Blood, skin
Mansonella streptocerca	Africa	Midge	Cutaneous	Connective tissues	Skin

adult worm is expectorated or found at bronchoscopy or when eggs are found in sputum or feces. Therapy consists of the removal of the worms during bronchoscopy, but mebendazole and thiabendazole have been used in case reports.

GNATHOSTOMIASIS

Nematodes of the genus *Gnathostoma* are widely distributed and usually infect the intestinal tract of carnivorous animals. Most human infections have been reported from Asia and have been caused by *G. spinigerum,* although human gnathostomiasis has also been described in Central and South America.[46,47] Infectious larvae are found in the tissues of freshwater fish, eels, frogs, and snakes and in animals fed on infected fish (e.g., poultry and pigs). Humans may be infected if they ingest any infected tissues, or possibly by accidental ingestion of the copepod (a tiny freshwater crustacean) that serves as an intermediate host. The larvae fail to develop to maturity within humans, but acute symptoms of nausea, vomiting, and urticaria may develop 1 to 2 days after infection. Larval penetration of the liver produces inflammation and right upper quadrant pain. Subsequently, larvae may migrate within the abdominal or thoracic cavities. Eosinophilia is initially marked but diminishes after about a month, when the larvae reach subcutaneous tissues. Ensuing larval migrations produce foci of serpiginous cutaneous or migratory subcutaneous inflammation and swelling. On occasion, larvae enter the CNS and cause eosinophilic meningitis.[39] Treatment options are oral albendazole (400 mg b.i.d. for 21 days), ivermectin (200 μg/kg/day for 2 days), surgical removal, or both.[19]

DRACUNCULIASIS

Dracunculus medinensis, the guinea worm, infects persons in 12 countries of Central and West Africa. A global eradication effort has reduced the annual incidence from 3.5 million cases in 1986 to less than 33,000 cases in 2003.[48] Infection results from drinking water containing microcrustacean *Cyclops* species that harbor larvae of the parasite. Gastric acid digests the *Cyclops,* releasing the larvae. The larvae then penetrate the duodenum, where they develop into adult worms within the subcutaneous tissues over the course of 60 to 90 days. Male and female worms then mate; after mating, adult male worms die. Adult females, however, move into the lower extremities, grow to 70 cm in length or more, and then emerge through the skin after about a year. This emergence, which may be preceded by a few days of urticaria, fever, and dyspnea, occurs with the formation of a blister that becomes pruritic and painful before rupturing. Larvae are released from the ruptured blister site if the lesion is immersed in water, as occurs during wading to fetch drinking water. The life cycle is completed when larvae are ingested by *Cyclops* and mature within them.

Clinical manifestations of dracunculiasis are usually related to the emergence of the worm and include premonitory symptoms and blister formation. Secondary bacterial infection often develops at the site of the blister and may extend retrograde along the length of the worm.

The conventional method of winding several centimeters of slowly emerging worm around a stick each day until the worm has fully emerged is an effective treatment. Removal is eased by administration of metronidazole (250 mg p.o. t.i.d. for 10 days), but surgical extraction is more rapid and effective.[49] In endemic areas, preventive efforts focus on breaking the *Dracunculus* life cycle by improving the safety of drinking water.

FILARIASIS

Several insect-transmitted filarial nematodes cause chronic infections in humans [*see Table 2*]. The major filarial nematodes are responsible for lymphatic filariasis, onchocerciasis, and loiasis. Other filarial nematodes include *Mansonella ozzardi, M. perstans* (formerly called *Tetrapetalonema perstans*), and *M. streptocerca* (formerly called *T. streptocerca*); these nematode species cause fewer cases of human infection than the major filarial nematodes and are of less certain pathogenicity, but they are thought to cause bronchospastic tropical pulmonary eosinophilic syndrome.

Lymphatic Filariasis

The most common filarial infections are caused by lymphatic tissue–dwelling filarial parasites, three species of which infect humans. It is estimated that 120 million persons in 76 countries are infected with lymphatic filarial parasites and that 44 million have overt clinical disease. However, the Global Alliance to Eliminate Lymphatic Filariasis (http://www.filariasis.org) has

brought the eradication of lymphatic filariasis within reach over the next decade by bringing together a strong group of collaborators whose efforts include the provision of powerful antiparasitic drugs.

Wuchereria bancrofti, the most common lymphatic filarial parasite, is broadly distributed in tropical regions. *Brugia malayi* is found in areas of Southeast Asia, and *B. timori* is found in parts of Indonesia. Mosquitoes serve as an intermediate host for all three species of filarial nematodes and introduce infectious larvae into humans by means of their bite (the life cycle of *B. malayi* is illustrated in the CDC PHIL [http://phil.cdc.gov/Phil]; photograph 3379). Different mosquito species are responsible for transmission in different areas; the major vectors include *Culex, Anopheles, Aedes,* and *Mansonia* species. The larvae develop into adult worms, which reside within lymphatic vessels and tissues. Offspring of the adult worms, called microfilariae, are covered by sheaths and may circulate in the bloodstream. In most endemic regions, microfilariae of *W. bancrofti* circulate in the bloodstream in greatest numbers during the night; in the South Pacific, however, no pronounced diurnal variation occurs. The time of day when the greatest numbers of microfilariae circulate correlates with the time of day when the principal mosquito vectors feed. Thousands of mosquito bites are probably required to produce an infection that results in patent microfilaremia. The incubation period until patent microfilaremia for *W. bancrofti* develops ranges from 3 months to the more usual 8 to 12 months.

Pathogenesis and clinical features Most clinical manifestations of lymphatic filariasis are attributable to inflammatory reactions caused by the adult worm; the immunopathogenesis, however, is poorly understood.[50] Many patients with microfilaremia experience no symptoms, although lymphadenopathy of the axillary, epitrochlear, and inguinal-femoral areas is common.

The more prominent clinical manifestations of lymphatic filariasis may be divided into two categories: inflammatory and obstructive. Inflammatory manifestations, which often become recurrent, include lymphadenitis, lymphangitis, funiculitis, orchitis, and epididymitis.[50] A typical presentation is the triad of lymphadenitis, lymphangitis, and fever. In contrast to bacterial ascending lymphangitis, the lymphangitis of filariasis characteristically progresses centripetally down involved extremities. Staphylococcal and streptococcal superinfections are commonly the cause. Fever is variable and may be associated with frank rigors; the patient's temperature may reach 40° C (104° F). Systemic symptoms, such as nausea and vomiting, develop in many of these recurrent episodes. Urticaria and areas of cutaneous erythema commonly develop. The episodes may continue for as long as 7 to 10 days before spontaneously resolving. In filariasis caused by *Brugia* species, suppurative abscesses may form in areas of involved lymphatic channels.

The obstructive phase of filariasis usually develops after decades of exposure to the parasite and reflects lymphatic compromise, the mechanism of which is poorly understood. Inflammatory features may coexist with the obstructive phase. Features of the obstructive phase include hydrocele formation, chyluria, elephantiasis of the extremities (shown in the CDC PHIL [http://phil.cdc.gov/Phil]; photograph 373), and, less commonly, elephantiasis of the breast.[50]

Tropical pulmonary eosinophilia develops in some individuals infected with lymphatic tissue–dwelling filarial parasites.[51] This illness is characterized by paroxysmal asthmalike attacks that are often nocturnal; by blood and pulmonary eosinophilia; and by elevated titers of antifilarial IgG, IgM, and especially IgE. Tropical pulmonary eosinophilia should be distinguished from the transient eosinophilic pneumonitis termed Löffler syndrome, which results from a transpulmonary migration of larval forms of *Ascaris* and, less commonly, hookworm and *Strongyloides* [*see* Intestinal Nematode Infections, *above*].

Laboratory findings Definitive diagnosis of lymphatic filariasis requires the demonstration of microfilariae or microfilarial antigens in the blood.[52] Stained blood smears may reveal microfilariae, but often, larger volumes of blood need to be examined either by centrifugal concentration after erythrocyte lysis or by filtration through 3 μm polycarbonate (Nuclepore) filters. In endemic areas where *W. bancrofti* microfilariae display nocturnal periodicity, detection of microfilariae requires examination of blood obtained after midnight or 60 to 90 minutes after daytime administration of a 2 mg/kg provocative dose of diethylcarbamazine (care should be taken if the patient is from a region where onchocerciasis is endemic, because diethylcarbamazine may precipitate a severe reaction as a result of lysis of *Onchocerca* microfilariae). Because microfilarial antigen of *W. bancrofti* can be found in the blood throughout the day, antigen measurement is more convenient than direct microfilaria determination. Microfilariae are rarely found in patients with elephantiasis or with tropical pulmonary eosinophilia and often cannot be found in patients with inflammatory or obstructive filarial manifestations. In males, ultrasonography can detect adult filariae within scrotal lymphatics.[50] Serologic tests may be helpful in making a diagnosis. Mild eosinophilia and elevations of serum IgE are common in lymphatic filariasis.

Treatment Lymphatic filariasis can be treated with diethylcarbamazine (2 mg/kg orally three times daily for 2 to 3 weeks). Treatment with ivermectin or a single dose of diethylcarbamazine (6 mg/kg)[50] is also effective at clearing microfilaremia, and the combination of these two anthelmintics has led to rapid and long-term clearance of microfilariae. There is insufficient reliable research to ascertain whether albendazole, alone or in combination with diethylcarbamazine, is an effective treatment for lymphatic filariasis,[53] but there is growing evidence that such treatment helps to suppress microfilaremia in patients from endemic areas. These short-term and combination therapies have been used more often in treatment of populations in filariasis control projects; for individual treatment, most experts favor the use of diethylcarbamazine for 2 to 3 weeks. Diethylcarbamazine must be used cautiously in patients exposed to *Loa loa* or *Onchocerca volvulus,* because patients infected with these filariae tend to have severe reactions to this drug.

Onchocerciasis

O. volvulus, the causative agent of onchocerciasis (river blindness), is found in equatorial Africa and in elevated regions of Mexico and Guatemala, with smaller foci in Yemen, Brazil, Ecuador, and Venezuela. It is estimated that 17 million people are infected. *Simulium* species (blackflies) transmit the infection. Onchocerciasis control programs, which are based on community therapy with ivermectin, have led to a substantial reduction in the incidence of disease. Repeated therapy is necessary, however, and control programs will have to continue for decades to eliminate onchocerciasis altogether.

Onchocerciasis typically occurs within several kilometers of rapidly flowing rivers and streams where blackflies breed. The

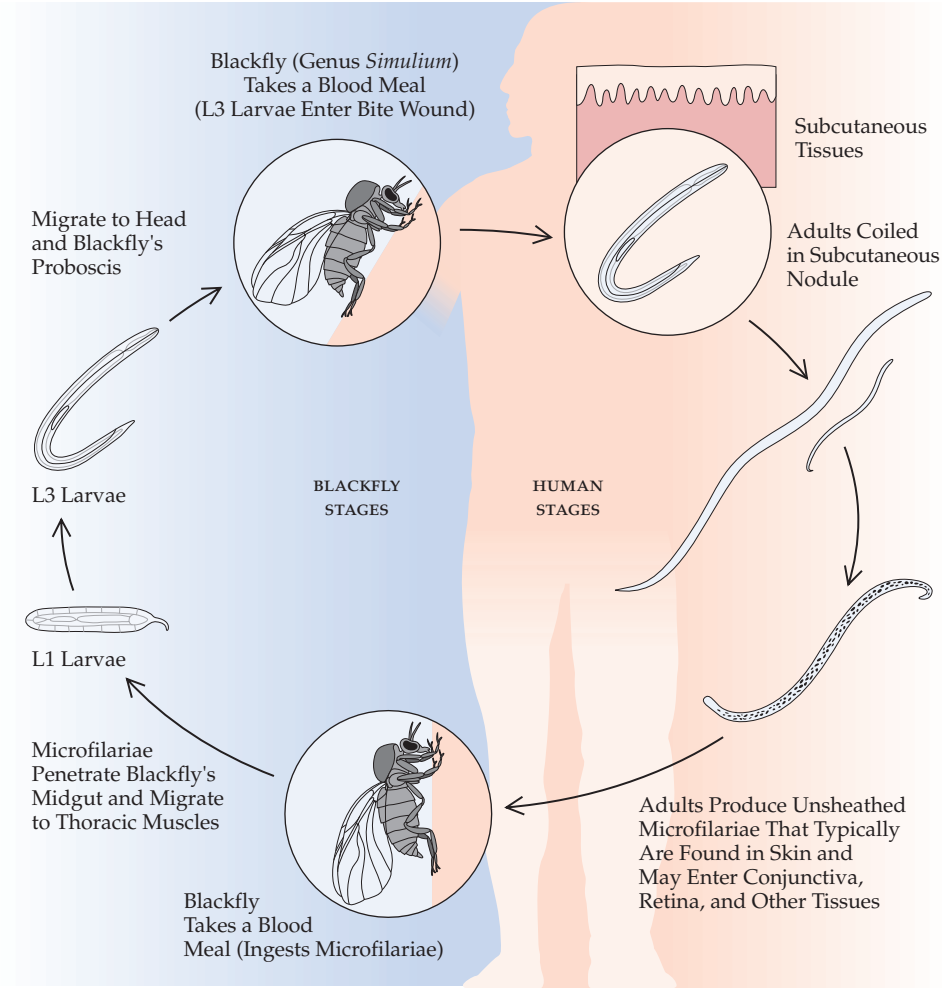

Figure 10 **Life cycle of *Onchocerca volvulus*, which causes river blindness and severe skin disease.**

life cycle of *O. volvulus* is similar to that of species causing lymphatic filariasis [*see Figure 10*]. Adult worms, however, reside in subcutaneous tissues, often enclosed in fibrous nodules. Microfilariae, which in this species lack an enveloping sheath, are released from female adults and localize in skin and subcutaneous tissues. Symbiotic endobacteria (of the genus *Wolbachia*) in filaria may cause some of the inflammatory damage of onchocerciasis.

Clinical features The skin is frequently involved in onchocerciasis, and pruritus is the most common clinical manifestation. With time, such complications as wrinkling, loss of elastic tissue, hypopigmentation or hyperpigmentation, papulovesicular lesions, and localized areas of eczematoid dermatitis may develop. Firm, nontender nodules containing adult worms surrounded by fibrous tissue are often palpable in subcutaneous tissues. In Central America, nodules commonly occur on the head; in Africa, nodules are more common over bony prominences of the body. Regional lymphadenopathy also develops.

Ocular involvement is characteristic of onchocerciasis and may result in blindness. Conjunctivitis with photophobia is common. Punctate keratitis, which is caused by the accumulation of inflammatory cells around dying microfilariae, may develop within the cornea and usually resolves without consequence. However, sclerosing keratitis and chorioretinal lesions may ensue and are the major causes of onchocercal blindness. Anterior uveitis, iridocyclitis, and, less frequently, optic nerve lesions may develop as well.

Laboratory findings The principal method of diagnosis involves finding microfilariae in the skin. A small piece of superficial skin obtained by excision or punch biopsy is weighed and then incubated for several hours in saline or tissue culture media. Microfilariae that exit the skin sample are then counted in the fluid. Care should be taken not to contaminate the skin with blood that might harbor microfilariae of other species. Skin snip sites can include scapular and gluteal areas and, in Africa, leg areas. A count of more than 100 microfilariae/mg of skin indicates a heavy infection.

Another diagnostic method involves administering a 50 mg provocative dose of diethylcarbamazine; the subsequent onset of symptoms, which may include pruritus, rash, fever, and conjunctivitis, constitutes the Mazzotti reaction, which strongly suggests a diagnosis of onchocerciasis. Caution must be exercised in the use of this test because heavily infected patients may experience serious adverse reactions.

Eosinophilia is often prominent during onchocerciasis. Serology can be helpful when parasite demonstration is difficult.

Treatment Therapy for onchocerciasis improved dramatically with the introduction of ivermectin. Single-dose ivermectin therapy is free of most of the immediate cutaneous, ocular, and systemic reactions that complicated therapy with diethylcarbamazine, the agent previously used to treat onchocerciasis. Ivermectin, given orally in a single dose of 150 μg/kg, leads to symptomatic improvement and clearance of microfilariae from the

skin. This dose is repeated every 3 to 12 months for 3 to 4 years.[19] Albendazole combined with ivermectin only transiently halts production of microfilaria, but doxycycline (200 mg daily for 4 to 6 weeks) interrupts microfilaria production for 18 to 24 months.[54] Doxycycline may act by depleting adult filaria of *Wolbachia* endosymbiont bacteria, which correlates with an interruption of embryogenesis.

Loiasis

Loiasis, which is caused by the filarial nematode *Loa loa,* occurs in the rainforest areas of central and western Africa and is transmitted by *Chrysops* species of horseflies and deerflies. Adult worms reside in subcutaneous tissues (the life cycle of *Loa loa* is illustrated in the CDC PHIL [http://phil.cdc.gov/Phil]; photograph 3399). The microfilariae, which are sheathed, circulate in the bloodstream with a diurnal periodicity in which peak levels are reached at about noon.

Many residents of endemic areas who have loiasis have asymptomatic microfilaremia. The prominent clinical presentations are related to migrations of adult worms. In the subcutaneous tissues, migrations may produce recurrent lesions termed Calabar swellings, which are erythematous areas of swelling and edema up to 10 cm in diameter that resolve after 1 to 3 days. Infection may also present dramatically when the worm migrates subconjunctivally across the eye.

In contrast, patients who acquire loiasis after brief stays in central and West Africa exhibit different clinical and immunologic responses.[55,56] They are usually free of detectable microfilaremia but may experience more severe and pruritic episodes of angioedema and have brisk immunologic responses, including elevated antifilarial antibody titers, an elevated serum IgE level, and prominent eosinophilia—often greater than 3,000 eosinophils/μl.

Parasitologic diagnosis of loiasis is made by demonstrating adult worms in subconjunctival or subcutaneous tissues or demonstrating microfilariae in the blood by means of a Nuclepore filter concentration technique. In contrast to *Wucheria* microfilaremia, *Loa loa* microfilaremia is found throughout the day. Microfilaremia may not be detectable, however. Eosinophilia may be marked, with elevations of 50% or greater. Filarial antibody titers are usually elevated. In the absence of detectable microfilaremia, the diagnosis is suggested by clinical features, a history of exposure, and eosinophilia.

Therapy consists of diethylcarbamazine (6 mg/kg/day) orally for 3 weeks and may require adjunctive antihistamines or corticosteroids.[19] Patients with microfilaremia should be treated initially with escalating doses of diethylcarbamazine for 3 days (one 50 mg dose on the first day, three 50 mg doses on the second day, and three 100 mg doses on the third day), followed by the full 3-week course. Albendazole therapy is useful to reduce microfilaremia in patients who cannot tolerate diethylcarbamazine. Some patients require repeated courses of therapy.[57]

Side effects are usually mild and include frequent occurrences of pruritus and the development of subcutaneous nodules soon after initiation of therapy. Patients with severe microfilaremia (> 50,000 microfilariae/ml) have developed fatal encephalopathy after diethylcarbamazine or ivermectin therapy. Diethylcarbamazine, given in a dosage of 300 mg orally once a week, is an effective chemoprophylactic agent against loiasis for persons who are planning long-term visits to areas of Africa where this infection is endemic.[58]

Zoonotic Filarial Infections

Although no human filarial parasites are indigenous to the continental United States, a variety of filarial parasites infect animals. In rare cases, these organisms may be transmitted via insect vectors to humans. Within the human host, they may develop into adult worms, which localize in the same organs in humans as in the definitive animal hosts. In this way, dog heartworm (*Dirofilaria immitis*), endemic in dogs along the Atlantic and Gulf coasts, in the Mississippi Valley, and in California, localizes to the human pulmonary arteries. A granulomatous response develops around the worm, producing a pulmonary nodule. Some patients experience chest discomfort, malaise, low-grade fever, cough, and, occasionally, hemoptysis. Typically, however, the pulmonary lesions are detected as a coin lesion on a chest x-ray.[59] Prominent blood eosinophilia is absent, and serologic tests for filariasis are negative. In the absence of reliable diagnostic tests for human pulmonary dirofilariasis, excisional biopsy serves both diagnostic and therapeutic purposes.

Other zoonotic filarial parasites include *D. repens,* which causes subcutaneous abscesses, and *B. beaveri,* which produces focal lymphadenopathy. No chemotherapy is required for these infections or for infections caused by *D. immitis*. Generalized lymphedema has developed in one immunodeficient child with a zoonotic *Brugia* infection.[60]

Trematode Infections

SCHISTOSOMIASIS

Schistosomiasis, a chronic trematode (fluke) infection of humans, constitutes a major worldwide health problem: 200 million persons are infected, 120 million are symptomatic, and 10 million have severe disease.[61] Three major species—*Schistosoma mansoni, S. japonicum,* and *S. haematobium*—infect humans. *S. mansoni* is found in Africa, the Arabian Peninsula, South America, and parts of the Caribbean; *S. japonicum* is found in Japan, China, and the Philippines; and *S. haematobium* is found in Africa and the Middle East. Two minor species, *S. mekongi* and *S. intercalatum,* are found in mainland Indochina and central West Africa, respectively. Transmission of schistosomiasis cannot occur in the United States because of the absence of the specific freshwater snail that is a requisite intermediary host [*see Figure 11*]. However, the disease may be encountered in immigrants or travelers from endemic areas.[62,63]

Diagnosis

The diagnosis of schistosomiasis is suggested by a history of possible exposure, even exposure that occurred many years ago, along with compatible gastrointestinal or urinary tract symptoms, hepatosplenomegaly, eosinophilia, or a combination of these findings.

Clinical features Three stages of disease may occur in schistosomiasis. The first stage, schistosomal dermatitis, may develop acutely within a day of cercarial penetration of the skin. Because this entity develops early after exposure, it usually will have subsided in patients before they are seen by physicians in the continental United States. Swimmer's itch, a similar reaction caused by exposure to animal schistosomes in freshwater and saltwater, is seen in the United States [*see Figure 12*].[64] The schistosomes penetrate human skin and then die, causing no further infection.

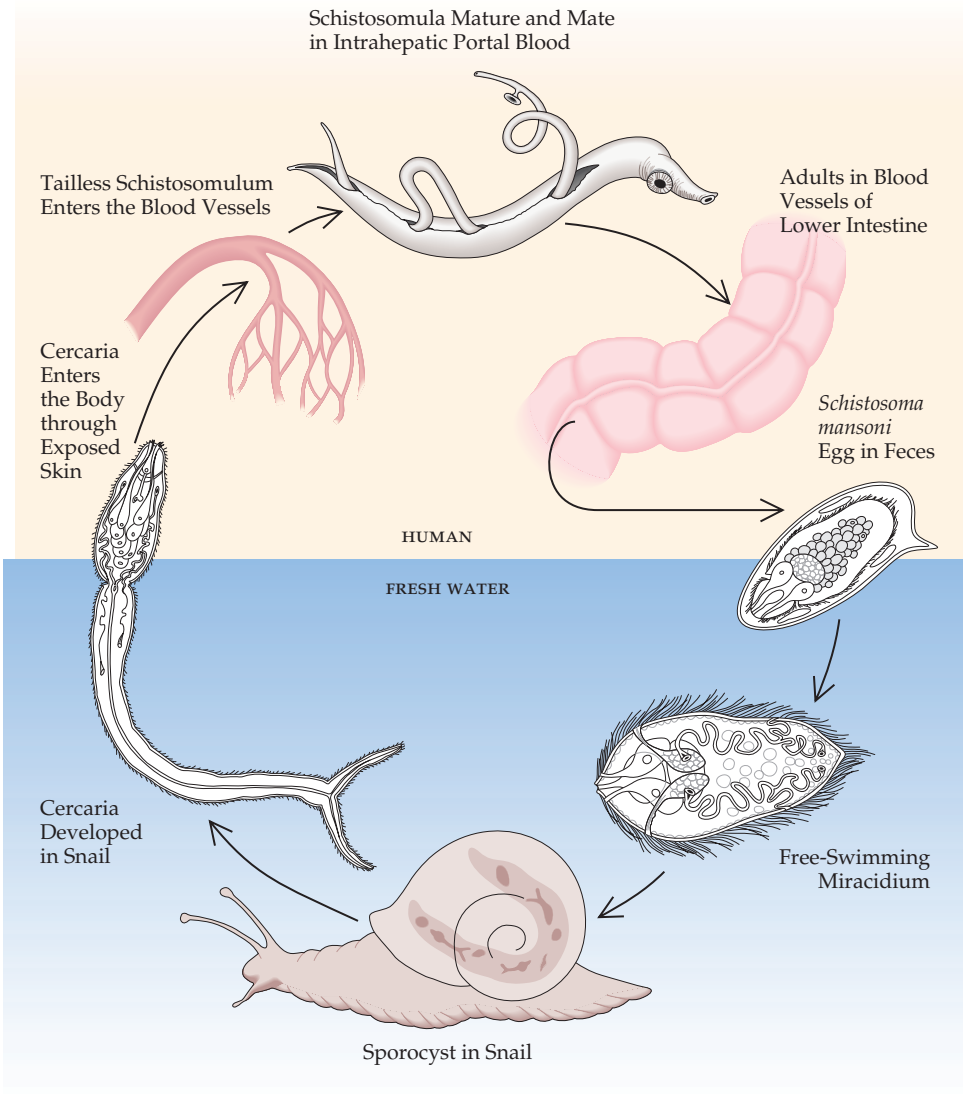

Figure 11 **Freshwater snails and the human body provide the living environment of the schistosomes *Schistosoma mansoni, S. japonicum, S. haematobium, S. mekongi*, and *S. intercalatum*. Eggs of each species hatch into schistosomal miracidia, which enter snails. Free-swimming cercariae released by the snails rapidly penetrate human skin and become tailless schistosomula, which enter the blood vessels. The schistosomula mature in the intrahepatic portal blood, form male-female pairs, and begin to mate. The pairs, still copulating, migrate to various sites: *S. mansoni, S. intercalatum*, and *S. mekongi* ultimately lodge in the blood vessels of the lower intestine; *S. japonicum* lodges in blood vessels throughout the intestine; and *S. haematobium* settles in blood vessels around the bladder. Adult worms subsequently begin laying eggs in the wall of the urinary bladder or intestine. From the intestinal sites, the eggs may be transported in the portal circulation to the liver, or they may be excreted in the feces. *S. hematobium*, by contrast, is excreted in the urine and does not tend to lead to liver disease but rather causes local bladder damage.**

The second stage of disease, acute schistosomiasis, or Katayama fever, develops 4 to 8 weeks after heavy (presumably, primary) infection. This stage is thought to be caused by a severe allergic response at the onset of egg-laying by the schistosomes. Patients have fever, cough (up to 10% also have pulmonary nodules), hepatosplenomegaly, malaise, myalgias, urticaria, and eosinophilia.[65-67] Deaths have ensued. Katayama fever is more severe in infection with *S. japonicum* than with other species, because of the high quantities of eggs produced by *S. japonicum.*

Chronic schistosomiasis, the third stage, is caused by the heavy deposition of eggs in the intestine or bladder and in the liver. In *S. haematobium* infection, the principal symptoms are hematuria, dysuria, and frequent urination. Hydronephrosis and pyelonephritis may develop as a result of fibrosis and infection. In *S. mansoni, S. mekongi,* or *S. japonicum* infection, manifestations may include fever, malaise, abdominal pain, diarrhea, blood in stools, and hepatosplenomegaly. Presinusoidal hepatic trapping of *S. mansoni, S. mekongi,* or *S. japonicum* eggs and the consequent granulomatous reaction induce portal hypertension and collateral esophageal varices. Eggs may then be shunted from the liver to the lung, with the possible sequela of pulmonary hypertension. Death may occur as a result of variceal bleeding. Hepatic encephalopathy rarely develops because the hepatic parenchyma is spared. Coinfection with *S. mansoni* and hepatitis B or C virus is associated with accelerated clinical deterioration.[61] Less common sequelae of chronic schistosomiasis include intestinal polyps, bladder carcinoma, and persistent *Salmonella* infections. An uncommon sequela of both acute and chronic schistosomiasis is focal neurologic dysfunction from aberrant localization of eggs in CNS tissue. Embolic deposition of *S. japonicum* eggs may produce cerebral granulomas, whereas *S. haematobium* and *S. mansoni* eggs may cause transverse myelitis involving the midthoracic or lumbar spinal cord.[68,69]

Laboratory findings and imaging studies Computed tomography, magnetic resonance imaging, or ultrasonography may detect hepatic periportal fibrosis and calcification, colonic wall calcifications, and changes in the bladder and ureter resulting from schistosomiasis. Serologic tests can help confirm the diagnosis; an indirect immunofluorescent test for gut-associated schistosome antigens is especially sensitive for the detection of acute schistosomiasis. Stool examination should include a search for eggs of all *Schistosoma* species [*see Figure 13*]. Urine specimens for detection of *S. haematobium* should be obtained between 10 A.M. and 2 P.M. If stool and urine specimens are negative, microscopic examination of biopsy specimens of rectal or bladder

Figure 12 **Swimmer's itch is a cutaneous reaction caused by exposure to animal schistosomes in freshwater and saltwater. The schistosomes penetrate the skin and then die, causing no further infection.**

mucosa may demonstrate eggs of all species. Detection of circulating antigens from adult worms and eggs are promising techniques that may supersede traditional egg demonstration.

Treatment

Praziquantel is used to treat infection caused by any of the five *Schistosoma* species; it reliably cures 60% to 90% of infected persons and reduces egg burden substantially in most others. For *S. haematobium* and *S. mansoni,* two oral doses of 20 mg/kg are given in 1 day. For *S. japonicum* and *S. mekongi,* the dosage is 20 mg/kg given orally three times in 1 day. The efficacy, the paucity of side effects, and the convenience of single-day therapy make praziquantel the drug of choice for all forms of schistosomiasis.[19] Resistance to praziquantel has been reported in *S. hematobium* and *S. mansoni* infections in Egypt and Kenya but has not yet become a widespread problem.[61] In addition to praziquantel, corticosteroids are beneficial for patients with spinal cord schistosomiasis[59] and acute schistosomiasis.

PARAGONIMIASIS

Humans acquire paragonimiasis after consumption of raw, salted, or wine-soaked crustacea (freshwater crabs or crayfish) infested with the metacercarial stage of lung flukes belonging to the genus *Paragonimus* (the life cycle of *Paragonimus* is illustrated in the CDC PHIL [http://phil.cdc.gov/Phil]; photograph 3415). It is estimated that 20 million people are infected with *Paragonimus* species.[70] *P. westermani* is endemic in parts of China, Korea, Japan, the Philippines, and Taiwan. Other *Paragonimus* species infect humans in western Africa and Central and South America. Although paragonimiasis is rare in the United States, it has developed in persons in Missouri from indigenous *Paragonimus* species.[71]

Ingested metacercariae undergo excystation in the duodenum and migrate through the wall of the gut into the peritoneal cavi-

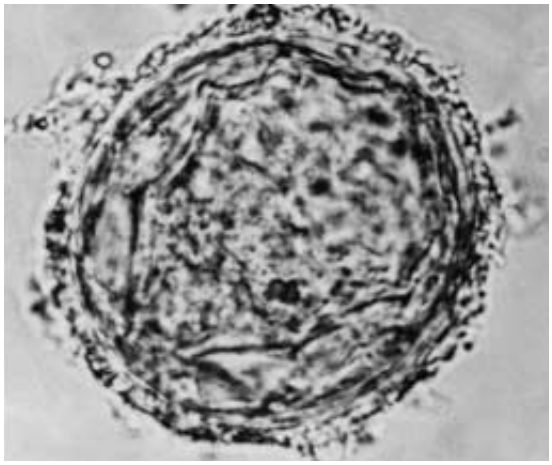

Figure 13 **Eggs of *S. japonicum* (*a*), *S. haematobium* (*b*), or *S. mansoni* (*c*) detected by microscopic examination of the stool, urine, or rectal mucosa biopsy specimens confirm the diagnosis of schistosomiasis. The magnification is about 400 times. (*d*) This *S. mekongi* egg was found in the stool of a Laotian refugee in the United States. The magnification is about 1,000 times.**

ty. Most pass through the diaphragm and penetrate the parenchyma of the lung. Neutrophilic and eosinophilic reactions, followed by a mononuclear leukocytic inflammatory reaction, develop around the fluke. As the lung parenchyma necrotizes, a fibrous capsule begins to surround the fluke. By about 5 to 6 weeks after ingestion, the flukes have matured and start laying eggs, which causes the capsule to enlarge and rupture, often into a bronchiole. The most common presentation of paragonimiasis is the production of brown-tinged sputum or hemoptysis, which derives from the admixture of eggs, inflammatory cells, and blood in the sputum. Sputum is often gelatinous and purulent as well as bloody. Patients usually appear well but may have a chronic cough, pleuritic pain, or night sweats.

Young flukes may migrate to nonpulmonary sites. Localization in the CNS produces signs and symptoms from a cerebral or spinal inflammatory mass lesion, which may calcify.[72] Less commonly, the parasites lodge in cutaneous or peritoneal sites.

During the early stages of infection, when the larvae migrate, blood eosinophilia is prominent. The chest x-ray may show transient, often basilar, infiltrations, as in Löffler syndrome. Later in the course of the disease, blood eosinophilia commonly disappears, and the chest x-ray may show areas of cavitation; ill-defined, so-called cotton-wool and streaky densities; and bubble-like cavities.[73] Pleural reaction, with or without pleural effusion or pneumothorax, can occur.

The diagnosis of paragonimiasis should be considered for patients from endemic areas with compatible clinical presentations.[74] Examination of the sputum for ova may confirm the diagnosis by revealing the operculated eggs of *Paragonimus*. Swallowed eggs appear in the stool; therefore, examining the stool for eggs may be helpful, especially in children. Fine-needle aspiration of pulmonary lesions also yields diagnostic eggs.[75] Paragonimiasis may resemble pulmonary tuberculosis both clinically and radiographically, yet *Paragonimus* eggs are usually not seen in acid-fast stains. Serologic tests are available.[70]

Praziquantel is an effective treatment of paragonimiasis, although its use remains investigational. The dosage is 25 mg/kg orally three times a day for 2 days.[19] Bithionol is somewhat effective, but its use is limited because of side effects such as diarrhea. Triclabendazole has been used and has been reported to cure cases in which praziquantel and bithionol had failed.[70]

CLONORCHIASIS

Clonorchis sinensis, the Chinese liver fluke, infects approximately seven million persons in the Far East, including South China, Hong Kong, Taiwan, Japan, Korea, and Vietnam.[76] Humans become infected with *C. sinensis,* a parasite of freshwater fish, by eating raw or undercooked fish containing encysted metacercariae (the life cycle of *C. sinensis* is illustrated in the CDC PHIL [http://phil.cdc.gov/Phil]; photograph 3385). Larvae, liberated by trypsin in the duodenum, migrate to the common bile duct and then to the distal biliary tree. There they mature into adult worms, which may persist for more than 20 years. Less commonly, adult worms are found in the gallbladder and pancreatic ducts.

In the acute phase of the infection, the epithelium of the biliary tree undergoes early desquamation, which is followed by hyperplasia and increased mucin production by the epithelial cells. The hyperplasia may progress to adenomatous changes. With chronic infection, fibrosis develops around dilated bile ducts. Clinically, the syndrome of acute clonorchiasis, manifested by fever, chills, and tender hepatomegaly, may develop 1 week after ingestion of infected fish. Later in the course of the infection, however, most patients with light infection and many with heavy infection are asymptomatic.[77] Occasionally, adult worms block pancreatic ducts, causing pancreatitis. By occluding the biliary tract, worms may contribute to acute suppurative cholangitis. Clonorchiasis predisposes to intrahepatic bile duct stone formation and to recurrent pyogenic cholangitis; infection with *C. sinensis* has been associated with cholangiocarcinoma.[78]

Leukocytosis, prominent eosinophilia, and elevation of alkaline phosphatase levels occur in symptomatic acute clonorchiasis. Sonography often detects diffuse dilatation of small intrahepatic bile ducts without dilatation of large intrahepatic or extrahepatic ducts. Adult flukes may be visualized in the gallbladder by ultrasonography and in the bile ducts by cholangiography.[79] In asymptomatic chronic clonorchiasis, eosinophilia is not present, and liver function tests and liver scans are normal. Egg laying begins within 2 to 3 weeks after infection; eggs may be found either in the stool or in duodenal aspirate. Diagnostic serologic tests are neither sensitive nor specific. The diagnosis should be considered in patients who have a history of travel or residence in the Far East, have eaten undercooked fish, and have a compatible clinical syndrome.

Praziquantel, which is considered investigational for clonorchiasis, constitutes effective and well-tolerated therapy for this disease. Praziquantel is administered at a dosage of 25 mg/kg orally three times a day for 1 day.[19] An alternative investigative therapy is albendazole, 10 mg/kg/day for 7 days.[19] Initially, complications of *C. sinensis* infection, including calculi, cholangitis, and pancreatitis, are managed medically, although surgical drainage may be required.

OPISTHORCHIASIS

Opisthorchiasis represents infection by either *Opisthorchis felineus* or *O. viverrini. O. felineus* infects 1.5 million persons in Kazakhstan, the Ukraine, central Europe, western Siberia, and parts of Asia; *O. viverrini* infects nine million persons in Thailand, Laos, and Cambodia.

Cats and wild carnivores are the definitive hosts of these species. Humans acquire infection by eating raw or undercooked fish that contains metacercariae of the parasite. Metacercariae undergo excystation in the duodenum and migrate into the bile ducts, where they mature.

Clinical features of opisthorchiasis are similar to those of clonorchiasis; complications include the development of cholangiocarcinomas.[77,78,80] The diagnosis is made by finding eggs in feces or in duodenal aspirate.

Therapy, which is considered investigational by the FDA, consists of praziquantel (25 mg/kg orally three times in 1 day).[19] Complications involving biliary tract sepsis require the administration of antibacterial agents.

FASCIOLIASIS

Fasciola hepatica, the liver fluke of sheep and cattle, is a major veterinary problem and can give rise to human fascioliasis.[78,81,82] Human infection with *F. hepatica* shows a wide geographic distribution that includes Europe, China, Africa, and Latin America; the disease is considered a public health problem in the Andean countries of South America, Iran, and western Europe.[82] Despite the prevalence of the parasite in sheep and cattle of the southern and western United States, autochthonous human cases are rare. Humans generally become infected by ingesting parasitic cysts attached to aquatic plants, most notably wild watercress.

Ingested metacercariae burrow through the intestinal wall into the peritoneal cavity and then penetrate the hepatic capsule and parenchyma; they then enter the bile ducts, where they mature into adults after 3 to 4 months. Acute fascioliasis runs its course during the months of penetration and maturation. Symptoms may be minimal or include fever, upper abdominal pain, hepatomegaly, and malaise. Pruritus, urticaria, jaundice, nonproductive coughing, and anemia occur less often.[78,83]

After the flukes mature in the biliary passages, hyperplasia and dilatation of the biliary ducts, as well as periductal fibrosis, develop. Clinical manifestations in the chronic stage of infection are variable and may include the same signs and symptoms experienced in the acute phase. Obstruction of the biliary tract, cholecystitis, and biliary cirrhosis are uncommon. In rare instances, flukes migrate to other tissues, including the lungs, muscles, and CNS.

Ingestion of raw sheep or goat liver containing young flukes produces halzoun, a disease recognized in the Near East. Lodging of the flukes in the pharynx produces a pharyngeal inflammatory mass lesion with attendant dysphagia and dyspnea.

Acute fascioliasis usually produces leukocytosis, marked eosinophilia, and cholestatic-type abnormalities on liver function testing. Eggs are not found until approximately 3 months after infection, when they may be detected in the stool or, with a higher yield, in biliary or duodenal fluid samples. Thus, the triad of fever, marked eosinophilia, and hepatomegaly suggests acute fascioliasis. A history of ingestion of potentially infected watercress supports the diagnosis. Serologic tests are available but may reflect cross-reactions with other helminthic parasites. Nodular hepatic lesions with diminished density may be visualized by CT or MRI.[84,85] In chronic fascioliasis, the extent of the abnormalities in liver function tests and cholangiograms correlates with the magnitude of biliary tract obstruction and hepatocellular damage.

Triclabendazole, given in a single oral dose of 10 mg/kg, is the drug of choice for fascioliasis, but in the United States it is available only from the manufacturer (Novartis). Bithionol (30 to 50 mg/kg on alternate days for 10 to 15 doses) and nitazoxamide (500 mg p.o., b.i.d. for 3 days) are alternatives.[19] Praziquantel is not effective for fascioliasis.

INTESTINAL FLUKES

Fasciolopsiasis

Fasciolopsiasis results from infection with the intestinal fluke *Fasciolopsis buski,* which is found in many parts of Asia.[86] This fluke principally parasitizes the intestine of the pig. Human infection is acquired by ingestion of water plants such as water chestnuts, which bear metacercariae of the parasite. The larvae undergo excystation in the duodenum and develop into large adult flukes, up to 7 cm long, that attach to the mucosa of the proximal small intestine. Inflammation and ulceration may occur at these intestinal sites. Light infection is asymptomatic; heavy infection is associated with abdominal pain, ulceration, hemorrhage, intestinal obstruction, malabsorption, and facial and generalized edema.[87] Blood eosinophilia is common. Diagnosis is made by finding adult flukes or, more commonly, by finding in feces the eggs of *F. buski,* which are difficult to distinguish from the eggs of *Fasciola hepatica*. Fasciolopsiasis is treated, on an investigational basis, with praziquantel, 25 mg/kg orally three times in 1 day,[10] although some sources advise that a single 15 mg/kg dose is effective.[86]

Other Intestinal Flukes

Infection with two small intestinal flukes, *Metagonimus yokogawai* (found in the Far East and Indonesia) and *Heterophyes heterophyes* (found in Tunisia, Egypt, and the Far East), occurs when humans ingest raw or undercooked fish that contains metacercariae of the parasites. The adult flukes are 2 to 3 cm long and attach to the mucosa of the small intestine. Heavy infection may cause abdominal pain and diarrhea.[88] Diagnosis is made by finding eggs, which resemble the eggs of *Clonorchis* species, in feces. Therapy consists of the investigational drug praziquantel (25 mg/kg orally three times in 1 day).[19]

Human infection with the intestinal fluke *Metorchis conjunctus,* acquired near Montreal, Canada, by consumption of the white sucker fish, has been described. Illness consisted of upper abdominal pain, low-grade fever, eosinophilia, and elevated liver enzyme levels. Diagnosis was made by finding eggs in the stool and by serology. Praziquantel (25 mg/kg three times in 1 day) is beneficial.[19,89]

The intestinal fluke *Nanophyetus salmonicola* has been recognized in humans who ate raw or kippered salmon. In most patients, symptoms and infection resolved without therapy, although treatment can be provided with praziquantel (20 mg/kg given three times in 1 day).[19,90]

Cestode Infections

Humans can harbor the adult form of fish, pork, and beef tapeworms (cestodes). These often do not cause disease but are noticed when segments of the worm are passed. Most often, these segments can be distinguished from other worms by their flat, tapelike appearance and their segmented proglottids. Examination of these proglottids or the head of the tapeworm can differentiate these three species. In general, larval forms of tapeworms, such as cysticercus (pork) and *Echinococcus* (dog), cause more severe disease by mass effect and inflammation.

FISH TAPEWORM

Humans acquire fish tapeworm infection by ingestion of inadequately cooked fish containing the infective plerocercoid stage of parasitic *Diphyllobothrium* species, including *D. latum* (the life cycle of *D. latum* is illustrated in the CDC PHIL [http://phil.cdc.gov/Phil]; photograph 5257).[91-93] The growing popularity of raw fish dishes, such as sushi, sashimi, seviche, and Dutch green herring, has increased the risk of acquiring diphyllobothriasis. Freshwater fish, including pike and yellow perch caught in the United States, may harbor *Diphyllobothrium* species, as may anadromous salmon. *Diphyllobothrium* species other than *D. latum* are found in Pacific salmon and Alaskan blackfish.[94] Adult tapeworms may grow up to 15 meters in length and live for 20 years or longer in the small intestine. Human infections are often asymptomatic, although some patients experience anorexia, nausea, or weight loss. Because *D. latum* competes with the host for vitamin B_{12}, megaloblastic anemia and neuropathy from vitamin B_{12} deficiency may develop. Diagnosis is made by finding the operculated eggs in the stool or by recovering proglottids in the stool after a saline purge. Therapy is with praziquantel (5 to 10 mg/kg, given once), which is investigational for this use.[19] An alternative is niclosamide, in a single oral dose of 2 g; however, this drug may be difficult to obtain in the United States and may be available only from compounding pharmacies.

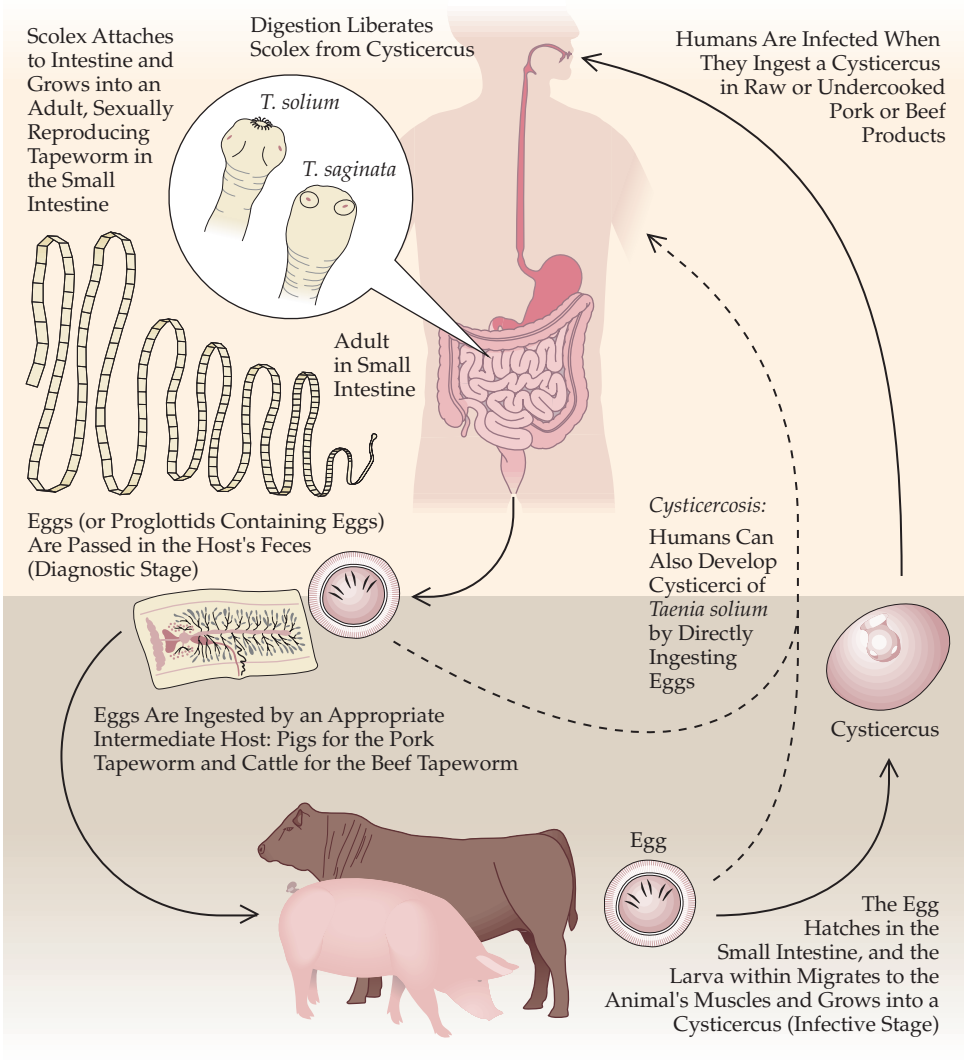

Figure 14 **Life cycle of *Taenia solium*, the pork tapeworm, which causes cysticercosis, and of *T. saginata*, the beef tapeworm.**

PORK TAPEWORM

Taenia solium, or pork tapeworm, causes two distinct types of disease, depending on the stage of the parasite that is ingested [*see Figure 14*].[95] If cysticerci in inadequately cooked pork are ingested, the adult tapeworm develops in the intestine, causing symptoms such as abdominal pain, weight loss, and weakness. Patients may describe passing proglottid segments of the worm. Eggs of *T. solium* are also passed in the feces. Eggs can be detected with greater frequency by applying clear cellulose acetate tape to the perianal skin and examining the tape, as described for pinworm [*see* Intestinal Nematode Infections, *above*]. *T. solium* eggs are indistinguishable from eggs of *T. saginata* (beef tapeworm); diagnostic differentiation between the two species requires recovery of mature proglottids or the head (scolex) from the stool [*see Figure 15*]. Therapy for adults infected with intestinal pork tapeworm consists of praziquantel (5 to 10 mg/kg, given once).[19] Some authorities suggest using niclosamide (2 g in a single oral dose) because it is not absorbed and will not cause neurologic symptoms in patients with asymptomatic neurocysticercosis cysts; however, this drug may be difficult to obtain in the United States and may be available only from compounding pharmacies.[95]

Cysticercosis, the second disease entity, is caused by the ingestion of *T. solium* eggs. In an uninfected person, such ingestion may occur by consumption of food contaminated by egg-containing feces from an infected person. In persons with an intestinal worm, ingestion may occur by autoinfection involving hand-to-mouth fecal carriage or by regurgitation of egg-laden proglottids into the duodenum or stomach. Most infections are encountered in developing countries, where intestinal *T. solium* infections occur frequently. Experience in the United States has

Figure 15 **Hooklets on the scolex (head) of *Taenia solium* give it an "armed" appearance.**

demonstrated, however, that cysticercosis may develop in those who have never traveled abroad, through transmission of infectious eggs from family members, domestic workers, or others infected with *T. solium*.[96-98]

The ingested eggs hatch in the stomach and upper intestine, and the resultant oncospheres circulate in the blood to various tissues. Cysticerci develop most often in subcutaneous tissue, skeletal muscle, and the brain, as well as in other organs, including the eyes, heart, liver, and lungs. Developing cysticerci elicit little host reaction, but as the cysticerci begin to degenerate, usually after several years, inflammation develops. Ultimately, the cysts, which range from 0.5 to about 2.0 cm in diameter, undergo necrosis and may become calcified.

Diagnosis

Clinical features Clinical signs and symptoms depend on the organ compromised by the cysticerci, the specific localization of a cysticercus within the organ, the state of inflammation surrounding the cysticerci, and the viability of the cestode. The most serious forms of cysticercosis are those with ocular, cardiac, and neurologic involvement. The manifestations of neurocysticercosis, which can be quite varied, depending on the site of lesions and the evolution of inflammatory reactions, include seizure disorders and focal deficits, hydrocephalus, arachnoiditis, and intracranial hypertension.[95] In endemic regions, cysticercosis is the most common cause of late-onset seizure disorders.[99]

Laboratory findings and imaging studies The use of CT and MRI has facilitated the recognition of CNS cysticercosis,[94,100,101] has helped delineate the various forms of neurocysticercosis,[83] and has provided a means for assessing the adequacy of therapy.[100,102] CNS imaging studies may reveal cysticerci in the brain parenchyma, within the ventricles, at the surface or the base of the brain, or within the subarachnoid space.

CT may miss early lesions, which have the same x-ray density as the brain, but hypodensity and contrast-enhancing ring lesions are seen with the development of inflammation around the cyst. As sclerosis occurs, a cystic lesion develops, and the cyst wall may calcify. Ultimately, degenerated cysts are replaced by small (1 to 4 mm in diameter) calcified lesions within the brain [*see Figure 16*].

The diagnosis of cysticercosis can be made with certainty only by biopsy of a cyst. Calcified cysts in subcutaneous tissue and muscle, which have a puffed-rice appearance on radiographs, should be sought. Although the signs and symptoms of neurocysticercosis are not specific, this diagnosis is supported by the finding of characteristic multiple cystic or calcified lesions on CT scans in a patient from an endemic area.

A serologic test, which should be used to test serum and CSF for antibody to *T. solium,* is available through the CDC. ELISA testing for antibody, however, may be negative in about 20% of patients with cysticercosis[103] and may be falsely positive in those with echinococcosis. An enzyme-linked immunoelectrotransfer blot assay for antibody is highly sensitive in patients who have several enhancing intracranial lesions; it is less sensitive in those who have only one lesion or calcified lesions.[101,104] Stool examination for *Taenia* eggs may detect concurrent infection with the tapeworm but is not directly pertinent to the diagnosis of cysticercosis.

Treatment

Therapy for cysticercosis may be medical or surgical. Patients with only calcified soft tissue or CNS lesions do not require medical therapy. Surgical excision was once the only approach for viable cysts, but praziquantel and albendazole have proved to be effective against neurocysticercosis.[100,102,105] Despite the improvements noted after medical therapy, the absence of controlled trials specifically comparing medically treated patients with untreated patients has left room for uncertainty concerning the efficacy of medical therapy for neurocysticercosis.[102,106] However, a randomized trial has demonstrated a trend toward fewer seizures in patients treated with albendazole and steroids, as compared with those treated with placebo.[107]

Albendazole is given in a dosage of 400 mg orally twice daily for 10 to 28 days; praziquantel is given in a dosage of 50 to 100 mg/kg/day in three divided doses for 30 days.[19] Albendazole appears to be slightly more effective than praziquantel at killing cysticercosis cysts.[102] Because treatment may cause inflammatory reactions to develop around cysticerci, ocular cysticercosis and spinal cysticercosis are not usually treated medically; an ophthalmologic examination is indicated before drug therapy to rule out intraocular cysticercosis, which could lead to devastating inflammation. For patients with neurocysticercosis, corticosteroids (e.g., dexamethasone, 4 to 16 mg/day, or prednisone, 60 to 100 mg/day) are usually given 1 to 2 days before and during treatment with albendazole or praziquantel to minimize inflammatory reactions. Patients who are taking anticonvulsant medications for neurocysticercosis should continue to use them during this treatment, but many such patients can stop taking antiseizure medications after cysticercosis therapy.[107,108] CT scanning should be repeated 3 to 6 months after therapy, to determine whether any of the cysts are still viable; therapy should be repeated if viable cysts remain.

BEEF TAPEWORM

T. saginata, or beef tapeworm, causes an intestinal infection in persons who have eaten undercooked beef containing cysticerci.[93] The infection is usually asymptomatic, although abdominal pain, weight loss, increased appetite, or passage of lengths of proglottids may be noticed because proglottids of *T. saginata* tend to be more motile than those of the other tapeworms [*see Figure 17*]. As noted, the detection of eggs in the feces or on the perianal skin is diagnostic of tapeworm infection, but differentiation between *Taenia* species requires identification of the proglottids. Therapy consists of praziquantel or niclosamide, as given for *T. solium* intestinal infection.[19] Infection with *T. saginata* does not lead to cysticercosis in humans.

DWARF TAPEWORM

Hymenolepis nana, a tapeworm measuring 3 to 4 cm long and 1 mm wide, has a broad geographic distribution.[91] In the United States, it is most commonly encountered in persons living in the southern states, in institutionalized patients, and in children. Unlike the other tapeworms, the larval and adult stages of *H. nana* develop in the same host. Infection is spread by the fecal-oral route and occurs when eggs, which are immediately infectious, are ingested. Thus, *H. nana* is one of the few helminths (along with *Enterobius, Capillaria,* and *Strongyloides*) that can propagate by autoinfection; children, in particular, can develop huge worm burdens and become symptomatic.

After an egg of *H. nana* has been ingested, an oncosphere hatches from the egg and penetrates the intestinal villi, where it develops into a cerocyst; the cerocyst reenters the lumen of the small intestine and develops into an adult worm. Eggs are liberated from the distal segments of the adult worm, which lives for

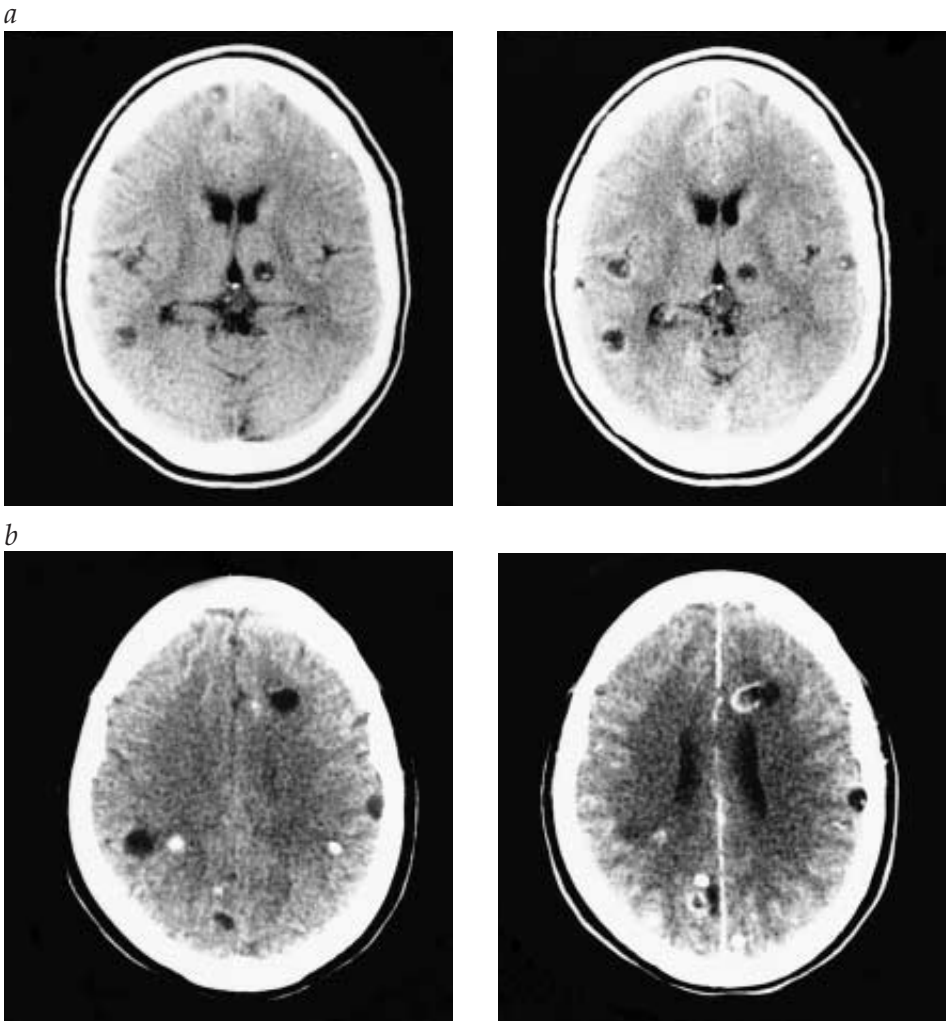

Figure 16 **Shown are CT scans of two patients (*a, b*) with seizures resulting from neurocysticercosis. The CT scans on the left are without contrast; those on the right are with contrast. Multiple cystic and calcified lesions are evident in both patients (the contrast agent enhances the cystic lesions). The scans from the first patient (*a*) show multiple cystic lesions, with a denser central spot that represents the scolex, a pathognomonic finding for neurocysticercosis.**

about 1 year. The eggs may cause internal reinfection. Light infection is usually asymptomatic; diarrhea and abdominal pain may accompany heavy infection. Diagnosis is made by finding eggs in feces. Therapy consists of praziquantel (25 mg/kg given once); this use of praziquantel is currently considered investigational. An alternative investigational therapy is nitazoxanide (500 mg p.o. daily for 3 days).

OTHER TAPEWORMS

Human infection with *H. diminuta,* a tapeworm of mice and rats, occasionally occurs when humans ingest insects that harbor developing cerocysts of the tapeworm; one such insect is the flea. Infection is more common in children and is associated with few or no symptoms. Diagnosis and treatment are the same as described for the dwarf tapeworm *H. nana* (see above).

Children are also more commonly infected with the dog tapeworm *Dipylidium caninum.* Infection is acquired by consuming infected fleas or lice. Adult worms develop in the small intestine and measure 15 to 70 cm in length. Mild intestinal symptoms may or may not be present. Diagnosis is made by finding

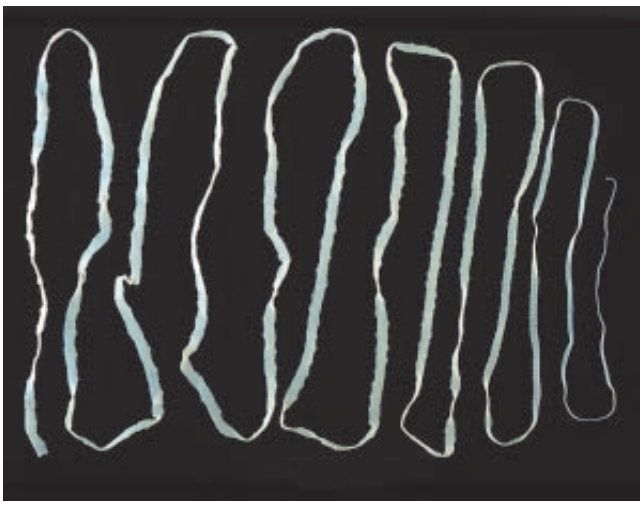

Figure 17 **Persons infected with the beef tapeworm, *Taenia saginata,* may pass lengths of proglottid in the stool. An entire adult beef tapeworm is shown.**

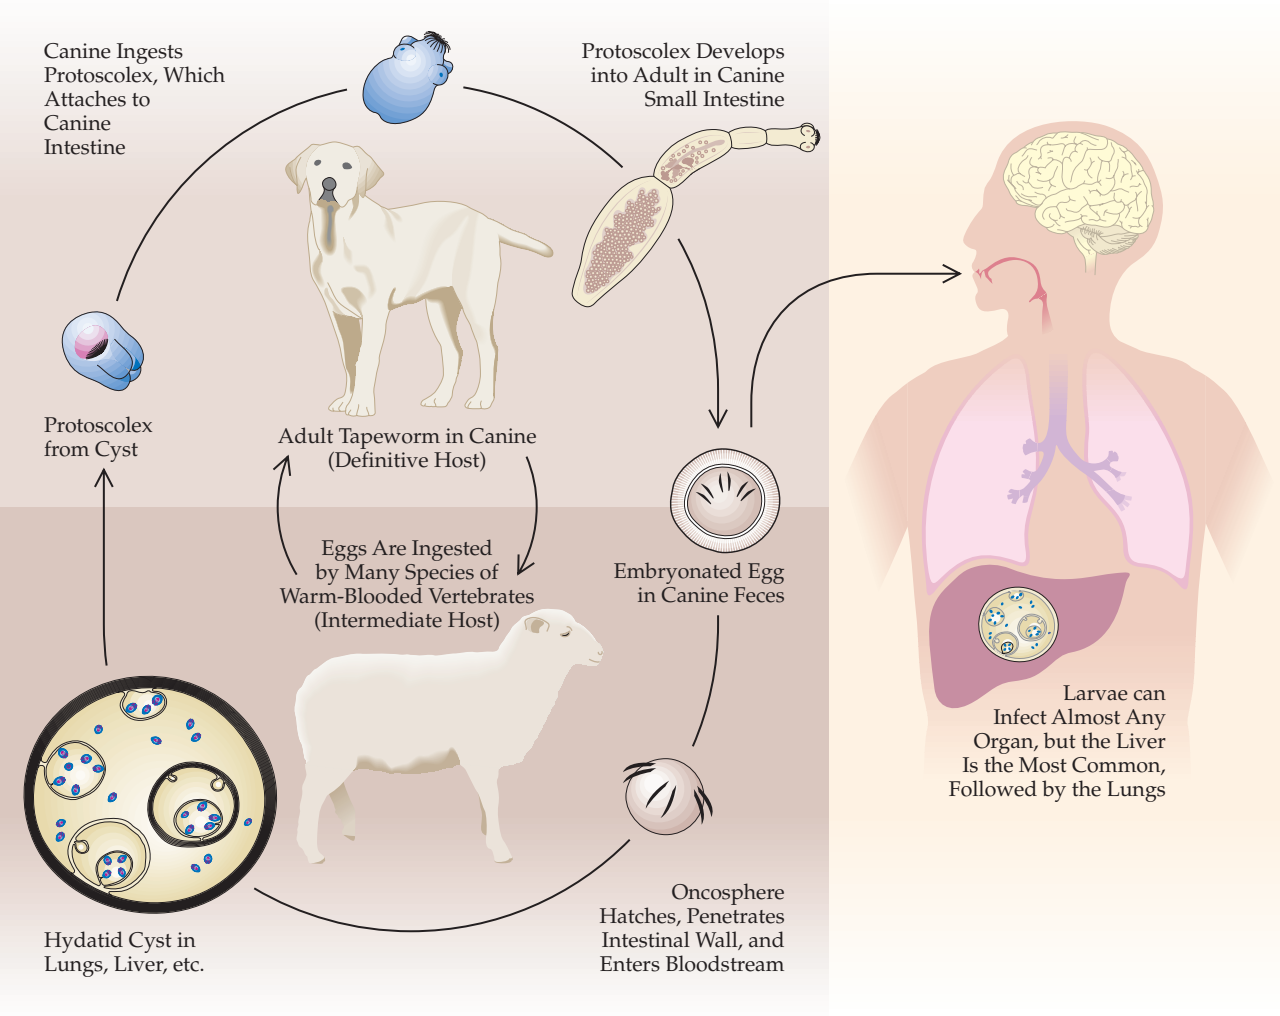

Figure 18 **Life cycle of *Echinococcus granulosus*. Adult *E. granulosus* cestodes live in the intestine of dogs and wolves. Infectious eggs are passed in the feces of these animals and may be ingested by intermediate hosts such as sheep, cattle, or humans. After the eggs are ingested, oncospheres are carried in the bloodstream to the liver, lungs, and other organs, where they form hydatid cysts. The cycle is maintained when dogs or wolves ingest the carcasses of intermediate hosts.**

proglottids or eggs in feces. Therapy for adults consists of praziquantel (5 to 10 mg/kg given once).[19]

Human infection with dog tapeworms of the genus *Multiceps* results in a syndrome termed coenurosis, which is similar to cysticercosis.[109] At present, surgical excision forms the basis of diagnosis and treatment.

Sparganosis represents infection by larval tapeworms of the genus *Spirometra,* which are closely related to tapeworms of the genus *Diphyllobothrium*. Most such infections occur in the Far East. Human infection results from drinking water containing microcrustacean *Cyclops* species that harbor procercoid larvae (spargana) of the parasite. Human infection may also be acquired by ingesting raw flesh of amphibians or snakes that contains larvae of the parasite or from applying such flesh to the skin as a poultice. After ingestion, the procercoid larvae migrate into subcutaneous tissues, where they usually present as a painless subcutaneous nodule that enlarges during the course of many months. Larvae may also migrate to the CNS.[110,111] Blood eosinophilia is commonly elicited. Surgical excision of larvae-containing nodules remains the basis of diagnosis and treatment.

HYDATID DISEASE

Echinococcosis in humans may result from infection with *Echinococcus granulosus,* which causes cystic hydatid disease; *E. multilocularis,* which causes alveolar hydatid disease; or *E. vogeli* or *E. oligarthus,* which causes polycystic hydatid disease and is found in areas of Central and South America.[93,112,113] Adult *E. granulosus* cestodes live in the intestine of dogs and wolves. Infectious eggs are passed in the feces of these animals and may be ingested by intermediate hosts such as sheep, cattle, or humans [*see Figure 18*]. The cycle is maintained when dogs or wolves ingest the carcasses of intermediate hosts. *E. granulosus* infection is most prevalent in sheep- and cattle-raising countries. It is also found in a number of western states, Alaska, and Canada, where autochthonous cases of human infection have been recorded.[114]

After the eggs are ingested, oncospheres are carried in the bloodstream to the liver, lungs, and other organs. Unilocular cysts, which may contain daughter cysts, develop most commonly in the liver; the second most common site is the lungs. In children, pulmonary involvement may be more common than hepatic involvement. Unilocular hydatid cysts enlarge concen-

trically, increasing in diameter by about 1 to 5 cm a year, depending on the density of the organs in which they are located. A cyst may attain a large size before the initial symptoms develop; these symptoms are usually attributable to a space-occupying mass lesion. The onset of symptoms has been reported to occur from before 1 year of age to 75 years of age, but in large series, most persons become symptomatic between 4 and 15 years of age. Pathologic fractures or neurologic symptoms can occur with osseous or CNS localization, respectively. When cysts leak, patients may experience bronchospasm, urticaria, or anaphylaxis; blood eosinophilia, which is otherwise usually not prominent, may increase. Communicating rupture of pulmonary or hepatic cysts can lead to the release of cyst contents into the bronchial or biliary systems. Because cysts contain multiple infective protoscolices, rupture of cysts can lead to dissemination of infection and the generation of new cysts from each released protoscolex.

E. multilocularis lives in the intestine of foxes and dogs. Its intermediate hosts are mice and other small mammals. *E. multilocularis* is found only in the Northern Hemisphere, including central western Europe, Russia, the central Asian republics, China, northern Japan, Canada, Alaska, and the north central United States.[113] Because the cysts of *E. multilocularis* lack a containing capsule, they progressively invade involved tissues and produce honeycombed alveolar hydatid cysts. The liver is most commonly affected. Severe damage caused by extensive alveolar hydatid cysts can result in jaundice and portal hypertension. The mortality in untreated alveolar disease is 90%.[115]

The diagnosis of hydatid disease can be strongly suggested by the results of radiographic studies.[113,116] Plain films detect pulmonary cysts[117] but often do not visualize cysts in other organs unless they are calcified—a process that occurs mostly in hepatic cysts. On CT and MRI, echinococcal cysts appear as well-defined, thick- or thin-walled cysts that may have calcified rims. [116-118] In older lesions, where scolices and daughter cysts form hydatid sand that settles in the dependent portion of the cyst, a layer of fluid can be visualized. Dependent movement of calcified hydatid sand, on repositioning and ultrasound monitoring, is strongly suggestive, if not pathognomonic, of a hydatid cyst. A pathognomonic CT finding in intact cysts is the presence of daughter cysts that are either free within the cyst or adherent to the inner germinal layer. Separation and collapse of cyst wall layers and the introduction of air into the space between the layers can be detected on plain films (as the meniscus, double arch, or water lily signs) and by CT scan.

Serologic tests can be helpful in making the diagnosis of echinococcosis but are not uniformly sensitive or specific.[92,119] A sensitive assay, such as ELISA or indirect hemagglutination, is performed first. Because of the possibility of false positive results produced by cross-reacting helminthic infections, specificity is confirmed with a less sensitive but more specific assay, such as an antigen-specific immunoblot or a gel diffusion assay for the *Echinococcus*-specific arc 5 immunoprecipitin band. Even with these assays, 5% to 25% of patients with neurocysticercosis have false positive results. Conversely, negative tests do not exclude the diagnosis, because approximately 50% of patients with isolated pulmonary cysts and 10% to 15% of those with hepatic cysts lack detectable antibodies against *Echinococcus*. Although leakage of cyst fluid poses risks of anaphylaxis or dissemination of infection, percutaneous aspiration of a cyst in a seronegative patient, with guidance provided by CT or ultrasonography, can yield diagnostic protoscolices or hydatid membranes.[120]

Therapeutic approaches to cystic and alveolar hydatid disease are quite complex, and consultation for expert advice is highly recommended.[113,115] For cystic hydatid disease, treatment should be reserved for symptomatic lesions or those affecting vital anatomic structures, because 75% of asymptomatic persons with cysts remain symptom-free for more than a decade.[113] When therapy is needed, the options are surgery, PAIR (puncture, aspiration, injection, and reaspiration; see below), or chemotherapy. Surgery offers the potential for total parasite removal and complete cure; nevertheless, cysts recur in 2% to 25% of patients treated with surgery.[113] Preoperative and postoperative albendazole therapy is highly advisable. The past practice of injecting protoscolicidal solutions (7% to 90% ethanol, 0.5% percent cetrimide, or 15% to 20% hypertonic saline) before resection is no longer recommended, because these agents are of uncertain efficacy and potentially dangerous to the patient because of chemical cholangitis and other complications.

The PAIR procedure, which consists of percutaneous aspiration, injection of protoscolicidal agents (e.g., 95% ethanol or 0.5% cetrimide), and reaspiration, has demonstrated efficacy as an alternative to surgery. A randomized, controlled trial showed PAIR to be as effective as surgery for hepatic cystic echinococcosis; moreover, patients treated with PAIR had lower postprocedure morbidity and a shorter hospital stay.[121-123] Like surgery, PAIR should be performed with albendazole therapy before and after the procedure to minimize dissemination of any leaked fluids containing infectious protoscolices.[124] PAIR is best used for liver cysts of 5 cm or greater that are anechoic, multiseptate, or multiple.[113] The PAIR procedure should not be performed if hepatic cysts communicate with the biliary tract. Complications are more common when PAIR is used to treat pulmonary lesions. PAIR may provoke acute allergic reactions.[113]

If neither surgery nor PAIR therapy is an option, medical therapy with albendazole is administered (mebendazole is an alternative that is considered less effective). Albendazole is given as a 400 mg dose twice a day for 28 days, often with additional 28-day courses given in subsequent months, with each course separated by 14-day treatment-free periods.[125] Most commonly, albendazole therapy is continued for 6 months. Patients need to be monitored for complications during long-term albendazole therapy, because hepatotoxicity, nausea, and neutropenia are common. Neither mebendazole nor albendazole is completely effective: 20% to 40% of patients experience no improvement. Albendazole therapy results in a cure in about one third of patients and leads to regression in cyst size and improvement in symptoms in another third. Both agents are contraindicated during pregnancy. Serial titers of echinococcal antibodies can be useful in monitoring therapeutic success.

Because alveolar hydatid disease is an aggressive and often fatal illness, the preferred therapy is radical resection of cysts, followed by albendazole therapy (up to 20 mg/kg/day) for at least 2 years.[113] Long-term chemotherapy can benefit patients who are not candidates for operation, as well as those patients who have undergone nonradical resections or liver transplantation.[113,126,127]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XXXVI BACTERIAL INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Jan V. Hirschmann, m.d.

Several barriers protect the central nervous system from bacterial infection. Considerable force is necessary to breach the skull and allow ingress of organisms into the brain or its coverings. Tight junctions between cells in the cerebral vasculature form the blood-brain barrier, limiting access by blood-borne pathogens. The vertebrae and the dura mater enveloping the spinal cord present strong defenses against incursions by microbes from contiguous areas.

Nevertheless, bacteria occasionally overwhelm or bypass these barriers, resulting in CNS infections. They usually arrive by one of three routes: (1) penetration as a result of trauma or surgery, (2) migration from an adjacent site of infection or colonization, or (3) hematogenous spread from another, often distant, location. The major bacterial infections that result are meningitis, brain abscess, epidural abscess, subdural empyema, and septic thrombophlebitis of the cerebral veins.

Acute Bacterial Meningitis

EPIDEMIOLOGY AND ETIOLOGY

Because vaccination has markedly decreased childhood *Haemophilus influenzae* type b infections, acute bacterial meningitis, previously most common in children, has become predominantly a disease of adults.[1] Bacterial meningitis may occur in otherwise healthy persons, but it usually afflicts those with significant underlying disorders, such as hypogammaglobulinemia, sickle cell anemia, alcoholism, cirrhosis, and concurrent infections of the ears, paranasal sinuses, lungs, or cardiac valves.[2] Patients with HIV disease have a substantially increased risk of bacterial meningitis, usually when their $CD4^+$ T cell count is less than $200/mm^3$. The most common organism is *Streptococcus pneumoniae;* bacteremia is nearly always present.[3] Patients with a splenectomy or poor splenic function may develop overwhelming sepsis, often including meningitis, from encapsulated bacteria, primarily *S. pneumoniae*. Deficiencies of some complement components increase susceptibility to infections with *Neisseria meningitidis,* and head trauma that disrupts the dura mater can lead to meningitis, usually from *S. pneumoniae.* Meningitis that occurs as a complication of neutropenia or cranial surgery is most commonly caused by gram-negative bacilli [*see Table 1*]. A viral upper respiratory tract infection may predispose to meningitis by allowing bacteria that are colonizing the respiratory tract, especially *N. meningitidis,* to enter the bloodstream and invade the meninges.

S. pneumoniae causes approximately 40% to 60% of adult cases of bacterial meningitis in the United States; these cases often occur secondary to bacteremic pneumococcal pneumonia. Other major organisms in community-acquired cases are *N. meningitidis,* primarily in young adults; *Listeria monocytogenes,* especially in immunocompromised or elderly hosts; *H. influenzae;* and group B streptococci (*S. agalactiae*). Usually, the organisms reach the meninges through bacteremia from a mucosal site or a distant infection. Occasionally, the bacteria enter the subarachnoid space from adjacent infectious foci or through direct inoculation via trauma, surgery, or invasive medical procedures, such as lumbar puncture.

DIAGNOSIS

Clinical Features

The duration of symptoms before patients seek medical attention varies from less than 24 hours to more than 1 week. A prodrome resembling a viral upper respiratory tract infection may occur; it is characterized by sore throat, rhinorrhea, and nasal congestion, sometimes accompanied by myalgias. The most common features of bacterial meningitis are headache, fever, nuchal rigidity, and neurologic findings. Less than half of patients have the classic triad of fever, neck stiffness, and a change in mental status; however, almost all have at least two of the four manifestations of headache, fever, neck stiffness, and altered mental status.[4] Fever is present in approximately 95% of patients and typically lasts 4 to 8 days after appropriate therapy has begun.[2,5,6] Stiff neck is apparent in about 90% of patients. Two physical findings that, like nuchal rigidity, arise from meningeal irritation and the neuromuscular response to it are the Kernig sign (when the hip is flexed at 90°, attempted extension of the knee meets resistance at 135°) and the Brudzinski sign (passive flexion of the neck causes knee and hip flexion).[7] Mental changes ranging from lethargy to confusion, stupor, and coma occur in about 80% of patients, somewhat more frequently in the elderly. Seizures, either focal or generalized, occur in about 10% to 30% of patients, usually within 24 hours of admission. Many such seizures arise from alcohol withdrawal. Focal neurologic findings other than seizures develop in about 30% of patients. They include cranial nerve palsies, aphasia, and hemiparesis as a consequence of infection-induced vasculitis or pressure of purulent exudate on neurologic structures. Papilledema occurs only occasionally; its absence does not exclude significantly increased intracranial pressure.

Laboratory Findings

Most patients with acute bacterial meningitis have leukocytosis, and some have hyponatremia, presumably because of inappropriate secretion of antidiuretic hormone. Blood cultures, which are positive in approximately 50% to 60% of cases, are always indicated. The most important diagnostic procedure is a lumbar puncture to obtain cerebrospinal fluid to determine the white cell count and differential, to measure protein and glucose levels, and for culture and Gram stain.

Table 1 Causes of Bacterial Meningitis in Adults[1,2]

Organism	*Approximate Frequency (%)*
Streptococcus pneumoniae	40–60
Neisseria meningitidis	15–25
Listeria monocytogenes	10–15
Haemophilus influenzae	5–10
Other	5–20
Culture negative	10–15

Clinicians commonly obtain a CT scan before doing a lumbar puncture, on the basis of two beliefs: that brain herniation is a frequent risk in meningitis and that CT scans can accurately predict its development. Neither belief is correct. Herniation occurs in approximately 1% of patients with bacterial meningitis,[2] sometimes without a preceding lumbar puncture.[8] CT scans are often normal in those who later experience brain herniation, and most patients who develop this complication have focal neurologic findings before the lumbar puncture that suggest that herniation has already begun: dilated, fixed pupils; Cheyne-Stokes respiration; decerebrate posturing; hemiplegia; and coma.[8] In addition to focal neurologic deficits and abnormal level of consciousness, findings that justify performing CT before lumbar puncture include the following: immune compromise; a history of CNS disease (e.g., mass lesion, stroke, or focal infection); papilledema (although the presence of venous pulsations suggests that the patient does not have increased intracranial pressure); and seizures within 1 week before presentation (some experts will not perform a lumbar puncture in patients with prolonged seizures and will delay lumbar puncture for 30 minutes in patients who have experienced short, convulsive seizures).[9] In the absence of such findings in patients with suspected bacterial meningitis, clinicians should not delay lumbar puncture to obtain a CT scan [*see Figure 1*].

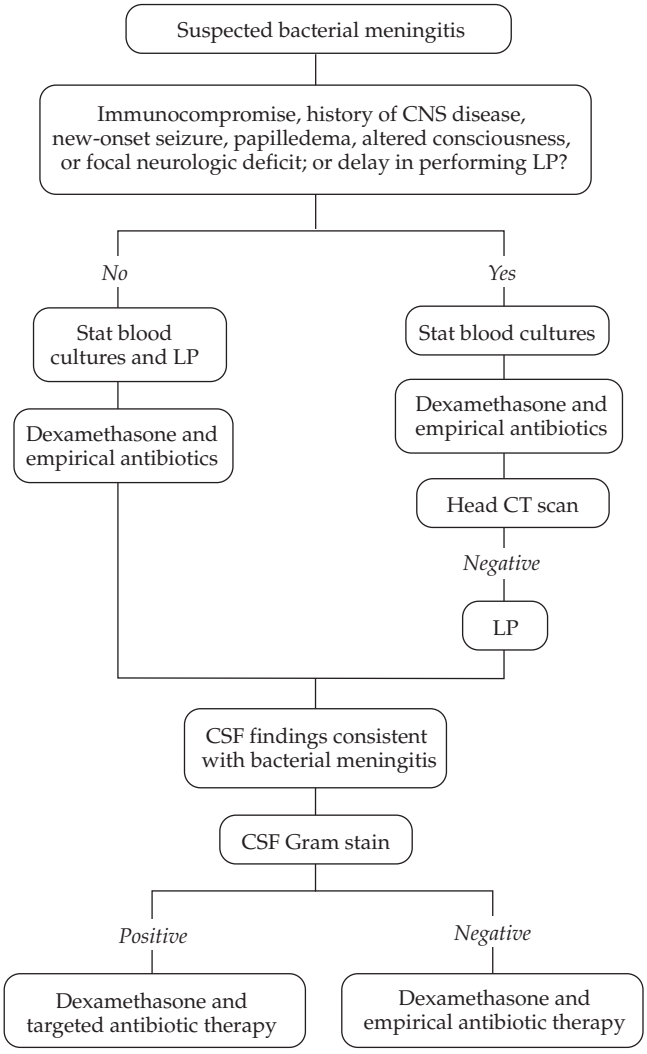

Figure 1 **Management of adult patients with suspected bacterial meningitis.[9] (CSF—cerebrospinal fluid; LP—lumbar puncture)**

In approximately 90% of patients, the opening pressure is above 180 mm H_2O; in 20%, it is above 400 mm H_2O; and in about 5%, it is above 500 mm H_2O. The CSF protein level exceeds 40 mg/dl in approximately 85%, and the glucose level is below 40 mg/dl in about 60%.[2] When bacterial meningitis develops in patients with diabetes and hyperglycemia, the CSF glucose level may be normal, but the ratio of CSF glucose to blood glucose in these patients is usually less than 0.31.[10] The CSF white cell count is greater than 100/mm^3 in about 90% of patients and exceeds 1,000/mm^3 in 15% to 20%. Neutrophils nearly always predominate, constituting at least 80% of cells in 80% to 90% of patients. Occasionally, lymphocytes constitute the majority, especially when the white cell count is very low; lymphocytes constitute the majority in about 25% of patients with meningitis caused by *L. monocytogenes*.[11] Several conditions can cause neutrophilia with low CSF glucose levels and can mimic acute bacterial meningitis [*see Table 2*].

Gram stain is positive in approximately 60% to 90% of patients, indicating a concentration of bacteria exceeding 10^5 organisms/ml. Misinterpretation may occur, especially through mistaking pneumococci for *Listeria*. In listerial meningitis, the Gram stain is positive in only 30% of cases.[12]

The CSF culture is positive in approximately 80% of patients. Previous oral antibiotic therapy has little effect on the WBC or differential cell counts, protein level, or glucose level, but it decreases the number of positive Gram stains by about 20% and the number of positive cultures by about 30%.[13] The effect of parenteral therapy is presumably much greater, especially if given more than a few hours before the lumbar puncture. In patients with negative Gram stains and cultures, latex agglutination tests of the CSF are highly specific for *H. influenzae* type b, meningococci, and pneumococci, but their sensitivity ranges from 50% to 80%.

Imaging Studies

Imaging techniques are ordinarily unnecessary in bacterial meningitis unless specific complications are suspected. The subarachnoid space may be distended on CT or MRI studies; however, this finding is often difficult to interpret in adults, in whom a degree of brain atrophy is common—especially in the elderly. Several days after infection, meningeal enhancement may occur after contrast injection because of meningeal inflammation and vascular congestion. Enhancement of areas in the cerebral cortex usually indicates brain infarction from occlusion of inflamed vessels. Brain edema may occur because of disturbed cerebrovascular autoregulation, dural sinus thrombophlebitis, leakage of fluid from damaged vessels, or cytotoxic edema from injured brain cells. Communicating or noncommunicating hydrocephalus occasionally develops because inflammation obstructs the normal flow of CSF, either at the arachnoid granulations where it is absorbed or at the sites where it leaves the ventricles.

TREATMENT

Intravenous Antibiotics

The most important therapeutic maneuver is prompt initiation of intravenous antibiotics after lumbar puncture, because delay in beginning treatment increases the mortality [*see Tables 3 and 4*].[14] In the rare situation in which lumbar puncture is justifiably postponed—for example, when signs of brain herniation

Table 2 Causes of Neutrophilia with Low Glucose Levels in the CSF

	Infectious Cause	*Noninfectious Cause*
Common	Bacterial meningitis	—
Uncommon	Viral meningitis* (in very early phase only) Certain parameningeal infections Subdural empyema* (usually produces lymphocytic–normal glucose profile) ?Early brain abscess at bacterial cerebritis stage* Cerebral abscess with leakage or rupture into ventricle Embolic cerebral infarction* (bacterial endocarditis) Amebic meningoencephalitis Tuberculous meningitis (only very early in the disease and only in a small percentage of cases) Acute hemorrhagic leukoencephalitis	Chemical meningitis Exogenous (e.g., contrast media, detergents used in cleaning needles) Endogenous (release of material into CSF from tumors: dermoids, craniopharyngiomas) Unusual diseases* Initial phase of Mollaret meningitis Behçet syndrome Hypersensitivity meningitis Drug-induced* (sulfonamides, tolmetin, ibuprofen, isoniazid)

*Glucose level in CSF usually normal.

are present (see above)—blood cultures should be obtained and antibiotics begun, even though they may reduce the yield of the subsequent CSF Gram stain and culture. The antimicrobial agent chosen should be bactericidal against the suspected pathogens and should achieve good CSF levels. In a Danish study, ceftriaxone plus penicillin was an appropriate choice for empirical treatment in 97% of the adult patients with bacterial meningitis in the study population.[15]

The findings on CSF Gram stain may help guide the choice of antibiotic; when the stain is negative, however, ceftriaxone (2 g I.V. every 12 hours, or 4 g I.V. every 24 hours) is a good choice in adults.[15] Ceftriaxone provides coverage for meningococci, *H. influenzae,* group B streptococci, and *S. pneumoniae,* including many penicillin-resistant strains. In a Danish study, ceftriaxone plus penicillin was an appropriate choice for empirical treatment in 97% of the adult patients with bacterial meningitis in the study population.[16]

With suspected high-level penicillin resistance, use of vancomycin (2 g every 12 hours) is prudent until culture and susceptibility test results are available. If Gram stain of the CSF is negative or if a distinction between pneumococci and *Listeria* is uncertain, the patient should receive, in addition, ampicillin at a dosage of 2 g every 4 hours to treat possible *L. monocytogenes* infection.

Although controlled studies have not delineated the optimal length of antibiotic therapy, the duration is usually 7 days for *H. influenzae* and 10 to 14 days for most other organisms. For meningococcal disease, treatment for 4 to 5 days is of proven efficacy, and in one study, 3 days of treatment with intravenous benzylpenicillin was effective.[17]

Repeat lumbar puncture during or after therapy is usually unnecessary unless treatment seems to be failing.

Systemic Corticosteroids

In adults with acute pneumococcal meningitis, adjuvant treatment with dexamethasone has been shown to lower the risk of an unfavorable outcome and to lower mortality, without increasing the likelihood of gastrointestinal bleeding.[18,19] Consequently, guidelines from the Infectious Diseases Society of America recommend that adults with suspected or proven pneumococcal meningitis receive adjunctive dexamethasone.[9] The dosage is 0.15 mg/kg every 6 hours for 2 to 4 days, with the first dose given 10 to 20 minutes before or at least concomitant with the first dose of antibiotics. Dexamethasone should be continued only if

Table 3 Empirical Antibiotic Therapy for Purulent Meningitis in Adults[9]

Patient Factor	*Common Bacterial Pathogens*	*Antibiotic*
Age 2–50 yr	*Neisseria meningitidis, Streptococcus pneumoniae*	Vancomycin plus a third-generation cephalosporin*; consider adding rifampin if dexamethasone is given
Age > 50 yr	*S. pneumoniae*, *N. meningitidis*, *Listeria monocytogenes*, aerobic gram-negative bacilli	Vancomycin plus ampicillin plus a third-generation cephalosporin*; consider adding rifampin if dexamethasone is given
Basilar skull fracture	*S. pneumoniae*, *Haemophilus influenzae*, group A β-hemolytic streptococci	Vancomycin plus a third-generation cephalosporin*
Penetrating head trauma	*Staphylococcus aureus*, coagulase-negative staphylococci, especially *S. epidermidis*; aerobic gram-negative bacilli, including *Pseudomonas aeruginosa*	Vancomycin plus cefepime, vancomycin plus ceftazidime, or vancomycin plus meropenem

§Consider adding an aminoglycoside.
‖Consider adding rifampin, 600 mg q.d.
MIC—minimum inhibitory concentration

the CSF Gram stain reveals gram-positive diplococci or if blood or CSF cultures are positive for *S. pneumoniae.* Dexamethasone treatment is unlikely to improve the outcome in adult patients who have already received antimicrobial therapy and hence should not be used in this circumstance.

COMPLICATIONS

Many complications may occur in meningitis patients, including secondary nosocomial infections, systemic venous thromboembolism, and adverse effects from the medications administered. The most common systemic complications occur from the initial infection, however, and include septic shock, disseminated intravascular coagulation, and the acute respiratory distress syndrome.[20] The most frequent neurologic complications other than seizures and altered mentation are cerebral edema, hydrocephalus, and cerebrovascular complications.[21]

In bacterial meningitis, the internal carotid, basilar, and vertebral arteries and their branches lie within a purulent subarachnoid exudate, which can provoke vascular inflammation and constriction. Smaller arteries may demonstrate vessel wall irregularities, occlusion, narrowing, or widening. Thrombosis of the superior sagittal sinus or the cortical veins can occur. These abnormalities may cause discrete areas of brain damage—which is evidenced by focal neurologic findings—or increased intracranial pressure that is produced by leakage of cerebral vessels (vasogenic edema), swelling of damaged neurons (cytotoxic edema), or increased blood volume that occurs when sinus venous thrombosis impedes drainage of blood from the brain.

PROGNOSIS

The mortality associated with meningitis is approximately 10% in meningococcal infections and is typically 20% to 30% in meningitis caused by other organisms. Factors associated with poorer prognoses include infection with *S. pneumoniae,* advanced age (> 60 years), onset of seizures during the first 24 hours after infection, hypotension, and coma or obtundation on hospital admission.[4,22] Most survivors recover completely. Approximately 30% of patients with pneumococcal meningitis have moderate to severe sequelae, including dementia, seizures, hearing loss, and gait disturbances; about 20% have mild problems, such as dizziness, slightly impaired memory, headaches, and phonophobia.[23]

Bacterial Meningitis in Special Circumstances

POSTTRAUMATIC BACTERIAL MENINGITIS

Epidemiology and Etiology

Bacterial meningitis develops in about 1% of persons who receive medical attention for blunt cranial injuries, most commonly from motor vehicle accidents.[24] At risk are those in whom the force of impact fractures the base of the skull, tearing the dura mater, the underlying arachnoid, and adjacent soft tissues. The trauma, however, need not be severe: coma or retrograde amnesia is absent or brief in 30% to 40% of cases.

The most common cause of posttraumatic meningitis is *S. pneumoniae,* which accounts for about 65% of cases. In the remainder of cases, the causes are primarily other streptococci, *H. influenzae,* meningococci, and *Staphylococcus aureus*. Enteric gram-negative bacilli are rare causes, except in patients who have previously received antimicrobial therapy.

Pathogenesis

The dural rent resulting from blunt cranial trauma creates a fistula between the subarachnoid space and the nasal cavity, paranasal sinuses, or ear. The most common site for these abnormal communications is the cribriform plate; the disruptions are multiple, however, in about 40% of cases. When these rents are large, they are evident as CSF rhinorrhea; smaller leaks may go unrecognized, and drainage may be delayed or intermittent when tissue occludes the dural laceration. When trauma weakens but does not tear the dura, CSF rhinorrhea may begin abruptly after sudden increases in cerebrospinal pressure from coughing, sneezing, or straining. When the dural fistula occurs in the middle cranial fossa because of a fractured temporal bone, CSF may exit through the ear canal (if the tympanic membrane ruptures) or drain into the pharynx through the eustachian tube and go unrecognized. Evidence of basilar skull fractures may appear shortly after the injury as periorbital bruising, anosmia, hemotympanum, bloody ear drainage, or Battle sign (ecchymoses behind the ear).

Diagnosis

Clinical features The usual clinical features of bacterial meningitis, including fever, headache, and stiff neck, are present in posttraumatic meningitis. Mortality is comparatively low (10%), however, perhaps because the fistula allows drainage of CSF (relieving intracranial hypertension) or because many patients with cranial trauma are young and otherwise healthy. The interval between blunt cranial injury and meningitis is usually less than 1 month, but infection may occur years later; when evaluating patients with unexplained meningitis, clinicians should therefore ask about any significant head trauma, even if such trauma occurred in the remote past.

Recognition of CSF rhinorrhea or otorrhea allows a diagnosis of a dural fistula. The discharge often increases with sudden movement, lowering of the head, performance of the Valsalva maneuver, or jugular vein compression. Unlike normal nasal secretions, the CSF fluid is not sticky, does not stiffen a handkerchief on drying, may taste salty, and has a glucose level greater than 30 mg/dl in the absence of infection. The most sensitive and specific way to identify CSF is by detection of a β_2-transferrin found only in that body fluid.[25]

Imaging studies Several techniques help localize the leak of CSF. CT scans may demonstrate the fistula site by disclosing sinus fractures, displaced bony fragments, or intracranial air (pneumocephalus). Radionuclide-labeled albumin and various dyes injected in the subarachnoid space may leak into the middle and superior meatus of the nose and become detectable on cotton pledgets placed in these locations. Magnetic resonance cisternography, a noninvasive and rapid procedure, seems highly accurate in detecting fistulas.[25] This technology relies on the fact that CSF gives a high signal on T_2-weighted images: demonstration of a continuous high signal through the cribriform plate or the paranasal sinuses that is similar to the signal given by the CSF in the basal cisterns indicates a dural fistula.

Treatment

Because many dural fistulas resolve spontaneously, repair is usually unnecessary unless problems persist for 2 to 3 weeks after the injury. Patients with facial fractures or meningitis are exceptions. Those with fracture sites accessible through the nose typically undergo transnasal closure with fibrin glue, fascia lata,

or local flaps. Otherwise, intracranial repair is required. Recurrences may develop if the dural fistula remains uncorrected. Vancomycin plus a third-generation cephalosporin (e.g., ceftriaxone or cefotaxime) is a good antibiotic choice for bacterial meningitis after closed head trauma when the CSF Gram stain is negative. A randomized trial of patients with acute traumatic pneumocephalus after mild head injury found that ceftriaxone was not effective in preventing meningitis in these patients.[26]

RECURRENT BACTERIAL MENINGITIS NOT CAUSED BY TRAUMA

Although a dural fistula created by blunt cranial trauma is the most common cause of recurrent bacterial meningitis, seemingly spontaneous leaks of CSF occasionally occur; most of these probably arise from a congenital or acquired weakness in the dura. Defects of the skull or of the floor of the middle cranial fossa are other potential sources of recurrent meningitis, as are bony complications from chronic ear infections. Congenital malformations can lead to dermal sinus tracts, often associated with intradural dermoid tumors, that connect the skin to the CSF. They commonly occur at the lumbodorsal spine but may be present anywhere along the midline. Abnormalities at the cutaneous exit site can include small tufts of hair, a nevus, or a dimple from which purulent drainage may emanate. Other conditions associated with recurrent bacterial meningitis are hypogammaglobulinemia, asplenia, and deficiencies of certain components of complement, which especially predispose to meningococcal meningitis [*see Table 5*].

Table 5 Causes of Recurrent Meningitis

*Bacterial Meningitis**
Predisposing anatomic defects
Congenital: meningomyeloceles, dermal sinuses
Traumatic: skull fractures through cribriform plate or petrous ridge
Postoperative: craniotomy, transsphenoidal hypophysectomy
Tumors: direct invasion through the dura
Empty sella syndrome
Parameningeal infections*
Mastoiditis, sinusitis, osteomyelitis of skull
Immunologic defects*
Immunoglobulin deficiencies: congenital or acquired (e.g., myeloma)
Asplenic state: splenectomy or functional asplenia (e.g., sickle cell anemia)
Complement deficiencies: C6, C7, or C8 deficiency
Endogenous Chemical Meningitis
Tumors†
Craniopharyngioma, epidermoid cyst
Unusual Nonbacterial Recurrent Meningitides
Mollaret meningitis†
Behçet syndrome†
Drug hypersensitivity†
Sulfonamides, ibuprofen
Systemic lupus erythematosus†
Uveoencephalitides‡ (Vogt-Koyanagi syndrome, Harada syndrome)

*Neutrophilic CSF pleocytosis.
†Either neutrophilic or lymphocytic CSF pleocytosis.
‡Lymphocytic CSF pleocytosis.

CEREBROSPINAL FLUID SHUNT INFECTIONS

CSF shunts, used to relieve hydrocephalus, usually consist of a ventricular catheter; a pressure-regulating valve and reservoir, commonly placed just outside the skull; and distal tubing that drains the CSF, most often into the peritoneum but sometimes into the right atrium, pleura, or other sites.

Etiology

Mechanisms of infection of CSF shunts include implantation of microbes during shunt insertion, entry through a break in the overlying skin, hematogenous dissemination from a distant site, and retrograde spread of organisms from the distal end (in the peritoneum or another body cavity).[27] The most common origin is contamination of the device by skin flora at the time of surgery. Most infections become apparent within a few weeks of the shunt's insertion. Entry of microbes into the shunt from overlying skin is probably the next most frequent cause of infection. Retrograde and hematogenous infections seem to be rare except in the case of ventriculoatrial shunts, in which the distal end lies within the bloodstream.

The bacteriology of CSF shunt infections reflects the probable cutaneous source of infection in most cases. The most common isolates are staphylococci, with coagulase-negative species accounting for approximately 50% to 60% of cases and *S. aureus* for approximately 20%. Streptococci, anaerobes, diphtheroids, and polymicrobial infections, primarily from these and other cutaneous species, constitute most of the remaining cases. About 10% of isolates are gram-negative bacilli, and about 5% are the same organisms that commonly cause community-acquired meningitis in patients without shunts: pneumococci, meningococci, and *H. influenzae*.

Diagnosis

Clinical features The manifestations of CSF shunt infections differ from the usual findings of bacterial meningitis and depend on the site involved. Fever is usually present. When ventriculitis occurs, nuchal rigidity rarely develops, because infected CSF typically does not communicate from the ventricle to the meninges. Mental changes, including headache, nausea, lethargy, and confusion, are the most common abnormalities; these may result from infection in the ventricle or from increased intracranial pressure caused by obstruction of the shunt anywhere along its route. Evidence of infection over the shunt may sometimes be detected by the presence of wound dehiscence, cellulitis, or purulent drainage. When the distal end lies within the atrium, bacteremia may occur, sometimes complicated by endocarditis. In chronic bacteremia, usually caused by coagulase-negative staphylococci, renal disease (so-called shunt nephritis) produced by deposition of immune complexes in the kidney may develop. When the distal end lies in the peritoneum, infection may cause peritonitis, manifested by abdominal pain and tenderness, anorexia, and fever. Often, the infection is more insidious, with enlarging cysts developing around the end of the catheter as the inflamed peritoneum fails to absorb the CSF.

Laboratory findings The peripheral white cell count is often normal. Blood cultures are characteristically positive in patients with infected ventriculoatrial shunts but are usually negative when the distal end lies elsewhere. The culture of CSF obtained through needle aspiration of the shunt reservoir or the culture of any fluid in contact with the shunt is the best approach to delineating the cause. The CSF will usually show pleocytosis, which is often mild, and an elevated protein level; the glucose level is typ-

ically normal or slightly decreased. Gram stain may reveal bacteria, but it is often negative.

Treatment

Treatment of shunt infections usually entails systemic antibiotics, shunt removal, and temporary placement of an external ventricular drain to control intracranial pressure (and to provide a conduit for intraventricular antibiotic administration). The systemic antimicrobials used for the treatment of shunt infections are nafcillin for susceptible strains of *S. aureus* and vancomycin for methicillin-resistant *S. aureus* and coagulase-negative staphylococci, often supplemented by oral rifampin (600 mg daily). Ceftriaxone is used for susceptible gram-negative bacilli; ceftazidime is appropriate for ceftriaxone-resistant organisms, including *Pseudomonas aeruginosa.* Empirical antibiotic treatment of CSF shunt infections is with vancomycin plus cefepime, ceftazidime, or meropenem. Intraventricular antibiotics are commonly employed in patients with ventriculitis (generally, vancomycin at a dosage of 10 to 20 mg daily for gram-positive organisms and gentamicin at a dosage of 4 to 8 mg daily for gram-negative bacilli). Once the infection has resolved (usually after several days), a new shunt can be inserted.

NOSOCOMIAL MENINGITIS AND MENINGITIS AFTER NEUROSURGERY

Epidemiology and Etiology

Nosocomial meningitis is quite rare except in patients who have recently undergone neurosurgery. A study of 51 hospitalized patients who underwent lumbar puncture to exclude bacterial meningitis revealed no cases, despite the presence of mental status changes in 78%, fever in 47%, and meningeal signs or headache in 22%.[28] By contrast, 92% of patients with community-acquired bacterial meningitis had either meningeal signs or headache. The conclusion is that lumbar puncture can be safely withheld in most hospitalized patients who have fever and changes in mental status; the exceptions to this rule are patients who have headache or nuchal rigidity and patients who have recently undergone neurosurgery.

Even after neurosurgery, bacterial meningitis is very uncommon, especially after spinal surgery or craniotomy; it is somewhat less rare, but still unusual, after transsphenoidal procedures. During neurosurgery, bacteria most commonly enter the subarachnoid space from contiguous sites of colonization on the skin and mucous membranes. Less frequent sources or causes of infection include contaminated instruments or irrigation solutions, airborne organisms, breaches of sterile technique, and organisms from adjacent sites of suppuration. Postoperative sources are wound infections at the operative site, indwelling catheters that allow organisms to enter the ventricle or subarachnoid space, and CSF leaks. A very uncommon cause is hematogenous spread from a distant site of infection, such as the lungs or urinary tract.

Approximately one half of cases of bacterial meningitis after craniotomy or spinal surgery occur in the first postoperative week, approximately 25% in the second week, and the remainder after the second week. After transsphenoidal surgery, about 85% of cases occur in the first week. The onset of meningitis may be inconspicuous, however, because headache, nuchal rigidity, and impaired consciousness are common after cranial surgery.

Diagnosis

Clinical features Nearly all patients with nosocomial or postneurosurgical meningitis have fever, often accompanied by worsening meningismus, deteriorating mentation, and erythema or purulence at the incision site. CSF rhinorrhea may appear in patients with dural defects.

Laboratory findings The peripheral white cell count is usually elevated; the elevation is accompanied by neutrophilia and increased bands. Blood cultures are positive in about 30% of cases. The most important diagnostic test is sampling of the CSF, usually after obtaining a CT scan to exclude brain abscesses or other fluid collections. In most cases of postoperative meningitis, the CSF protein level is 100 to 500 mg/dl and the white cell count exceeds 1,000/mm^3, with neutrophilic predominance. The CSF glucose level is decreased in 85% of cases; Gram stain discloses the responsible bacteria in 50% to 80%.

The infecting organisms are primarily gram-negative bacilli, including *P. aeruginosa* and species of *Klebsiella* and *Enterobacter*. In patients with ventricular drains, coagulase-negative staphylococci predominate. The bacteria isolated in meningitis after transsphenoidal surgery are more diverse, reflecting various nasal mucosal organisms—especially as altered by hospitalization and previous antimicrobial therapy. Causes include gram-negative bacilli, streptococci, staphylococci, diphtheroids, anaerobes, *Haemophilus* species, and, sometimes, polymicrobial isolates.

Differential Diagnosis

A confounding diagnostic problem in neurosurgical patients with a negative Gram stain is that an aseptic meningitis may develop several days after surgery, probably in response to blood in the subarachnoid space. Fever, nuchal rigidity, nausea, vomiting, and altered mentation may all occur, and the findings on lumbar puncture resemble a bacterial infection, including marked pleocytosis, neutrophilic predominance, increased protein, and, sometimes, decreased glucose. However, in one study, no patients with postneurosurgical chemical meningitis had a CSF white cell count above 7,500/mm^3 or a CSF glucose level below 10 mg/dl.[29]

Treatment

Antimicrobial therapy should be directed by the results of CSF Gram stain and culture. For gram-negative bacilli, ceftazidime (2 g I.V. every 8 hours) is the drug of choice unless the organism is known to be susceptible to ceftriaxone. Often, ceftazidime is combined with intrathecal or intraventricular injection of gentamicin (4 to 8 mg daily). For gram-positive organisms, parenteral vancomycin, supplemented by oral or parenteral rifampin and intrathecal or intraventricular vancomycin (10 to 20 mg daily), is a good regimen. When the Gram stain is negative, a combination of ceftazidime and vancomycin is reasonable until culture results become available.

When the distinction between bacterial and aseptic meningitis is unclear, a reasonable approach is to initiate appropriate empirical antimicrobial therapy. If the cultures remain negative, it is appropriate to withdraw the antibiotics and administer systemic corticosteroids, which seem useful in this form of chemical meningitis.[30]

Brain Abscess

EPIDEMIOLOGY AND ETIOLOGY

Brain abscesses are about two to three times more frequent in males than in females. About 50% arise from contiguous infec-

tions, such as sinusitis and otitis media, with the organisms arriving in the brain from direct extension or retrograde spread through the venous system. Pathogens from distant areas of suppuration may reach the brain via a hematogenous route through the cerebral arteries. Occasionally, abscesses develop after penetrating trauma or surgery, with organisms directly inoculated into the cerebral tissue. In approximately 20% to 30% of brain abscesses, the source of origin is inapparent.[31]

Chronic otitis media is a common predisposing factor, with the abscesses most frequently forming in the temporal lobe or cerebellum. Those occurring secondary to frontal sinusitis usually develop in the frontal lobe, whereas abscesses originating from the sphenoidal sinus are typically in the temporal lobe. Hematogenous infections from distant sites are commonly multiple and most likely to cause suppuration in the territories supplied by the distal middle cerebral artery. Frequently, these arise when blood-borne organisms bypass the ordinary filtering mechanisms of the lung in such conditions as left-sided endocarditis, pulmonary infections, and right-to-left cardiac or pulmonary shunts. In patients with shunts, concurrent hypoxemia and secondary erythrocytosis may cause brain damage that predisposes them to subsequent infection. Immunocompromised patients, especially patients who have undergone bone marrow transplantation or solid organ transplantation, have an increased risk of developing brain abscesses, usually through hematogenous spread.

Brain abscesses begin as localized—but poorly demarcated—areas of encephalitis, often called cerebritis. At this stage, tissue has not liquefied, and needle aspiration or surgery is unhelpful. Over several days, necrosis occurs, with pus forming in the center of the infection. With time, a capsule of fibrous tissue develops, delimiting the suppuration, but pus may rupture through it into the ventricle or adjacent cerebral tissue, forming satellite abscesses.

The most common organisms isolated from brain abscesses are aerobic, microaerophilic, or anaerobic streptococci; other anaerobic bacteria; staphylococci; and gram-negative bacilli (especially when the abscess arises from chronic ear infection). Common associations are *Klebsiella pneumoniae* and viridans streptococci in brain abscess from hematogenous spread; *S. aureus*, *K. pneumoniae*, and viridans streptococci in postneurosurgical brain abscess; viridans streptococci from paranasal sinusitis infections; and *Proteus* species in polymicrobial brain abscesses of otogenic origin.[32] *K. pneumoniae* is an especially common pathogen in patients with diabetes.[33]

DIAGNOSIS

Clinical Features

Most patients with brain abscess have symptoms for several days to weeks before they seek medical attention. Fever is present in only about 40% to 50% of cases. The most common symptom is headache, which may be diffuse or localized to the abscess area. Other frequent findings are altered mental states, such as confusion, aberrant behavior, and somnolence; generalized or focal seizures; and specific neurologic abnormalities, depending on the abscess site. With temporal lobe involvement, contralateral sensory or motor signs, aphasia, and an upper homonymous quadrantanopia may occur. In cerebellar abscesses, ataxia in the ipsilateral extremities, nystagmus, signs of increased intracranial pressure, and ataxic gait are characteristic. Frontal lobe involvement commonly results in hemiparesis, aphasia, and impaired mentation, whereas the main finding in occipital lobe abscesses is homonymous hemianopsia. Typical features of parietal lobe abscesses include hemianesthesia, homonymous hemianopsia, neglect of one half of the body, alexia, and impaired spatial perception. Papilledema is infrequent, irrespective of the abscess site.

Laboratory Findings

Leukocytosis occurs in approximately 50% of patients, and an elevated erythrocyte sedimentation rate occurs in about 60%. Lumbar punctures are not recommended unless meningitis is strongly suspected, because of the low risk of brain herniation and the low likelihood of positive cultures. Examination of the CSF usually shows a pleocytosis with mixed neutrophils and lymphocytes, elevated protein levels, normal glucose levels, and a negative Gram stain. Blood cultures are positive in about 10% to 20% of patients.

Imaging Studies

During the cerebritis phase, CT scans show low-density abnormalities with mass effect, sometimes with patchy enhancement. On MRI, the characteristic findings are areas of low density on T_1-weighted images and, on proton-density or T_2-weighted images, high-intensity areas surrounded by areas of patchy enhancement with gadolinium. In a mature abscess, the CT scan shows a low-density lesion with uniform ring enhancement and a surrounding area of low density, representing cerebral edema [*see Figure 2*]. On T_1-weighted images, the encapsulated abscess appears as a round, low-intensity lesion with mass effect and a surrounding area of low density, signifying edema. On proton-density and T_2-weighted images, the abscess has a high-intensity signal in the center and in the surrounding parenchyma as a consequence of the adjacent cerebral swelling. Ring enhancement occurs with gadolinium.

TREATMENT AND PROGNOSIS

Most patients should undergo prompt stereotactic-guided needle aspiration of pus[34] or craniotomy with excision of the abscess. If possible, antimicrobials should be withheld until a specimen is obtained, to avoid reducing the yield on cultures. Gram stain and culture determine antibiotic choice; appropriate empirical therapy that can be used until the microbiologic results become available include agents effective against anaerobes, streptococci, staphylococci, and gram-negative bacilli. A good regimen is a combination of ceftriaxone and metronidazole.[35] Patients with significant cerebral edema should receive dexamethasone. Some patients may respond to antibiotic therapy alone—especially those with cerebritis only, those with numerous abscesses that are inaccessible to drainage, or those with small abscesses who have stable neurologic function.

Mortality may range from 5% to 25%. Factors associated with poor prognosis include a low Glasgow Coma Scale score, immunodeficiency, or the presence of underlying disease.[36] Many patients have residual neurologic problems, most commonly focal seizures.

Spinal Epidural Abscess

PATHOGENESIS AND PATHOPHYSIOLOGY

The epidural space, an area posterolateral to the spinal cord containing fat and blood vessels, can potentially extend anteriorly to where the dura adheres to the posterior vertebral bodies.

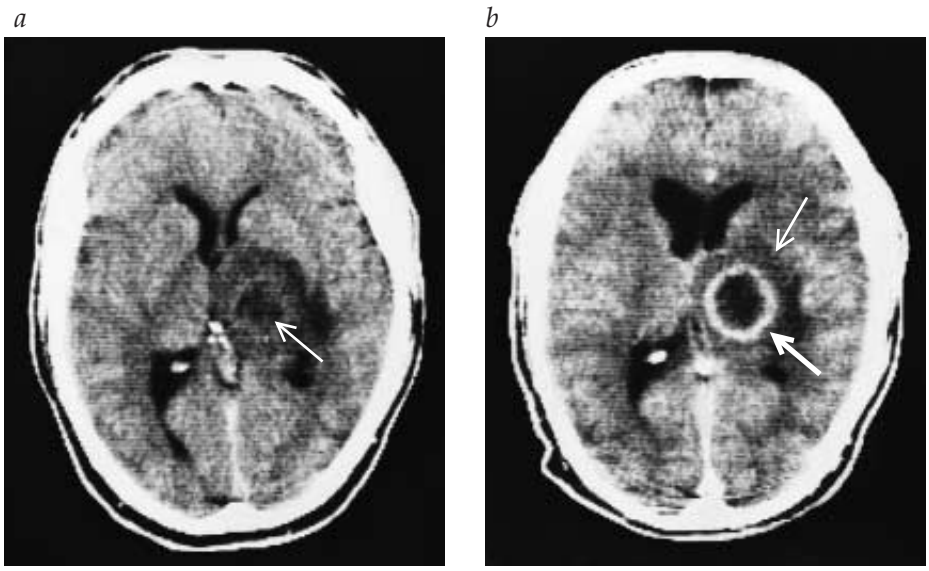

Figure 2 **(*a*) CT scan of a 39-year-old patient reveals a large thalamic abscess. Plain scan demonstrates abscess and a surrounding zone of what may be either increased vascularity or an actual capsule formation (arrow). (*b*) Intravenous administration of contrast media enhances definition of the surrounding zone (thick arrow). A wide area of periabscess edema (thin arrow) is also evident. The mass effect can be seen clearly in the asymmetry of the ventricles.**

Most epidural abscesses occur in midthoracic and lumbar locations, where the space is largest. Cervical abscesses are less common, in part because the epidural space is very small in that area. Because no anatomic barriers prevent superior and inferior extension, abscesses typically involve several (an average of four) adjacent vertebral segments.[37]

Organisms may arrive in the epidural space from contiguous infection, especially vertebral osteomyelitis, but also from retropharyngeal, psoas, perivertebral, or perinephric abscess. All these infections are predominantly anterior to the spinal cord. Microbes also enter the epidural space as a result of penetrating trauma, surgery, and epidural catheterization for analgesic administration. Hematogenous spread may occur from distant foci of infection, including the skin and soft tissue, urinary tract, heart valves, and respiratory tract. Patients with frequent or prolonged bacteremias, such as intravenous drug users and those undergoing hemodialysis, are at increased risk.[38] Diabetes mellitus, alcoholism, and underlying disease in the affected spinal area are other predisposing factors. Many patients report recent trauma near the affected location, suggesting hemorrhage at the site with subsequent bacteremic superinfection. Often, the source of infection is inapparent. Males are more frequently affected than females, for unclear reasons.

Pus and granulation tissue in the epidural space can damage the spinal cord, in part by compression, which may impede arterial flow and cause ischemia. Inflammation and increased pressure can also provoke thrombophlebitis or venous thrombosis, which can lead to cord edema and infarction.

ETIOLOGY

S. aureus is the most common isolate from spinal epidural abscess; most of the other isolates are streptococci and gram-negative bacilli. Usually, only a single species of organism is responsible, but polymicrobial infections occur in approximately 5% to 10% of cases. In the United States, *Mycobacterium tuberculosis* is an occasional cause of epidural abscess. In such cases, the infection usually arises from an adjacent vertebral osteomyelitis. Patients may feel back pain for quite some time (weeks to months) before neurologic symptoms appear. Most of these patients have no evidence of pulmonary tuberculosis at the time of epidural infection.

DIAGNOSIS

Clinical Features

The most common symptom of spinal epidural abscess is back pain over the infected area. It is typically persistent and unrelieved by altered position or bed rest. Localized tenderness is often present; fever is common but is not invariable. With time, patients may develop radicular pain, primarily along the route of the affected level of the spinal cord. The next stage is usually marked by muscle weakness, typically paraparesis with thoracic involvement or quadriparesis with cervical infection. At this stage, findings of upper motor neuron disease are usually predominant; such findings include spasticity, hyperreflexia, and extensor plantar responses. Bilateral sensory loss and impaired bladder and bowel function may occur. Without treatment, paralysis develops, sometimes abruptly, and is usually irreversible.

Laboratory Findings

Leukocytosis is common in patients with epidural abscess, but white cell counts may be normal, especially in patients with protracted symptoms. The erythrocyte sedimentation rate is usually elevated. A lumbar puncture is not ordinarily recommended, except when needed for myelography; however, when a lumbar puncture is performed, the specimen typically demonstrates pleocytosis of up to a few hundred cells, commonly with a mixture of lymphocytes and neutrophils. The glucose level is normal; the protein level is usually elevated, sometimes by more than 1 g/L when the spinal canal is completely blocked. Gram stain and culture of CSF are usually normal. Blood cultures, which are commonly positive in epidural abscess, are worth obtaining in all suspected cases.

Imaging Studies

When the abscess arises from vertebral osteomyelitis, plain films of the spine may demonstrate erosion of the cortical margins of the vertebrae, narrowed or obliterated intervertebral disk spaces, and bone destruction. Myelograms show evidence of blockage of CSF circulation at the level of the epidural abscess but are rarely necessary when CT or MRI scans are available. CT scans detect vertebral osteomyelitis well; characteristic findings

include narrowed intervertebral disk spaces, eroded vertebral end plates, and bony destruction of the vertebral bodies. The epidural abscess is present as a low-density focal epidural mass, which may be better delineated with CT myelography. The best imaging modality, however, is MRI, which discloses a low-intensity or isointense image on T_1-weighted scans (when compared with the spinal cord image) and a high signal on proton-density or T_2-weighted scans. Epidural abscesses typically appear enhanced with gadolinium. Demonstration of the extent of the mass is simple on MRI with both longitudinal and transverse sections, and vertebral osteomyelitis is easily visualized as high-intensity areas on T_2-weighted images.

TREATMENT

Neurosurgery

The most important element of therapy is urgent neurosurgery for removal of pus and granulation tissue—which, rather than purulent material, is sometimes the major or sole finding. Decompressive laminectomies are performed for posterior epidural abscesses, whereas more complicated anterior approaches with bone graft fusion to establish spinal stability may be necessary for ventral collections. Occasionally, patients with absent or minimal neurologic findings respond to antimicrobial therapy alone,[39] but even these patients may benefit from surgery when imaging procedures show significant evidence of spinal cord compression. In such patients, the organism should be identified by blood culture or abscess aspiration, and clinicians should realize that neurologic decline may occur abruptly.[39]

Antimicrobial Therapy

Antimicrobial therapy alone may also be appropriate for patients who are at high surgical risk because of concurrent medical problems, for those who have very extensive spinal involvement, and for patients with paralysis that has lasted more than 48 hours, after which significant neurologic recovery is highly unlikely.

If the infecting organism is unknown, empirical antibiotic therapy should include an agent effective against gram-negative bacilli (e.g., gentamicin or a third-generation cephalosporin) plus an agent active against *S. aureus* (e.g., a penicillinase-resistant penicillin such as nafcillin).

When methicillin-resistant *S. aureus* is a possibility, vancomycin should be used. Results of microbiologic evaluation of surgical specimens or blood cultures can then dictate the appropriate choice. In general, treatment is continued for 3 to 4 weeks in the absence of vertebral osteomyelitis and continued for 6 to 8 weeks when it is present. Patients with tuberculous epidural abscesses should receive antituberculous chemotherapy for at least 6 months.

PROGNOSIS

The prognosis in spinal epidural abscess depends on several factors, the most important of which is the extent of neurologic deficiency at the time of surgery. Poor outcomes are common when paresis or, especially, paralysis is present. Other unfavorable prognostic features are advanced age (> 60 years), substantial thecal sac compression on neuroimaging, and longer duration of symptoms.[40] About 40% of patients recover completely, 25% have residual weakness, 20% have permanent paralysis, and 15% die.

Subdural Empyema

PATHOGENESIS AND PATHOPHYSIOLOGY

A subdural empyema is a collection of pus between the dura mater and the underlying arachnoid. Because this space contains no septations, except where the arachnoid granules lie within the dura, purulent material easily spreads over the surface of the brain. Most cases occur as a complication of sinusitis in older children and young adults, especially males, who account for about 75% of cases.[41] The frontal sinus is nearly always involved, usually along with one or more of the other paranasal sinuses. Another cause is ear infection, either otitis media or mastoiditis; in such cases, the empyema may lie below the tentorium.

In these infections, pathogens probably reach the subdural space via blood draining from the infected sites through the venous sinuses in the dura. Subsequent septic thrombophlebitis of these vessels spreads organisms into the subdural space. Direct extension from contiguous infectious foci through erosion of the bones of the sinus or the ear may also occur. Other possible sources of the organisms causing subdural empyema are bacteremic infection of a preexisting subdural hematoma and direct inoculation of microbes into the area from penetrating head trauma or intracranial surgery.

Once the subdural space is infected, pus may spread widely over the convexities of the ipsilateral cerebrum; it may also travel along the falx separating the two hemispheres. The clinical features arise from pressure exerted on the underlying brain, the systemic effects of infection, and septic thrombophlebitis that spreads to the cortical and subcortical veins, causing brain infarction or infection.

ETIOLOGY

In most cases, only one species of organism is isolated from the pus, but polymicrobial infections can occur. The usual pathogens are aerobic or anaerobic streptococci and other anaerobes, especially with infections arising from sinusitis. Staphylococci and gram-negative bacilli are common causes in postoperative infections. Approximately 20% of cultures are negative, possibly because of inadequate microbiologic techniques (especially in isolating anaerobic bacteria) or previous antimicrobial therapy.

DIAGNOSIS

Clinical Features

Many patients have had a preceding sinusitis or a nonspecific upper respiratory tract illness; in some patients, however, symptoms of subdural empyema arise suddenly. The most common features are fever, stiff neck, and headache, which can be diffuse or localized to the area of empyema or underlying sinusitis. Neurologic abnormalities are usually present, including hemiparesis, seizures, aphasia, hemianesthesia, hemianopsia, and altered mentation, such as confusion, drowsiness, disorientation, and even coma. Papilledema may occur, indicating increased intracranial pressure, which can also cause palsies of the third and sixth cranial nerves. Sinus tenderness and periorbital edema may develop, reflecting the underlying sinusitis. With infratentorial empyema, which usually originates from neglected otic infections, the clinical features include stiff neck, altered consciousness, signs of increased intracranial pressure, otorrhea, and fever.[42] Patients typically deteriorate rapidly.

The presence of fever, headache, nuchal rigidity, and focal neurologic signs, especially in an adolescent boy or young man

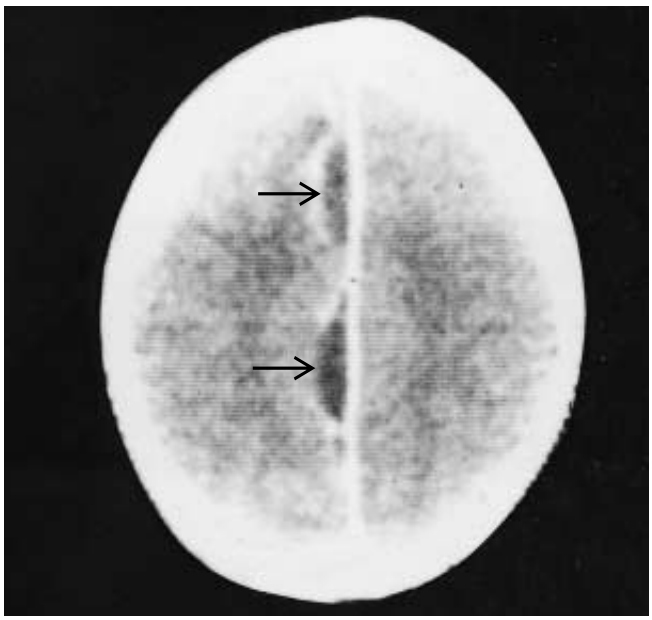

Figure 3 **CT scan of a 17-year-old patient with a subdural empyema shows two loculations (arrows) that are restricted to the interhemispheric area. Contrast-enhanced margins surround the two loculations.**

with sinusitis, should strongly suggest the presence of a subdural empyema and the necessity of immediate neuroimaging with CT or, preferably, MRI.

Laboratory Findings

A peripheral leukocytosis is common. Lumbar puncture is inadvisable because of the risk of brain herniation from increased intracranial pressure, but it is often performed because the clinical features suggest acute bacterial meningitis. Fortunately, serious complications rarely occur. The opening pressure is elevated, and pleocytosis of several hundred white cells or fewer is present. There is commonly a mixture of neutrophils and lymphocytes; either may predominate, but frequently the two cell types are equal in number. The protein level is typically increased, but the glucose level is almost always normal, and both Gram stain and culture are characteristically negative.

Imaging Studies

CT scans may show the empyema as isodense to low-density collections over one hemisphere and in the interhemispheric space, with a contrast-enhanced rim [*see Figure 3*]. MRI is a more sensitive and accurate imaging technique, however, revealing the empyema as isointense masses on T_1-weighted images but showing high signal on proton density or T_2-weighted images. The rim may be enhanced with gadolinium.[41] These imaging techniques may also demonstrate concurrent complications, which are relatively common and include brain abscess, cranial epidural abscess, cortical thrombophlebitis, and venous infarction.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for subdural empyema includes bacterial meningitis, brain abscess, and encephalitis. Clinical distinction among these infections may be difficult; however, focal findings are unusual in meningitis, and a stiff neck is uncommon with brain abscesses and encephalitis.

TREATMENT

The most important therapy is removal of the subdural pus through use of multiple bur holes or craniotomy. It is unclear which method is better; the choice may depend on the location of the infection and the patient's neurologic status. With either procedure, but especially with bur holes, multiple operations are often necessary because of inadequate drainage of pus. Antibiotic therapy, usually continued for 3 to 4 weeks after surgery, can be dictated by the results of Gram stain and culture of pus. The combination of ceftriaxone and metronidazole is a reasonable empirical regimen to use until the results of the Gram stain and culture are received.

PROGNOSIS

The prognosis depends greatly on the patient's state of consciousness at the time of surgery, with worsening outcomes accompanying decreasing levels of awareness. Overall mortality is approximately 15%. Significant neurologic sequelae, such as speech abnormalities and hemiparesis, occur in approximately 15% to 20% of survivors, and seizures occur in about 30%. These problems may emerge long after the surgery.

Septic Thrombophlebitis of the Major Cerebral Veins

The dural sinuses drain blood from the brain into the jugular veins. These sinuses lack valves, allowing flow in either direction, depending on the prevailing pressure gradient. Septic thrombophlebitis of these vessels, which may result from intracranial suppuration or spread of infection from extracranial veins, causes increased intracranial pressure, focal cerebral edema, or brain infarction. Usually, the initiating site of infection is clinically obvious in the middle ear, mastoid, paranasal sinuses, or facial skin. The cavernous, lateral, and superior sagittal sinuses are the most commonly involved vessels.[43]

CAVERNOUS SINUS THROMBOPHLEBITIS

Cavernous sinus thrombophlebitis most frequently develops from infections in the paranasal sinuses or the facial skin, especially on the medial third near the eyes and nose. Most cases are caused by *S. aureus*.[44] Other causative pathogens are streptococci, gram-negative bacilli, and anaerobes.

The earliest symptom is usually headache, which often precedes fever and other findings by several days. The pain typically involves areas innervated by the ophthalmic and maxillary divisions of the trigeminal nerve, which traverse the cavernous sinus. Hyperesthesia or decreased sensation may be demonstrable in the dermatomes served by these nerves. Other focal findings may arise from obstructed ophthalmic veins: unilateral chemosis, proptosis, and edema of the ipsilateral eyelids, nose, and forehead. With time, the findings become bilateral as the phlebitis extends to the opposite cavernous sinus. Compression of cranial nerves III, IV, and VI, which course through the cavernous sinus, leads to varying degrees of ophthalmoplegia. The pupils may dilate and fail to react to light. Retinal veins engorge, visual acuity may lessen, and hemorrhages and papilledema can occur. Lethargy and coma may supervene, reflecting increased intracranial pressure and neuronal damage. Occasionally, bacteremia with metastatic foci of infection develops.

LATERAL SINUS THROMBOPHLEBITIS

Lateral sinus thrombophlebitis is almost always a complication of mastoiditis. Anaerobes, staphylococci, and gram-negative

bacilli, especially *Proteus* organisms, are the most common isolates.

The clinical course is usually subacute, with symptoms lasting for several weeks. Earache and drainage are often the first symptoms. Persistent, severe unilateral headache, followed by nausea and vomiting, indicates the development of lateral sinus thrombophlebitis. Fever, chills, and manifestations of increased intracranial pressure, including confusion and papilledema, are commonly present. Postauricular tenderness, venous engorgement, and edema represent involvement of the mastoid emissary vein. Extension into the jugular vein may occur.

Otoscopic examination commonly reveals a perforated or inflamed tympanic membrane. Focal neurologic findings are usually absent except for unilateral sixth nerve palsy, reflecting compression of the inferior petrosal sinus.

SUPERIOR SAGITTAL SINUS THROMBOPHLEBITIS

Superior sagittal sinus thrombophlebitis complicates bacterial meningitis, paranasal sinusitis, contiguous osteomyelitis, and dural infection. The most common organisms are *S. pneumoniae*, other streptococci, and gram-negative bacilli. Thrombosis of only the anterior portion of the sinus is often asymptomatic, but posterior involvement causes increased intracranial pressure. The predominant feature is acute headache, often with nausea and vomiting, followed in a few days by confusion and eventually coma. Focal or generalized seizures are common, and most patients are febrile. Extension of the thrombophlebitis to cortical veins may cause infarction of the underlying cortex, producing such neurologic manifestations as focal seizures and hemiparesis.

DIAGNOSIS

With septic thrombophlebitis in any of the cerebral veins, examination of the CSF may yield normal results or may demonstrate findings consistent with a parameningeal focus of infection: increased protein level, normal glucose level, and a pleocytosis of mixed neutrophils and lymphocytes that rarely exceeds a few hundred cells. Increased opening pressure is also common in all types.

Plain films of the skull are rarely helpful except in cases of septic lateral sinus thrombosis, in which they nearly always reveal mastoiditis. Certain findings on CT scan suggest cerebral venous thrombosis, but MRI provides a much better study. Acutely thrombosed cerebral veins lack a flow void. They are isointense on T_1-weighted images and hypointense on T_2-weighted images. In subacute thrombosis, the methemoglobin in the veins produces areas of high intensity on both images.

TREATMENT

Management of cerebral vein thrombophlebitis includes appropriate antibiotic therapy. For each of these disorders, when the infecting organisms are unknown, a good empirical antibiotic regimen is a combination of ceftriaxone and metronidazole. With cavernous sinus thrombosis in which *S. aureus* is prominent, vancomycin may be added if methicillin-resistant strains are likely.

Occasionally, treatment of cerebral vein thrombophlebitis includes surgery for the areas of purulence from which the infection arose. When paranasal sinusitis is the underlying cause, drainage of the infected sinuses may be necessary to obtain a good clinical response. In lateral sinus thrombophlebitis, radical mastoidectomy and exploration over the lateral sinus are commonly performed to remove purulent material.

Other medical treatment may include mannitol and dexamethasone in superior sagittal thrombophlebitis to help relieve the severe cerebral edema that is often present. The role of anticoagulation in cerebral vein thrombophlebitis remains unsettled; it seems valuable in cavernous sinus thrombosis[45] but appears potentially hazardous in superior sagittal and lateral sinus thrombophlebitis because of the frequent concurrent hemorrhagic venous cortical infarcts that it may exacerbate.

PROGNOSIS

Septic thrombophlebitis of the superior sagittal and cavernous sinuses imposes a high mortality, even with appropriate therapy; however, most patients with involvement of the lateral sinus have a good prognosis.

XXXVII MYCOTIC INFECTIONS

Carol A. Kauffman, m.d.

Overview of Endemic Mycosis

The endemic mycoses (histoplasmosis, blastomycosis, coccidioidomycosis, and sporotrichosis) are caused by fungi that share several important characteristics but differ greatly in other respects. The fungi are all dimorphic, existing as molds in the environment and as either yeasts or spherules in tissues. Each organism occupies a different ecological niche; infection is directly related to exposure to the mycelial or mold phase of the organism in the environment. These fungi are true pathogens in that they are capable of causing infection in otherwise healthy individuals. The severity of infection is determined both by the extent of the exposure to the organism and by the immune status of the patient. Three of the four organisms (*Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*) are inhaled, have the propensity to disseminate hematogenously, and are able to reactivate years later; the fourth organism, *Sporothrix schenckii*, usually causes primary infection after cutaneous inoculation and does not reactivate. Although many of the disease manifestations overlap, each of the four has its own distinctive characteristics.

The endemic mycoses mimic many common infections involving lungs, skin, and other organs, and frequently, the diagnosis of fungal infection is not entertained; this is especially true for patients who present outside of the areas endemic for these specific mycoses. Because of an increase in travel and leisure activities over the past several decades, patients often present with illness outside endemic areas. When faced with an elderly retiree who spends winters in Arizona and who has developed fever, headache, and visual complaints, a physician who practices in Ohio and who may have never seen coccidioidomycosis must remember that this fungal infection causes chronic meningitis. Similarly, an AIDS patient with fever, hepatosplenomegaly, and pancytopenia who lives in Seattle but who spent his childhood in Arkansas and has not returned there for the past 20 years may well be experiencing reactivation of disseminated histoplasmosis.

The most useful diagnostic tests differ for each of the endemic mycoses, but as a general rule, histopathologic demonstration of the fungi in biopsy specimens is the most expeditious way to make a diagnosis, especially in a severely ill patient; growth of the organism in vitro is definitive. For most patients with an endemic mycosis, treatment will be with an azole antifungal agent. For those who are severely ill, initial therapy with amphotericin B followed by consolidation therapy with an azole is standard.

A review of antifungal agents and guidelines for their use in the treatment of mycotic infections is found after the descriptions of specific manifestations of each endemic mycosis [*see* Antifungal Therapy, *below*].

Histoplasmosis

epidemiology

H. capsulatum is a dimorphic fungus that every year infects hundreds of thousands of individuals in the United States. The organism is endemic in the Mississippi and Ohio River valleys and Central America. Soil containing high concentrations of bird or bat guano supports the profuse growth of the mycelial phase of *H. capsulatum*. Exposure typically occurs as a result of activities that generate aerosols containing the organism. Although most cases are sporadic and the exact source of exposure is unknown, many point-source outbreaks have been well described in association with disruption of soil; the cleaning of attics, bridges, or barns; tearing down old structures laden with guano; and spelunking.[1-3] Massive outbreaks of infection with *H. capsulatum* occurred when urban demolition exposed hundreds of thousands of people to the organism.[1] Infection is very common in the endemic area, most persons having been infected before adulthood.

pathogenesis

During the mycelial phase of the organism's life cycle, the microconidia are inhaled into the alveoli, causing a localized pulmonary infection. Neutrophils and macrophages phagocytize the organism, which converts to the yeast phase; the organism is then able to survive and travel within the macrophage. Spread to the hilar and mediastinal lymph nodes ensues, and hematogenous dissemination subsequently occurs throughout the reticuloendothelial system before specific immunity has developed. After several weeks, cell-mediated immunity that is specific for *H. capsulatum* activates macrophages, which then kill the organism.[4] Of all the human mycoses, histoplasmosis exemplifies best the pivotal importance of the cell-mediated immune system. The corollary of this observation is that most patients with severe infection are those with cellular immune deficiencies.

The extent of disease is determined by the number of conidia that are inhaled and the immune response of the host. A healthy individual may develop severe life-threatening pulmonary infection if a large number of conidia are inhaled. This might occur during demolition or renovation of an old building or as a result of spelunking in a heavily infested cave. Conversely, a small inoculum can cause severe pulmonary infection or progress to acute symptomatic disseminated histoplasmosis in a patient with advanced HIV infection whose cell-mediated immune system is unable to contain the organism.

Most persons who have been infected experience asymptomatic dissemination; only rarely will this lead to symptomatic acute or chronic disseminated histoplasmosis. However, by virtue of this dissemination, latent infection can persist for a lifetime. Reactivation of quiescent infection can occur years later if immunosuppression occurs.[5] Reinfection has also been documented, though rarely, in persons previously known to have had histoplasmosis. Such reinfection almost always occurs in the setting of exposure to a heavy inoculum of *H. capsulatum* conidia.

clinical presentations

Pulmonary Histoplasmosis

Infection is asymptomatic in the vast majority of persons who have been infected with *H. capsulatum*. Most patients who have symptomatic pulmonary infection will have a self-limited illness characterized by fever, chills, and cough that is usually nonproductive; such infection is often associated with anterior chest discomfort, myalgias, arthralgias, and fatigue. A patchy lobar or multilobar nodular infiltrate is noted on chest radiography.[6] The diagnosis is usually not made in individual cases until the patient fails to respond to several courses of antibiotics given for atypical pneumonia.

The diagnosis of acute pulmonary histoplasmosis is more easily made when the patient has been involved in an outbreak.[2] A careful history of the patient's activities as well as the patient's colleagues' activities—especially if the history reveals participation in outdoor activities, activities around a demolition site, or spelunking several weeks before the onset of symptoms—may point to histoplasmosis. High spiking fever, prostration, dyspnea, and cough are prominent in severe cases in which the number of conidia inhaled is large. Diffuse nodular infiltrates are noted on the chest radiograph, and development of the acute respiratory distress syndrome (ARDS) can ensue.

In patients with cell-mediated immune deficiencies, including those who have advanced HIV infection, those with a hematologic malignancy, those who have received a transplant, and those who are receiving immunosuppressive medications, pulmonary infection is more severe than in otherwise healthy patients. Although pulmonary infection may be the only manifestation of histoplasmosis, in most immunosuppressed patients, pulmonary involvement is merely one component of widespread dissemination.[7] Prostration, fever, chills, marked dyspnea, and hypoxemia are prominent, and chest radiographs show diffuse infiltrates.

Chronic cavitary pulmonary histoplasmosis is a progressive, fatal form of histoplasmosis that usually develops in older patients who have chronic obstructive pulmonary disease (COPD). Typical symptoms include fever, fatigue, anorexia, weight loss, cough that is productive of purulent sputum, and hemoptysis.[8,9] On chest radiography, infiltrates can be either unilateral or bilateral and are almost always located in the upper lobes. Cavities may be multiple and are frequently quite large; extensive fibrosis occurs in the lower lobes.[6]

Disseminated Histoplasmosis

Hematogenous dissemination typically occurs in immunosuppressed patients and young children early in the course of infection with *H. capsulatum*. Patients who have HIV infection and whose $CD4^+$ T cell counts are less than 150 cells / mm^3 are at great risk for acquiring histoplasmosis, which almost always presents as disseminated infection. Symptoms and signs of acute disseminated histoplasmosis include chills, fever, malaise, anorexia, weight loss, dyspnea, hepatosplenomegaly, and skin and mucous membrane lesions. Pancytopenia, diffuse pulmonary infiltrates seen on chest radiographs, and blood cultures that yield *H. capsulatum* are common.[7,10] Adrenal insufficiency may also be present.

A chronic progressive disseminated form of histoplasmosis that occurs mostly in middle-aged to elderly men who have no known immunosuppressive illness is characterized by fever, night sweats, weight loss, and fatigue.[11] Patients appear chronically ill and frequently have hepatosplenomegaly, mucocutaneous ulcerations, and signs of adrenal insufficiency. Typical findings include an increase in the erythrocyte sedimentation rate, an elevation in the alkaline phosphatase level, pancytopenia, and diffuse pulmonary infiltrates seen on chest radiograph. If not diagnosed and treated appropriately, this form of histoplasmosis is fatal.

diagnosis

Culture

The definitive diagnostic test for histoplasmosis is growth of *H. capsulatum* in culture, which, unfortunately, may take as long as 6 weeks.[5] Sputum, bronchoalveolar lavage fluid, or tissue biopsy material should be sent to the laboratory for culture. For those patients who have evidence of dissemination, cultures of blood are useful. The best yield is with the lysis-centrifugation system (Isolator aerobic blood culture system, Wampole Laboratories). The laboratory should be informed that pulmonary histoplasmosis is a diagnostic consideration, so that a special medium that decreases the growth of commensal fungi, such as *Candida*, can be used for the culture of pulmonary samples. As soon as growth of a mold has been detected, a DNA probe specific for *H. capsulatum* confirms the identity of the organism.

Serologic Studies

In contrast to several other endemic mycoses, serology plays an important adjunctive role in the diagnosis of histoplasmosis.[12] Both complement fixation (CF) and immunodiffusion (ID) tests are available. ID is more specific than CF (> 95% specificity versus 85% to 90%); both are only modestly sensitive (75% to 85% sensitivity). False negative serologic test results occur in immunosuppressed patients who cannot mount an antibody response. However, most patients with pulmonary histoplasmosis are not immunosuppressed, and thus, in this group, antibody tests are helpful.

Patients with chronic cavitary pulmonary histoplasmosis almost always have an elevated CF antibody titer (> 1:32), and either an M precipitin band or both H and M precipitin bands are seen on ID in these patients. In a patient with acute pneumonia, a documented fourfold increase in CF titer or the appearance of an M precipitin band on ID establishes the diagnosis of histoplasmosis. Serologic tests are less definitive in patients with mediastinal lymphadenopathy and should always be confirmed by tissue biopsy. False positive test results, especially false positive results on CF, occur in patients with lymphoma, tuberculosis, sarcoidosis, and other fungal infections, all of which may present as mediastinal masses. In most patients with the chronic disseminated form of histoplasmosis, both precipitin and CF antibodies are present.

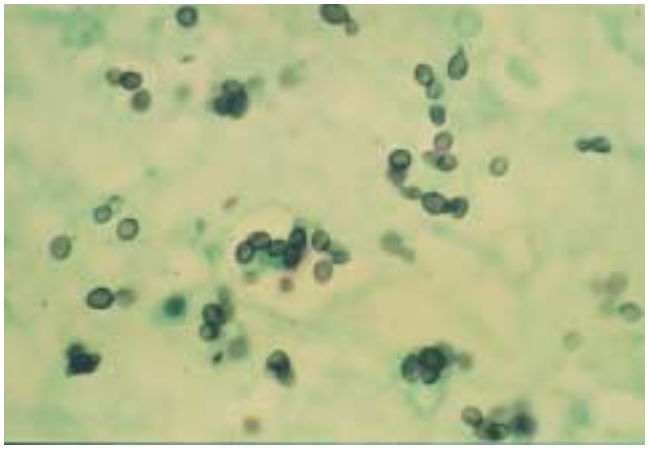
Antigen Tests

Enzyme immunoassays for the detection of *H. capsulatum* polysaccharide antigen in urine and serum are extremely helpful in AIDS patients who have disseminated infection and a large fungal burden.[13,14] They are less useful for patients with pulmonary histoplasmosis; antigen is detected in only about 20% of patients with pulmonary histoplasmosis. Cross-reactivity occurs in a small number of patients with blastomycosis, paracoccidioidomycosis, and penicilliosis.

Tissue Biopsy

For an acutely ill person, evidence of *H. capsulatum* on tissue biopsy allows the physician to make the diagnosis of histoplasmosis in a timely fashion.[5] The organisms appear as distinctive, fairly uniformly shaped, oval budding yeasts 2 to 4 μm in diameter. Tissue biopsy is most useful for the diagnosis of disseminated disease; bone marrow, liver, and mucocutaneous lesions reveal many organisms [*see Figure 1*]. For most patients with acute pulmonary histoplasmosis, biopsy is not indicated unless the patient is severely ill. For patients with chronic pulmonary histoplasmosis or granulomatous mediastinitis, biopsy of lung or lymph nodes may reveal the organism. Routine hematoxylin-eosin staining will not show the tiny *H. capsulatum* yeasts; biopsy material must be stained with methenamine-silver stain, periodic acid–Schiff stain, or both. In contrast to larger yeasts, such as *B. dermatitidis*, it is extremely unusual to find *H. capsulatum* on cytologic examination of sputum or bronchoalveolar lavage fluid.

a



b

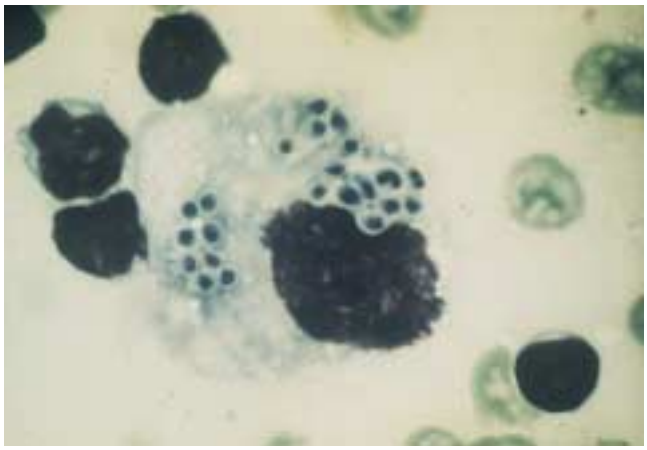


Figure 1 **Shown are biopsy samples from an elderly man with chronic progressive disseminated histoplasmosis. (*a*) Tongue ulcer stained with methenamine-silver stain shows several budding yeast forms measuring 2 to 4 μm. (*b*) A smear from a lung biopsy sample, which is stained with Giemsa stain, shows small intracellular yeasts inside a macrophage.**

Skin Tests

Skin tests with histoplasmin antigen are not useful for the diagnosis of histoplasmosis in individual patients. In the endemic area, as many as 85% of adults have positive results on skin testing because of previous exposure to the organism; cross-reactions occur in those with other fungal infections, especially blastomycosis; and negative test results occur frequently in patients who have severe infection.

differential diagnosis

Acute pulmonary histoplasmosis is most difficult to differentiate from acute pulmonary blastomycosis. The clinical and radiographic findings of these two diseases are similar, the regions in which these diseases are endemic overlap, and the CF antibody tests for the two organisms show cross-reactivity. For either disease, culture of the causative organism from sputum is diagnostically definitive. However, results of sputum cultures are often negative for patients with acute pneumonia caused by either fungus. Treatment, fortunately, is the same for the two diseases. Atypical pneumonias caused by *Mycoplasma*, *Legionella*, and *Chlamydia* are included in the differential diagnosis of acute pulmonary histoplasmosis. Hilar and mediastinal lymphadenopathy, which is very common with histoplasmosis, is uncommon in patients with atypical pneumonia caused by these other organisms.

Chronic pulmonary histoplasmosis mimics tuberculosis in regard to symptoms, signs, and radiographic findings. Other chronic fungal pneumonias, especially blastomycosis and sporotrichosis, and nontuberculous mycobacterial infections also must be differentiated from this form of histoplasmosis. Sputum culture and serology are most useful in differentiating these infections.

Patients with acute disseminated histoplasmosis can present with a sepsis syndrome associated with ARDS and disseminated intravascular coagulation that is indistinguishable from sepsis of any bacterial or viral etiology. Helpful findings supporting the diagnosis of histoplasmosis are pancytopenia, diffuse nodular pulmonary infiltrates, and hepatosplenomegaly; the hematology laboratory may make the diagnosis when they find small yeasts inside white cells on the peripheral smear. In AIDS patients, the main infections that must be excluded are those caused by cytomegalovirus, *Mycobacterium avium* complex, and *M. tuberculosis*. Biopsy of involved tissues should be performed as soon as possible to help differentiate between these conditions. Culture of blood by means of lysis-centrifugation (Isolator system) for fungus and *Mycobacteria* and use of urinary antigen testing for *H. capsulatum* are very helpful diagnostic tests in this circumstance.

Patients with chronic disseminated histoplasmosis usually present with fever of unknown origin. The disease that mimics histoplasmosis most closely is miliary tuberculosis; lymphoma, brucellosis, and sarcoidosis also must be excluded. Serology is helpful, but histopathologic evidence of yeasts in tissue granulomas and confirmatory culture of the organism from bone marrow, mucous membrane lesions, or liver are definitive. It should be emphasized that the diagnosis of sarcoidosis requires firm evidence that the patient does not have histoplasmosis or tuberculosis; corticosteroid use for the treatment of suspected sarcoidosis in patients who in fact have histoplasmosis frequently leads to defervescence for a short period, followed by further worsening of the infection.[15]

treatment

Guidelines for the treatment of histoplasmosis have recently been published by the Mycoses Study Group and the Infectious Diseases Society of America.[16] Efficacy has been defined primarily by open-label trials in patients with and without AIDS and through anecdotal experience[17-22]; there are no studies that directly compare azoles with amphotericin B. The only blinded, randomized treatment trial studied liposomal amphotericin B versus amphotericin B deoxycholate in a very restricted patient population: AIDS patients with severe disseminated histoplasmosis.[23] In spite of the lack of controlled treatment trials, it is clear that for the treatment of most patients with histoplasmosis, itraconazole is the drug of choice.[18-20] Fluconazole should be considered a second-line agent; primary response rates are lower for fluconazole in patients with and without AIDS, and relapse rates for AIDS patients receiving fluconazole are higher than those noted in previous studies with itraconazole.[21,22] If a patient does not tolerate itraconazole, fluconazole can be used, but the dosage should be 400 to 800 mg daily. Side effects, drug absorption, and drug-drug interactions are important considerations in antifungal therapy,

particularly in long-term regimens such as those frequently required for AIDS patients [*see* Antifungal Therapy, *below*].

Pulmonary Histoplasmosis

Treatment recommendations are based on the type of histoplasmosis and the immune status of the host.[16] Treatment is generally not recommended for patients with acute pulmonary histoplasmosis; in fact, the diagnosis is often not made until after the patient's symptoms have resolved. However, if the patient remains symptomatic after 4 weeks, therapy with itraconazole, 200 mg daily for 6 to 12 weeks, is recommended. Children with acute pulmonary histoplasmosis should be treated with itraconazole, 5 to 7 mg / kg / day.

Although pneumonia resolves without treatment in most patients with acute outbreak-related histoplasmosis, those with severe infection should receive treatment. Immunosuppressed patients with acute pulmonary histoplasmosis should always be treated. Initial therapy should be administration of amphotericin B, 0.7 mg / kg / day. After a favorable response is noted, which usually occurs quite soon after initiation of therapy, therapy can be changed to oral itraconazole. Treatment should continue until the infiltrate has resolved.

Antifungal therapy is required for all patients with chronic pulmonary histoplasmosis.[8,16] Itraconazole, 200 mg once or twice daily for 12 to 24 months, is the treatment of choice. Even with appropriate antifungal therapy, outcome is poor.

Disseminated Histoplasmosis

All patients with symptomatic disseminated histoplasmosis should receive antifungal therapy.[11,16] Patients with acute disseminated disease who have only mild to moderate symptoms and most patients with chronic progressive disseminated histoplasmosis should be treated with itraconazole, 200 mg twice daily; this recommendation applies both to patients with AIDS and to those who do not have AIDS. For patients who do not have AIDS, a total of 12 months of therapy is usually adequate, but the length of therapy will be determined by the patient's clinical course; this is especially true for patients with chronic progressive disease. Patients who have AIDS should initially receive itraconazole twice daily for 12 weeks; after that period, they should receive a maintenance course of long-term suppressive therapy with itraconazole, 200 mg daily.[20]

Young infants, who frequently have overwhelming infection, and immunosuppressed patients with moderately severe to severe symptoms should be treated initially with amphotericin B, 0.7 to 1.0 mg / kg / day. For most adults, therapy can be changed to itraconazole after they become afebrile and are able to take oral medications. Infants should receive a full course of amphotericin B because experience with itraconazole is limited in this population group. When therapy is with amphotericin B deoxycholate only, the total dose should be 35 mg / kg.[16]

In a blinded, randomized clinical trial, liposomal amphotericin B, 3 mg / kg / day, was found to be superior to amphotericin B deoxycholate, 0.7 mg / kg / day, for initial treatment of AIDS patients who had severe disseminated histoplasmosis. In this study, the 51 patients receiving liposomal amphotericin B became afebrile sooner than the 22 receiving amphotericin B deoxycholate (P = 0.01); in addition, mortality was decreased and toxicity was lessened in the liposomal amphotericin B arm.[23] However, it is not clear whether these results should affect clinical decision making regarding the treatment of disseminated histoplasmosis in patients who do not have AIDS. The main drawback to the use of the liposomal formulation of amphotericin B is that it is extremely costly in comparison with the standard formulation.

complications

Granulomatous mediastinitis is an uncommon complication of pulmonary histoplasmosis in which lymphadenopathy persists for months.[5] The enlarged nodes can erode into the esophagus; can lead to the formation of tracheoesophageal fistulas; and can cause traction diverticula. Chest radiography and CT scanning reveal enlarged hilar and mediastinal lymph nodes; necrosis and calcium deposition in the nodes are commonly noted on CT scan. Mediastinoscopy and biopsy reveal caseous material, which may contain a few yeastlike organisms typical of *H. capsulatum*. In most patients, the disease follows a self-limited, although protracted, course, and patients do not develop fibrosing mediastinitis. Patients may benefit from itraconazole, 200 mg twice daily, but there are no clinical trials proving efficacy.[16]

Fibrosing mediastinitis is a rare complication of pulmonary histoplasmosis in which an excessive amount of fibrosis develops in the mediastinal lymph nodes in response to infection.[24,25] The exuberant fibrous tissue entraps the great vessels, causing heart failure, pulmonary emboli, and superior vena cava syndrome. Odynophagia, dyspnea, cough, wheezing, and hemoptysis are commonly noted. There is no effective therapy for this progressive disease.

Pericarditis is a self-limited illness that occurs as an inflammatory response to acute pulmonary histoplasmosis.[5] Pleural effusions and mediastinal lymphadenopathy are commonly noted with pericarditis. The pericardial fluid is exudative. Drainage is required if tamponade occurs, but this is rare. Pericarditis should be treated with nonsteroidal anti-inflammatory drugs; corticosteroids should be used for severe cases. Antifungal agents should not be used.[16] The long-term outcome is excellent; only rarely has constrictive pericarditis occurred.

prognosis

Most patients with histoplasmosis respond quite well to antifungal agents. Even patients with advanced AIDS respond quickly and completely to therapy and continue to do well as long as they receive suppressive therapy with an azole. Patients with chronic progressive disseminated histoplasmosis usually experience a return to their baseline function, but it often takes months for this to occur. The patients who do poorly are those whose underlying illness precludes a return to normal function. For example, patients with chronic cavitary pulmonary histoplasmosis frequently have progressive respiratory insufficiency because of their severe underlying emphysema and the fibrosis caused by the fungal infection.

Blastomycosis

epidemiology

Although the dimorphic fungus *B. dermatitidis* is present in many diverse geographic areas worldwide, most cases of blastomycosis are reported from the south central and north central United States.[26] The endemic area for blastomycosis overlaps that for histoplasmosis but extends further north into Wisconsin, Minnesota, and the southern portions of the Canadian provinces of Manitoba, Saskatchewan, and Alberta. Most cases are reported from Arkansas, Mississippi, and Kentucky.

The ecology of *B. dermatitidis* is not as well understood as that of the other endemic mycoses. It is assumed that the natural niche is soil, but the yield of soil cultures is quite low. Most cases occur sporadically, but several well-described outbreaks have helped define the presumed natural habitat.[27,28] The largest outbreak to date involved 95 students in northern Wisconsin who camped along a beaver pond and explored a beaver lodge.[27] Decomposed wood on the pond bank and samples from the lodge yielded *B. dermatitidis.*

Most, but certainly not all, patients who develop blastomycosis are men who have an outdoor occupation or hobby. Cases have been described in hunters and their dogs; in these cases, it is presumed that the hunters and their dogs were exposed to the same environmental source. For most sporadic cases, the source of exposure to the fungus is unknown.

pathogenesis

Most patients with blastomycosis have no underlying illnesses, but the disease is more severe in immunosuppressed patients.[29] Blastomycosis is acquired by inhaling the conidia of *B. dermatitidis* into the alveoli. The organisms change to the yeast form in the lungs and then reproduce by budding. The immune response to *B. dermatitidis* appears to include both neutrophils and cell-mediated immune mechanisms involving T cells and macrophages.

Even though a major clinical manifestation of blastomycosis is cutaneous lesions, blastomycosis is only very rarely spread through inoculation. Examples of such cases include accidental inoculation in laboratory workers, conjugal inoculation from a genital lesion, and inoculation from the bite of an infected dog. The organism travels to the skin and other common target organs, including osteoarticular structures and the genitourinary tract, by the hematogenous route. Most persons infected with *B. dermatitidis* are asymptomatic or have mild pulmonary symptoms. Hematogenous dissemination occurs without clinical manifestations, and only later do patients present with skin lesions in the absence of other obvious organ involvement.

clinical presentations

Pulmonary Blastomycosis

Blastomycosis begins as a pulmonary infection, but many patients never develop symptoms, and others have an acute illness with fever, cough, and a pulmonary infiltrate that is diagnosed as an atypical pneumonia. Overwhelming pulmonary disease with ARDS can occur; this appears to be more common in older adults.[30] Whether severe infection occurs because the patient has been exposed to a large number of conidia or has a defect in his or her immune response has not been clarified.

A more common presentation is a subacute to chronic pulmonary infection that is clinically and radiographically similar to tuberculosis. Fever, night sweats, weight loss, and fatigue are common symptoms. Cough, sputum production, hemoptysis, and dyspnea are noted. The lesions may be cavitary, nodular, fibrotic, or masslike in appearance.[31,32] Hilar and mediastinal lymphadenopathy and pleural effusions are uncommonly seen.

Disseminated Blastomycosis

Many patients with blastomycosis have no pulmonary symptoms.[26,31] They present with cutaneous lesions that are well circumscribed, nonpainful papules, nodules, or plaques that often become verrucous and develop punctate drainage areas in the center. The lesions are common on the face and extremities but can appear anywhere. There may be only a single lesion, or there may be multiple lesions. An uncommon manifestation seen mostly in immunocompromised patients is the appearance of hundreds of acute pustular lesions associated with widespread visceral involvement and an acute downhill course.

Additional manifestations of disseminated blastomycosis include prostatitis, septic arthritis, osteomyelitis, laryngeal and oropharyngeal nodules, and, less commonly, central nervous system involvement. Genitourinary involvement may be asymptomatic, or it may be associated with signs of prostatism. Although osteoarticular infection can be associated with a contiguous skin lesion, bone involvement often occurs at sites distant from the cutaneous lesions. It is helpful to obtain a bone scan for all patients with disseminated blastomycosis because of the propensity of the organism to seed into bone and because osteomyelitis requires prolonged antifungal therapy. All patients with manifestations of dissemination, even patients with only one skin lesion, need to be treated with systemic antifungal therapy to prevent progression of disease.[33]

diagnosis

Culture

The most definitive method for diagnosing blastomycosis is growth of the organism from an aspirate, tissue biopsy, sputum, or body fluid.[34] For patients with disseminated blastomycosis, urine obtained before and after prostatic massage should be sent for fungal culture. *B. dermatitidis* generally takes several weeks to grow at room temperature. Once growth has occurred, highly specific and sensitive DNA probes are used to rapidly identify the mold as *B. dermatitidis.*

Biopsy and Cytologic Studies

Biopsy specimens of skin lesions characteristically show pseudoepitheliomatous hyperplasia; when distinctive, large, thick-walled yeasts with a single broad-based bud are seen, a firm diagnosis of blastomycosis can be made before the results of cultures are known. In patients who have pulmonary lesions, the distinctive yeast forms should be sought on potassium hydroxide (KOH) preparations or Papanicolaou stains performed for cytologic examination of sputum or bronchoalveolar lavage fluid and on lung biopsy specimens [*see Figure 2*].

Serologic Studies

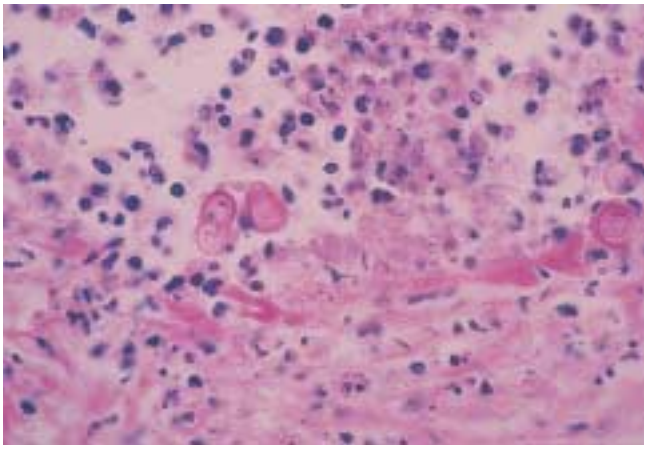
Standard CF and ID serologic assays for blastomycosis are neither sensitive nor specific. Several different enzyme immunoassays have been developed that enhance both specificity and sensitivity,[34] but they are not currently available.

differential diagnosis

The skin lesions of blastomycosis clinically mimic those caused by mycobacteria, especially nontuberculous mycobacteria; other fungal infections, especially coccidioidomycosis or paracoccidiodomycosis; mycosis fungoides; the lesions associated with bromide use; and atypical pyoderma granulosum. The histopathologic characteristics of pseudoepitheliomatous hyperplasia occur in response to other chronic infections and to bromoderma. Culture of biopsy material is of crucial importance in differentiating between these conditions.

Acute pulmonary blastomycosis is almost always misdiagnosed as a bacterial or atypical pneumonia and is then treated

a



b

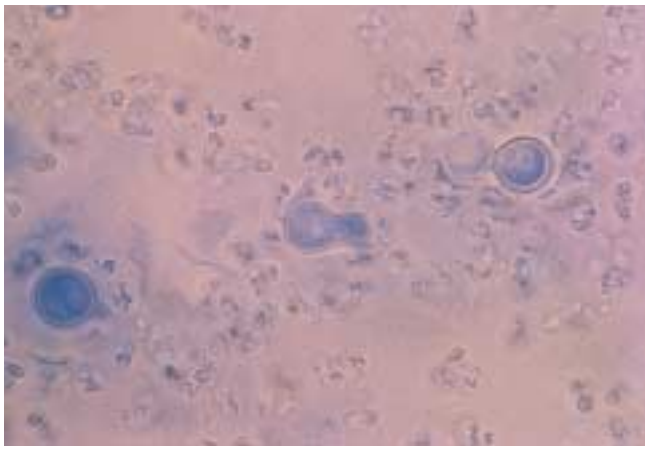


Figure 2 **Thick-walled, broad-based budding yeasts typical for *B. dermatitidis* are seen on biopsy material; they allow a definitive diagnosis of blastomycosis. (*a*) A lung biopsy specimen is stained with periodic acid–Schiff stain. The patient presented with a mass lesion in the right lower lobe and was initially thought to have lung carcinoma. (*b*) Purulent material was aspirated from one of numerous skin lesions in a patient with disseminated blastomycosis. Lactophenol cotton blue stain was used to prepare the slide.**

with antibiotics. Development of skin lesions is a strong clue suggesting blastomycosis. The masslike pulmonary lesion that is frequently noted with blastomycosis is usually thought to be lung cancer until biopsy results are reported. Likewise, lesions in the upper airways, which are usually firm and nodular, are frequently assumed to be squamous cell carcinoma until biopsy is performed. The clinical and radiographic signs and symptoms of patients with chronic pulmonary blastomycosis are indistinguishable from those associated with tuberculosis, histoplasmosis and other fungal infections, and sometimes sarcoidosis. Histopathologic studies and culture studies from biopsy material are most important in differentiating between these conditions.

treatment

Guidelines for the treatment of blastomycosis have been published by the Mycoses Study Group under the auspices of the Infectious Diseases Society of America.[33] The current recommendations are based on several multicenter, nonrandomized, open-label treatment trials and a few retrospective and prospective reports from individual institutions.[17,18,35,36] There have been no trials comparing amphotericin B with azoles for the treatment of blastomycosis.

In general, patients with pulmonary or disseminated forms of blastomycosis can be treated in a similar manner. Those patients who have mild to moderate illness should be treated with an azole; patients who have severe blastomycosis, either pulmonary or disseminated, and all patients with CNS involvement should receive amphotericin B as initial therapy.[33]

Itraconazole is the drug of choice for the treatment of mild to moderate blastomycosis.[18,33] Although lesions often begin to resolve within the first month of therapy, treatment should be continued for 6 to 12 months to achieve a mycologic cure and to prevent relapse. The usual dosage is 200 mg once or twice daily for 6 to 12 months. Children with blastomycosis should be treated with itraconazole, 5 to 7 mg/kg/day. Osteoarticular involvement requires therapy for at least a year. Fluconazole is not as effective as itraconazole for blastomycosis.[35,36] However, if a patient is unable to take itraconazole because of drug interactions or problems with absorption, fluconazole can be used; the dosage should be high—a total daily dosage of 400 to 800 mg given in once-daily or twice-daily doses for 6 to 12 months.

Amphotericin B should be reserved for patients who have severe blastomycosis, are immunosuppressed, or have CNS involvement.[33] The daily dosage is 0.7 to 1.0 mg/kg until a total of 1 to 2 g has been given. An alternative and preferred approach is to first administer amphotericin B until the patient has improved and then to switch to itraconazole, 200 mg twice daily, for a total of 6 to 12 months of therapy.

Side effects, drug absorption, and drug-drug interactions are important considerations in the use of antifungal therapy [*see* Antifungal Therapy, *below*].

prognosis

In patients with pulmonary and cutaneous manifestations of blastomycosis who undergo treatment with itraconazole, the clinical and mycologic response rates are 90% to 95%.[18] If relapse occurs, a second treatment with itraconazole is generally successful. Most reported deaths from blastomycosis occur early in the course of disease in patients who present with overwhelming pneumonia and ARDS. The outcome for patients with osteoarticular infection is good, but antifungal therapy should be given for at least a year to effect a cure.

Coccidioidomycosis

epidemiology

The dimorphic fungus *Coccidioides immitis*, the cause of coccidioidomycosis, occupies the most specific ecological niche of the endemic mycoses commonly seen in the United States.[37,38] The organism grows in the semiarid desert regions known as the Lower Sonoran Life Zone, which encompasses portions of California, Arizona, New Mexico, Nevada, and western Texas. The organism is also found in discrete areas of Central and South America.

The mycelial form of the organism produces arthroconidia, which can be widely dispersed and are highly infectious. Although persons who work outdoors are at highest risk for infection, the wide dispersal of arthroconidia ensures that most of the people who live in the endemic areas become infected before they reach adulthood. In recent years, as the allure of the sun belt has increased, there has been an increase in coccidioidomycosis in older adults. When patients with coccidioidomycosis were sub-

jected to a case-control analysis, the greatest risk factor for the development of infection was a recent move into an area endemic for *C. immitis*.[39]

Periodic outbreaks of coccidioidomycosis in the endemic area have been reported; these outbreaks are probably related to environmental cycles of rain and drought in the desert.[40] Severe infection can follow massive exposure, as might occur during participation in activities such as anthropologic excavations, in which many arthroconidia are dispersed. In addition, catastrophic massive dust storms and earthquakes have been linked to the spread of *C. immitis* to areas far beyond those normally considered endemic for the disease.[40,41]

pathogenesis

Coccidioidomycosis is acquired after the arthroconidia are inhaled into the alveoli. In the lung, the arthroconidia undergo morphologic changes that result in the formation of spherules, which are large (20 to 80 μm), thick-walled structures that become filled with huge numbers of endospores. When filled, the spherule ruptures, releasing the endospores, each of which forms a new spherule and thus propagates the infection. *C. immitis* does not form yeasts in tissues, as do other endemic mycoses.

The primary host defense against *C. immitis* is cell-mediated immunity. Neutrophils are present in most lesions but are ineffective at eradicating spherules. In hosts with deficient T cell immunity, such as patients with AIDS, the organism has the propensity to disseminate widely by the hematogenous route. Not yet elucidated is the reason for the well-known observation that dark-skinned races are at high risk for dissemination and severe infection. The highest risk appears to be among African Americans; higher but less dramatic risks for dissemination are also noted in persons from the Philippines, Native Americans, and Hispanics. Women who develop primary coccidioidomycosis while pregnant, especially in the third trimester, are also at increased risk for disseminated infection.

clinical presentations

Pulmonary Coccidioidomycosis

Most persons with acute infection with coccidioidomycosis have no symptoms or have symptoms that are seen in many types of pneumonias, such as fever, nonproductive cough, chest pain, dyspnea, fatigue, myalgias, and arthralgias. Chest radiographs show a patchy pneumonitis. Erythema nodosum occurs during acute pulmonary coccidioidomycosis in as many as 25% of women and a smaller percentage of men and is a clue to the diagnosis. For most otherwise healthy patients, acute pulmonary coccidioidomycosis is a self-limited infection.

In rare cases, when exposure to the organism is extensive or the host is immunosuppressed, acute overwhelming pneumonia, characterized by high fevers, hypoxemia, and diffuse reticulonodular infiltrates, is seen. This is most commonly noted in patients with advanced HIV infection; in many cases, the pulmonary symptoms are merely one manifestation of widely disseminated infection.

It is estimated that fewer than 5% of patients will have residual manifestations of the acute pulmonary infection.[38] Other than nodules or coccidioidomas, the most common manifestations are cavitary lesions that persist for months to years. These are generally asymptomatic, solitary, thin-walled, peripherally located lesions. Although almost half of these cavities will resolve, for some patients they can last for years and cause hemoptysis, with or without the presence of a mycetoma; they rarely rupture into the pleura. Chronic progressive coccidioidal pneumonia is rare but is more likely to occur in older patients who have COPD and diabetes mellitus; this form of coccidioidomycosis mimics tuberculosis or chronic cavitary histoplasmosis clinically and radiographically.[42]

Disseminated Coccidioidomycosis

As with other endemic mycoses, hematogenous dissemination of *C. immitis* is probably common and mostly asymptomatic. However, approximately one in every 200 people will develop symptoms of extrapulmonary coccidioidomycosis.[37] The manifestations of extrapulmonary infection with *C. immitis* are protean; they may be focal and related to only one organ system that has been seeded, or they may be systemic. The sites involved most often are skin, bones, subcutaneous tissues, and the meninges. In a recent study, risk factors for disseminated disease included African-American race, low socioeconomic status, and pregnancy.[42] Other studies have noted an increased risk of dissemination in patients with hematologic malignancies, those who have received an organ transplant, and, not surprisingly, those with AIDS.[37,38]

The skin lesions of coccidioidomycosis are typically papular or pustular initially and then become plaquelike or verrucous; facial lesions are common. Ulceration can occur, but drainage is usually minimal. Subcutaneous abscesses are commonly noted in disseminated coccidioidomycosis. Sinus tracts form, and they may drain intermittently for years. There often is underlying osteomyelitis contiguous with these subcutaneous abscesses. Bony lesions may be single or multiple and can appear in any area of the body; vertebral involvement is particularly common. Although skin and soft tissue abscesses respond fairly well to antifungal therapy, osteomyelitis and coccidioidal arthritis are characterized by an indolent, relapsing course in spite of antifungal therapy.

C. immitis can infect any organ system, but the most dreaded complication of dissemination is meningitis. Chronic progressive meningeal infection is typically concentrated in the basilar area. Meningitis may be only one of several manifestations of severe disseminated coccidioidomycosis, or it may be the sole manifestation of coccidioidomycosis. The symptoms include headache, cranial nerve palsies, and signs of increased intracranial pressure. Vasculitis occurs throughout the brain in a minority of patients with coccidioidal meningitis, and spinal cord involvement at any level of the spinal cord is not uncommon. If not treated, this form of coccidioidomycosis is fatal in virtually all patients within 2 years of diagnosis. Even with treatment, which must be lifelong, the outcomes are poor.

diagnosis

Culture

The definitive diagnostic test is growth of the organism. The mold phase of *C. immitis* grows within several days to a week on most laboratory media. DNA probes can identify the organism very specifically once growth has occurred. Also very helpful is histopathologic identification of the very distinctive large spherules of *C. immitis* in tissue biopsy, on cytologic preparations from body fluids, and even on KOH smears from sputum or from purulent material of an abscess [*see Figure 3*].

Serologic Studies

Serology is quite helpful in the diagnosis of various forms of coccidioidomycosis, as discussed in several excellent reviews.[38,43]

For serologic tests to be as useful as possible, it is important that they be sent to a reference laboratory that is experienced in performing fungal serologic analyses. Early appearance of IgM antibodies, detected through an ID test, is helpful for the diagnosis of acute coccidioidomycosis, but this test is not always sensitive enough to detect early infection. An enzyme immunoassay that is not standardized appears to be more sensitive, but false positive results are common. For patients with chronic infections and to follow the course of infection, an IgG CF assay is generally used. A decrease in the CF antibody titer or reversion to a negative titer is associated with a good clinical response, and a stable high (> 1:16) titer or a rising titer is a poor prognostic sign. A positive CF antibody titer obtained on cerebrospinal fluid is diagnostic of coccidioidal meningitis; cultures of CSF very infrequently yield *C. immitis.*

Skin Tests

Skin testing with coccidioidal antigens is helpful for the diagnosis of acute infection in a person who has just entered an endemic area, but it is of little benefit for residents of endemic areas. A negative skin test result in a patient with known coccidioidomycosis implies absence of cell-mediated immunity and portends a poor prognosis.

differential diagnosis

Coccidioidomycosis mimics many other infections. Acute pulmonary coccidioidomycosis is often diagnosed as an atypical pneumonia caused by a virus, *Mycoplasma,* or *Chlamydia.* Chronic cavitary pneumonia is radiographically similar to tuberculosis and other endemic mycoses. The diffuse pulmonary infiltrates seen in immunosuppressed patients are no different from those noted in patients with *Pneumocystis carinii* infection, histoplasmosis, tuberculosis, nocardiosis, and many other infections. The importance of tissue biopsy for histopathology and culture in these settings cannot be overemphasized.

The cutaneous lesions can appear similar to those seen in patients with blastomycosis, or they can mimic squamous or basal cell carcinomas. The bone involvement associated with coccidioidomycosis, which is frequently accompanied by subcutaneous abscesses, is typical of that seen in patients with blastomycosis or tuberculosis. The differential diagnosis of chronic coccidioidal meningitis includes tuberculosis, other fungal infections (cryptococcosis, histoplasmosis, and, rarely, sporotrichosis or blastomycosis), and sarcoidosis and other disorders of noninfectious etiology.

treatment

The Mycoses Study Group and the Infectious Diseases Society of America have recently published guidelines for the treatment of coccidioidomycosis.[44] Except for one recently completed randomized, blinded comparative trial,[45] the appropriate treatment for various forms of coccidioidomycosis has been defined by open-label, nonrandomized, multicenter trials and anecdotal experience from experienced clinicians who practice in areas endemic for coccidioidomycosis.[37,38,45-49] In contrast to the other endemic mycoses, either fluconazole or itraconazole can be used to treat coccidioidomycosis. A head-to-head, blinded, randomized comparison of fluconazole and itraconazole (each given in dosages of 400 mg daily for 1 year) showed no overall statistically significant difference in efficacy between the drugs.[45] However, for skeletal coccidioidomycosis, itraconazole was significantly superior to fluconazole (the response rates were 70% versus 30% after 1 year of therapy).[45]

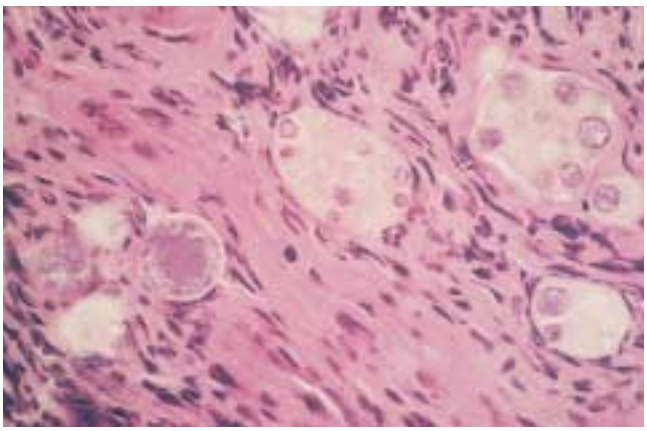

Figure 3 **Shown is a transbronchial lung biopsy specimen, stained with hematoxylin-eosin stain, from a patient with advanced HIV infection and diffuse reticulonodular pulmonary infiltrates. Large spherules (measuring 60 to 80 μm) of *C. immitis* in various stages of maturation are evident.**

Side effects, drug absorption, and drug-drug interactions are important considerations in the use of antifungal therapy [*see* Antifungal Therapy, *below*].

Pulmonary Coccidioidomycosis

Most patients with acute pulmonary coccidioidomycosis do not require therapy with an antifungal agent, and in fact, most are not seen by a physician or the diagnosis is not made until after improvement has occurred. For patients with symptoms lasting 3 to 4 weeks who show no sign of improvement, therapy with either itraconazole, 200 mg twice daily, or fluconazole, 400 mg daily, for 3 to 6 months is recommended.[44] Any patient with underlying immunosuppression, especially immunosuppression associated with HIV infection, solid-organ or stem cell transplantation, or corticosteroid therapy, should be treated because the risk of dissemination is high. Pregnant women are also at risk for dissemination and should be treated. However, azoles cannot be used in pregnant women; rather, amphotericin B, which is safe in pregnancy, is required. Consideration should be given for treatment of African-American and Filipino patients because of the high risk of dissemination in these populations.

When diffuse pulmonary infiltrates are present, patients should receive amphotericin B, 0.7 mg / kg / day initially, followed by azole therapy, for a total of at least 1 year of therapy. Patients who have chronic cavitary coccidioidomycosis should receive therapy with itraconazole, 200 mg twice daily, or fluconazole, 400 mg daily for 1 to 2 years, depending on the patient's response. However, patients with asymptomatic cavities are often observed, and treatment with an azole is begun only if the cavities increase in size or complications such as rupture into the pleural cavity have occurred or seem imminent. Surgical removal of cavities is preferred if the patient is a good operative candidate.

Disseminated Coccidioidomycosis

Disseminated coccidioidomycosis should always be treated. Patients who are seriously ill require therapy with amphotericin B, 0.7 mg / kg / day; patients with mild to moderate symptoms can be treated with an azole.[44] Treatment should be given for at least 1 year; for some patients, especially those with HIV infection and African Americans, lifelong azole therapy may be required to prevent relapse.

The most difficult form of coccidioidomycosis to treat is meningitis. The preferred treatment is fluconazole; the dosage probably should be 800 mg daily, although initial studies of this therapy employed doses of only 400 mg daily.[48,49] Itraconazole has been reported to be as effective as fluconazole, but experience with itraconazole is limited and most physicians prefer fluconazole. Approximately 20% to 25% of patients will not respond to fluconazole. Amphotericin B administered by both the intravenous and the intrathecal routes is used for those in whom fluconazole therapy fails. Intrathecal amphotericin B is not well tolerated. Repeated administration of amphotericin B into the lumbar area leads to arachnoiditis, and this is an inefficient method of delivering drug to the basilar meninges. Ideally, the drug should be administered into the cistern, but most physicians cannot perform this procedure. An alternative method is delivery through an intraventricular reservoir, but this method also does not deliver drug to the basilar meninges as efficiently as intracisternal injection. Therapy must be individualized and must be given for life.[49]

prognosis

Of all the endemic mycoses, infection with *C. immitis* is the least responsive to currently available antifungal agents. Success rates with azoles are highest in patients with soft tissue infections (approximately 70% of such patients respond after 12 months of therapy); success rates are lower in patients with chronic pulmonary infection (response rates of 50% to 60% are seen in these patients).[45-47] Relapses are more common with coccidioidomycosis than with other endemic mycoses. For patients with chronic relapsing disease, who are often of African-American descent, lifelong azole therapy may be required. For patients with meningitis, cures are rare, and suppressive therapy must be continued indefinitely.[49]

Sporotrichosis

epidemiology

The dimorphic fungus *Sporothrix schenckii* is found worldwide. The environmental niches for the organism include sphagnum moss, decaying vegetation, hay, and soil. Infection is seen most often in persons whose vocation or avocation brings them into contact with the environment. Landscaping, rose gardening, Christmas tree farming, topiary production, baling hay, and motor vehicle accidents have all been associated with sporotrichosis.[50-52] Less commonly, pulmonary sporotrichosis results from inhalation of *S. schenckii* conidia from soil. Cases of sporotrichosis usually occur sporadically, but outbreaks have been described. The largest outbreak in the United States involved 84 patients in 25 states and was traced back to conifer seedlings that had been packed in sphagnum moss from Wisconsin.[50]

S. schenckii can also be acquired through exposure to animals that are either infected or are able to passively transfer the organism from soil through scratching or biting. A variety of animals have been reported to transmit sporotrichosis, but cats with ulcerated skin lesions appear to be the most infectious. Clusters of sporotrichosis involving families and veterinarians caring for infected cats have been described.[53]

pathogenesis

Sporotrichosis typically develops in an otherwise healthy person who becomes exposed to the fungus while outdoors. The typical clinical picture is that of localized cutaneous or lymphocutaneous disease. After inoculation of *S. schenckii* conidia, the organism converts to the yeast form, which reproduces by budding. Strains that grow poorly at temperatures higher than 35° C tend to be found in fixed cutaneous lesions; these strains do not have the ability to spread along lymphatics, as do most strains of *S. schenckii*.[54]

In patients with underlying illnesses, including alcoholism, diabetes mellitus, COPD, and HIV infection, *S. schenckii* can disseminate to involve osteoarticular structures, lungs, meninges, and other organs. Neutrophils and macrophages are able to ingest and kill the yeast phase of *S. schenckii* in the presence of nonimmune human serum. A role for cell-mediated immunity as a host defense against *S. schenckii* is suggested by the observation that sporotrichosis is more severe in those with HIV infection.[55]

clinical presentations

Lymphocutaneous Sporotrichosis

Days to weeks after cutaneous inoculation of the fungus, a papule develops at the site of inoculation. The primary lesion can become nodular, but most often, it ulcerates. The drainage is not grossly purulent and has no odor, and the lesion is not terribly painful. Similar lesions subsequently occur along the lymphatic channels proximal to the original lesion. A fixed cutaneous lesion that is verrucous or ulcerative and that is not associated with lymphatic extension can also occur.[56]

Visceral Sporotrichosis

Pulmonary sporotrichosis occurs most often in middle-aged men who have COPD and abuse alcohol.[57] In contrast to most forms of sporotrichosis, systemic symptoms, including fever, night sweats, weight loss, and fatigue, are common. Dyspnea, cough, purulent sputum, and hemoptysis are common respiratory symptoms. A chest radiograph shows unilateral or bilateral upper lobe cavities with variable amounts of fibrosis and nodular lesions.

Osteoarticular sporotrichosis is found most often in middle-aged men and occurs more frequently in patients with alcoholism.[58] Although some patients experience osteoarticular involvement after local inoculation, this form of infection most often develops through hematogenous spread. Infection may involve one joint or multiple joints. The joints most commonly affected are the knee, elbow, wrist, and ankle. Isolated cases of bursitis and tenosynovitis, sometimes presenting as nerve entrapment syndromes, have been reported.

S. schenckii has rarely been reported to cause localized infection of the meninges, pericardium, eye, perirectal tissues, larynx, breast, epididymis, spleen, liver, bone marrow, or lymph nodes.[54] Disseminated sporotrichosis is very uncommon, with cases occurring primarily in patients with advanced HIV infection.[55] Most patients have widespread ulcerative cutaneous lesions and may or may not have visceral dissemination.

diagnosis

Culture

Growth of *S. schenckii* from material aspirated from a lesion, a tissue biopsy specimen, sputum, or body fluid is the most sensitive method for establishing a diagnosis of sporotrichosis. Growth of the mold phase of *S. schenckii* is usually evident a few days after inoculation onto Sabouraud agar. Synovial tissue provides a better yield than synovial fluid.

Biopsy

Histopathologic examination of biopsy material shows a mixed granulomatous and pyogenic process. The organisms often are not visualized, even with special stains for fungi, because they are rarely present in large numbers. When visualized, *S. schenckii* yeasts are 3 to 5 μm in diameter; they are oval to cigar-shaped and may show multiple buds.

Serologic Studies

Serology is less useful in the diagnosis of sporotrichosis than in histoplasmosis and coccidioidomycosis. A tube agglutination test is available at the Centers for Disease Control and Prevention; however, the sensitivity and specificity of this assay has not been established.

differential diagnosis

The differential diagnosis of lymphocutaneous sporotrichosis includes atypical mycobacterial infections, especially *M. marinum* infections; *Nocardia* infections, particularly *N. brasiliensis* infections; *Leishmania brasiliensis* infections; and tularemia.[59] Both clinically and radiographically, pulmonary sporotrichosis mimics tuberculosis; nontuberculous mycobacterial infections; other fungal infections, especially histoplasmosis; and sarcoidosis. Osteoarticular sporotrichosis is often thought to have a bacterial etiology and is often treated with antibiotics, to no avail. Growth of the organism in culture is the most important method of differentiating between these conditions.

treatment

Guidelines for the management of the various forms of sporotrichosis have recently been published by the Mycoses Study Group and the Infectious Diseases Society of America.[60] No comparative randomized, blinded treatment trials have been performed comparing various antifungal agents for the treatment of sporotrichosis. The guidelines are based entirely on open treatment trials and anecdotal experience.[58,61-64] Because most *S. schenckii* infections are subacute to chronic and are localized, oral antifungal agents are preferred; amphotericin B is reserved for the uncommon visceral infections.

Lymphocutaneous Sporotrichosis

Itraconazole is the drug of choice for lymphocutaneous sporotrichosis.[60] The usual dose is 200 mg/day. Treatment should continue for several weeks after all lesions have disappeared, usually for a total of 3 to 6 months.[58,62,63] Fluconazole is less active against *S. schenckii* but may be effective when a daily dose of 400 mg is used.[64] Saturated solution of potassium iodide (SSKI) is also effective and is much less costly than therapy with an azole. The initial dose is 5 to 10 drops three times daily in water or juice; the dose is increased each week to a maximum of 40 to 50 drops three times daily. SSKI is difficult for many patients to administer and tolerate; side effects include a metallic taste, salivary gland swelling, rash, and fever.[61]

Terbinafine appears to be effective for sporotrichosis, but few patients have been treated with this agent to date.[65] Local hyperthermia, induced by a variety of different warming devices or baths, also has been used with minimal side effects for localized cutaneous sporotrichosis.[66]

Visceral Sporotrichosis

For a seriously ill patient with pulmonary sporotrichosis, amphotericin B, 0.7 to 1.0 mg/kg/day, should be used as initial therapy.[60] After the patient has shown improvement, therapy can be changed to itraconazole, 200 mg twice daily. Azole therapy should be continued for at least 1 to 2 years. For patients who are not acutely ill, therapy can be initiated with itraconazole, 200 mg twice daily.[58] Surgical resection has proved to be useful for patients who have focal lesions and whose pulmonary function is adequate to withstand a lobectomy.[61]

Almost all patients who have osteoarticular sporotrichosis can be treated with itraconazole, 200 mg twice daily.[60] Therapy should continue for 1 to 2 years.[58] Other azoles are less effective, and SSKI is ineffective. Intravenous amphotericin B is rarely required.

Amphotericin B, 0.7 to 1.0 mg/kg/day, is the drug of choice for disseminated sporotrichosis, including meningeal infection.[60] Itraconazole, 200 mg twice daily, can be used in those patients with disseminated skin lesions and other nonmeningeal manifestations as soon as the patient's condition has stabilized. AIDS patients with disseminated sporotrichosis should receive lifelong maintenance therapy with itraconazole, 200 mg daily.[55]

prognosis

The success rate for treatment of lymphocutaneous sporotrichosis is 90% to 100%, but it is much lower for all other forms of the disease. This is undoubtedly related partly to delays in diagnosis and partly to the underlying diseases of the hosts who have noncutaneous forms of sporotrichosis. Joint function after cure of sporotrichal arthritis is often poor, and pulmonary function after treatment of pulmonary sporotrichosis is often marginal. The outcome of disseminated sporotrichosis in patients with HIV infection has been poor,[55] but almost all reports are from studies conducted before the era of highly active antiretroviral therapy. Presumably, combination antifungal therapy and highly active antiretroviral therapy would improve the prognosis.

Antifungal Therapy

For treatment of the endemic mycoses, the choice of azoles or amphotericin B is dependent on the severity of the infection and the underlying conditions and the immune status of the host. In general, most mild to moderately ill patients can be very effectively treated with an azole; most severely ill patients should receive amphotericin B as initial therapy.[67] Induction amphotericin B therapy can almost always be followed by consolidation therapy with an azole. The length of therapy is measured in months to years and is obviously managed primarily in the outpatient settting. For some patients (e.g., those with AIDS), lifelong maintenance therapy is required to prevent relapse. Thus, issues of compliance, absorption, and drug-drug interactions assume great importance in current treatment regimens for the endemic mycoses.

use of azoles to treat endemic mycoses

There are three azole antifungal agents currently available: ketoconazole, itraconazole, and fluconazole. Ketoconazole, which is available only in tablet form, is used infrequently now because of its greater toxicity, poor absorption, and modest spectrum of antifungal activity when compared with the other azoles.[68] However, it is still used for some patients who require long-term therapy with an azole because it is much less expensive than itraconazole and fluconazole. For most patients, itraconazole has supplanted ketoconazole because it is both more effective and better tolerated. Fluconazole is less active than itraconazole against most of the endemic mycoses,[21,22,35,36,64] and except for coc-

cidioidomycosis,[45,48] it is a second-line agent. The newer azoles, voriconazole, posaconazole, and ravuconazole, have not been studied for the treatment of the endemic mycoses, with the exception of a very small trial that used posaconazole for the treatment of coccidioidomycosis. These agents are not indicated for the treatment of the endemic mycoses at this time.

Side Effects

Idiosyncratic, non–dose-related hepatitis, which can sometimes be severe, occurs rarely with all azoles.[68,69] Before therapy is started, liver enzyme and bilirubin levels should be measured; they should be measured again after several weeks of therapy and then every 1 to 2 months in patients receiving long-term therapy. Mild elevations in the levels of alanine aminotransferase (ALT) or aspartate aminotransferase (AST) (i.e., a twofold to threefold increase over normal levels) do not require discontinuance of the drug, but such increases do require very careful follow-up. If the ALT and AST levels continue to rise, the drug should be discontinued. If therapy with an azole is required, another azole can be cautiously given after the ALT and AST levels return to normal, but liver enzyme levels should be assessed weekly, and the drug must be stopped if the ALT and AST levels rise threefold or more while the patient is receiving the second azole.

It is uncommon for hypertension, edema, and hypokalemia to occur with itraconazole therapy; such side effects usually occur in older adults and require discontinuance of the drug.[70] Whether these effects are related to the recently described myocardial dysfunction noted with itraconazole has not yet been elucidated.[71]

Rash and nausea can occur with all azoles. Long-term therapy with fluconazole has been associated with alopecia, which is reversible when the drug is discontinued.[72] All azoles are contraindicated during pregnancy; teratogenicity in animals has been noted, and several cases of fetal malformations have been reported in women taking fluconazole during pregnancy.[73]

Absorption Issues

Both ketoconazole and itraconazole require gastric acid for absorption, and the capsule formulation of itraconazole also requires food for absorption. Therefore, histamine receptor antagonists (H_2 receptor blockers), antacids, and proton pump inhibitors cannot be administered to patients receiving these agents.[68] Older adults, who are often achlorhydric, may not absorb these agents well. For the treatment of endemic mycoses, itraconazole is commonly used at a daily dose of 400 mg; regardless of whether solution or capsules are prescribed, the drug should be administered in twice-daily doses of 200 mg, rather than a once-daily dose of 400 mg, to achieve appropriate serum drug levels. At doses higher than 200 mg, decreased absorption of the drug occurs.

The oral-suspension formulation of itraconazole was developed specifically to overcome the poor absorption characteristics of the capsules. The suspension requires neither acid nor food for absorption. When taken on an empty stomach, absorption is approximately 30% better than when the capsule formulation is given with both food and acid.[74] Although compliance with long-term use of the oral suspension may be difficult, the suspension is preferred to ensure adequate serum levels. In patients with serious infection and those who do not respond to therapy, serum itraconazole levels should be obtained at a reference mycology laboratory to ensure that absorption is adequate.

Use of the intravenous formulation of itraconazole, solubilized in cyclodextrins, avoids absorption problems.[75] The intravenous formulation has been approved for use for periods of only 2 weeks because of concerns about the nephrotoxicity of the cyclodextrin vehicle, which is used to solubilize the drug. The intravenous formulation cannot be given if the rate of creatinine clearance is less than 30 ml / min. The dosage of the intravenous formulation is 200 mg twice daily for 2 days, followed by 200 mg daily for the next 12 days; intravenous therapy is usually followed by treatment with the oral supension.

Fluconazole, which is nearly 100% bioavailable, has none of the absorption problems that have been so troublesome with itraconazole. It distributes into most body compartments, including the eye and the CSF; is excreted as active drug in the urine; and can be given in a once-daily dose.

Drug-Drug Interactions

The azoles interact with many other drugs primarily through their interactions with cytochrome P-450 3A4 but also to a lesser extent through their interactions with several of the other cytochrome enzymes and with P-glycoprotein.[69] These interactions

Table 1 Effects of Concomitantly Administered Drugs on Serum Levels of Azoles

Drug Affecting Azole Serum Level	*Effects That Other Drugs Have on Azole Serum Levels*		
	Ketoconazole	*Itraconazole*	*Fluconazole*

*Significant interaction; monitoring of drug serum levels, clinical status, or both is required.
†Life-threatening interaction; these agents should not be used together.

can be serious and even life-threatening. It is absolutely essential that the patient's concomitant medications be reviewed and the package insert read before use of any azole for the treatment of any fungal infection. Major interactions for the azoles are detailed [*see Tables 1 and 2*].

Itraconazole and ketoconazole have the most drug-drug interactions, but fluconazole shares several significant interactions. Increased serum levels of warfarin, phenytoin, and oral hypoglycemic agents occur when azoles are given with these commonly used drugs. Itraconazole increases serum levels of digoxin in some but not all patients. Thus, serum levels of these agents must be closely monitored in those receiving an azole.

Itraconazole and ketoconazole should never be given to patients receiving cholesterol-lowering agents, such as simvastatin and lovastatin, because of the potential for life-threatening rhabdomyolysis, nor should these agents be given to those receiving midazolam or triazolam because of the possibility of markedly increased sedation. Coadministration of an azole with cisapride, astemizole, or terfenadine is contraindicated because azoles potentiate the prolongation of the QT interval that is induced by these drugs.

Several commonly used drugs have the effect of inducing the metabolism of the azoles and thus decreasing serum azole concentrations and diminishing effectiveness. This has been reported with rifampin, phenytoin, and carbamazepine.

use of amphotericin b to treat endemic mycoses

Amphotericin B is fungicidal against a broad range of fungi. The major drawbacks are the need for intravenous administration and the inherent toxicity of the drug.[76] Some, but not all, of the infusion-related reactions to amphotericin B can be minimized with the use of preinfusion medications[77]; however, nephrotoxicity will almost always develop during the course of therapy with this agent.[78]

In an attempt to decrease the toxicity of amphotericin B, the drug has been incorporated into liposomes and other lipid delivery vehicles. Three formulations are currently available: liposomal amphotericin B (AmBisome, L-AmB); amphotericin B lipid complex (Abelcet, ABLC); and amphotericin B colloidal dispersion (Amphotec or Amphocil, ABCD). Each differs from the others and from amphotericin B deoxycholate with regard to composition, pharmacologic parameters, toxicity, recommended

dosages, and cost.[79,80] All of these preparations are clearly less nephrotoxic than amphotericin B deoxycholate, and two of the three cause fewer infusion-related reactions than amphotericin B deoxycholate. However, they are all much more costly than standard amphotericin B. Because of cost considerations, many hospitals restrict the use of these preparations to patients who have preexisting renal disease or have developed some degree of renal failure related to amphotericin B deoxycholate administration (as evidenced, for example, by a serum creatinine level of more than 2 or 3 mg / dl).

Other than two studies that show liposomal amphotericin B to be superior to amphotericin B deoxycholate for the treatment of severe histoplasmosis in AIDS patients and for the empirical treatment of febrile neutropenic patients,[23,81] there is little evidence to suggest that lipid formulations of amphotericin B are more efficacious than the standard formulation. Thus, for most patients, a lipid formulation of amphotericin B will not be used as a first-line antifungal agent but will be reserved for patients who cannot tolerate amphotericin B deoxycholate.

Nephrotoxicity Nephrotoxicity is seen in most patients receiving amphotericin B. Diminished creatinine clearance is the major manifestation, but profound hypokalemia, hypomagnesemia, or both are also common. Patients with underlying renal disease show a more rapid rise in creatinine levels than patients with normal renal function. Use of other nephrotoxic drugs, such as aminoglycosides, cisplatinum, cyclosporine, or tacrolimus, should be avoided when amphotericin B is being used.

Sodium loading is now routinely employed in an attempt to decrease nephrotoxicity[82] [*see Table 3*]. Potassium and magnesium losses can be large and can contribute to other organ dysfunction; for this reason, electrolytes should be monitored carefully, and electrolytes should be replaced as soon as the serum levels show even a slight decrease. In many patients, intravenous repletion is ultimately required to keep pace with the renal loss. Early oral repletion will obviate the need for intravenous repletion in many patients.

Infusion-related reactions Infusion-related reactions are the most common adverse events experienced by patients receiving amphotericin B. Chills or rigors, fever, nausea, headache, and myalgias occur in the majority of patients treated with amphotericin B. Most of these side effects can be diminished by prescribing a variety of medications before infusion of amphotericin B[77] [*see Table 3*].

Patients with life-threatening infections that require immediate treatment with large doses of amphotericin B are more likely to have infusion-related reactions. Pretreatment medications should be given before the first dose of amphotericin B in these patients. For others who have subacute to chronic infections, the dosage of amphotericin B can be increased gradually over a few days, decreasing the risk of immediate reactions.

Other side effects Most patients receiving amphotericin B develop a normocytic, normochromic anemia, but transfusion is rarely required.[83] Other side effects, including leukopenia, thrombocytopenia, hepatotoxicity, neuropathy, and acute pulmonary edema, are rare.

Table 3 Administration of Amphotericin B for Treatment of the Endemic Mycoses

General Guidelines

- Do not use in-line filters; no need to cover drug while infusing
- Use central I.V. catheter if at all possible. With peripheral I.V. catheter, 1,000 units of heparin can be added to the drug in an attempt to decrease phlebitis
- Dilute drug to a concentration of 0.1 mg / ml
- For the initial dose, infuse very slowly for the first 20 minutes and assess for the rare occurrence of anaphylaxis or arrhythmias
- Infuse drug over 2 to 4 hours; for patients with infusion-related reactions, slower infusion times are often better tolerated; for others, 2-hr infusion times are appropriate
- For subacute or chronic infections, start with 0.2 mg / kg and increase daily by the same increment until the desired daily dose is reached; use pretreatment medications only if required
- For life-threatening infections, give the desired daily dose within the first 24 hr; preinfusion medications should be given before the first dose because reactions are frequent

Measures to Decrease Infusion-Related Reactions (chills, fever, nausea and vomiting, headache, myalgia)

- Medications before beginning infusion of amphotericin B: acetaminophen (650 mg p.o.), diphenhydramine (50 mg p.o.), prochlorperazine (25 mg p.o. for nausea and vomiting), and meperidine (50–75 mg I.V. or I.M. for rigors); administer hydrocortisone (25–50 mg I.V.) if reactions do not improve with the above drugs

Measures to Reduce Nephrotoxicity

- Assess volume status before treatment; stop diuretics, if possible; do not restrict sodium
- Before each dose, infuse 500 ml 0.9% saline over 1 hr

Required Laboratory Studies to Assess Toxicity

- Baseline creatinine, blood urea nitrogen, potassium, magnesium levels; blood count, liver function tests
- Monitor creatinine, blood urea nitrogen, potassium, magnesium levels every other day
- Monitor blood count weekly; repeat liver function tests if clinically indicated

XXXVIII MYCOTIC INFECTIONS IN THE COMPROMISED HOST

Jo-Anne van Burik, m.d., f.a.c.p.

Opportunistic fungal infections have become increasingly important over the past several decades, paradoxically because advances in medical practice have improved the survival of debilitated and immunosuppressed patients. Opportunistic fungal pathogens may originate as human commensals (e.g., *Candida albicans*) or have an environmental reservoir (e.g., *Aspergillus fumigatus*). They may have yeast (budding, unicellular) or mold (branching, tubular hyphal cell) phenotypes. Timely diagnosis of opportunistic fungal infection depends on an understanding of host characteristics, environmental risk factors, clinical presentation, and diagnostic testing. In treatment, correction of predisposing conditions can be as important as the use of antifungal medication. Localized infections may require surgery. Immunocompromised patients require either prophylaxis or early empirical treatment during high-risk periods.

Candidiasis

EPIDEMIOLOGY

C. albicans is a yeast that is virtually ubiquitous in humans. Acquired at or soon after birth, it becomes part of the normal flora of the gastrointestinal and vaginal tracts. In healthy persons, overgrowth of *Candida* at those commensal sites is a common cause of minor skin and mucous membrane infections—notably, oral candidiasis, diaper rash in infants, and vaginal candidiasis in women. In persons with immune system aberrations or iatrogenic factors that predispose to infection, candidal infections can become invasive; the organism may enter the bloodstream and disseminate to normally sterile tissues.

C. albicans has the best adherence mechanisms of the various *Candida* species and is therefore the predominant yeast colonizing the mouth, gut, and vagina. Treatment with systemic antifungal drugs may result in the replacement of *C. albicans* by other candidal species and their appearance as opportunistic pathogens. This phenomenon has grown with the wider use of such agents. In particular, *C. glabrata* and *C. krusei* bloodstream infections have become more common since the introduction of fluconazole in the early 1990s.[1,2] Other *Candida* species regarded as frequent human pathogens include *C. parapsilosis*, *C. tropicalis*, *C. lusitaniae*, *C. dubliniensis*, and *C. guilliermondii*.[3] *C. lusitaniae* is notable for resistance to amphotericin. *C. parapsilosis* is notable for nosocomial transmission from an exogenous source, such as hyperalimentation fluids. In a hospital, a series of infections with the same non-*albicans Candida* species in several patients over a short period of time suggests a common nosocomial point source.

ETIOLOGY

Candidal infection often reflects a combination of environmental and host defense factors; this is especially true of localized mucocutaneous infection from overgrowth of commensal *C. albicans.* Wearing diapers or dentures provides an environment conducive to candidal growth, as does antibiotic treatment that reduces the commensal bacteria that normally help keep *Candida* in check. Host factors include the normal life phases of infancy and pregnancy (especially third trimester) and pathologic conditions such as vitamin deficiencies and malnourishment, diabetes mellitus and other endocrine abnormalities, congenital or acquired defects in cell-mediated immunity, and malignancy. Iatrogenic contributors include radiotherapy, systemic or inhaled steroids, and other immunosuppressive medications.[4]

PATHOGENESIS

Candida can reach normally sterile tissues through iatrogenic means: contamination of plastic catheters may lead to localized infection, such as peritonitis from peritoneal dialysis catheters and cystitis or upper urinary tract infection from urinary (Foley) catheters.[5] Alternatively, *Candida* may spread from colonized surfaces to contiguous tissues. Depending on the original site, such invasion can lead to esophagitis, sinusitis, mastoiditis, and, in rare cases, primary pneumonia. A breakdown of GI mucosa through damage from cancer chemotherapy, radiation, trauma, or concurrent viral ulcers may allow a commensal *Candida* strain to gain access to the bloodstream. Tissue abscesses from hematogenous dissemination can form in the lung, brain, liver, spleen, kidney, bone, joints, heart valves, skin, and eye. In short, *Candida* infections can affect almost every organ system in the body.

DIAGNOSIS

Clinical Manifestations

Oropharyngeal candidiasis Patients with oropharyngeal candidiasis may complain of sore throat or raw tongue; eating may be so uncomfortable that patients lose weight. Pseudomembranous candidiasis (thrush) presents as loosely adherent white patches and plaques on the buccal mucosa, palate, oropharynx, or tongue. Erythematous candidiasis presents as redness without pseudomembranes. An erythematous, smooth plaque on the dorsal surface of the tongue characterizes median rhomboid glossitis. Angular cheilitis presents as erythema, maceration, and fissuring at the corners of the mouth.

Gastrointestinal candidiasis Esophageal candidiasis causes painful swallowing, a feeling of obstruction on swallowing, and substernal or retrosternal chest pain. Thrush may also be evident.[6] Candidiasis elsewhere in the GI tract presents as pain in the abdominal quadrant where the affected organs are located.

Genital candidiasis Candidal vaginitis may present as intense pruritus of the vulva and a cervical discharge that can vary from scant to thick and white. There may be edema of the vulva and erythema of the vagina and labia that extends onto the perineum.

Balanitis can begin as itching or burning, with vesicles or white patches on the penis. Plaques may extend onto the thighs, buttocks, and scrotum.

Diaper rash *Candida* diaper rash causes itching and maceration in the perianal area that may spread to the entire skin region of diaper contact. Satellite lesions may be present. Girls may have a vaginal discharge.

Hematogenous candidiasis Patients with hematogenous *Candida* infection and major organ involvement may have fever, with or without additional manifestations in the organ system involved (central nervous system, lungs, heart, urinary tract, bones, joints, liver, spleen, gallbladder, or eyes). Even in the absence of ocular symptoms, patients with positive blood cultures for *Candida* should have a dilated eye examination to look for the white cotton ball–like chorioretinitis lesions of hematogenous *Candida* endophthalmitis, which can result in permanent blindness unless treated appropriately.

Candiduria A laboratory report of *Candida* in the urine may represent contamination of the sample by vaginal flora, colonization of a urinary catheter or the lower urinary tract, or infection. Asymptomatic colonization of the lower urinary tract is the most common source of candiduria; treatment is of questionable value in such patients, because the candiduria may resolve without treatment or return despite initially successful treatment.[7,8] Systemic antifungal treatment is typically reserved for symptomatic patients and for those who are at increased risk for *Candida* infection; this population includes recent renal transplant recipients, patients with neutropenia, patients with diabetes, and those undergoing genitourinary tract manipulation.[9]

Laboratory Tests

Candidal lesions can be so distinctive that diagnosis does not require testing. When the appearance is uncertain, pseudomembranes should be scraped and sent for staining and culture. Fungal forms (4 to 6 μm oval yeast cells, pseudohyphae, and hyphae) can be visualized using 40× to 100× magnification after staining with potassium hydroxide—with or without calcofluor—or with Gram stain. Culture plates specific for yeast include bromocresol green and Sabouraud dextrose agar, although candidal organisms are easily cultured on blood agar. In immunosuppressed patients, endoscopy specimens from esophageal and other GI sites should be submitted for viral culture in addition to fungal culture, because such patients can have concurrent herpesvirus infections.

Diagnosis of hematogenous and major organ candidiasis requires culture of blood, radiographic imaging of the organ system involved, and culture of any localized fluid collections. Blood culture is used for diagnosis of fungemia, catheter-related infection, vascular infection, endocarditis, and liver and spleen infection. Even repeated cultures—both of blood and of biopsy tissue—are often negative in visceral (hepatosplenic) candidiasis, however.[10]

The current generation of automated blood culture systems has improved the ability to detect *Candida*, and *Candida* species are now the fourth most common nosocomial bloodstream isolate. When culture growth is noted, a germ tube test can be performed to distinguish *C. albicans* from other species of *Candida.* The organism is inoculated into serum and incubated for 2 to 3 hours at 37° C. If an elongated hypha (a germination tube) is seen extending from the yeast, the species is *C. albicans.*

Antifungal susceptibility testing should be requested for the first bloodstream isolate from a new infection episode. Susceptibility testing is available for azoles (e.g., fluconazole, voriconazole) but not for echinocandins.

DIFFERENTIAL DIAGNOSIS

In patients with mucocutaneous manifestations that do not fit the classic picture of *C. albicans* infection, non-*albicans* candidal species, bacteria, mold, and viruses need to be considered. Bacterial infection is especially likely in patients with findings such as abscesses or fever, whereas viral infection may be present in those with ulcerations of the mucosal surface. Infections in severely debilitated patients may have multiple copathogens. Candidiasis must also be distinguished from noninfectious syndromes such as aphthous ulcers.

TREATMENT

Active Infection

Management of candidal infections should include attempts to correct any factors that can predispose to candidal overgrowth. In some cases, this will involve local measures: with diaper rash, for example, the affected areas should be kept dry. Other cases require general measures, such as tighter control of glucose levels in diabetic patients or minimizing the number and dosage of antibacterial or immunosuppressive medications.

Antifungal drug therapy for candidiasis may be topical or systemic[11] [*see Table 1*]. For mucocutaneous infections in particular, it is important to try topical agents before giving systemic ones. The use of topical agents can prevent the replacement of *C. albicans* with other candidal strains and the development of drug resistance, and it avoids the side effects of systemic treatment.

When systemic treatment is required, fluconazole is often the drug of choice for *C. albicans* infections. *C. glabrata* infections should be considered fluconazole resistant and treated with a different agent until sensitivities are known. Importantly, *C. krusei* is innately resistant to fluconazole, so infections caused by this organism should be treated with a different agent.

In the first years of the 21st century, several new antifungal agents have gained important roles in the treatment of candidiasis and other fungal infections. Voriconazole, a new triazole with wide-spectrum antifungal activity and high bioavailability, has proved effective as empirical antifungal therapy in patients with neutropenia and persistent fever.[12] Caspofungin is the first in a new class of antifungal agents called echinocandins, which inhibit synthesis of an integral component of the fungal cell wall, β-(1,3)-D-glucan. The Food and Drug Administration has approved caspofungin for the first-line treatment of candidemia, esophageal candidiasis, and other *Candida* infections (e.g., intra-abdominal abscesses, peritonitis, and pleural space infections).[13,14] A comparison study found caspofungin to be at least as effective as amphotericin B for the treatment of invasive candidiasis and, more specifically, candidemia.[15] Caspofungin is also approved by the FDA for the empirical treatment of presumed fungal infection in febrile neutropenic patients, and it appears to be as effective as, as well as generally better tolerated than, liposomal amphotericin B when used for this purpose.[16] Micafungin, the second echinocandin to become clinically available, is approved by the FDA for intravenous treatment of esophageal candidiasis and for *Candida* prophylaxis in hematopoietic stem cell transplant recipients.[17,18]

Adjunctive measures are important in controlling severe candidal infections and in boosting the immune function of severely debilitated patients. For patients with catheter-related infections, strong consideration should be given to catheter removal from any affected site (intravascular, genitourinary, and peritoneal) if possible. Neutropenic patients may benefit from colony-stimulating factors or granulocyte transfusions. In patients with a central venous catheter, infections accompanied by tenderness or erythema along the catheter tunnel tract may require surgical de-

Table 1 Treatment of Infections Caused by *Candida* Species

Infection	*Drug*	*Dosage*	*Relative Efficacy*	*Comments*
Denture stomatitis	Fluconazole	100–400 mg p.o. daily for 1–14 days	First-choice agent	Remove dentures at night
Gingivostomatitis	Nystatin	Swish 4–6 ml of 100,000 units/ml q.i.d., or suck 200,000-unit lozenges q.i.d., daily for 2 wk	First-choice topical agent	—
	Clotrimazole	Suck 10 mg troches five times daily for 2 wk	Alternative topical agent	Less bitter than nystatin
	Gentian violet	Apply 1% solution to oropharynx once, repeat weekly as needed	Alternative topical agent	Stains tissue
	Fluconazole	100–400 mg p.o. daily for 1–14 days	First-choice systemic agent	May lead to replacement of *C. albicans* with other *Candida* strains
	Itraconazole	100 mg p.o., b.i.d., or 200 mg daily of oral solution for 14 days	Alternative systemic agent	Capsule absorption improved by acidic stomach contents
	Amphotericin	0.5 mg/kg I.V. daily for 2 wk beyond the last clinical symptoms, then once or twice weekly as maintenance	Alternative systemic agent	—
Sinusitis/ mastoiditis	Fluconazole	400–800 mg p.o. or I.V. daily for 3 wk	First-choice agent	—
	Amphotericin	0.5 mg/kg I.V. daily for 3 wk	Alternative agent	—
	Itraconazole	200 mg p.o. or I.V. twice daily or 400 mg daily of oral solution for 3 wk	Alternative agent	Capsule absorption improved by acidic stomach contents
Pneumonia	Amphotericin	0.5 mg/kg I.V. daily for 2 wk ± 50 mg nebulized daily	First-choice agent	—
	Fluconazole	400–800 mg p.o. or I.V. daily for 2 wk	Alternative agent	—
	Itraconazole	200 mg p.o. or I.V. b.i.d., or 400 mg daily of oral solution for 2 wk	Alternative agent	Capsule absorption improved by acidic stomach contents
	Flucytosine	25 mg/kg p.o., q.i.d., for duration of amphotericin therapy	Adjunct to amphotericin	Follow levels and adjust dose for renal insufficiency
Meningitis				Remove foreign bodies
	Amphotericin	0.7–1.0 mg/kg I.V. daily for 2–6 wk ± 1 mg intrathecal or intraventricular daily	First-choice agent	—
	Flucytosine	37.5 mg/kg p.o., q.i.d., for duration of amphotericin therapy	Adjunct to amphotericin	Follow levels and adjust dose for renal insufficiency
	Fluconazole	400–800 mg p.o. or I.V. daily for duration of risk factors that led to infection	First-choice agent	May be used for maintenance after amphotericin
Brain macroabscess		[*See* Meningitis, *above*] ; continue therapy until lesion has resolved		Debulk or drain abscess
Esophageal infection		Continue *all* therapy for 2 wk after clinical resolution		—
	Fluconazole	100–400 mg p.o. daily	First-choice oral systemic agent	—
	Micafungin	150 mg daily I.V	First-choice I.V. systemic agent	—
	Itraconazole	100–200 mg p.o., b.i.d., or 200–400 mg daily of oral solution	Alternative agent	Capsule absorption improved by acidic stomach contents
	Caspofungin	50 mg daily by slow I.V. infusion	Alternative agent	Reduce dose for hepatic insufficiency
	Voriconazole	200 mg q. 12 hr p.o.	Alternative agent	Taken ≥ 1 hr before or after meal
	Amphotericin	0.5 mg/kg I.V. daily	Alternative agent	—
Liver/spleen infection				Correct neutropenia
	Amphotericin	0.5–1.0 mg/kg I.V. daily until fevers have resolved and lesions appear smaller on CT scan	First-choice agent	—
	Fluconazole	6–12 mg/kg p.o. or I.V. daily for the duration of lesions on serial CT scans	First-choice agent	May be used for maintenance after amphotericin

Table 1 (*continued*)

Infection	*Drug*	*Dosage*	*Relative Efficacy*	*Comments*
Spleen infection		[*See* Liver/Spleen Infection, *above*]		May require splenectomy
Peritoneum infection				Remove peritoneal catheter
	Amphotericin	0.5–1.0 mg/kg I.V. daily until fevers have resolved and peritoneal fluid appears less infected, for 3-4 wk after last positive culture	First-choice agent	—
	Fluconazole	6–12 mg/kg p.o./I.V. daily until fevers have resolved and peritoneal fluid appears less infected, for 3-4 wk after last positive culture	First-choice agent	May be used for maintenance after amphotericin
	Caspofungin	50 mg daily by slow I.V. infusion, for 3-4 wk after last positive culture	Alternative agent	Reduce dose for hepatic insufficiency
Cystitis, uncomplicated				Asymptomatic candiduria may represent colonization or specimen contamination rather than infection, and may not require treatment; remove urinary catheter
	Fluconazole	200 mg p.o./I.V. on first day, then 100 mg p.o. daily for 4 more days	First-choice agent	If poor response, rule out fungus ball in renal pelvis
	Amphotericin	Bladder irrigation with 5 mg in 100 ml water at 42 ml/hr for 1–2 days, or 0.3 mg/kg I.V. once	Alternative agent	If poor response, rule out fungus ball in renal pelvis
Pyelonephritis	Amphotericin	0.5–1.0 mg/kg I.V. daily for 2 wk, or longer if fevers have not resolved	First-choice agent	Resolve concomitant nephrolithiasis
	Voriconazole	6 mg/kg q. 12 hr for first 24 hr, then 3–4 mg/kg q. 12 hr; when oral medication tolerated, 200 mg p.o., q. 12 hr for 2–4 wk after cultures become negative	First-choice agent	Oral form taken ≥ 1 hr before or after meal
Renal/perinephric abscess	Amphotericin	0.5–1.0 mg/kg I.V. daily until several weeks after scan shows resolution of abscess	First-choice agent	Drain abscess
	Voriconazole	6 mg/kg q. 12 hr for first 24 hr, then 3–4 mg/kg q. 12 hr; when oral medication tolerated, 200 mg p.o., q. 12 hr until several weeks after scan shows resolution of abscess	First-choice agent	Oral form taken ≥ 1 hr before or after meal
Vulva/cervix infection				Stop antibacterial agents
	Clotrimazole	One applicator per vagina each evening for 3–7 days	First-choice topical agent	—
	Gentian violet	Apply 0.25%–1% solution to vagina two to three times daily for 3 days	Alternative topical agent	Stains tissue
	Fluconazole	100–400 mg p.o. daily for 1–14 days	First-choice systemic agent	—
	Itraconazole	100 mg p.o., b.i.d, or 200 mg daily of oral solution for 14 days	Alternative systemic agent	Capsule absorption improved by acidic stomach contents
Balanitis/ balanoposthitis				Reduce predisposing factors
	Clotrimazole	1% cream applied twice daily for 1 wk	First-choice topical agent	—
	Fluconazole	Single oral 150 mg dose	First-choice systemic agent	—
Diaper/perianal rash				Keep affected area dry
	Nystatin	Cream or powder applied after every diaper change for 1 wk	First-choice topical agent	—
	Miconazole	Ointment applied after every diaper change for 1 wk	First-choice topical agent	—
Osteomyelitis/ septic arthritis				May require surgery
	Amphotericin	0.5–1.0 mg/kg I.V. daily for 4–12 wk	First-choice agent	Follow ESR
	Flucytosine	25 mg/kg p.o., q.i.d., for duration of amphotericin therapy	Adjunct to amphotericin	Follow levels and adjust dose for renal insufficiency
	Fluconazole	6–12 mg/kg p.o. daily for 1-6 mo	Maintenance	Follow ESR

Table 1 (*continued*)

Infection	*Drug*	*Dosage*	*Relative Efficacy*	*Comments*
Endocarditis/ pericarditis				May require surgery
	Amphotericin	0.5–1.0 mg/kg I.V. daily, often continued for 6–10 wk after corrective surgery	First-choice agent	Follow ESR
	Flucytosine	25–37.5 mg/kg p.o., q.i.d., for duration of amphotericin therapy	Adjunct to amphotericin	Follow levels and adjust dose for renal insufficiency
	Fluconazole	6–12 mg/kg p.o. daily for 1–6 mo	Maintenance	Follow ESR
Chronic mucocutaneous candidiasis	Ketoconazole	400 mg p.o. daily for 3–9 mo	—	Take with food
Folliculitis	Fluconazole	100–400 mg p.o. daily for 1–6 wk	First-choice agent	—
	Econazole	1% cream rubbed into affected area twice daily	Adjunctive agent	—
	Ketoconazole	400 mg p.o. daily for 1–6 wk	Alternative agent	Take with food
	Itraconazole	200 mg p.o. daily for 1–6 wk	Alternative agent	—
Paronychia/ onychomycosis				Avoid moisture
	Fluconazole	6–12 mg/kg p.o. daily for 2–6 mo	First-choice agent	—
	Itraconazole	200 mg p.o. daily for 2–6 mo	Alternative agent	Capsule absorption improved by acidic stomach contents
Keratitis				May require adjunctive penetrating keratoplasty
	Natamycin	1 drop 5% suspension every 1–2 hr for first 2 days, then decrease gradually over 3 wk	First-choice agent	—
	Fluconazole	0.2% topical, 1 drop to affected eye q. 5 min for four doses for 4–6 wk	Alternative agent	—
Endophthalmitis	Amphotericin	Intravitreal 0.005–0.010 mg in 0.1 ml once, with repeat dosing based on ophthalmologic opinion	Ophthalmologist will make decision to use	Advanced vitritis may require systemic amphotericin and/or vitrectomy
	Voriconazole	6 mg/kg q. 12 hr for first 24 hr, then 3–4 mg/kg q. 12 hr; when oral medication tolerated, 200 mg p.o., q. 12 hr; duration determined by ophthalmologist		
	Caspofungin	50 mg daily by slow I.V. infusion; duration determined by ophthalmologist		
Systemic infection				Halt fungemia
	Amphotericin	0.5–1.0 mg/kg I.V. daily for 7 days after the last positive blood culture, then switch to fluconazole, 6–12 mg/kg p.o. daily for 7 additional days; fluconazole may be continued longer if neutropenia has not resolved; if the *Candida* species recovered is resistant to fluconazole, continue amphotericin for a total of 14 days after the last positive blood culture	First choice for patients who are neutropenic, deteriorating, or otherwise unstable	Use lipid formulation, not generic, for patients with nephrotoxicity or infusion toxicity; remove catheters and replace at new sites; check for metastatic lesions (e.g., endophthalmitis)
	Fluconazole	6–12 mg/kg I.V. or p.o. daily for 14 days after the last positive culture	First choice for stable patients who are not neutropenic	Remove catheters and replace at new sites; check for metastatic lesions (e.g., endophthalmitis)
	Caspofungin	50 mg daily by slow I.V. infusion for 14–28 days after the last positive culture	Alternative agent	Reduce dose for hepatic insufficiency
	Voriconazole	6 mg/kg q. 12 hr for first 24 hr, then 3–4 mg/kg q. 12 hr; when oral medication tolerated, 200 mg p.o., q. 12 hr for 14–28 days after the last positive culture	Alternative agent	Oral form taken ≥ 1 hr before or after meal
Prevention of candidiasis in hematopoietic stem cell transplant recipients	Micafungin	50 mg I.V. daily until 5 days after engraftment	—	—

Note: Major pathogens include *C. albicans*, *C. tropicalis*, *C. parapsilosis*, and *C. pseudotropicalis*. *C. lusitaniae* and *C. guilliermondii* are usually resistant to amphotericin. *C. glabrata* and *C. krusei* are usually resistant to fluconazole.
ESR—erythrocyte sedimentation rate

Table 2 Treatment of Infections Caused by *Cryptococcus* Species

Infection Site	*Drug*	*Dosage*	*Relative Efficacy*	*Comments*
CNS	Amphotericin	0.7–1.0 mg/kg I.V. daily for AIDS patients, 0.5–0.8 mg/kg I.V. daily for non-AIDS patients; continue for 2–6 wk	First-choice agent	Continue until patient is stable and afebrile
	Flucytosine	37.5 mg/kg p.o., q.i.d., for duration of amphotericin therapy	Adjunct to amphotericin	Adjust dose for renal insufficiency
	Fluconazole	6 mg/kg p.o. daily for 8–10 wk, then 3 mg/kg for duration of suppressed cell-mediated immunity	Maintenance/prophylaxis	—
Pulmonary	Fluconazole	6 mg/kg I.V./p.o. daily for 2–6 mo	First-choice agent	—
	Amphotericin	0.5–1.0 mg/kg I.V. daily for 2–6 wk, then change to fluconazole	Alternative agent	—

bridement of the tract. Macroabscesses may require surgical drainage or debulking. Patients with recurrent positive cultures despite receiving both systemic medication and adjunctive measures should be reexamined clinically and radiologically to look for an occult focus of *Candida* organisms, such as an infected thrombus or abscess.

Prophylaxis

Secondary pharmacologic prophylaxis for mucocutaneous infection may be started in patients who have experienced several episodes of thrush (in advanced AIDS) or vaginitis (in pregnancy). Profoundly neutropenic patients with sufficient mucosal breakdown to provide portals of entry for *Candida* into the bloodstream require primary pharmacologic prophylaxis until the mucosal barriers have recovered their protective function. Examples of such mucosal barrier breakdown include, but are not limited to, mucositis during bone marrow transplant procedures, GI graft versus host disease (GVHD), and viral gastroenteritis. Prophylactic medications can be topical or systemic, depending on the site involved and the patient's tolerance of individual agents.

The use of antifungal chemotherapy can shift GI yeast flora from *C. albicans* to fluconazole-resistant species. For that reason, candidal infections that occur during fluconazole prophylaxis require culture and sensitivity testing to determine definitive treatment.

PROGNOSIS

Fortunately, most candidal infections are readily manageable, provided that further diagnostic investigation (e.g., susceptibility testing and radiography) is pursued for poorly responsive infections. Morbidity and mortality remain highest for patients with hematogenous and major-organ candidiasis.

Cryptococcosis

EPIDEMIOLOGY

Cryptococcus neoformans is a yeast that is widely distributed in nature. Environmental sources of *C. neoformans* include aged pigeon droppings, pigeon nesting areas, dust, and eucalyptus trees.[19] However, most persons exposed to environmental sources of *C. neoformans* do not experience symptomatic disease. Suppressed cell-mediated immunity is the most important risk factor for symptomatic infection; currently, AIDS patients with $CD4^+$ T cell counts below $100/mm^3$ account for 80% to 90% of cases of clinical cryptococcosis. In the United States, the annual incidence of cryptococcosis in AIDS patients decreased substantially during the 1990s, with more than two thirds of cases occurring in patients who did not receive highly active antiretroviral therapy.[20] Person-to-person transmission has not been documented other than through transplanted organs.

ETIOLOGY

Cryptococcus infection begins with the inhalation of aerosolized organisms and localized proliferation with pulmonary invasion. In immunocompetent individuals, pulmonary infection may be asymptomatic and resolve spontaneously. Immunocompromised persons may have an acute, symptomatic pulmonary infection, which may disseminate by hematogenous spread—most often to the CNS, but also to the skin, soft tissue, genitourinary tract, bone, or joints. Cryptococcal CNS infection may become symptomatic while pulmonary infection clears because cerebrospinal fluid lacks several soluble anticryptococcal factors that are present in serum, such as complement components. Organ transplant recipients who receive calcineurin inhibitors such as tacrolimus as their primary immunosuppressive agent may be protected from cryptococcal infections, because calcineurin is thought to be a potential virulence factor for the yeast. Moreover, only a minority of cryptococcal infections in organ transplant recipients involve the CNS.[21] Rarely, *Cryptococcus* can be directly inoculated through intact skin as a route of infection.

PATHOGENESIS

C. neoformans is a round or oval yeastlike structure, 4 to 6 μm in diameter, that grows well at body temperature. A large protective polysaccharide capsule surrounds each cell. The highly negative surface charge may contribute to resistance to leukocyte phagocytosis.

DIAGNOSIS

Clinical Manifestations

CNS infection Cryptococcosis of the CNS may present as mild and nonspecific complaints, such as persistent headache, nausea, dizziness, ataxia, impaired memory and judgment, irritability, somnolence, clumsiness, confusion, and obtundation. Patients may or may not have fever, and most have minimal or no nuchal rigidity. Papilledema is noted in up to one third of cases and cranial nerve palsies in about one fifth. If the cranial nerves become involved, patients may experience decreased vi-

sual acuity, diplopia, facial numbness or weakness, or catastrophic vision loss.[22] As the disease progresses, seizures may occur.

Respiratory infection Pulmonary cryptococcosis may present as cough, dyspnea, blood-streaked sputum, and a dull ache in the chest.

Cutaneous infection Skin lesions may be single or multiple and commonly begin as painless lesions of the face or scalp. Skin lesions may take the form of erythematous or umbilicated papules, pustules, acneiform lesions, indurated plaques, palpable purpura, soft subcutaneous masses, sinus tracts, cellulitis, vesicles, or large ulcers with undermined edges.

Prostatic infection The prostate can provide a sequestered focus of active cryptococcosis after therapy for systemic cryptococcal infection. These foci may occur even in patients who did not have prostatic involvement initially, and the foci can be a source of recurrent systemic infection. Prostatic cryptococcosis may present as a peripheral prostatic nodule, but patients often have no symptoms. Diagnosis requires culture of urine obtained after prostatic massage.

Laboratory Tests

Routine blood studies remain normal in cryptococcosis. Lumbar puncture is indicated in immunosuppressed patients with CNS abnormalities; characteristic findings include elevated opening pressure, depressed glucose level, increased protein concentration, and lymphocytic pleocytosis. The latex agglutination test detects antigen in CSF or serum in more than 90% of patients with cryptococcal meningitis, whereas India ink smear of CSF detects cryptococci in 25% to 60%.

In cryptococcal CNS infection, CT or MRI scans of the head may be normal or reveal hydrocephalus, cerebral edema or atrophy, or a focal space-occupying mass lesion. Gelatinous cryptococcal pseudocysts may appear as nonenhancing lesions.

In pulmonary cryptococcosis, chest x-rays most often show one or more circumscribed masses or nodules, often in the upper lobes, without hilar involvement. Less common radiographic patterns include segmental pneumonia, single thick-walled cavities, pleural effusion, and miliary disease.

Antigen titers in either serum or CSF can be used to follow the course of disease, but a lack of standardization among manufacturers of cryptococcal antigen tests means that reliable results can be obtained only if the same kit is used for serial measurements. For definitive diagnosis of cryptococcosis, positive antigen test results must be confirmed by culture. Sputum cultures are often negative, however, and may be falsely positive. Bone lesions appear on radiographic studies as round, lytic lesions.

DIFFERENTIAL DIAGNOSIS

CNS cryptococcosis may resemble coccidioidomycosis, histoplasmosis, tuberculosis, brucellosis, syphilis, viral meningoencephalitis, meningeal metastases, sarcoidosis, and chronic benign lymphocytic meningitis. Cryptococcomas may resemble pyogenic, nocardial, or mold-associated abscesses; tuberculosis; toxoplasmosis; hemorrhage; or lymphoma or other neoplasms. Pulmonary cryptococcosis may be indistinguishable from tuberculosis, histoplasmosis, pneumocystosis, and neoplasm. Cutaneous cryptococcosis may resemble comedones, acne, lipoma, syphilis, tuberculosis, sarcoidosis, molluscum contagiosum, and basal cell carcinoma. Bone lesions resemble those of other mycoses and tuberculosis.

TREATMENT

In patients with cryptococcal CNS infection, therapy begins with intravenous amphotericin B plus oral flucytosine [*see Table 2*].[23] Once the patient is clinically stable and afebrile, which usually takes 2 to 6 weeks to achieve, those agents are replaced with fluconazole. After 8 to 10 weeks of maintenance therapy, fluconazole is continued at a reduced dose for the duration of suppressed cell-mediated immunity, to prevent relapse.[24]

A condition that resembles immune reconstitution syndrome has been reported in organ transplant recipients with *C. neoformans* infection. Onset of this condition was observed a median of 5.5 weeks after the initiation of antifungal therapy and was marked by worsening of clinical manifestations despite negative cultures for *C. neoformans.* In some patients, this condition may be misconstrued as a failure of therapy. Immunomodulatory agents may have a role as adjunctive therapy.[25]

Pulmonary disease from *C. neoformans* can be treated with amphotericin or fluconazole. Secondary prophylaxis for pulmonary disease is often not indicated in patients whose immunosuppression is not severe.

COMPLICATIONS

Elevated CSF pressure in CNS cryptococcosis is associated with blindness and death. An absolute pressure under 250 to 300 mm H_2O can be maintained by removing CSF to decrease pressure by 50%.[26] Hydrocephalus can lead to permanent loss of cognitive function even in patients whose infection is considered cured. Relief of hydrocephalus with a shunt is vital to ensure an optimal outcome.[27]

PROGNOSIS

In CNS cryptococcosis, a good prognosis is associated with normal mental status, a CSF leukocyte level of more than 20 cells/mm^3, and a CSF cryptococcal antigen titer of less than 1:1,024. Even in patients who respond to therapy initially, up to 40% may have residual neurologic defects and up to 25% of the 40% may experience relapse.

For HIV-negative patients who had cryptococcosis between 1990 and 1996, overall mortality was 30% and attributable mortality 12%. Significant predictors of mortality included age greater than 60 years, hematologic malignancy, and organ failure.[28] For solid-organ transplant recipients, renal failure at the time of hospital admission has been identified as an independent predictor of death.[21]

Pneumocystosis

EPIDEMIOLOGY

Common and apparently harmless in the lungs of healthy persons, *Pneumocystis jiroveci* (formerly known as *P. carinii*) can cause pneumonia in those with prolonged lymphopenia. AIDS patients remain the single largest group at risk, although prophylaxis has markedly reduced the incidence of the disease in that population.[29] The risk of *Pneumocystis* pneumonia (PCP) is also higher in the setting of primary immune deficiencies, severe malnutrition (which accounted for epidemics in Central Europe during World War II), organ transplantation, and long-term corticosteroid treatment with monthly doses above 20 mg of pred-

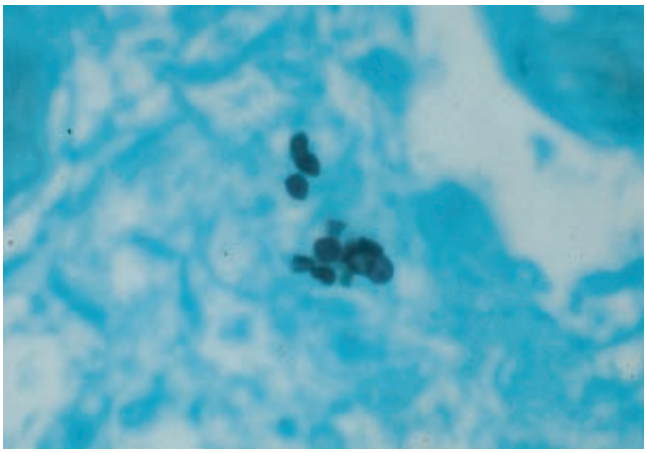

Figure 1 **Cysts of *Pneumocystis*, which stain black and measure approximately 4 to 5 μm, are visible on a methenamine-silver stain of a cytospin preparation from a bronchoscopic alveolar lavage fluid sample.**

nisone or the equivalent. For solid-organ transplant (except lung transplant) recipients, the incidence of *P. jiroveci* pneumonia is highest during the first year after transplantation.[30]

ETIOLOGY

Once *P. jiroveci* is inhaled, it attaches to lung epithelial cells. Pulmonary infection focuses on the interstitium and the alveoli.

Uncommonly, *P. jiroveci* infection spreads beyond the lungs. Patients receiving aerosolized pentamidine as prophylaxis are at risk for upper lung lobe and extrapulmonary disease because this is primarily a topical treatment; the aerosol does not penetrate into the less well ventilated portions of the lungs, and the drug is not absorbed into the circulation. Sites of extrapulmonary involvement include lymph nodes, abdominal organs, bone marrow, eyes, and thyroid.[31]

PATHOGENESIS

Although *Pneumocystis* was formerly classified as a protozoan, nucleic acid comparison studies have identified this organism as a fungus. Host immune defects in humoral and cellular immunity allow unchecked replication of the organism. In the absence of $CD4^+$ T cells, alveolar macrophages are unable to contain infection.

DIAGNOSIS

Clinical Manifestations

Most patients with PCP have a fever.[32] Tachypnea and tachycardia are common in acutely ill patients. Clinical manifestations may develop insidiously and may not interfere with the person's daily routine initially. Consequently, some patients present with several weeks of pulmonary symptoms, including dyspnea, nonproductive cough, hypoxemia, chest pain, and hemoptysis. Nevertheless, lung auscultation may reveal only scant abnormal findings.[33]

Laboratory Tests

Chest x-rays show bilateral infiltrates in most patients. Patients who have received aerosolized pentamidine as prophylaxis but experienced breakthrough infection are more likely to have disease confined to the apices.[31]

Methenamine-silver staining of induced sputum or bronchoscopic alveolar lavage specimens can usually confirm the diagnosis [*see Figure 1*]. At 4 μm in diameter, the cysts of *Pneumocystis* are similar in size to the 5 μm cysts of *Histoplasma.* Pulse oximetry and arterial blood gases are among the methods for testing the level of oxygenation that are used to evaluate disease severity and monitor progression.

DIFFERENTIAL DIAGNOSIS

Any immunocompromised patient with respiratory symptoms, fever, and an abnormal chest radiograph should be considered to have PCP. Nevertheless, many other infectious agents and noninfectious diseases can mimic PCP.

TREATMENT

Active Infection

The treatment of choice for *P. jiroveci* infection is high-dose intravenous trimethoprim-sulfamethoxazole (TMP-SMX). Severely hypoxemic patients should receive adjunctive corticosteroid therapy.[34] Approximately 25% of patients receiving high-dose TMP-SMX have a poor therapeutic response or hypersensitivity reactions. Alternative treatment regimens include pentamidine, trimethoprim-dapsone, clindamycin-primaquine, trimetrexate-leucovorin, and atovaquone [*see Table 3*].

Prophylaxis

Primary prophylaxis is indicated for HIV and organ transplant patients whose $CD4^+$ T cell count is below $200/mm^3$, and secondary prophylaxis is indicated for those with a history of PCP. In HIV-infected patients who respond to highly active antiretroviral therapy, primary and secondary *Pneumocystis* prophylaxis can be safely discontinued once the $CD4^+$ T cell count has remained above $200/mm^3$ for more than 3 months.[35]

TMP-SMX is the first choice for pharmacologic prophylaxis. Along with helping prevent PCP, TMP-SMX has the added benefit of providing protection against toxoplasmosis, salmonellosis, *Haemophilus* infection, and staphylococcal infection.[36] The dosage for TMP-SMX prophylaxis is specific to different immunocompromised patient populations.

There is a significant incidence of adverse reactions to TMP-SMX (rash, nausea, and, in rare cases, myelosuppression or cholestasis). However, because of its superior efficacy and low cost, desensitization should be attempted before switching to a second-choice agent in patients who experience side effects from TMP-SMX [*see Table 4*]. Other options for prophylaxis include dapsone, aerosolized pentamidine, atovaquone, and trimetrexate[37] [*see Table 3*]. Breakthrough infection with *P. jiroveci* may occur despite prophylaxis, especially in patients who have unrecognized poor compliance with a regimen of TMP-SMX or high-dose dapsone (100 mg daily).

PROGNOSIS

Prognosis is related to the degree of hypoxemia at presentation, degree of infiltrates on chest radiographs, elevated lactate dehydrogenase level, the presence of copathogens, prior lung damage, severity of the underlying disease, and general markers of debility. Spontaneous pneumothorax is associated with a poor prognosis.

Aspergillosis

Aspergillus is an environmental saprobe whose spores (coni-

dia) readily become airborne. Conidia of *A. fumigatus,* the principal *Aspergillus* species involved in human infection, are the ideal size for deposition into lungs and sinuses, with a diameter of 2 to 5 μm. *Aspergillus* thrives in wet areas such as crawl spaces, basements, and water-treatment facilities. Renovations may result in the release of spore-bearing dust. Potted plants and marijuana have been suggested as sources of spores.

After it is inhaled, *Aspergillus* can cause a localized infection that may result in allergic or invasive disease. Allergic bronchopulmonary aspergillosis (ABPA) and invasive aspergillosis are the two major clinical variants.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Epidemiology

ABPA affects patients with a hypersensitive immune status, such as those with atopy, asthma, extrinsic alveolitis, and cystic fibrosis.[38] Genetic determinants of immune response are thought to help explain why ABPA develops in only some patients with those conditions. ABPA is equally distributed between males and females with asthma and probably also in those with cystic fibrosis. Diagnosis is usually made in the late teenage years or in the 20s.

Etiology

In susceptible individuals, exposure to *Aspergillus* antigens causes the formation of IgE antibodies directed at the antigen. Reexposure will then result in mast cell degranulation and eosinophilic infiltration, with wheezing and fleeting pulmonary infiltrates.

Pathogenesis

Aspergillus does not invade tissue in ABPA; rather, it colonizes pulmonary secretions. The severity of ABPA probably varies with the intensity of exposure to spores, the species of *Aspergillus* involved, and the immune status of the host. Initially, fungal spores are trapped within thick bronchial mucus. As the fungus proliferates, the bronchi fill with mucus and become dilated; fungal hyphae can be identified in mucoid impactions. ABPA has been divided into five stages [*see Table 5*]. Patients do not necessarily progress through these stages in linear fashion.[39]

Diagnosis

Clinical manifestations Patients with ABPA may have cough, wheezing, expectoration of sputum containing brown plugs, fever, weight loss, dyspnea, malaise, pleuritic chest pain, sweats, and hemoptysis.

Table 3 Treatment and Prophylaxis of *Pneumocystis jiroveci* Pneumonia

	Drug	*Dosage*	*Relative Efficacy*	*Comments*
Treatment				All treatments last 21 days
	Trimethoprim sulfamethoxazole (TMP-SMX)	Two double-strength tablets p.o., or 5 mg/kg of the trimethoprim component I.V. q. 8 hr	First-choice agent	Rash or fever in 19% of patients
	Corticosteroid (oral prednisone or I.V. prednisolone)	40 mg b.i.d. for 5 days, then 40 mg daily for 5 days, then 20 mg daily for 11 days; administer 30 min before TMP-SMX	Adjunctive agent	If arterial oxygen pressure < 70 mm Hg or arterial-alveolar gradient > 35 mm Hg
	Pentamidine	4 mg/kg I.V. daily	Alternative agent for severe disease	—
	Trimethoprim-dapsone	Trimethoprim, 5 mg/kg p.o., t.i.d., and dapsone 100 mg p.o. daily	Alternative regimen for mild to moderate disease	Rash or fever in 10% of patients
	Clindamycin-primaquine	Clindamycin 300–450 mg p.o., q.i.d., or 600 mg I.V. q. 8 hr, and primaquine base 15 mg p.o.daily	Alternative regimen	Give clindamycin I.V. for more severe infections; rash or fever in 21% of patients
	Atovaquone	750 mg suspension p.o., b.i.d.	Alternative agent for mild to moderate disease	Take with food; less effective than TMP-SMX but fewer side effects
	Trimetrexate-leucovorin	Trimetrexate, 45 mg/m^2 I.V. daily; leucovorin, 20 mg/m^2 q. 6 hr for 3 days after trimetrexate	Alternative regimen	—
Prophylaxis		Discontinue when CD4$^+$ cell count > 200/mm^3 for 3 mo		
	TMP-SMX	One double-strength or single-strength tablet, minimum three times per week but usually taken daily	First-choice agent	Provides cross-protection for toxoplasmosis and some bacteria
	Dapsone	100 mg p.o. daily	Alternative agent	Well tolerated if glucose-6-phosphatase levels are normal
	Pentamidine	300 mg in 6 ml sterile water by aerosol every 4 wk	Alternative agent	Breakthrough disease occurs in upper lung lobes
	Atovaquone	1,500 mg p.o. daily	Alternative agent	Take with food
	Dapsone-pyrimethamine–leucovorin	Once weekly: dapsone, 200 mg p.o.; pyrimethamine, 75 mg p.o.; leucovorin 25 mg p.o.	Alternative regimen	Provides cross-protection for toxoplasmosis

Table 4 Desensitization of Adult Patients with Sulfa Allergy*

TMP-SMX Preparation	*Day*	*Dose (ml)*	*SMX Equivalent (mg)*
Pediatric oral suspension (40 mg/200 mg per 5 ml), 1 ml diluted with 9 ml normal saline, to equal 4 mg SMX/ml	1	0.25	1
	2	0.5	2
	3	1	4
	4	2	8
	5	4	16
Pediatric oral suspension, full strength	6	0.5	20
	7	1	40
	8	2	80
	9	4	160
Single-strength tablet	10–30	One tablet	400

*If the patient has had no reaction after 30 days of continuous therapy, the full dose can be given.
TMP-SMX—trimethoprim-sulfamethoxazole

Lung auscultation in patients with active, recurrent, or corticosteroid-dependent disease (stages I, III, or IV) gives variable results, ranging from normal to localized rales in areas of consolidation to wheezes. In fibrotic disease (stage V), patients may have digital clubbing or cyanosis.

Laboratory tests Primary criteria for a diagnosis of ABPA include episodic bronchial obstruction (asthma), immediate skin reactivity to *A. fumigatus* antigen, precipitating antibodies against *A. fumigatus* antigen, increased total serum IgE concentration (> 1,000 ng/ml), history of transient or fixed pulmonary infiltrates, peripheral blood eosinophilia, and central bronchiectasis. Secondary criteria include *A. fumigatus* in sputum, history of expectoration of brown plugs or flecks, and late skin reactivity to *Aspergillus* antigen. Eosinophilia has diurnal variation and may decrease with steroid use or during remission (stage II). Pulmonary function tests are useful in defining the stage of disease and underlying asthmatic activity.

Differential Diagnosis

Allergic bronchopulmonary syndromes can be triggered by molds other than *A. fumigatus.* Allergic fungal sinusitis is histologically identical to ABPA; if it is caused by *A. fumigatus*, the serologic findings will be positive in the absence of asthma and lower respiratory findings.

Treatment

Active infection ABPA is treated with systemic corticosteroids supplemented with oral itraconazole [*see Table 6*]. Itraconazole reduces the burden of colonizing fungal organisms, thereby decreasing chronic antigen stimulation, permitting a lower corticosteroid dose, and decreasing future recurrences of ABPA.[40-42] Measures of clinical response can be followed serially and include decreasing serum IgE concentration, improvement in exercise tolerance and pulmonary function, and resolution of pulmonary infiltrates.

Corticosteroid-dependent (stage IV) patients will have disabling wheezing and dyspnea after oral corticosteroids are tapered or stopped. Patients with fibrotic disease (stage V) require supplemental oxygen and moderate doses of alternate-day prednisone.

Prophylaxis Serum IgE levels should be monitored monthly for 2 years and then every 2 months in patients who have had ABPA. Pulmonary function tests should be performed annually. An increase in serum IgE above remission levels should prompt an evaluation for exacerbation.

Table 5 Clinical Stages of Allergic Bronchopulmonary Aspergillosis

Stage	*Clinical Findings*	*IgE Level*	*Eosinophilia*	Aspergillus fumigatus *Precipitating Antibodies*	*Chest Films*
I – Active	Asthma	Extremely elevated	Extreme	Present	Infiltrates
II – Remission	Normal	Below active levels but not normal	None	± Slightly elevated	Clear
III – Exacerbation	Asthma	Twice normal	Extreme	Not followed	Infiltrates
IV – Corticosteroid dependent	Tapering steroid therapy worsens asthma	Usually elevated but may be normal	—	Not followed	Central bronchiectasis
V – Fibrotic	Dyspnea, cyanosis, rales, clubbing, cor pulmonale	—	—	Not followed	Fibrosis

Note: IgE levels and eosinophilia are less often followed in patients with stage IV or V disease.

Table 6 Treatment of Disease Caused by *Aspergillus* Species

Disease	*Drug*	*Dosage*	*Relative Efficacy*	*Comments*
Allergic bronchopulmonary aspergillosis	Corticosteroid (prednisone)	0.5 mg/kg daily for 2 wk, then 0.5 mg/kg every other day for 3 mo, then taper to discontinuance over another 3 mo	First-choice agent	Follow serum IgE monthly
	Itraconazole	200 mg p.o., b.i.d., for 4 mo	Adjunctive agent	Capsule absorption improved by acidic stomach contents
Invasive aspergillosis	Voriconazole	6 mg/kg q. 12 hr for first 24 hr, then 4 mg/kg q. 12 hr; when oral medication tolerated, 200 mg p.o., q. 12 hr; treat for minimum of 12 wk	First-choice agent	Oral form taken ≥ 1 hr before or after meal
	Caspofungin	70 mg I.V. loading dose, then 50 mg I.V. daily; treat for minimum of 12 wk	Alternative agent	Reduce dose for hepatic insufficiency
	Amphotericin	1.0–1.5 mg/kg I.V. daily for 2–12 wk, then switch to maintenance therapy	Alternative agent	Use lipid formulation, not generic, for patients with nephrotoxicity or infusion toxicity
	Itraconazole	200–300 mg p.o., b.i.d., for 2–12 mo or duration of clinical disease	Maintenance or alternative agent	Solution has better bioavailability than capsule; document blood levels

INVASIVE ASPERGILLOSIS

Epidemiology

Invasive aspergillosis typically occurs during periods of immune suppression, including neutropenia, treatment of GVHD, and treatment of threatened rejection in transplant recipients. Other factors that may predispose immunosuppressed patients to invasive infection include diminished cough reflex, impairment of mucociliary function, and ischemic damage in the perioperative period or at surgical sites. Except in outbreaks, the incidence of invasive aspergillosis should not be higher than 10% to 15%, even in high-risk patients.

Etiology

In bone marrow transplant recipients, invasive aspergillosis has two distinct periods of onset. The first peak, termed early disease, occurs at a median of 16 days after transplantation, when recipients of both autologous and allogeneic bone marrow have absolute neutropenia and lymphopenia, allowing any form of silent colonization to develop rapidly into invasive and often fatal disease. The second peak, late disease, occurs at a median of 96 days. Late disease develops indolently in recipients of allogeneic bone marrow who have recovered from absolute neutropenia but remain immunosuppressed[43] [*see Figure 2*]. Risk factors for early aspergillosis include allogeneic and especially un-

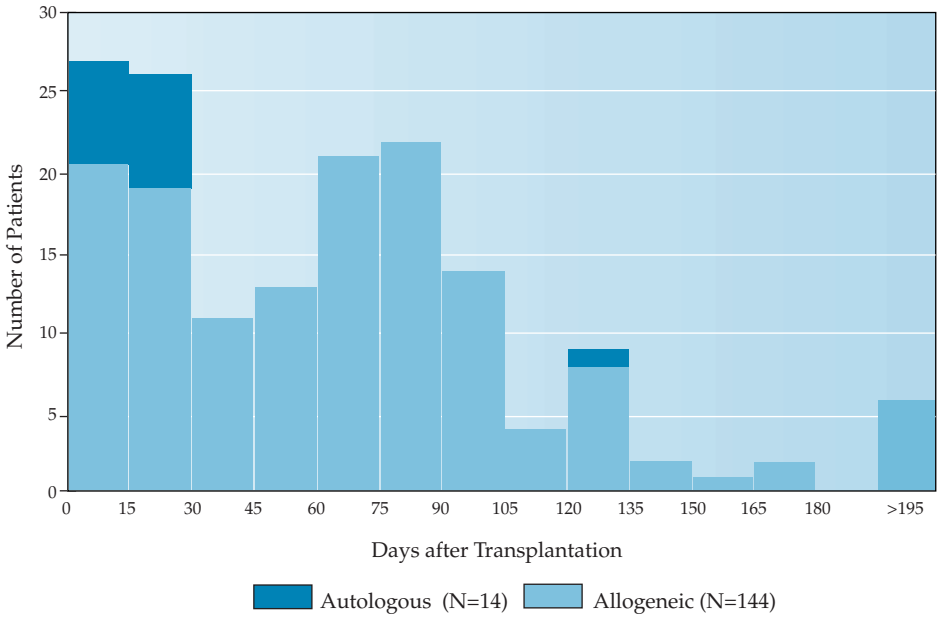

Figure 2 ***Aspergillus* infection during the first 6 months after bone marrow transplantation has a bimodal distribution. The first peak (early disease) occurs at a median of 16 days. Early disease is associated with profound neutropenia and develops rapidly. The second peak (late disease) occurs at a median of 96 days. Late disease is associated with corticosteroid use and develops indolently.[43]**

related donors, male gender, summer season, and transplantation outside of laminar airflow rooms. Risk factors for late aspergillosis are construction in the vicinity of the hospital, acute GVHD, and corticosteroid therapy. The risk for both early and late disease is higher with older age and increasing severity of the underlying oncologic condition. The 1-year survival estimate for bone marrow transplant patients with invasive aspergillosis is less than 10%.

Pathogenesis

Along with *A. fumigatus* and *A. flavus,* emerging species involved in invasive aspergillosis include *A. terreus*, *A. nidulans*, *A. niger*, *A. glaucus*, *A. versicolor*, and *A. ustus*. Sinusitis or pneumonia accounts for 90% of invasive disease and develops after inhalation of *Aspergillus* spores in patients with prolonged neutropenia or other intense forms of immunosuppression.[44] *Aspergillus* spores can also enter the body after direct inoculation through intact skin or ingestion. Intestinal *Aspergillus* infection has led to fatal GI bleeding in severely immunocompromised patients. For that reason, health-food supplements made from natural substances that are not quality controlled for mold spores are contraindicated in immunocompromised patients. Dissemination of invasive disease can occur either as contiguous extension (such as erosion of paranasal sinus infection into the brain) or by hematogenous spread after the organism erodes into blood vessels.

Diagnosis

Clinical manifestations Symptoms and signs of invasive aspergillosis reflect the sites of infection.[45] Patients with pulmonary disease may have fever, dyspnea, tachypnea, cough, brown sputum, pleuritic chest pain, hemoptysis, wheezing, and rhonchi. Sinus infection may present as headache and sinus pressure or tenderness. Cutaneous disease may present as skin lesions (with or without eschar) at the site of primary inoculation or, in the case of secondary dissemination, in multiple noncontiguous sites. Invasive GI disease may present as abdominal discomfort or distention, peritonitis, small bowel obstruction, or melena; it can involve the liver, spleen, appendix, or peritoneum or cause bowel infarction. Liver transplant recipients are at particular risk for *Aspergillus* infection of the abdominal suture line or peritoneum.

Laboratory tests CT scans of the lungs and sinuses should be done in all patients suspected of having an invasive mold infection. Air crescents or so-called ground-glass halos around lung lesions on CT are considered pathognomonic for invasive aspergillosis. Patients with indeterminate pulmonary abnormalities (e.g., new infiltrates or nodules) should undergo bronchoscopy unless the lesions are peripheral. Transbronchial biopsy is performed with bronchoalveolar lavage if the platelet count and bleeding time indicate a low risk of bleeding. A patient with a solitary unilateral pulmonary nodule should undergo CT-guided fine-needle aspiration or in toto resection if the nodule is discrete and large enough.[46] CT or MRI scan of the head should be performed before surgical resection to confirm a lack of hematogenous dissemination.

Lung transplant recipients are at risk for localized infection of the bronchial anastomosis, which can result in circumferential anastomotic dehiscence with herniation of perianastomotic fat.[47] In the early stages of tracheobronchitis, onset of pulmonary symptoms may precede the appearance of radiographic abnormalities. Bronchoscopy will reveal lesions of the mainstem and segmental bronchi. Although most of the lesions are ulcerative, other lesions such as plaquelike lesions, pseudomembranes, or nodules occasionally develop. Disease can vary from localized tracheobronchitis discovered incidentally to extensive bronchial obstruction contributing to respiratory failure.

Opacified sinuses and sinuses containing air-fluid levels should be cultured by an otolaryngologist. However, sinuses showing mucosal thickening and viscous air-fluid levels are inflamed and provide low yields upon culture. If cultured by swab rather than by aspiration or biopsy, they have a predictably low yield of pathogens. If a CT scan demonstrates bony erosion of sinus walls, bone biopsy samples should be taken and examined histopathologically.

Although the diagnostic tests used on a given specimen depend on the body site from which the specimen was taken, specimens are usually submitted for culture, cytology, and histopathologic evaluation. Recovery of the organism in culture and demonstration of hyphae invading tissue make the diagnosis definitive. Growth occurs after 2 to 14 days of incubation. Hyphal cells or cell fragments should be visible with hematoxylin-eosin or methenamine-silver staining. Typical *Aspergillus* hyphal cells have frequent septations and join at 45° angles (dichotomous branching).

An enzyme-linked immunosorbent assay for the detection of *Aspergillus* galactomannan antigen in serum is commercially available, and has become an important tool for the early diagnosis of invasive aspergillosis.[48] In one study, the test had a sensitivity of 75% and a specificity of 100%.[49] The assay is increasingly being used on specimens of body fluids other than serum, including urine, bronchoalveolar lavage fluid, and CSF.[50]

Differential Diagnosis

Although invasive aspergillosis is the most common cause of pulmonary nodules in immunocompromised patients, in at least 10% of such cases the pathogen (or copathogen) will be a non-*Aspergillus* fungus or a bacterium (e.g., *Nocardia*, *Legionella*, or atypical *Mycobacterium*). Other conditions that must be excluded are septic emboli, pulmonary edema, diffuse alveolar hemorrhage, drug reactions, acute respiratory distress syndrome, idiopathic pneumonia syndrome, and bronchiolitis obliterans.

Treatment

Active infection The recommended agent for treatment of invasive aspergillosis is voriconazole.[51,52]

An alternative regimen is amphotericin B, either conventional or lipid formulations, in dosages equivalent to 1 mg/kg/day of standard amphotericin B. Caspofungin is approved by the FDA for patients who fail to tolerate or to improve with standard therapy (salvage treatment) [*see Table 6*].[53,54] Adjunctive measures include colony-stimulating factors, surgical resection of unilateral pulmonary nodules (in patients with no evidence of CNS dissemination), and granulocyte transfusions.

Prophylaxis Environmental and pharmaceutical prophylaxis options are used in patients who are profoundly neutropenic for 3 weeks or longer, because in such patients, invasive aspergillosis occurs with 5% to 10% frequency and mortality is high. Environmental prophylaxis includes high-efficiency particulate air (HEPA) filtration for allogeneic hematopoietic stem cell transplant recipients, rather than laminar airflow; in addition, severely immunocompromised patients should use high-efficiency respiratory-protection devices (e.g., N95 respirators)

when they leave their rooms if dust-generating activities are ongoing in the building.[55]

Pharmacologic antimold prophylaxis is not standardized. In a 2004 clinical trial comparing micafungin with fluconazole for fungal prophylaxis during the preengraftment period of hematopoietic stem cell transplantation, there was a trend toward fewer *Aspergillus* infections in micafungin-treated patients during the study period (one infection versus seven infections, $P = 0.08$).[18] Some centers begin pharmacologic prophylaxis at or before the onset of neutropenia in select patient populations.

Secondary prophylaxis should be started at the onset of neutropenia in patients with a history of aspergillosis who are entering major periods of immunosuppression, such as hematopoietic stem cell transplant recipients.[56] Voriconazole and caspofungin have been replacing amphotericin B for secondary prophylaxis in these patients; the lower toxicity of these agents permits wider use of drug prophylaxis, but the agents are being used in off-label fashion. Adjunctive measures such as nonmyeloablative conditioning procedures and granulocyte transfusions may be used.[57] In general, however, granulocyte transfusions are not effective for secondary prevention of fungal infection during profound neutropenia.

Prognosis

In the 1990s, the overall case-fatality rate for aspergillosis was 58%. Mortality was highest (> 85%) in bone marrow transplant recipients and patients with CNS or disseminated aspergillosis.[43,44] Death often results from the erosion of blood vessels by fungal invasion, with massive hemoptysis or other fatal hemorrhage.

Zygomycosis

EPIDEMIOLOGY

The agents of zygomycosis (a broad term that includes the better-known mucormycosis) cause disease that closely resembles invasive aspergillosis. However, this group of organisms is taxonomically different, belonging to the phylum Zygomycota. The principal pathogens include *Rhizopus*, *Mucor*, and *Rhizomucor;* occasional pathogens include *Absidia*, *Cunninghamella*, *Mortierella*, *Saksenaea*, *Cokeromyces*, and *Apophysomyces.*

Different populations are at risk for zygomycosis at different sites. Cutaneous infection most often develops in patients who are severely ill from trauma; only 50% have systemic immunocompromising disease. Conditions that increase risk for pulmonary, rhinocerebral, and disseminated zygomycosis include poorly controlled diabetes (particularly ketoacidosis) and immunosuppression (e.g., neutropenia, sustained immunosuppressive therapy, or long-term prednisone use). Iron overload, such as that from repeated dialysis or blood transfusions, increases susceptibility to zygomycosis because iron is an essential element for the growth and metabolism of Zygomycetes. Infection may occur in patients receiving the iron chelator deferoxamine to reduce iron overload, because Zygomycetes can readily use iron even when it is bound to deferoxamine.

Persons at risk for zygomycosis of the GI tract are those with some form of severe protein-calorie malnutrition, such as uremia, kwashiorkor, or chronic diarrhea. In the United States, a *Mucor* liver abscess developed in a transplant recipient who consumed health-food supplements made from natural substances that were not quality controlled for mold spores.[58]

ETIOLOGY

Cutaneous infection usually occurs by traumatic inoculation; it is preceded by skin trauma in greater than 80% of cases. Sources of trauma have included surgery, burns, motor vehicle accidents, knives, and even insect bites. A well-publicized series of infections occurred between 1978 and 1980 from elasticized surgical dressings that were found to be contaminated with *Rhizopus*.[59]

Pulmonary, rhinocerebral, and disseminated zygomycosis are acquired via airborne spores deposited in the nasal turbinates or pulmonary alveoli. GI tract disease follows ingestion of fungal spores in moldy food.

PATHOGENESIS

Onset of cutaneous infection usually occurs a few days after the initiating trauma. The pace of cutaneous illness varies: necrosis may spread slowly over weeks, resembling an arterial insufficiency ulcer, or progress rapidly over days, resembling synergistic gangrene. Secondary cutaneous dissemination is unusual, except perhaps in burn victims.

Infection that starts as colonization in the nasal turbinates or paranasal sinuses may extend contiguously. When infection extends directly along veins that drain the orbit and facial tissues, cavernous sinus thrombosis results. With posterior extension, frontal lobe necrosis with brain abscess ensues. Zygomycetes can also enter the CNS by hematogenous spread.

DIAGNOSIS

Clinical Manifestations

Cutaneous disease can occur anywhere on the body, but it is most often found on the extremities.[60] Cutaneous lesions are usually characterized by central dermal necrosis surrounded by a margin of red-to-purple edematous cellulitis, sometimes with bullae indicating epidermal necrosis. Mold may be visible on the edge of a wound. If dermal necrosis is present, pain is common. Fever may be present or absent.

Pulmonary disease typically displays the usual pneumonia symptoms of fever, dyspnea, pleuritic chest pain, hoarseness, and gross hemoptysis. Rhinocerebral disease may begin with fever, leukocytosis, ketoacidosis, facial pain, sinus drainage, or headache. A black eschar on the nasal or palatal mucosa should immediately raise suspicion for rhinocerebral disease. With orbital extension, clinical findings may include orbital swelling or cellulitis, extraocular muscle paresis, proptosis, and chemosis.

Rhinocerebral disease may result in cranial nerve abnormalities, most commonly a seventh-nerve palsy. In patients with cavernous sinus thrombosis, venous engorgement from outflow obstruction is noted in the retina, conjunctiva, and eyelid. Paresis of cranial nerves III, IV, and VI may result in diplopia. Less often, proptosis, meningeal irritation, epistaxis, and involvement of cranial nerve V may occur.

Laboratory Tests

Most patients with pulmonary or disseminated disease will have abnormal chest imaging results, but there is no specific radiographic appearance or lobar predilection. In neutropenic patients with early disease, chest films may show little infiltrate, perhaps because these patients may lack inflammatory cells to cause infiltrate. If pulmonary disease progresses to tissue necrosis and hemorrhage, however, the radiographic changes will become obvious.

A CT scan of the head is indicated in patients with clinical signs of rhinocerebral disease. Scans may show bone destruc-

tion, a brain infarct, or a space-occupying brain lesion and can be used to guide surgical intervention.

Definitive diagnosis is made by recovery of Zygomycetes in culture. Growth occurs after 2 to 5 days of incubation. Wound surfaces can be swabbed for fungal culture, but specimens should also be taken from rapidly spreading infections, nonwound cutaneous lesions, and lesions such as a black eschar on the hard palate or nasal mucosa.

Specimens should be immediately examined with potassium hydroxide, calcofluor white stains, or both. Histologic studies should be done by using hematoxylin-eosin and methenamine-silver staining. In cutaneous disease, hyphae are seen in the middle of an acute neutrophilic infiltrate. Zygomycetes hyphal cells should have infrequent septations, be of variable diameter, join at 90° angles, and twist in ribbonlike fashion upon one another. In the uncommon instance where all those histologic findings are obvious, a tentative pathologic diagnosis of Zygomycetes infection can be made. However, the usual situation is that the tangle of fungal hyphae cannot be distinguished from *Aspergillus*.

Histology may be the only basis for diagnosis, however, given that Zygomycetes grow less frequently in culture than other filamentous molds. One reason is that Zygomycota mold cells are large, because they have few or no septations (i.e., they are pauciseptate or aseptate). Consequently, when the microbiology technologist uses a razor blade to mince tissue being prepared for fungal culture, one slice through the cell wall can lead to leakage of cytoplasm and death, leaving no intact cells for growth. Homogenization of tissue submitted for culture also leads to a high rate of false negative results.

DIFFERENTIAL DIAGNOSIS

Cutaneous zygomycosis can look like ecthyma gangrenosum, which is more often caused by *Aspergillus* and *Pseudomonas.* Pulmonary zygomycosis should be differentiated from aspergillosis, pneumonia caused by other less common bacteria and molds, and pulmonary embolism. Rhinocerebral zygomycosis can resemble orbital tumors, cavernous sinus thrombosis from *Staphylococcus* infection, or aspergillosis.

TREATMENT

Active Infection

Zygomycosis is currently treated with maximal-dosage intravenous amphotericin, 1.0 to 1.5 mg/kg daily for 2 to 12 weeks or for the duration of clinical disease. In addition to intravenous infusions, intracavitary or topical amphotericin may be required for CNS disease; topical amphotericin can be applied to cutaneous disease. Posaconazole, an orally administered triazole, is effective against zygomycosis[61] but is not yet approved by the FDA.

Treatment should include adjunctive measures such as debridement of any adherent mycelial masses at accessible sites of infection. Debridement should be repeated as often as every other day until cultures of the debrided tissues are negative. Some patients may be candidates for granulocyte transfusions or hyperbaric oxygen.

Prophylaxis

Pharmacologic prophylaxis of zygomycosis infections is unusual because the frequency of infection with this group of organisms is low even in high-risk patient groups. Additionally, the medication for prophylaxis is intravenous amphotericin, which is toxic and is expensive when the lipid formulations are used; however, posaconazole may have a role in the future. Topical or systemic preemptive therapy may be appropriate for individual patients, such as burn victims in whom surveillance cultures of wounds demonstrate fungal hyphae.

PROGNOSIS

Hosts with zygomycoses may not be as immunocompromised as hosts with some of the more common opportunistic mold infections; hence, zygomycoses may be associated with better survival.

Fusariosis

EPIDEMIOLOGY

Fusarium is a soil-borne mold that can cause human disease if a portal of entry is available, such as skin, nails, the airways, or the eyes. Species responsible for the majority of human disease are *F. solani*, *F. moniliforme*, and *F. oxysporum*. The number of organisms and the depth of penetration may determine the course of infection. Eye infection can occur after contamination of soft-contact-lens paraphernalia through inadequate washing of soil-borne spores from the hands or contamination of the lens during use; under windy conditions, aerosolized spores can be blown into the eye.

The single most important host risk factor for invasive fusariosis in immunocompromised patients is neutropenia.[62,63] Good clinical outcomes have clearly been linked to recovery from neutropenia, and fatal relapse of disease has been linked to recurrent neutropenia.[64] Other immune system defects linked to infection include heatstroke, systemic corticosteroid use, and topical steroid use at the site of colonization.[65]

Some *Fusarium* species produce secondary metabolites called mycotoxins. Under favorable environmental conditions, those species can grow on grains and contaminate them with mycotoxins. Consumption of mycotoxin-laden foodstuffs can result in both infection and poisoning—especially in malnourished persons, who have enhanced susceptibility to the toxin. An important historical example is an outbreak of toxic alimentary aleukia that occurred in the Soviet Union at the end of World War II. Starving people harvested grains that had been left in the fields over the winter and had become heavily contaminated with *Fusarium* mycotoxin. Those who ate more than 2 kg of food made from the grains suffered an illness that progressed from mucosal inflammation to pancytopenia to mucosal necrosis with fatal bacterial infection. Hundreds of thousands of people died of the illness.

ETIOLOGY

Opportunistic *Fusarium* infection begins by colonization of broken skin, the upper airways, sinuses, or conjunctivae. Reported causes of skin-barrier breakdown include catheters (central venous and peritoneal dialysis), burns, trauma, surgical procedures (coronary bypass), and denuding of skin from infection (as from varicella). When the host has an immune system defect, tissue inflammatory reactions at the site of colonization are reduced, enabling the organism to grow and spread.

PATHOGENESIS

The mold form of *Fusarium* consists of septate hyphae with branches at acute angles. Growth of hyphae in skin lesions may result in subcutaneous granulomas. Once infection has pene-

Table 7 Treatment of Infections Caused by *Fusarium* Species

Infection Site	*Drug*	*Dosage*	*Relative Efficacy*	*Comments*
Invasive fusariosis				Surgery may be needed
	Amphotericin	1.0–1.5 mg/kg I.V. daily for 2–12 wk	First-choice agent	Use lipid formulation, not generic, for patients with nephrotoxicity or infusion toxicity
	Voriconazole	6 mg/kg q. 12 hr for first 24 hr, then 4 mg/kg q. 12 hr; when oral medication tolerated, 200 mg p.o., q. 12 hr; continue treatment for several months, or for minimum 2 wk after recovery from neutropenia, with resumption if patient becomes neutropenic again after an infection	Alternative agent	Oral form taken ≥ 1 hr before or after meal
Keratitis/corneal ulcer	Natamycin 5% suspension	1 drop q. 1–2 hr for first 2 days, then decrease gradually over 3–6 wk	First-choice agent	May require surgery
Skin lesions (as part of invasive disease)				Treat primarily as invasive disease; continue topical therapy until lesions are dry scabs
	Nystatin	Cream twice daily to affected areas	Adjunct to I.V. amphotericin	—
	Amphotericin	Topical compound twice daily to affected areas	Adjunct to I.V. amphotericin	Compound locally

trated into the lumen of blood vessels, hyphae can disseminate through the body to produce embolic infection whose hallmark is necrotic skin lesions and, less often, endophthalmitis or brain abscess.[66]

DIAGNOSIS

Clinical Manifestations

Manifestations of focal *Fusarium* infection vary with the organ involved. Keratitis presents as a corneal ulcer; if therapy is delayed, infection may progress to endophthalmitis. Primary cutaneous infections present in many forms, including ulcers, necrosis, pustules, vesicles, painful nodules, mycetomas, and panniculitis. Onychomycosis presents as a milky-white area in the nail, which may spread until the entire nail becomes opaque; the free border of the nail may become thickened.

With disseminated infection, secondary cutaneous lesions may be the first characteristic finding. These may take the form of multiple erythematous subcutaneous nodules, painful lesions with progressive central infarction, or target lesions with ecthyma gangrenosum–like centers surrounded by a rim of erythema.[67]

Laboratory Tests

Fusarium is the only opportunistic mold that can be easily recovered from the bloodstream; blood cultures will be positive in 40% to 60% of patients with disseminated infection. Many clinical laboratories identify *Fusarium* to only the genus level; speciation would not alter the prognosis or treatment. Patients with fever and neutropenia should have cultures of blood, as well as biopsy and culture from any body sites suspicious for infection. Because *Fusarium* often colonizes nonsterile tissues, the mycologic data should be combined with histopathologic data to distinguish colonization from tissue infection. Biopsies of suspicious skin lesions should be taken from the center of the lesion and should extend to subcutaneous fat, because mold organisms easily invade blood vessels of the dermis and subcutis, resulting in an overlying ischemic cone. Part of the biopsy specimen, or a second biopsy specimen, should be sent for culture.

DIFFERENTIAL DIAGNOSIS

In addition to *Fusarium,* a variety of other organisms can be responsible for new skin lesions in an immunocompromised host; these include *Aspergillus*, other molds, *Pseudomonas,* and varicella.

TREATMENT

Fusarium species are relatively resistant to treatment with antifungal agents, and sensitivity testing for *Fusarium* is not standardized. Fluconazole, itraconazole, and 5-fluorocytosine have no activity against *Fusarium* species, and amphotericin, ketoconazole, miconazole, and terbinafine have limited activity.

Active Infection

Invasive disease is usually treated with high-dose systemic amphotericin [*see Table 7*]. Topical amphotericin or nystatin cream is sometimes added to the systemic amphotericin regimen in attempts to increase local delivery of drug. Voriconazole is approved by the FDA for salvage therapy for *Fusarium* infections. Corneal ulcers caused by *Fusarium* infection are treated with topical amphotericin or natamycin.

Because outcome is clearly linked to recovery from neutropenia, adjunctive measures are essential.[64] Colony-stimulating-factor injections and neutrophil transfusions have been used to increase the neutrophil count. Further episodes of electively induced myelosuppression should be avoided because there is a high incidence of recurrence and multiple-organ failure in patients with subsequent neutropenic episodes.

Surgical treatment has an important role in the management of localized infection; examples include enucleation of an affected eye, wide excision, and nail removal. In an extreme situation, amputation of a limb can be used to cure fusarial soft tissue infections.

Prophylaxis

Prevention of primary *Fusarium* infection involves the same environmental measures that would be used to prevent other mold infections in patients at risk. In general, patients with chronic neutropenia or those about to receive myelosuppressive

therapy should wash their hands regularly and avoid contact with soil or inhalation of dust. Myelosuppressive therapy should be given in an inpatient environment with air filtration to reduce the number of aerosolized spores.

Secondary prophylaxis is required when a patient with known recent *Fusarium* infection has an episode of neutropenia. A systemic antifungal agent with activity against *Fusarium* is used at treatment doses. Efforts to shorten the duration of neutropenia with colony-stimulating factors are sometimes employed. The use of neutrophil transfusions as secondary prophylaxis for patients without fever or skin lesions is difficult to justify and is rarely done.

Infection by Dematiaceous Fungi

EPIDEMIOLOGY

Dematiaceous fungi live in soil and rotting wood. Current taxonomy has more than 100 species of dematiaceous fungi spread out among more than a dozen different families, falling under several classes and orders. All contain melanin pigment in the walls of hyphae or spores, resulting in a color that is dark brown, greenish gray, or black. They are an important group of opportunists, because some species have a tendency to cause CNS infection.[68] Species that appear to be particularly neurotropic include *Cladophialophora*, *Cladosporium*, *Bipolaris*, *Exserohilum*, *Dactylaria*, *Exophiala*, and *Fonsecaea*.

Most reports of infection by dematiaceous fungi emphasize cerebral disease in an immunocompromised patient.[69] However, there is a growing literature describing these infections in specific at-risk patient populations (such as solid-organ-transplant recipients) and in immunocompetent patients, who may experience nasal polyps and an obstructive fungal ball destroying the sinuses.[70,71]

ETIOLOGY

Injury to the skin can implant dematiaceous fungus in subcutaneous tissues; inhalation of spores can cause a minimal infection in the lung or sinuses. Sinus infection can erode through bone into the brain, or unrecognized pulmonary infection can metastasize to the brain.

PATHOGENESIS

Primary cutaneous disease usually exhibits one of three histopathologic patterns: solid granulomas, stellate abscesses, or cavitary lesions. Cystic lesions probably start as solid granulomas, which undergo focal necrosis to form stellate abscesses. The abscesses can then coalesce into a unilocular fluctuant abscess.

DIAGNOSIS

Clinical Manifestations

Dematiaceous fungi cause primarily skin and soft tissue infections.[70] Analogous syndromes seen in tropical and subtropical areas of the world include mycetoma (tumorous growth of the skin with tissue granules) and chromoblastomycosis (verrucous skin infection with sclerotic bodies). Immunocompetent persons develop an asymptomatic initial lesion: a discrete, well-encapsulated, erythematous to flesh-colored plaque or nodule. The nodule center tends to become necrotic, forming a localized, encapsulated abscess. In immunocompromised persons, subcutaneous lesions may not encapsulate and may spread contiguously or systemically.

Systemic infections may present as unexplained fever during neutropenia that persists despite administration of broad-spectrum antibiotics. Metastatic disease may involve the lungs, joints, esophagus, heart, peritoneum, or bone, but the favored site is the CNS.

Laboratory Tests

Histopathology and culture of a tissue specimen are generally necessary to identify an infection as dematiaceous. Fungi are visible in cells lining an abscess, in the lumen of an abscess, or free in the granulation tissue of a cyst wall. The fungi appear as yeastlike cells that can be solitary or arranged in short chains, pseudohyphal-like fungal elements, or septate hyphae of varying lengths. The hyphae may differ from *Aspergillus*, *Fusarium*, or the Zygomycetes by having thicker walls, irregular diameter, variable branching, or constrictions at the septations. Because the degree of visible pigment can vary between patients infected with the same species, a melanin stain such as Masson-Fontana can be used to reveal cell wall pigment in tissue sections.

In patients with CNS involvement, dematiaceous infection often presents as rim-enhancing brain abscesses on CT scan.

DIFFERENTIAL DIAGNOSIS

On histopathologic examination, the septate fungal hyphae of dematiaceous fungi bear close resemblance to *Aspergillus.* The pathologist will usually label such specimens as *Aspergillus*-like, because less than 0.1% of them will culture out as a dematiaceous fungus. The Masson-Fontana melanin stain can discriminate dematiaceous fungus from *Aspergillus* but is rarely used in histopathology laboratories, so the distinction is usually made by culture.

TREATMENT

Complete surgical excision appears critical in the management of cutaneous lesions. If the entire lesion is removed in an immunocompetent host, antifungal therapy may not be needed. Disseminated disease requires systemic antifungal medication, sometimes combined with surgery. Amphotericin, 0.8 to 1.2 mg/kg I.V. daily for 2 to 12 weeks, is typically used, but the choice of medications should be evaluated on an individual basis. The new triazoles and echinocandins may come to replace amphotericin for this purpose.[72]

The duration of therapy is determined by the immune competence of the host, the site and extent of involvement, disease responsiveness, and the susceptibility of the organism. Neutrophil transfusions may be added for patients with systemic infection and low levels of circulating neutrophils, but no controlled studies of this approach have been performed.

XXXIX INFECTIONS DUE TO MYCOBACTERIUM LEPRAE AND NONTUBERCULOUS MYCOBACTERIA

Michael K. Leonard, Jr., m.d.
Henry M. Blumberg, m.d., f.a.c.p.

Mycobacterium leprae infection (i.e., leprosy) is a disease that has been recognized—and has often been misunderstood—since ancient times. Nontuberculous mycobacteria (NTM) (i.e., mycobacteria other than *M. tuberculosis* complex [*M. tuberculosis, M. bovis, M. africanum,* and *M. microti*] and *M. leprae*) have been recognized to cause human disease since at least the 1950s. The emergence of the AIDS pandemic and the development of newer culture methodologies and molecular diagnostic tools have brought about increased interest in the epidemiology, diagnosis, and treatment of human infections from NTM.

More than 100 species of NTM have been identified; approximately 50 of these may be pathogenic for humans, causing a broad spectrum of disease.[1] Most NTM organisms are readily recovered from the environment, including environmental and drinking water, soil, and aerosols.[1,2] NTM organisms are important environmental pathogens that can cause a broad spectrum of diseases. NTM disease usually develops in immunocompromised hosts, such as development of *M. avium* complex [MAC] infection and other NTM infections in persons with HIV infection; but occasionally, NTM disease does occur in immunocompetent persons, such as those with underlying lung disease. Other types of NTM infection are skin and soft tissue infections from rapidly growing mycobacteria in postoperative patients and *M. marinum* infection after aquatic exposure. NTM infections also occasionally develop in otherwise healthy patients. This chapter covers both *M. leprae* and selected NTM organisms, including MAC; *M. kansasii*; *M. marinum;* and rapidly growing mycobacteria such as *M. chelonae*, *M. fortuitum,* and *M. abscessus*. Discussion of other NTM pathogens is beyond the scope of this chapter, but these other organisms are discussed in several reviews.[1,2-5] *M. ulcerans*, the causative agent of Buruli ulcer, which is common only in children in rural tropical areas, primarily in West Africa (i.e., Ghana, Côte d'Ivoire, and Benein), is also discussed elsewhere.[6,7]

Leprosy (*M. leprae* Infection)

A classic scourge described in ancient medical texts and the Bible, leprosy (Hansen disease) is a mycobacterial disease caused by *M. leprae* that affects the skin and peripheral nerves and can lead to severe disfigurement. Worldwide, about one to two million people are affected, with 763,917 new cases reported in 2002.[8] In the United States, however, fewer than 100 new cases are diagnosed each year, almost all of them in immigrants from endemic areas.[9] Secondary transmission from imported cases has not been recognized. Prompt recognition is imperative to limit morbidity from irreversible nerve damage. The disease is curable with multidrug therapy.

M. leprae has two unique properties: it is thermolabile, growing best at 27° to 30° C, and it divides extremely slowly—the generation time is 12 to 14 days (in the mouse footpad model; the organism cannot be cultured in artificial media). Because of this slow growth, the incubation period in humans is long: a minimum of 2 to 3 years, with the average incubation time thought to be 5 to 7 years and the maximum time as long as 40 years. Because of the long and variable incubation period of the disease, its epidemiology and pathophysiology remain incompletely understood. Humans are the principal reservoir for *M. leprae*, but leprosy has also been found in armadillos and primates.[9] The main modes of disease transmission are by aerosolized droplets from lepromatous persons and, much less commonly, by direct skin contact.[9] Transmission is thought to occur by the respiratory route because large numbers of bacilli are often found in the nasal discharge of untreated patients with multibacillary disease [*see* Diagnosis, Laboratory Studies, *below*]. Although these are believed to be the main modes of transmission, many patients have no identifiable contacts.[10]

Host genetics are thought to play an important role in both development of disease in exposed persons and the pattern of disease that develops. The vast majority of the world's population is not susceptible to leprosy; however, familial clustering of leprosy has been demonstrated, and twin studies have revealed high concordance rates.[10] Susceptibility appears to be governed at least partly by the *nramp1* gene, which controls susceptibility to mycobacteria in mice. A human leukocyte antigen (HLA) association appears to play a role in the clinical spectrum of disease, with the HLA-DR3 genotype overrepresented in tuberculoid leprosy and the HLA genotype DQ1 or MT1 more often seen in lepromatous disease.[10]

Diagnosis

Clinical Manifestations and Classification

Because *M. leprae* grows at cooler temperatures, leprosy primarily affects skin and nerves in the peripheral tissues. The clinical features are a result of interaction of the organism with the host's immune system. Infection of sensory neurons results in the loss of the sensation of pain; this leads to the mutilation that is characteristic of advanced leprosy. Infection of motor neurons causes paralysis. The manifestations of leprosy depend on the infected person's immune response to the causative agent, *M. leprae*.[10] Clinically, leprosy may resemble many dermatologic and neurologic conditions; thus, a high index of suspicion is necessary for accurate diagnosis.

Early leprosy and indeterminate leprosy, which are characterized by hypopigmented, ill-defined skin lesions, often heal on their own and may even be ignored by some patients. Nevertheless, all such patients should receive chemotherapy. If healing does not occur, the disease progresses along a clinical spectrum [*see Figure 1*]. Leprosy typically presents as anesthetic skin lesions associated with thickened peripheral nerves.[10] The appearance of the skin lesions varies according to the spectrum of disease.

Advanced infection can be divided into two polar forms: tuberculoid leprosy and lepromatous leprosy. The stages of the spectrum of disease, in order of decreasing cell-mediated im-

mune response to *M. leprae,* are tuberculoid leprosy, which is characterized by few skin lesions and low bacterial loads; borderline tuberculoid leprosy; borderline leprosy; borderline lepromatous leprosy; and lepromatous leprosy, which is characterized by diffuse skin lesions and high bacterial loads. The cell-mediated immunity of patients with tuberculoid leprosy is intact. Patients who have lepromatous leprosy are anergic and show severely impaired cell-mediated immunity to *M. leprae* and thus have a high burden of disease.

Tuberculoid leprosy Patients at the tuberculoid pole of the disease spectrum typically present with a limited number (i.e., less than six) of large, asymmetrical, well-defined skin lesions. The skin is rough, anhidrotic, and usually anesthetic; central healing of lesions may occur. Neurologic involvement is limited to a few peripheral nerves. Enlargement of a single nerve is common, and marked nerve damage can occur early in the course of tuberculoid disease, often resulting in wristdrop, clawing of the hand, and footdrop.[10] Tuberculoid leprosy often involves the greater auricular, radial cutaneous, ulnar, common peroneal, and posterior tibial nerves. Early treatment is key to minimizing nerve damage. Skin lesions of patients with tuberculoid leprosy contain predominantly helper T cells, well-formed granulomas, and few organisms.

Lepromatous leprosy Patients at the lepromatous pole of the spectrum of disease present with skin lesions that are widely and symmetrically disseminated, often demonstrating only slight hypopigmentation or erythema. The major defect in lepromatous leprosy appears to be a specific inability of T cells to respond to *M. leprae*; as a result, these patients are unable to generate the chemokines and lymphokines that normally activate macrophages and thereby enhance killing of the organisms. Because of the poor cell-mediated immune response to *M. leprae,* the bacterial burden becomes quite large in patients with lepromatous leprosy. Typically, skin lesions are numerous. At times, the entire skin surface can be involved, yielding a diffuse, waxy appearance. Loss of eyebrows and hypertrophy of earlobes produce the characteristic leonine facies. Neurologic involvement is widespread. A symmetrical peripheral neuropathy progresses proximally; sensory loss precedes paralysis. Other cool tissues are often involved, including the anterior chamber of the eye, the upper airway, and the testes. Sustained bacillemia with multisystem infection can occur.

On biopsy, skin lesions of patients with lepromatous leprosy are practically devoid of granulomas and helper T cells; instead, they contain suppressor T cells and numerous bacilli. A biopsy specimen showing many organisms and foam cells but no granulomas confirms the diagnosis, as does the finding of numerous acid-fast bacilli (AFB) in smears of skin-slit preparations. If left untreated, lepromatous leprosy is relentlessly progressive.

Borderline leprosy Many patients with leprosy have disease that falls between the tuberculoid and lepromatous forms. These patients are classified as having borderline tuberculoid or borderline lepromatous disease [*see Figure 1*].

Laboratory Studies

According to the World Health Organization (WHO) classification of leprosy, patients have paucibacillary disease when no bacilli are demonstrated on skin smears, and have multibacillary disease when bacilli are seen on skin smears.[11] The diagnosis of leprosy is usually suspected on clinical grounds. However, demonstration of acid-fast bacilli in slit-skin smears provides laboratory confirmation of the diagnosis in cases of multibacillary disease. Samples for skin smears are obtained by using a scalpel blade to scrape the openings of small slits made in pinched skin. The tissue fluid obtained is smeared on a slide and stained for AFB by the Fite method.[10,11]

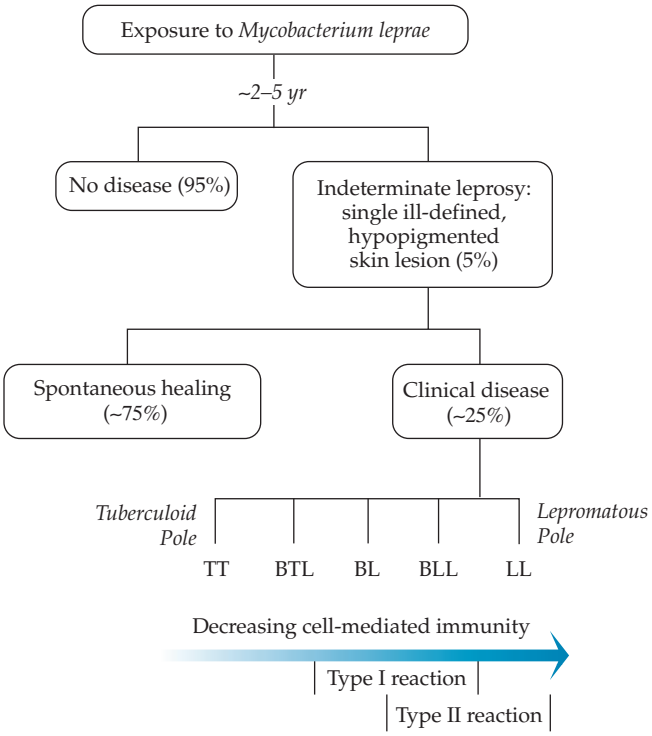

Figure 1 **The natural history and clinical spectrum of leprosy. (BL—borderline leprosy; BLL—borderline lepromatous leprosy; BTL—borderline tuberculoid leprosy; LL—lepromatous leprosy; TL—tuberculoid leprosy)**

Skin biopsy is another method of diagnosing leprosy, especially in patients with paucibacillary disease, and it can be used to classify the disease according to the clinical spectrum. Bacilli are frequently not seen in specimens from patients with disease in the tuberculoid end of the spectrum. In such cases, a biopsy that shows well-formed granulomas but few or no organisms can help establish the diagnosis of tuberculoid leprosy; the finding of inflamed nerves usually confirms the diagnosis.[10]

Serologic testing has little clinical utility in diagnosing leprosy.

TREATMENT

Patients with leprosy should be treated by physicians who are experienced in the management of this disease. Antimicrobial agents that are used include rifampin, dapsone, clofazimine, ofloxacin, and minocycline. The WHO has recommended treatment regimens for leprosy [*see Table 1*].

Rifampin is the most effective agent against *M. leprae* and can render lepromatous patients noninfectious within days. Patients with paucibacillary disease that is indeterminate, tuberculoid, or borderline tuberculoid receive monthly rifampin (under supervision) and daily dapsone (self-administered) therapy for 6 months. In the past, dapsone was used alone, but this is no longer recommended, because monotherapy led to the emergence of drug resistance. Patients with a single-lesion paucibacil-

Table 1 World Health Organization Recommendations for Treatment of Leprosy[12]

Disease Classification (Leprosy Type)	*Drugs*	*Dosages*	*Duration*
Paucibacillary (indeterminate, tuberculoid, or borderline tuberculoid)	Rifampin Dapsone	600 mg once monthly, supervised 100 mg daily, self-administered	6 mo
Single-lesion, paucibacillary	Rifampin Ofloxacin Minocycline	600 mg 400 mg 100 mg	Single dose
Multibacillary (borderline, borderline lepromatous, or lepromatous)	Rifampin Dapsone Clofazimine	600 mg once monthly, supervised 100 mg daily, self-administered 300 mg once monthly, supervised *or* 50 mg daily, self-administered	12 mo

lary disease can be treated with triple-drug therapy consisting of a single dose of rifampin, ofloxacin, and minocycline. Multibacillary disease requires a minimum of 12 months of therapy with a three-drug regimen that includes daily dapsone and monthly rifampin therapy plus clofazimine therapy either monthly or daily; monthly medication is given under supervision, whereas daily medication is self-administered.[12] Long-term follow-up is often suggested because late relapses may occur.

Leprosy Reactions

After initiation of therapy for *M. leprae,* patients may experience episodic immunologically mediated acute inflammatory responses called reactions, which are important mechanisms for causing nerve damage [*see Table 2*]**.** These immune reconstitution reactions can be characterized by swelling and edema in preexisting skin lesions or by peripheral neuropathy and neuritis, which can cause pain, tenderness, and loss of function. If not recognized and treated aggressively, these reactions can lead to irreversible nerve damage and permanent limb deformity.

There are two types of leprosy reactions. Type I reactions, or reversal reactions, are characterized by cellular hypersensitivity. Type II reactions, or erythema nodosum leprosum (ENL), are characterized by a systemic inflammatory response to immune complex distribution. Reversal reactions typically occur after initiation of leprosy treatment but can occur spontaneously before or after multidrug therapy. Treatment of type I reactions includes the use of anti-inflammatory agents; thalidomide is indicated for treatment of type II reactions.[13] A decline in ENL has been observed since the introduction of multidrug therapy, perhaps in part because of the anti-inflammatory effects of clofazimine.

CHALLENGES

The enormous progress in chemotherapy, which has helped to reduce the number of leprosy cases by nearly 90% over the past 10 years, makes the worldwide elimination of leprosy a realistic goal. However, there are challenges to eradicating this disease: many patients present late in the course; multidrug therapy is still not used in some endemic areas, so relapses may occur; and unfortunately, the disease still carries a stigma, which can interfere with effective disease management.

Nontuberculous Mycobacteria Infections

NTM infections are associated with several major clinical syndromes [*see Table 3*]. Selected NTM infections are associated with pulmonary disease, lymphadenitis, skin and soft tissue disease, skeletal infection, and infections related to catheters and other foreign bodies. In addition, disseminated disease (e.g., caused by

Table 2 Characteristics and Treatment of Leprosy Reactions[13]

Type	*Clinical Features*	*Risk Factors*	*Pathogenesis*	*Management*
Type I: reversal reactions	Occurs in BT and BB, but most common in BL; skin lesions are new, or there is increased inflammation in preexisting lesions; acute inflammation of nerve trunks may or may not occur	Recent pregnancy, facial plaques, extensive skin involvement, and preexisting neuritis	Increase in cell-mediated immunity to bacilli in dermis and Schwann cells, leading to inflammation of skin and nerve trunks	Prolonged anti-inflammatory therapy, analgesia, and physical support of active neuritis; high-dose steroids (1 mg/kg) for 4–6 mo; azathioprine and cyclosporine are also effective; surgical decompression of swollen nerves if medical therapy is unsuccessful
Type II: erythema nodosum leprosum	Occurs in BL and LL; skin lesions are new, small, tender, erythematous subcutaneous nodules; fever, arthralgia, neuritis, vasculitis, adenopathy, iridocyclitis, orchitis, and dactylitis are present	Pregnancy, age < 40 yr	Systemic inflammatory response to deposition of extravascular immune complexes formed from *Mycobacterium leprae* antigen	Thalidomide is the drug of choice; systemic symptoms and pain are alleviated in 24–48 hr, and nodules involute in 3 days; starting dose, 200 mg, may be decreased with control of symptoms; pentoxifylline and colchicine may be effective in mild cases; neuritis requires systemic steroids

BB—borderline leprosy BL—borderline lepromatous leprosy BT—borderline tuberculoid leprosy LL—lepromatous leprosy

MAC) is common in persons with advanced HIV infection.

Traditionally, NTM infections have been categorized on the basis of characteristic colony morphology, growth rate, and pigmentation (i.e., the Runyon system of classification). The availability of rapid molecular diagnostics has reduced the usefulness and importance of this system. However, growth rates and colony pigmentation continue to provide a practical way for grouping mycobacteria specimens in the clinical microbiology laboratory. Rapidly growing mycobacteria include nonpigmented and pigmented species that produce mature growth on agar plates within 7 days. So-called slowly growing mycobacteria include species that require more than 7 days to reach mature growth on solid media; this group includes MAC and *M. kansasii*, which are pigmented and require 7 to 10 days to mature on solid media. *M. marinum* grows optimally at 28° to 30° C (which in large part explains its proclivity to cause skin and soft tissue infections), whereas *M. gordonae* (a common laboratory contaminant that rarely causes human disease) grows best at 35° to 37° C.

Although growth characteristics on solid media may be used to help categorize NTM infections, molecular diagnostic tests provide a definitive diagnosis for many NTM infections. Current guidelines recommend that for culture of NTM, as with culture for *M. tuberculosis*, both solid and liquid media be used to optimize recovery of mycobacterial species.[14,15] Mycobacteria grow more quickly in broth or liquid media than on solid media, which can decrease time to detection of a positive culture; in addition, liquid media may be more sensitive than solid media for some mycobacteria. Commercially available genetic probes for identification of selected NTM are available, including an acridinium ester–labeled nonradioactive DNA probe based on the detection of ribosomal RNA (rRNA). These probes are approved by the Food and Drug Administration for identification of *M. tuberculosis* and some common species of NTM, including *M. kansasii*, MAC, and *M. gordonae*.[14] No commercial probes are available for identification of other NTM species, but polymerase chain reaction (PCR) has proved useful for identification of rapidly growing mycobacteria. High-performance liquid chromatography, which is generally available at large reference laboratories (e.g., state public health laboratories, the Centers for Disease Control and Prevention) is useful in identifying *Mycobacterium* species.

MYCOBACTERIUM AVIUM COMPLEX

MAC comprises two closely related species, *M. avium* and *M. intracellulare*. MAC is encountered most often as an opportunistic pathogen in immunosuppressed patients, especially those with advanced HIV infection or AIDS. However, MAC infection can occur in immunocompetent hosts; it is especially likely to cause pulmonary infections in persons with underlying chronic

lung disease. The environmental reservoirs for MAC include both water and soil. The portal of entry is the respiratory tract or the gastrointestinal tract. When isolated from immunocompetent patients, MAC may be a simple contaminant or a true pathogen.[16] Because MAC is an organism of relatively low virulence, especially compared with *M. tuberculosis*, its presence does not always represent disease; colonization by MAC must be excluded through consideration of the clinical, radiographic, and pathologic features of the disease.

MAC Infection in the Immunocompetent Host

Chronic pulmonary disease is the clinical condition that is most often associated with MAC infection in the immunocompetent host; lymphadenitis and, rarely, disseminated disease are also seen. MAC pulmonary disease was initially described predominantly in men with underlying lung disease; often, such patients had a history of tobacco or alcohol consumption, and some had a prior history of tuberculosis.[17] The radiographic presentation is similar to that of tuberculosis, with upper lobe fibronodular or cavitary disease.[18] Patients with these radiographic abnormalities may present with pulmonary and systemic symptoms. CT findings may include multiple nodular infiltrates and bronchiectasis.[17]

Since the late 1980s, pulmonary MAC has been described in other immunocompetent patients, such as nonsmoking elderly women with fibronodular bronchiectasis and those with limited radiographic changes.[19,20] In addition, carriage of a cystic fibrosis or an abnormal α_1-antiproteinase gene appears to predispose to the development of MAC lung disease.[18] Older women without previous lung disease may present with fewer systemic symptoms and less pronounced radiographic findings. Pulmonary MAC infection in women, typically elderly women, with a radiographic pattern of nodules initially in the middle or lingual lobes has been termed the Lady Windermere syndrome and has been attributed to habitual voluntary suppression of cough.[21] Pulmonary MAC infection may develop in patients with cystic fibrosis. A hypersensitivity pneumonitis has been reported in persons exposed to MAC aerosolized from contaminated hot tubs or pools.[22] The radiographic picture is similar to that of other hypersensitivity pneumonitides.

Criteria for the diagnosis of NTM infection include repeated isolation of a potentially pathogenic species, the absence of other pathogens, and a compatible clinical, radiologic, or pathologic picture. The American Thoracic Society has developed criteria for the diagnosis of NTM infection, including pulmonary infection by MAC [*see Table 4*].[23]

Lymphadenitis from MAC typically affects previously healthy children who are 1 to 5 years of age.[24] Submandibular lymph nodes are most often involved. The patient usually does not have evidence of pulmonary or systemic illness. The lymph node may become tender and erythematous, and it may eventually drain. Diagnosis is made by pathologic examination of the excised node, which in most cases reveals caseating granulomas and positive AFB smears. Without culture data or nucleic acid testing, it is impossible to distinguish NTM lymphadenitis from tuberculous lymphadenitis. Excision of the infected node is the treatment of choice, because incision and drainage may lead to the formation of a draining fistulous tract.[25] Treatment with antimicrobials is rarely indicated except for serious disease or recurrences.

MAC Infection in AIDS

Disseminated MAC infection is an opportunistic disease that typically occurs late in the course of AIDS—in patients with $CD4^+$ T cell counts lower than $50/mm^3$—when other opportunistic infections and neoplasia have already occurred. The mode of acquisition of MAC in patients with AIDS is not clear. The genetic diversity of MAC isolates from patients with AIDS implies that the organisms may be acquired from multiple environmental sources.

MAC produces widely disseminated infection in patients with AIDS.[26] Systemic symptoms predominate, including fever, chills, night sweats, and profound weight loss. Fever and night sweats are the most common manifestations, occurring in more than 75% of patients.[27] Gastrointestinal symptoms, notably diarrhea, are present in at least a third of patients. Pulmonary symptoms are often present, but their significance is difficult to interpret because other opportunistic pathogens (e.g., cytomegalovirus and *Pneumocystis*) are often present, as well. Anemia and an elevated alkaline phosphatase level are frequently observed laboratory abnormalities.

Disseminated MAC infection can be readily documented by recovery of the organism from AFB and mycobacterial blood

Table 4 American Thoracic Society Criteria for Diagnosis of Nontuberculous Mycobacterial Lung Disease[21*]

Radiographic Criteria	*Laboratory Criteria*
Infiltrate, reticulonodular infiltrate, or cavitary disease on chest x-ray *or* Multifocal bronchiectasis or multiple small nodules on high-resolution chest CT	Two positive respiratory (sputum and/or bronchial wash) cultures within 12 mo, if one or both specimens are AFB smear positive *or* Three positive sputum/bronchial wash cultures within 12 mo, if none of the specimens are AFB smear positive *or* In patients unable to produce sputum, one positive bronchial wash culture with a 2+, 3+, or 4+ AFB smear and/or growth on solid media *or* A transbronchial biopsy yielding NTM *or* Biopsy showing mycobacterial histopathologic features (granulomatous infiltration and/or AFB) and one or more sputa/bronchial washings are positive for NTM

cultures. Blood is the preferred source of diagnostic specimens, but organisms may also be seen (and recovered by AFB culture) in biopsy specimens of the lung, liver, spleen, bone marrow, and lymph nodes. Despite the presence of many mycobacteria in macrophages, well-formed granulomas are typically absent; this so-called lepromatous histology reflects the profound impairment of cell-mediated immunity and explains the inability to contain the MAC infection. Intestinal or pulmonary infection may precede MAC bacteremia, but smears and cultures of these sites are not sensitive enough to be used as screening tests for early infection. Positive intestinal and pulmonary smear and culture results may represent colonization; however, positive cultures of stool and sputum are strongly predictive of subsequent dissemination in patients with low $CD4^+$ T cell counts.[28]

Treatment

Immunocompetent patients Treatment of pulmonary MAC is lengthy (longer than 1 year), but success rates have increased with the availability of newer macrolide drugs. Multidrug therapy is indicated to prevent the development of resistance. The cornerstone of therapy is the administration of a macrolide; clarithromycin is the preferred agent, with azithromycin an alternative. Ethambutol and rifabutin are used in conjunction with a macrolide. In severe cases, an aminoglycoside (e.g,. amikacin) may be needed. Treatment should be continued for at least 12 months after sputum cultures have converted to negative. Surgical resection may be indicated in patients with severe, refractory disease or in those who develop severe complications (e.g., life-threatening hemoptysis).

HIV-infected patients The treatment and survival of AIDS patients with MAC infection have improved greatly, especially since the advent of highly active antiretroviral therapy (HAART). More effective agents for MAC prophylaxis and treatment are now available, and the use of HAART can reduce the burden of disseminated MAC.[27] Patients with $CD4^+$ T cell counts of $50/mm^3$ or lower should receive MAC prophylaxis with azithromycin (1,200 mg weekly) or clarithromycin (500 mg twice daily).[29] The drugs are equally effective, but azithromycin is often preferred for MAC prophylaxis because of its greater convenience. Rifabutin is an alternative prophylactic agent for patients who cannot tolerate a macrolide.[30] An AFB blood culture should be obtained before the initiation of MAC prophylaxis to rule out disseminated disease.

Macrolides are the cornerstone of treatment of MAC disease. In HIV-infected patients with disseminated MAC, treatment should consist of clarithromycin or azithromycin plus ethambutol [*see Table 5*]. The addition of rifampin or rifabutin may be indicated in patients with advanced AIDS who are not receiving antiretroviral treatment and who have a high mycobacterial load.[31] Clarithromycin is the preferred macrolide for initial therapy. Clarithromycin may be slightly more active than azithromycin, but it is associated with more gastrointestinal side effects.[23] The debate continues as to which rifamycin is best. Rifabutin has lower minimum inhibitory concentrations than rifampin, but rifampin achieves higher serum levels.[32] Rifampin is also associated with many more drug interactions than rifabutin and cannot be given with protease inhibitors; this is an important consideration in patients receiving treatment for HIV infection. In some patients who do not respond to therapy, the addition of a third and even a fourth drug may be indicated. Amikacin or a fluoroquinolone such as levofloxacin is used for this purpose.[31,33]

HIV-infected patients who start antiretroviral therapy can discontinue primary prophylaxis for MAC infection when their $CD4^+$ T cell counts exceed $100/mm^3$ for more than 6 months.[34] Maintenance therapy (i.e., secondary prophylaxis) for MAC infection may be discontinued after 12 months if the patient remains asymptomatic and the $CD4^+$ T cell count has been above $100/mm^3$ for at least 3 months.[29,31]

Immune reconstitution syndromes can be an adverse event in the treatment of patients with HIV infection who have disseminated MAC. These syndromes sometimes occur in HIV-infected patients with unrecognized MAC who are started on antiretroviral agents. Pathogen-specific immune responses to MAC can occur in the first few months after the initiation of highly active antiretroviral therapy.[35] Immune reconstitution reactions to MAC usually manifest themselves as fever and lymphadenopathy (peripheral, intrathoracic, or intra-abdominal). Bacteremia does not occur. In severe cases, treatment with corticosteroids or nonsteroidal anti-inflammatory drugs may be necessary to ameliorate the symptoms associated with the immune response.

MYCOBACTERIUM KANSASII

M. kansasii is found in the United States, Europe, and Japan; but in the United States, most cases are clustered in the Midwest—hence the name *M. kansasii*. Cases are also clustered in the South. Water is the only known reservoir; this organism has not been found in soil. *M. kansasii* is the second most common organism responsible for NTM pulmonary disease. Risk factors include cigarette smoking, pneumoconiosis, and HIV infection. *M. kansasii* is also the second most common NTM infection causing disseminated disease in patients with AIDS.[36] Infection probably occurs through the respiratory route. Clinical symptoms of *M. kansasii* infection can be identical to those of pulmonary tuberculosis (i.e., fever, cough, weight loss, and hemoptysis). The radiographic presentation usually involves fibronodular or fibrocavitary upper lobe disease resembling pulmonary tuberculosis, except that the cavities may be thin walled and look like bullae.[37] In patients with HIV infection who have $CD4^+$ T cell counts above $200/mm^3$, *M. kansasii* pulmonary disease can be cavitary. Patients with lower $CD4^+$ T cell counts are more likely to have noncavitary pulmonary disease, sometimes in association with disseminated disease.

Treatment

Treatment for *M. kansasii* includes isoniazid, rifampin, and ethambutol given for a total of 18 months, with continuation of therapy for at least 12 months after the patient is culture negative [*see Table 5*].[23] *M. kansasii* is resistant to pyrazinamide; hence, this drug is not used. Treatment failures may result from rifampin resistance. Fluoroquinolones and aminoglycosides are alternative agents in selected cases. HIV-infected patients may benefit from the addition of clarithromycin as a fourth agent.[1]

RAPIDLY GROWING MYCOBACTERIA

Rapidly growing mycobacteria constitute a group of nonpigmented and pigmented NTM species that produce growth on agar plates within 7 days. Of the rapidly growing mycobacteria, three groups account for most disease in humans: the *M. fortuitum* group, the *M. chelonae-abscessus* group, and the *M. smegmatis* group [*see Table 6*].[3,38] The use of molecular tools, including 16S ribosomal gene (rDNA) sequencing, has led to a recategorization of rapidly growing mycobacteria and recognition of new taxa. This is particularly the case with the *M. chelonae-abscessus* group,

Table 5 Treatment Regimens for Selected Nontuberculous Mycobacterial Infections[1]

Species	*Clinical Syndrome*	*Treatment*	*Duration*
M. avium complex	Pulmonary disease (e.g., HIV seronegative patients)	Clarithromycin, 500 mg b.i.d. (preferred) *or* Azithromycin, 600 mg q.d.* *plus* Ethambutol, 15–25 mg/kg/day *plus* Rifabutin, 300 mg q.d. *or* Rifampin, 600 mg q.d. *with or without* Streptomycin, 1 g q. 3–5 days/wk for 6–12 wk Amikacin, 7.5–15 mg/kg I.V. q.d.† (may add initially for cavitary disease)	Until 12 mo after sputum cultures become negative (usually at least 18 mo of therapy)
	Disseminated disease (e.g., HIV-infected patients)	Clarithromycin, 500 mg b.i.d. (preferred) *or* Azithromycin, 600 mg q.d.* *plus* Ethambutol, 15 mg/kg/day *with or without* Rifabutin, 300 mg q.d.‡ *or* Rifampin, 600 mg q.d.§	For HIV-infected patients, duration depends on $CD4^+$ T cell count
M. kansasii	Infiltrate/invasive pulmonary disease Disseminated disease	Rifampin, 600 mg q.d. *plus* Ethambutol, 15 mg/kg/day *plus* Isoniazid, 300 mg q.d. For severe disease, consider streptomycin, 0.5–1 g I.M. three times/wk or clarithromycin, 500 mg b.i.d., p.o., for first 2–4 mo	18 mo total therapy, with 12 mo of therapy after patient becomes culture negative
	Disease in HIV-infected patients	As for pulmonary disease, but replace rifampin with rifabutin, 150 µg q.d. for patients on a protease inhibitor; clarithromycin, 500 mg b.i.d., can be substituted for rifampin/rifabutin in patients unable to take either drug	
M. abscessus	Pulmonary, disseminated, or extensive cutaneous disease	Amikacin, 15 mg/kg/day I.V. in one or two doses, with peaks at 20 µg/ml if given in two divided doses *plus* Clarithromycin, 500 mg b.i.d. *plus* Cefoxitin, 200 mg/kg, usually 3 g q. 6 hr I.V. *or* Imipenem, 500–750 mg t.i.d. I.V.	Unknown; surgical resection is the only curative therapy for pulmonary disease, but intermittent treatment with clarithromycin or azithromycin alone for weeks to months may be an alternative in selected patients
	Cutaneous localized disease	Clarithromycin, 500 mg b.i.d.	4–6 mo
M. fortuitum	Pulmonary or cutaneous disease	Clarithromycin, 500 mg b.i.d. *plus* Doxycycline, 100 mg b.i.d. *or* Trimethoprim-sulfamethoxazole, 800/160 mg b.i.d. *or* Levofloxacin, 500–750 mg q.d. *or* Gatifloxacin, 400 mg q.d.	For pulmonary disease, 6–12 mo; for cutaneous disease, 4–6 mo
M. marinum	Cutaneous disease	Ethambutol, 15 mg/kg/day *plus* Rifampin, 600 mg q.d. *or* Clarithromycin, 500 mg b.i.d. *or* Minocycline, 100 mg b.i.d. *or* Doxycycline, 100 mg b.i.d.	Minimum, 3 mo (see text)
M. ulcerans	Cutaneous disease	Rifampin, 600 mg q.d. *or* Amikacin, 15 mg/kg b.i.d. I.M. *or* Streptomycin, 15 mg/kg/day I.M. *with or without* Surgical resection, if possible	4–6 wk

*Maximum dosage used in clinical study; adjust on individual basis depending on drug toxicity; dosages of 250 mg/day, 500 mg/day, or 500 mg three times/wk have been discussed.
†A possible alternative is to give amikacin two or three times a week in doses of 15 to 20 mg/kg.
‡Rifabutin dose may need to be adjusted in HIV-infected patients on antiretroviral therapy.
§Rifampin cannot be given with certain antiretroviral agents, including protease.

Table 6 Principal Species of Rapidly Growing Mycobacteria That Are Human Pathogens

Group	*Species*
M. fortuitum	*M. fortuitum* (formerly *M. fortuitum* biovar *fortuitum*) *M. peregrinum* (formerly *M. fortuitum* biovar *peregrinum*) *M. mucogenicum* (formerly *M. chelonae*–like organism) *M. senegalense* *M. septicum* *M. magertiense* *M. porcinum* *M. houstonense* *M. bonickei* *M. neworleansense*
M. chelonae-abscessus	*M. chelonae* (formerly *M. chelonae* subsp. *chelonae*) *M. immunogenum*
M. smegmatis	*M. smegmatis* sensu stricto *M. goodie* *M. wolinskyi*

which consists of *M. chelonae* (formerly *M. chelonae chelonae*) and *M. abscessus* (formerly *M. chelonae abscessus*), along with *M. immunogenum*. Rapidly growing mycobacteria are associated with a variety of clinical syndromes, but they most commonly cause skin and soft tissue infections, both in the community and in hospitalized postoperative patients; other infections include skeletal infections (e.g., bone, joint, tendon), pulmonary disease (*M. abscessus*), and, on occasion, catheter-related infections [*see Table 3*].

Skin, Soft Tissue, and Skeletal Infections

The skin and soft tissues are the most common sites of infection from rapidly growing mycobacteria; indeed, of all NTM species, rapidly growing mycobacteria are the most common cause of skin and soft tissue infections. The *M. fortuitum* group and the *M. chelonae-abscessus* group cause localized infections, usually after local trauma or surgery.[1,38] Unlike infections with the *M. chelonae-abscessus* group, however, most *M. fortuitum* infections occur in patients who have no underlying chronic disease or immunosuppression. Furunculosis from *M. fortuitum* and *M. fortuitum*–group organisms have been reported in association with whirlpool footbaths in customers of nail salons.[39,40] Shaving the legs with a razor before a pedicure was a risk factor for infection. In these cases, molecular typing techniques were used to match rapidly growing mycobacteria recovered from the footbaths with isolates recovered from patients.

Like other NTM species, rapidly growing mycobacteria can cause infections of tendon sheaths, bursae, bones, and joints after direct inoculation through accidental trauma, surgery, puncture, or injection.[1] Surgical debridement is often necessary for the diagnosis and treatment of such infections, along with chemotherapy (see below).

Health Care–Related Infections

There have been a number of reports of nosocomial or health care–associated infections caused by rapidly growing mycobacteria.[41-43] These include infections from colonization of long-term venous access devices or peritoneal dialysis catheters, postinjection abscesses, and surgical wound infections (e.g., after cardiac bypass surgery, as well as augmentation mammoplasty, facelifts, and other plastic surgery; postoperative keratitis has been reported after ophthalmic surgery). Clusters of infections and outbreaks of true infection and pseudoinfections have occurred from contaminated fluids, irrigation with or exposure to tap water, injectable medicines, and topical skin solutions and markers. Most have involved *M. fortuitum* or *M. abscessus,* but *M. chelonae* has also been reported as a pathogen.[41]

Pulmonary Infections

M. abscessus is the third most common cause of pulmonary infection from NTM, after MAC and *M. kansasii*. *M. abscessus* causes 80% of the pulmonary disease from rapidly growing mycobacteria; *M. fortuitum* accounts for about 15%.[44] *M. chelonae* and other rapidly growing mycobacteria cause pulmonary disease less commonly. Adolescents with cystic fibrosis are at increased risk for NTM-related pulmonary disease; MAC is the most common pathogen in these cases, but other mycobacteria, especially *M. abscessus*, have been reported with increasing frequency.

Signs and symptoms of pulmonary disease caused by rapidly growing mycobacteria are variable and nonspecific. Most patients have a cough that becomes productive as the disease progresses. Fatigue and weight loss may also occur as the disease progresses. In many patients, symptoms have been present for months to years and have been attributed to chronic bronchitis or bronchiectasis.

The chest radiograph usually demonstrates patchy, reticular, nodular opacities—usually in the upper lobes, although any portion of the lung can be involved. Cavitation occurs in less than 20% of cases.[44] CT scan may show findings similar to those noted in patients with pulmonary MAC infection.

The diagnostic approach to lung disease that is suspected to be caused by rapidly growing mycobacteria is the same as that followed with infections from MAC and other NTM infections [*see Table 4*]. All patients with suspected mycobacterial infection should have three sputum specimens examined microscopically for AFB and cultured for mycobacteria.

Disseminated Cutaneous Infections

Disseminated cutaneous disease from rapidly growing mycobacteria is unusual. When it does occur, the pathogen is usually from the *M. abscessus-chelonae* group. More than 90% of patients with disseminated cutaneous disease from rapidly growing mycobacteria are immunocompromised. They generally have risk factors such as chronic renal failure, renal transplantation, or, especially, long-term use of corticosteroid therapy; few have HIV infection, however.[38]

Treatment

Selection of antimicrobial agents for infections from rapidly growing mycobacteria depends on the site of infection and the presumed pathogen. Empirical therapy is usually required initially, because final species identification and susceptibility testing are often performed at reference laboratories, and it may take weeks to obtain the results. Susceptibility testing should be performed on all clinically significant initial isolates, as well as on isolates recovered from patients who experience therapeutic failure or relapse.[21] Standardization guidelines for susceptibility testing of all *Mycobacterium* species, including rapidly growing mycobacteria and other NTM species, have been recommended by the Clinical and Laboratory Standards Institute (formerly the

National Committee for Clinical Laboratory Standards).[15] To meet these standards, rapidly growing mycobacteria should be tested against clarithromycin, amikacin, cefoxitin, imipenem, tobramycin, doxycycline, ciprofloxacin, and trimethoprim-sulfamethoxazole; other drugs that may be included are linezolid and the newer fluoroquinolones (e.g., levofloxacin, gatifloxacin, and moxifloxacin).

Treatment regimens for infections from rapidly growing mycobacteria have been developed [*see Table 5*]. Recommendations are based on in vitro and case series reports, because data from controlled trials are lacking. For pulmonary disease from *M. abscessus*, antimicrobial therapy alone is usually unsuccessful.[45] Surgical resection of the involved lung is recommended, preferably after an initial period of antimicrobial therapy.[1] Unfortunately, some patients with *M. abscessus* lung disease have bilateral disease and thus are not surgical candidates.

Treatment of *M. fortuitum* pulmonary disease with antimicrobial therapy alone has been much more successful. A 6- to 12-month regimen is recommended, starting with clarithromycin plus a second drug (e.g., doxycyline, trimethoprim-sulfamethoxazole, or a newer fluoroquinolone such as levofloxacin, gatifloxacin, or moxifloxacin) [*see Table 5*]. Therapy should be adjusted on the basis of susceptibility-testing results.

Generally, the length of treatment with any of the current antimicrobials for most skin and soft tissue infections from rapidly growing mycobacteria has been 4 months for mild disease and 6 months for serious disease.[38] For more serious disease, treatment may include the use of injectable agents; however, these are usually limited to the first 2 to 6 weeks of therapy, to minimize cost and drug toxicity. Surgical excision or debridement of the wound site combined with appropriate antimicrobial therapy is recommended because of better outcomes (e.g., healing without relapse).[38] Treatment of cutaneous infection from rapidly growing mycobacteria generally includes the use of a newer macrolide such as clarithromycin [*see Table 5*]. Treatment of skeletal infections such as osteomyelitis from rapidly growing mycobacteria has been accomplished by surgical wound debridement plus a minimum of 6 months of drug therapy with agents selected on the basis of the in vitro susceptibilities of the isolate. Treatment of disseminated cutaneous disease involves drainage of abscesses plus appropriate antimicrobial therapy (usually including clarithromycin) for at least 6 months. Because of the risk of the development of clarithromycin resistance with monotherapy for disseminated disease (estimated to be about 10% to 20% in this setting), therapy for the first 3 to 6 weeks should include other drugs, selected on the basis of in vitro susceptibilities whenever possible.[38]

MYCOBACTERIUM MARINUM

M. marinum is an NTM organism (group I of the Runyon classification) that causes skin infections in humans. *M. marinum* causes disease in many fish species from cold water, warm water, freshwater, or saltwater; and human infection follows contact with diseased fish or contaminated water.[46] *M. marinum* is distributed widely in aquatic environments, especially in relatively still or stagnant water, such as in fish tanks and in naturally occurring bodies of water; swimming pools are rarely reported as a source at present, likely because of chlorination. First described as so-called swimming-pool granulomas, *M. marinum* skin infections have also been termed fish-tank granulomas, because infection is most often acquired from aquarium maintenance.[46] Additional investigations are needed to further develop preventive strategies; some investigators have suggested that gloves be worn when cleaning fish tanks.

Infection is acquired by direct inoculation of the bacterium through broken skin in an aquatic environment; typically, this is seen after lacerations or abrasions are exposed to freshwater or saltwater or in injuries from fish spines. Human skin and soft tissue infections are manifested by cutaneous ulcers, nodules, or nodular lymphangitis; such infections can result in significant morbidity.[47] Although infection is most commonly limited to skin, it can spread to deeper structures, resulting in tenosynovitis, arthritis, and osteomyelitis. Disseminated infections are rare. Delays in diagnosis have been noted and can lead to adverse outcomes. In a number of cases, delayed or missed diagnoses led to the use of corticosteroids, which may have facilitated the spread of infection.[46] Clues in the clinical history, such as exposure to fish, natural bodies of water, or swimming pools, can expedite diagnosis and therapy in patients presenting with cutaneous infections.[47] The median incubation period after exposure to *M. marinum* is about 3 weeks, but the incubation period was longer than 30 days for more than a third of the patients in one series, and the incubation period can be up to months after exposure.[47]

A definitive diagnosis of *M. marinum* infection is made by biopsy and AFB culture results. The optimal therapy for *M. marinum* infection is unknown; there are no controlled trials on which to base treatment decisions, and data on *M. marinum* susceptibility are scarce.[46] Data from case series suggest that most skin infections can be adequately treated with antibiotics alone, with surgical intervention considered for those who do not respond to initial antimicrobial therapy. Adjunctive surgical debridement has been suggested for patients with deeper infections.[46] The length of treatment is also not standardized and has ranged from 3.5 months to 8 months in different series.[48] Treatment includes clarithromycin or minocycline (as monotherapy or in combination with other agents) or rifampin plus ethambutol [*see Table 5*]. Some authors recommend using at least two drugs.[48] A minimum of 3 months of therapy is recommended, with longer courses of therapy advocated for patients with more invasive infection (beyond skin and soft tissue) and those requiring surgical debridement. Some authors have suggested that treatment of *M. marinum* should include two drugs for 1 to 2 months after resolution of lesions, typically 3 to 4 months in total.[48] Although routine susceptibility testing has not been recommended for *M. marinum*,[1] it may be considered in special situations, such as for patients who do not respond clinically after several months of therapy and for those who continue to have positive cultures.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

I MANAGEMENT OF POISONING AND DRUG OVERDOSE

Kent R. Olson, m.d.
Manish M. Patel, m.d.

Drug overdose and poisoning are leading causes of emergency department visits and hospital admissions in the United States, accounting for more than 500,000 emergency department visits[1] and 11,000 deaths[2] each year. Exposure to poison can occur in several ways. The patient may have ingested it accidentally or for the purpose of committing suicide, may be a victim of accidental intoxication from acute or long-term exposure in the workplace, may be suffering from unexpected complications or overdose after intentional drug abuse, or may be a victim of an assault or terrorist attack. Poisons can include drugs, chemicals, biotoxins in plants or foods, and toxic gases. In all cases of poisoning, the clinician has several priorities: (1) immediately stabilize the patient and manage life-threatening complications; (2) perform a careful diagnostic evaluation, which includes obtaining a directed history, performing a physical examination, and ordering appropriate laboratory tests; (3) prevent further absorption of the drug or poison by decontaminating the skin or gastrointestinal tract; and (4) consider administering antidotes and performing other measures that enhance the elimination of the drug from the body. For expert assistance with identification of poisons, diagnosis and treatment, and referral to a medical toxicologist, the clinician should consider consulting with a regional poison-control center.

Initial Stabilization

In many cases of poisoning, the patient is awake and has stable vital signs, which allows the clinician to proceed in a stepwise fashion to obtain a history and to perform a physical examination. In other cases, however, the patient is unconscious, is experiencing convulsions, or has unstable blood pressure or cardiac rhythm, thus requiring immediate stabilization [*see Table 1*].

The first priority is airway patency. The airway's reflex protective mechanisms may be impaired because of drug-induced central nervous system depression (e.g., from opioids or sedative-hypnotic agents), excessive bronchial and oral secretions (e.g., from organophosphate insecticides), or swelling or burns (e.g., from corrosive agents or irritant gases). The airway should be cleared by the use of suction and by repositioning the patient; if the patient has an impaired gag reflex or other evidence of airway compromise, a cuffed endotracheal tube should be inserted. The adequacy of ventilation and oxygenation should be determined by clinical assessment, pulse oximetry, measurement of arterial blood gases, or a combination of these techniques. Supplemental oxygen should be administered, and if necessary, ventilation should be assisted with a bag/valve/mask device or a ventilator.[3] Even if the patient is not unconscious or hemodynamically compromised on arrival in the emergency department, continued absorption of the ingested drug or poison may lead to more serious intoxication during the next several hours. Therefore, it is prudent to keep the patient under close observation, with continuous or frequent monitoring of alertness, vital signs, the electrocardiogram, and pulse oximetry.

Management of Common Complications

COMA

Poisoning or drug overdose depresses the sensorium, the symptoms of which may range from stupor or obtundation to unresponsive coma. Deeply unconscious patients may appear to be dead because they may have nonreactive pupils, absent reflexes, and flat electroencephalographic tracings; however, such patients may have a complete recovery without neurologic sequelae as long as they receive adequate supportive care, including airway protection, oxygenation, and assisted ventilation.[4]

All patients with a depressed sensorium should be evaluated for hypoglycemia because many drugs and poisons can directly reduce or contribute to the reduction of blood glucose levels. A finger-stick blood glucose test and bedside assessment should be performed immediately; if such testing and assessment are impractical, an intravenous bolus of 25 g of 50% dextrose in water should be administered empirically before the laboratory report arrives.[5] For alcoholic or malnourished patients, who may have vitamin deficiencies, 50 to 100 mg of vitamin B_1 (thiamine) should be administered I.V. or I.M. to prevent the development of Wernicke syndrome.[5] If signs of recent opioid use (e.g., suspicious-looking pill bottles or I.V. drug paraphernalia) are in evidence or if the patient has clinical manifestations of excessive opioid effect (e.g., miosis or respiratory depression), the administration of naloxone may have both therapeutic and diagnostic value. Naloxone is a specific opioid antagonist with no intrinsic opioid-agonist effects.[6,7] Initially, a dose of 0.2 to 0.4 mg I.V. should be administered; if there is no response, repeated doses of up to 4 to 5 mg should be given. Doses as high as 15 to 20 mg may be administered if overdose with a resistant opioid (e.g., propoxyphene, codeine, or some fentanyl derivatives) is suspected.[6,7] Patients with opioid intoxication usually become fully awake within 2 to 3 minutes after administration of naloxone.

Table 1 The ABCDs of Initial Stabilization of the Poisoned Patient

Airway
Position the patient to open the airway; suction any secretions or vomitus; evaluate airway-protective reflexes; consider endotracheal intubation

Breathing
Determine adequacy of ventilation; assist ventilation, if necessary; administer supplemental oxygen

Circulation
Evaluate perfusion, blood pressure, and cardiac rhythm; determine QRS complex; attach continuous cardiac monitor

Dextrose
Quickly determine blood glucose by finger-stick test; give dextrose if patient is suspected of having hypoglycemia

Decontamination
Perform surface and gastric decontamination to limit absorption of poisons

Table 2 Mechanisms of Drug-Induced Hypotension

Mechanism	*Selected Causes*
Hypovolemia	
Vomiting and diarrhea	Iron; arsenic; food poisoning; organophosphates and carbamates; mushroom poisoning; thallium
Sweating	Organophosphates and carbamates
Venodilatations	Barbiturates; other sedative-hypnotic agents
Depressed cardiac contractility	Tricyclic antidepressants; beta blockers; calcium antagonists; class IA and class IC antiarrhythmic agents; sedative-hypnotic agents
Reduced peripheral vascular resistance	Theophylline; beta$_2$-adrenergic stimulants; phenothiazines; tricyclic antidepressants; hydralazine

Failure to respond to naloxone suggests that (1) the diagnosis is incorrect [*see* Differential Diagnosis, *below*]; (2) other, nonopioid drugs may have been ingested; (3) a hypoxic insult may have occurred before the victim was found and resuscitated; or (4) an inadequate dose of naloxone was given.

Flumazenil, a short-acting, specific benzodiazepine antagonist with no intrinsic agonist effects, can rapidly reverse coma caused by diazepam and other benzodiazepines.[5,7] However, it has not found a place in the routine management of unconscious patients with drug overdose, because it has the potential to cause seizures in patients who have been consuming large quantities of benzodiazepines on a long-term basis or who have ingested an acute overdose of benzodiazepines and a tricyclic antidepressant or other potentially convulsant drug [*see* Sedative-Hypnotic Agents, *below*].[5,7,8]

HYPOTENSION AND CARDIAC DYSRHYTHMIAS

The hypotension that commonly complicates drug intoxication has many possible causes [*see Table 2*].[9,10] Hypotension may result from volume depletion caused by severe drug-induced vomiting or diarrhea. In addition, relative hypovolemia may be caused by the venodilating effects of many drugs. Certain drugs or poisons can have direct negative inotropic or chronotropic effects on the heart, reducing cardiac output. Others can cause a severe reduction in peripheral vascular resistance. Some drugs or poisons can cause shock by a combination of these mechanisms.

Treatment of drug-induced shock includes rapid assessment of the likely cause, which is suggested by the history of exposure and the clinical findings. Hypotension with tachycardia suggests that the cause is volume depletion or reduced peripheral vascular resistance, whereas hypotension with bradycardia suggests that the cause is a disturbance of cardiac rhythm or that shock is a result of the generalized cardiodepressant effects of the drug. Regardless of the etiology, most patients benefit from an I.V. bolus of fluid (e.g., 0.5 to 1 L of normal saline) and empirical pressor therapy with dopamine or norepinephrine.[11] However, if hypoperfusion persists, it may be necessary to insert a pulmonary arterial catheter to obtain more specific information about volume and hemodynamic status.

A variety of cardiac dysrhythmias may occur as a result of drug intoxication or poisoning [*see Table 3*]. In addition to the direct pharmacologic actions of the drug or poison, impaired ventilation and oxygenation may trigger disturbances of cardiac rhythm.[11]

Treatment of a cardiac dysrhythmia depends on its etiology. Because conventional advanced cardiac life support (ACLS) protocols were not designed with poisoning in mind, use of these guidelines may have inappropriate or dangerous effects.[12] For example, a patient with tricyclic antidepressant intoxication (see below) may have wide-complex tachycardia resulting from severe depression of sodium-dependent channels in the myocardial cell membrane. However, use of the ACLS protocols for wide-complex tachycardia or possible ventricular tachycardia may lead the treating physician to administer procainamide, a class IA antiarrhythmic agent with cardiodepressant effects that are additive to those of the tricyclic antidepressants.[11] A patient with multiple premature ventricular contractions or who experiences episodes of ventricular tachycardia after intoxication with chloral hydrate or inhalation of a chlorinated solvent would respond more readily to a beta blocker than to lidocaine, the drug recommended by the ACLS protocols.[13] Finally, cardiac dysrhythmias from digitalis intoxication are most appropriately treated with digoxin-specific antibodies (see below).

HYPERTENSION

Although hypertension is not commonly recognized as a serious pharmacologic effect of drug intoxication, it may have life-threatening consequences and requires aggressive treatment. Hypertension may result from generalized CNS and sympathetic stimulation (e.g., by amphetamines or cocaine) or from the peripheral actions of drugs such as phenylpropanolamine, a potent alpha-adrenergic agonist.[14] (Although the Food and Drug Administration removed phenylpropanolamine from the market in the United States in November 2000, phenylpropanolamine is still available in other countries.) In addition, hypertension may result from the pharmacologic interaction of two agents, such as in the use of a stimulant or the ingestion of an inappropriate food by a person taking monoamine oxidase (MAO) inhibitors.[15] Severe hypertension can lead to intracranial hemorrhage, aortic dissection, or other catastrophic complications.[16,17]

Hypertension may be accompanied by tachycardia, as commonly occurs in cases of intoxication with generalized stimu-

Table 3 Causes of Cardiac Disturbances

Type of Disturbance	*Selected Causes*
Sinus tachycardia	Anticholinergic agents (e.g., diphenhydramine, atropine, tricyclic antidepressants); theophylline and caffeine; cocaine and amphetamines; volume depletion
Bradycardia or atrioventricular block	Beta blockers; calcium antagonists; tricyclic antidepressants; class IA and class IC antiarrhythmic agents; organophosphate and carbamate insecticides; digitalis glycosides; phenylpropanolamine (hypertension with reflex bradycardia)
Widening of the QRS complex	Tricyclic antidepressants; class IA and class IC antiarrhythmic agents; diphenhydramine; thioridazine; propoxyphene; hyperkalemia; hypothermia
Ventricular tachycardia or ventricular fibrillation	Tricyclic antidepressants; cocaine and amphetamines; theophylline; digitalis glycosides; fluoride or hydrofluoric acid burns (hypocalcemia); trichloroethane and numerous other chlorinated, fluorinated, and aromatic solvents; chloral hydrate; agents that cause prolongation of the QT interval (e.g., quinidine, sotalol)

lants such as cocaine and amphetamine derivatives. Hypertension may also be accompanied by bradycardia or even atrioventricular (AV) block, which may occur after phenylpropanolamine overdose because of the reflex baroreceptor response.

Treatment is directed at the cause of the hypertension. In patients who have taken cocaine, amphetamines, or other generalized stimulants, mild or moderate increases in blood pressure may be reduced simply by providing a quiet environment and administering a sedative agent such as diazepam. In persons who have taken an overdose of phenylpropanolamine or other alpha-adrenergic stimulant, administration of a specific alpha-adrenergic antagonist, such as phentolamine (2 to 5 mg I.V.), is extremely effective and usually leads to normalization of the slow heart rate or reversal of the AV block.[14] In general, beta blockers should not be used as single agents in the treatment of drug-induced hypertension, because their use may lead to unopposed alpha-adrenergic activity with paradoxically worsened hypertension.[18]

SEIZURES

Seizures may result from a number of factors, including a variety of drugs and poisons. The drugs that most commonly induce seizures are tricyclic antidepressants, bupropion, cocaine and related stimulants, antihistamines, and isoniazid [*see Table 4*].[19,20] Prolonged or repeated convulsions can lead to serious complications, including hyperthermia, rhabdomyolysis, brain damage, and death. In addition, seizure activity causes metabolic acidosis, which may worsen cardiotoxicity in patients who have taken an overdose of a tricyclic antidepressant.[11,19] Seizures can also result from hypoxia, hypoglycemia, head trauma, stroke, or serious CNS infections [*see* Differential Diagnosis, *below*].

Treatment of seizures includes taking immediate steps to protect the airway and provide oxygen while administering anticonvulsant drugs. The blood glucose level should be determined and dextrose administered if needed [*see* Coma, *above*]. Initial anticonvulsant therapy consists of diazepam (5 to 10 mg I.V.), lorazepam (1 to 2 mg I.V.), or midazolam (3 to 5 mg I.V. or, if I.V. access is not immediately available, 5 to 10 mg I.M.). Repeated doses are given if the initial therapy is ineffective. Because it is often ineffective, phenytoin is not a first-line anticonvulsant agent for drug- or toxin-induced seizures.[19] If convulsions persist, phenobarbital should be administered at a dosage of 15 to 20 mg/kg (1 to 1.5 g) I.V. over 20 to 30 minutes.[21] If seizure activity continues, the physician should consult with a neurologist and consider administering pentobarbital, another short-acting barbiturate, or propofol.[21] In addition, inducing neuromuscular paralysis (e.g., with pancuronium) should be considered to control the muscle hyperactivity, which may be necessary for controlling hyperthermia, rhabdomyolysis, or metabolic acidosis. If neuromuscular paralysis is induced, however, the physician should be aware that seizure activity in the brain may persist but may not be apparent.[21] If isoniazid poisoning is suspected, 5 g of pyridoxine (vitamin B_6) should be administered intravenously; or if more than 5 g of isoniazid was ingested, pyridoxine should be administered in an amount (in grams) equal to that of the isoniazid overdose.

HYPERTHERMIA

Hyperthermia is an underrecognized complication of poisoning and drug overdose that is associated with high morbidity and mortality.[22] It may result from the pharmacologic effects of the agent or as a consequence of prolonged muscle hyperactivity or seizures [*see Table 5*]. Severe hyperthermia (rectal temperature > 104° F [40° C]) that goes untreated may lead to brain damage, coagulopathy, rhabdomyolysis, hypotension, and, ultimately, death.[22]

Because it is immediately life threatening, hyperthermia warrants immediate and aggressive treatment.[22] Therapy is directed at the underlying cause, which is usually excessive muscle activity or rigidity. For mild or moderate cases, the physician should use appropriate pharmacologic agents (e.g., sedatives for cases of stimulant-induced psychosis and hyperactivity and anticonvulsants for cases of seizure), remove the patient's clothing, and maximize evaporative cooling by spraying the exposed skin with tepid water and fanning the patient. For severe cases, the most rapidly effective treatment is neuromuscular paralysis accompanied by maximal evaporative cooling.[22] In some cases, a specific antidote or therapeutic agent may be available [*see Table 5*].

Table 4 Drug-Induced Seizures

Common Causes	*Comments*
Tricyclic antidepressants	Seizure activity and resulting metabolic acidosis often aggravate cardiotoxicity; protracted seizures with absent sweating may lead to hyperthermia; phenytoin worsens cardiotoxicity in animal models; treat with benzodiazepines or phenobarbital
Cocaine and amphetamines	Seizures are usually brief and self-limited and are often preceded by tremors, agitation, hallucinations, or tachycardia; bupropion most commonly implicated in seizures, sometimes even with therapeutic use
Theophylline	Seizures are often prolonged, recurrent, and refractory to anticonvulsant therapy; phenytoin is ineffective in animal models; administer high-dose phenobarbital (at least 15–20 mg/kg I.V.); for patients with serum theophylline levels > 100 mg/L or status epilepticus, consider hemoperfusion or hemodialysis
Diphenhydramine	Seizures are usually brief and self-limited; in patients with massive intoxication (e.g., > 4–5 g), tricyclic-like cardiotoxicity may also occur
Isoniazid	Seizures are often accompanied by severe lactic acidosis; the specific antidote for seizures and coma is vitamin B_6 (pyridoxine), 5–10 g I.V., or, if the amount of ingested isoniazid is known, the equivalent gram-for-gram amount of vitamin B_6

HYPOTHERMIA

Hypothermia may accompany drug overdose and is usually caused by environmental exposure combined with inadequacy of the patient's response mechanisms. These inadequate mechanisms may include impaired judgment (in patients who have taken opioids, sedative-hypnotic agents, or phenothiazines or who have underlying mental disorders), a reduced shivering response (in those who have taken phenothiazines or sedative-hypnotic agents), and peripheral vasodilatation (in those who have taken phenothiazines or vasodilators).[23] Severe hypothermia (core temperature < 82° F [28° C]) may cause the patient to appear to be dead and may be associated with barely perceptible blood pressure, heart rate, or neurologic reflexes. Hypotension, bradycardia, and ventricular arrhythmias may fail to respond to pharmacologic treatment until the patient is warmed.[23,24] Because no controlled trials comparing rewarming methods exist, man-

Table 5 Drug-Induced Hyperthermia

Mechanisms	*Selected Causes and Comments*
Increased metabolic activity	Causes include salicylates, dinitrophenol, and cocaine and amphetamines
Reduced sweating	Causes include anticholinergic agents (e.g., tricyclic antidepressants, antihistamines, many plants, and some mushrooms)
Increased muscle activity or exertion	Causes include cocaine and amphetamines, phencyclidine, and exertional heatstroke
Neuroleptic malignant syndrome	Causes include haloperidol, related antipsychotic agents, and lithium; patients have lead-pipe rigidity, acidosis, and an elevated creatine kinase level that are caused by CNS dopamine blockade; specific treatment is bromocriptine (2.5–10.0 mg by nasogastric tube two to six times daily)[157]; treat severe hyperthermia with neuromuscular paralysis
Malignant hyperthermia	An inherited disorder of muscle cell function, commonly triggered by certain anesthetic agents (e.g., succinylcholine or halothane); causes severe muscle rigidity and acidosis not responsive to neuromuscular paralysis; treatment is dantrolene (2–5 mg/kg I.V.)[158]
Serotonin syndrome	Associated with the use of serotonin-enhancing agents (e.g., meperidine, dextromethorphan, fluoxetine, paroxetine, sertraline, L-tryptophan, or trazodone), especially in patients taking monoamine oxidase inhibitors; causes muscle rigidity, acidosis, and hyperthermia; treatment is neuromuscular paralysis; for mild cases, consider cyproheptadine (4 mg p.o. every hour for three or four doses)[159] or methysergide (2 mg p.o. every 6 hr for three or four doses)[160]

agement protocols vary institutionally and are often controversial.[23] Treatment of hypothermia is generally administered gradually because more aggressive management may precipitate cardiac dysrhythmias. Passive external rewarming is an acceptable treatment if the patient's condition is stable. Administration of a warmed mist inhalation or warmed I.V. fluids may be helpful, as may gastric or peritoneal lavage with warmed fluids, although the heat transfer involved in these measures is variable. For profound hypothermia accompanied by evidence of severe hypoperfusion (e.g., cardiac arrest or ventricular fibrillation), more aggressive measures, such as partial cardiopulmonary or femorofemoral bypass, may be required.[23,24] Of note is that patients with severe hypothermia can withstand cardiorespiratory arrest longer than normothermic patients—hence the old adage, "No one is dead until warm and dead."

RHABDOMYOLYSIS

Rhabdomyolysis, a common complication of severe poisoning or drug overdose, may result from direct myotoxic effects of the agent, from prolonged or recurrent muscle hyperactivity or rigidity, or from prolonged immobility with mechanical compression of muscle groups.[25] Severe rhabdomyolysis (usually associated with markedly elevated serum creatine kinase levels) may cause massive myoglobinuria that results in acute tubular necrosis and renal failure. Myoglobinuria is usually recognized by the pink or reddish hue of spun serum or by a positive dipstick test for hemoglobin in the urine, with few or no red blood cells seen on microscopic examination. Severe rhabdomyolysis may also cause hyperkalemia, which results from loss of potassium from dead or injured cells.

Treatment of rhabdomyolysis includes measures to prevent further muscle breakdown (e.g., control of muscle hyperactivity and treatment of hyperthermia) and to prevent deposition of toxic myoglobin in the renal tubules. Unequivocally, the mainstay of treatment in rhabdomyolysis is aggressive volume expansion with normal saline early in the disease to maintain urine output of 200 ml/hr in those who can tolerate the fluid load.[25] Nonrandomized trials have also shown alkalinization of urine to be beneficial, but the role of mannitol and furosemide in rhabdomyolysis is less clear.[25]

Clinical Evaluation

Although the history recounted by patients who have intentionally taken a drug overdose may be unreliable, it should not be overlooked as a valuable source of information. If the patient is unwilling or unable to specify which drugs were taken and when they were ingested or to provide a pertinent medical history, family and friends may be able to do so. Family members should be asked about other medications available in the household and about exposure in the workplace and through hobbies. In addition, paramedics should be asked for any pill bottles or drug paraphernalia that they may have obtained at the scene.

A directed toxicologic physical examination may yield important clues about the drugs or poisons that have been taken. Pertinent variables include the patient's vital signs, pupil size, lung sounds, peristaltic activity, skin moisture and color, and muscle activity; the presence or absence of unusual odors; and the presence or absence of track marks associated with I.V. drug

Table 6 Autonomic Syndromes Induced by Drugs or Poisons

Autonomic Syndrome	*Selected Causes*	*Empirical Interventions*
Sympathomimetic (agitation; dilated pupils; elevated BP and HR; sweaty skin; hyperthermia)	Cocaine; amphetamines; pseudoephedrine	Induce sedation; initiate aggressive cooling; treat hypertension with phentolamine; treat tachycardia with beta blockers
Sympatholytic (lethargy or coma; small pupils; normal or low BP and HR; low temperature)	Barbiturates; opioids; clonidine; benzodiazepines	Give naloxone for suspected opioid overdose; consider flumazenil for benzodiazepine overdose
Cholinergic (pinpoint pupils; variable HR; sweaty skin; abdominal cramps and diarrhea)	Organophosphate and carbamate insecticides; chemical warfare nerve agents	Give atropine and pralidoxime; obtain measurements of serum and RBC cholinesterase activity
Anticholinergic (agitation; delirium; dilated pupils; tachycardia; decreased peristalsis; dry, flushed skin)	Atropine and related drugs; antihistamines; phenothiazines; tricyclic antidepressants	Obtain immediate ECG tracing to evaluate for poisoning with tricyclic antidepressants; consider physostigmine only if tricyclics are not involved

Table 7 Use of the Clinical Laboratory in the Initial Diagnosis of Poisoning

Test	*Finding*	*Selected Causes*
Arterial blood gases	Hypoventilation (elevated Pco_2)	CNS depressants (e.g., opioids, sedative-hypnotic agents, phenothiazines, and ethanol)
	Hyperventilation	Salicylates; carbon monoxide; other asphyxiants
Electrolytes	Anion-gap metabolic acidosis	Salicylates; methanol; ethylene glycol; carbon monoxide; cyanide; iron; isoniazid; theophylline
	Hyperkalemia	Digitalis glycosides; fluoride; potassium
	Hypokalemia	Theophylline; caffeine; beta-adrenergic agents (e.g., albuterol); soluble barium salts
Glucose	Hypoglycemia	Oral hypoglycemic agents; insulin; ethanol
Osmolality and osmolar gap	Elevated osmolar gap*	Ethanol; methanol; ethylene glycol; isopropyl alcohol; acetone
ECG	Wide QRS complex	Tricyclic antidepressants; quinidine and other class IA and class IC antiarrhythmic agents
	Prolongation of the QT interval	Quinidine and related antiarrhythmic agents
	Atrioventricular block	Calcium antagonists; digitalis glycosides
Plain abdominal x-ray	Radiopaque pills or objects	Iron; lead; potassium; calcium; chloral hydrate; some foreign bodies
Serum acetaminophen	Elevated level (> 140 mg/L 4 hr after ingestion)	Acetaminophen (may be the only clue to a recent ingestion)

*Osmolar gap = measured osmolality – calculated osmolality. Measured osmolality is performed in the laboratory using a freezing-point-depression device (do not use the vaporization method). Calculated osmolality = 2(Na) + [BUN/2.8] + [glucose/18]. The normal osmolar gap is 0 ± 5 mOsm/L.
BUN—blood urea nitrogen Pco_2—carbon dioxide tension

abuse. Signs of one of the so-called autonomic syndromes [*see Table 6*] may suggest diagnostic possibilities and potential empirical interventions.[10]

The clinical laboratory may provide useful information that obviates an expensive and time-consuming toxicology screen. Recommended laboratory tests in the patient with an overdose of unknown cause include a complete blood count; measurements of glucose, electrolytes, blood urea nitrogen, creatinine, aspartate aminotransferase (AST), and serum osmolality (both measured and calculated); ECG; and plain abdominal x-ray (KUB [kidneys, ureters, and bladder] view) [*see Table 7*]. A quantitative serum acetaminophen level should be obtained immediately because acetaminophen overdose may be difficult to diagnose in the absence of a complete and reliable history, does not produce suggestive clinical or laboratory findings, and requires prompt administration of an antidote in patients with a serious acute ingestion if hepatic injury is to be prevented.[10,26,27]

Obtaining a thorough history, performing a careful physical examination, and using the clinical laboratory in a logical manner can often enable the physician to make a tentative diagnosis and to order specific quantitative measurements of certain drugs (e.g., salicylates, valproic acid, or digoxin) when the results of such tests may alter therapy. It is rarely useful, especially in the emergency management of a poisoning victim, to order a comprehensive toxicology screen. Generally, this test is performed at an outside reference laboratory at considerable expense, and patients often awaken and confirm the tentative diagnosis before results are available (usually 1 to 2 days after testing). In addition, many common dangerous drugs and poisons (e.g., isoniazid, digitalis glycosides, calcium antagonists, beta blockers, metals, and pesticides) are not included in the screening procedure; thus, a negative toxicology screen does not rule out the possibility of poisoning.[28] So-called drugs-of-abuse screens for opioids, amphetamines, and cocaine are commonly performed by hospital laboratories and are useful in identifying intoxication by these substances, but they should not be mistaken for a comprehensive toxicologic screening test.

Differential Diagnosis

Whenever a patient with suspected poisoning or drug overdose is evaluated, the possibility that other illnesses are mimicking or complicating the presentation should always be considered. These illnesses include head trauma (e.g., in the ethanol-intoxicated patient, who often falls); cerebrovascular accident; meningitis; metabolic abnormalities, such as hypoglycemia, hyponatremia, and hypoxemia; underlying liver disease; and the postictal state. In any patient with altered mental status, computed tomography of the head and lumbar puncture should be considered.

Management Issues

DECONTAMINATION AFTER ACUTE INGESTION

Nowhere in the field of toxicology is there more controversy than in the debate about gastrointestinal decontamination.[29-31] Techniques for gut decontamination include emesis, gastric lavage, administration of activated charcoal, and whole bowel irrigation [*see Table 8*].

Ipecac-induced emesis has been almost completely abandoned in the clinical setting.[32] In 2003, the American Academy of Pediatrics advised against routine home use of ipecac and recommended disposing of all ipecac found in the home.[33] One reason it has fallen out of favor is that treated patients run the risks of sudden, unexpected deterioration from the effects of the overdose and subsequent pulmonary aspiration; more important, however, is the lack of evidence of the efficacy of ipecac-induced emesis, especially when emesis is induced more than 1 hour after the ingestion.[29,30]

Gastric lavage is still an accepted method for gut decontamination in hospitalized patients who are obtunded or comatose, but several prospective, randomized, controlled trials failed to show that lavage in conjunction with the administration of activated charcoal provides better clinical results than administration of activated charcoal alone. In one study, patients given a

Table 8 Methods of Gastrointestinal Decontamination

Method and Technique	*Useful Situations*	*Comments*
Emesis: give syrup of ipecac, 30 ml p.o. in adults (15 ml in children), along with one to two glasses of water; may repeat after 30 min if no emesis occurs; alternatively, give 1–2 tbsp of liquid handwashing or dishwashing soap	Possible benefit in rare circumstances after a potentially lethal ingestion when medical care is more than 60 min away, but only under the guidance of a poison control center	No longer used in emergency departments; American Academy of Pediatrics recommends against routine home use of ipecac[32]; contraindicated in ingestions of corrosive agents and most hydrocarbons, when the patient is lethargic, or when the ingested substance is likely to cause abrupt onset of coma or seizures
Gastric lavage: insert large-bore nasogastric or orogastric tube, empty stomach contents, and lavage with 100–200 ml aliquots of water or saline until clear	Useful in obtunded or comatose patients, in recent ingestions (< 1 hr), or in ingestion of anticholinergic agents or salicylates (delayed gut emptying)	Obtunded patient should have prior endotracheal intubation to protect airway; best position is left lateral decubitus to reduce movement of poison into small intestine
Activated charcoal: give 50–60 g of charcoal slurry p.o. or by gastric tube; goal is approximately 10:1 ratio of charcoal to ingested poison; usually given with one dose of a cathartic agent	Often useful because it adsorbs most drugs and poisons; may be equally effective when given alone as when given after emesis or lavage	Not effective for ingestions of iron, lithium, potassium, sodium, or alcohols; may need to repeat two or three times or more for large ingestions; repeated dosing may also enhance elimination of some drugs
Whole bowel irrigation: give Colyte or GoLYTELY, 1–2 L/hr p.o. or by gastric tube, until rectal effluent is clear or x-ray is negative for radiopaque materials	Useful in ingestions of iron, lithium, sustained-release or enteric-coated pills, and drug packets or other foreign bodies	Generally well tolerated; no significant fluid or electrolyte gain or loss occurs; most useful in awake, ambulatory patients; may reduce effectiveness of activated charcoal

regimen of activated charcoal and patients given a combination regimen of gastric lavage and charcoal showed no significant differences in all outcome parameters, including clinical deterioration, length of hospital stay, complications, and mortality.[34] Studies of volunteers have shown that only about 30% of ingested material is returned with gastric lavage.[29,31] However, many authors agree that it may still be useful if the ingested material has caused slowing of peristalsis (e.g., in the case of anticholinergic agents or opioids) or pyloric spasm (e.g., in the case of salicylates) or if a potentially life-threatening amount of poison (e.g., 5 g of a tricyclic antidepressant) was ingested.[29] Some investigators have suggested that gastric lavage is associated with an increased rate of complications, although adverse events are rare in clinical practice.[31,35]

Activated charcoal—a fine powder produced from the distillation of various organic materials—has a large surface area that is capable of adsorbing many drugs and poisons.[31] Studies of volunteers and clinical trials have suggested that administration of activated charcoal without gastric lavage may be as effective as, or superior to, its administration after gut emptying.[29,31,34] Although it seems logical that gastric lavage in combination with the use of activated charcoal would be more effective than the use of activated charcoal alone, this hypothesis has not been proved. Most clinicians now employ oral activated charcoal without prior gut emptying in the awake patient who has taken a moderate overdose of a drug or poison; some clinicians still recommend lavage after a massive ingestion of a highly toxic drug.

There is no consensus about the use of cathartic agents with activated charcoal, although it seems logical to hasten passage of the charcoal-drug material from the intestinal tract. If a cathartic agent is used, it should be limited to a single dose, and the potential adverse effects should be taken into account.[36] Adverse effects may more likely occur in the very young or old (who may not be able to tolerate fluid shifts associated with osmotic cathartics such as sorbitol) or in patients with renal insufficiency (who may not be able to tolerate large doses of magnesium or sodium).

Whole bowel irrigation is a technique that was introduced for gut cleansing before surgical or endoscopic procedures and that has recently been adopted for gut decontamination after certain ingestions.[31,37] It involves the use of a large volume of an osmotically balanced electrolyte solution, such as Colyte or GoLYTELY, that contains nonabsorbable polyethylene glycol and that cleans the gut by mechanical action without net gain or loss of fluids or electrolytes. Whole bowel irrigation is well tolerated by most awake patients. Although no controlled clinical trials to date have demonstrated improved outcome, it is recommended for those who have ingested large doses of poisons that are not well adsorbed to charcoal (e.g., iron or lithium), for those who have ingested sustained-release or enteric-coated products, and for those who have ingested drug packets or other potentially toxic foreign bodies.[31,38]

ENHANCED ELIMINATION

Measures to enhance the elimination of drugs and poisons are less popular than they were 20 years ago, primarily because it has since been recognized that the available techniques do not have a significant effect on total drug elimination of many of the most commonly ingested products and that they have little effect on the clinical course of intoxication.[9] In addition, hemodialysis is an invasive procedure that requires systemic anticoagulation and that is associated with potential morbidity. For a drug or poison to be considered for removal by hemodialysis, it should have a relatively small volume of distribution, have a slow intrinsic rate of removal (clearance), and cause life-threatening intoxication that is poorly responsive to supportive measures.[9] Only a few drugs and poisons meet these criteria [*see Table 9*]. Continuous renal replacement therapy has been utilized for enhanced removal of a few poisons (e.g., lithium), but data on its efficacy are limited.[39]

Repeated oral doses of activated charcoal can reduce the elimination half-life of some drugs and poisons by interrupting enterohepatic or enteroenteric recirculation.[29,40] This technique was introduced in the late 1970s, after studies reported its efficacy in volunteers, and it was considered a benign, noninvasive treatment. However, reports of fluid depletion and shock caused by

excessive coadministration of sorbitol, as well as the paucity of evidence of clinical benefit, have reduced the initial optimism about this treatment.[29,40]

Specific Drugs and Poisons

ACETAMINOPHEN

Acetaminophen is a widely used analgesic and antipyretic drug that is found in a number of over-the-counter and prescription products. When it is taken in combination with another drug that has acute toxic effects (e.g., an opioid), the more obvious and more rapidly apparent manifestations of the second drug may cause the clinician to overlook the subtle and nonspecific symptoms of acetaminophen poisoning. As a result, the opportunity to administer the highly effective prophylactic antidote acetylcysteine may be missed.

Acetaminophen is metabolized by various processes in the liver and, to a lesser extent, in the kidneys. One of the minor pathways of acetaminophen metabolism in the liver involves the cytochrome P-450 system (CYP 2E1), which generates a highly reactive intermediate metabolite. Normally, this toxic intermediate metabolite is readily scavenged by the intracellular antioxidant glutathione. In overdose, however, exhaustion of glutathione stores by production of the toxic intermediate metabolite allows the metabolite to react with cellular macromolecules, leading to cell injury and death. A similar process occurs in kidney cells.

The minimum acutely toxic single dose of acetaminophen is approximately 150 to 200 mg/kg, or about 7 to 10 g in adults.[41] Alcoholics are at risk for toxicity at lower doses, particularly when the drug is taken for several days, presumably because they have increased cytochrome P-450 metabolic activity and reduced glutathione stores.[42] Enhanced susceptibility to toxic effects has also been reported in persons who are fasting and in patients receiving long-term anticonvulsant therapy[43] or taking isoniazid.[42] Severe toxicity may result in fulminant hepatic and renal failure.[41]

Table 9 Methods of and Indications for Enhanced Drug Removal

Drug or Poison	*Preferred Elimination Method and Indications*
Carbamazepine	Hemoperfusion is indicated for severe poisoning with status epilepticus or cardiotoxicity; repeated doses of charcoal are of possible benefit for mild to moderate poisoning and for gut decontamination
Ethanol, isopropyl alcohol	Hemodialysis is rarely indicated because supportive care is generally successful; consider hemodialysis for deep coma with refractory hypotension
Lithium	Hemodialysis is indicated for severe neurologic manifestations (deep coma or seizures); I.V. saline is fairly effective for mild to moderate intoxication
Methanol, ethylene glycol	Hemodialysis is indicated for severe acidosis or for estimated or measured drug levels > 20–50 mg/dl
Phenobarbital	Hemoperfusion is indicated for refractory shock and drug levels > 200 mg/L; repeated doses of charcoal are of questionable clinical benefit
Salicylates	Hemodialysis is indicated for severe acidosis and drug levels > 100 mg/dl; consider hemodialysis at lower salicylate levels (> 60 mg/dl) in elderly patients with chronic, accidental intoxication
Theophylline	Hemoperfusion or hemodialysis is indicated for drug levels > 100 mg/L or status epilepticus; repeated doses of charcoal are indicated for less severe cases
Valproic acid	Hemodialysis or hemoperfusion is indicated for severe cases (coma, acidosis, and drug levels > 1,000 mg/L); repeated doses of charcoal are of theoretical benefit

Diagnosis

Early after acute ingestion of acetaminophen, the patient may have few or no symptoms.[44] Vomiting is not uncommon in those who have taken large doses. Other than what can be found in the patient's history, the only reliable early diagnostic clue is provided by a quantitative measurement of the serum acetaminophen level, which can be provided immediately by most hospital laboratories. Clinical evidence of liver and kidney damage is usually delayed for 24 hours or more after ingestion. An acute massive overdose of acetaminophen (i.e., levels greater than 500 to 600 mg/L) can cause transient metabolic acidosis.[45]

The earliest evidence of toxicity in most patients is elevated levels of hepatic aminotransferases (i.e., AST and alanine aminotransferase [ALT]), followed by a rising prothrombin time (PT) and bilirubin levels. Hypoglycemia, metabolic acidosis, and encephalopathy are signs of a poor prognosis.[41]

Treatment

Oral activated charcoal should be administered. Ipecac-induced emesis is not recommended, because it often leads to protracted vomiting, which makes administration of the oral antidote difficult. A serum acetaminophen level should be obtained approximately 4 hours after ingestion, and the result should be plotted on the Rumack-Matthew nomogram [*see Figure 1*]. Ingestion of massive quantities of acetaminophen or a modified-release preparation or the coingestion of a drug that slows gastric emptying may result in delayed peak serum acetaminophen levels; in such cases, repeated measurements of serum concentrations should be obtained. If the acetaminophen level is above the "probable toxicity" line (many clinicians use the "possible toxicity" line instead), treatment should be initiated with acetylcysteine. If the patient has additional risk factors for hepatotoxicity (e.g., long-term alcohol abuse, long-term use of anticonvulsants or isoniazid, or an unreliable history of time of ingestion), it is prudent to treat for toxicity even with levels below the lower possible toxicity line. Acetylcysteine, an antioxidant that substitutes for glutathione as a scavenger, is highly effective in preventing liver damage from acetaminophen toxicity, especially if therapy is initiated within 8 to 10 hours after the ingestion of acetaminophen.[44] It is less effective when initiated 12 to 16 hours after acetaminophen ingestion; but it should be given in such cases anyway because it still has beneficial effects, presumably owing to its antioxidant and anti-inflammatory properties and because it increases survival in patients with hepatic failure.[44] The dose of oral acetylcysteine is 140 mg/kg initially (diluted in soda or juice) followed by 70 mg/kg every 4 hours. The treatment protocol approved by the FDA for the oral administration of acetylcysteine stipulates that 17 doses (approximately 3 days of therapy) be administered; however, shorter courses have been shown to be equally effective in patients who were treated within 8 to 10 hours after ingestion of acetaminophen.[44,46] At our institution, we usually administer oral acetylcysteine until 36 hours after the in-

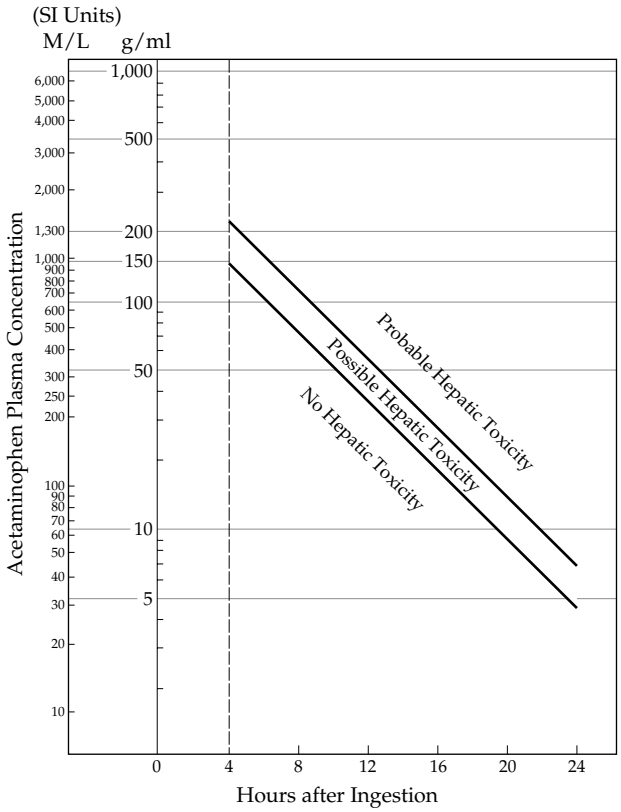

Figure 1 **The Rumack-Matthew nomogram for acetaminophen poisoning.**

gestion and then stop its administration if the liver enzymes (e.g., AST and ALT) reach normal levels. A retrospective study showed that the 36-hour regimen has a safety and efficacy profile similar to that of the traditional 72-hour protocol.[47] A longer course may be given to high-risk patients (e.g., patients who arrive in the emergency department late in the course of overdose or who have evidence of liver injury).[44]

Aggressive intervention is recommended to ensure that the loading dose is given within the first 8 hours of overdose. Occasionally, however, patients cannot tolerate oral acetylcysteine because the drug has a disagreeable odor and they are already vomiting. In such cases, it is advisable to administer the drug by the I.V. route. In 2004, the FDA approved a 20-hour acetylcysteine protocol for the treatment of acetaminophen overdose.[48] The initial loading dose is 150 mg/kg in 200 ml of 5% dextrose in water (D5W) over 15 minutes. This is followed by 50 mg/kg in 500 ml D5W over 4 hours, then 100 mg/kg in 1 L D5W over the next 16 hours. Intravenous administration can cause an anaphylactoid reaction (i.e., skin flushing and hypotension), and we usually slow the rate of the initial loading dose, administering it over 45 to 60 minutes.[49]

ANTICHOLINERGIC AGENTS AND ANTIHISTAMINES

Intoxication with anticholinergic agents can involve a variety of over-the-counter and prescription products, including antihistamines, antispasmodic agents, antipsychotic drugs, and antidepressants. In addition, several plants and mushrooms (e.g., *Datura stramonium* [angel's trumpet],[50] *Atropa belladonna,* and *Amanita phalloides*) contain potent anticholinergic alkaloids [*see Amanita phalloides* Mushrooms, *below*]. Anticholinergic agents competitively inhibit the action of acetylcholine at muscarinic receptors. Antihistamines are commonly found in a variety of over-the-counter and prescription medications for the treatment of cough and cold symptoms, itching, dizziness, nausea, and insomnia. The most commonly used nonprescription antihistamine is diphenhydramine.

Diagnosis

Clinical manifestations of intoxication with anticholinergic agents include delirium, flushed skin, dilated pupils, tachycardia, ileus, urinary retention, jerky muscle movements, and, occasionally, hyperthermia. Coma and respiratory arrest may occur. Tricyclic antidepressants (see below) and phenothiazines may also cause seizures and quinidinelike cardiac conduction abnormalities. Therefore, an ECG should be obtained and the QRS complex and cardiac rhythm monitored in any patient who displays anticholinergic manifestations of intoxication.

Antihistamine intoxication is similar to anticholinergic poisoning and may also be associated with seizures[19] and tricyclic-like cardiac conduction abnormalities.[51] The older nonsedating antihistamines terfenadine and astemizole were associated with prolongation of the QT interval and the occurrence of atypical (torsade de pointes) ventricular tachycardia both after overdose and after coadministration of macrolide antibiotics or other drugs that interfere with their elimination.[52] Because safer agents are available, both of these drugs were removed from the United States market by the manufacturers in 1999.[53]

Treatment

Activated charcoal and a cathartic agent should be administered to patients with anticholinergic or antihistamine intoxication. Gastric lavage should be considered in cases of a large ingestion; this measure may be appropriate even if some time has passed since ingestion, because ileus may delay gastric emptying. Coma and respiratory depression should be treated with the usual supportive measures. The physician should consider administering physostigmine, 0.5 to 2.0 mg in a slow I.V. infusion, in patients with pure anticholinergic intoxication (i.e., intoxication with agents other than tricyclic antidepressants or antihistamines) and severe delirium.[54] Drowsiness, confusion, and sinus tachycardia usually resolve without aggressive intervention. Prolongation of the QT interval and atypical ventricular tachycardia can be treated with magnesium, 1 to 2 g I.V., or overdrive pacing.

ANTICOAGULANTS

The anticoagulants include warfarin and the so-called superwarfarin rodenticides. Accidental intoxication with warfarin may result from long-term therapeutic overmedication or from the addition of a drug that interacts with it (e.g., allopurinol, cimetidine, nonsteroidal anti-inflammatory drugs, quinidine, salicylates, or sulfonamides). Acute ingestion of a single dose of warfarin rarely causes significant anticoagulation. However, a single dose of brodifacoum or one of the other superwarfarins can cause severe and prolonged anticoagulation that lasts for weeks to months.[55]

Diagnosis

All anticoagulants inhibit the hepatic production of clotting factors II, VII, IX, and X and prolong the PT. Circulating factors are not affected; the peak effect of anticoagulants on the PT is not seen until 36 to 48 hours after administration, when circulating

factors are degraded. Severe anticoagulation can result in hemorrhage, which may be fatal.[55]

Treatment

Acute superwarfarin overdose should be treated with oral activated charcoal and a cathartic agent. A baseline PT should be obtained on presentation and 24 and 48 hours later. If prolongation of the PT occurs, the physician should administer oral vitamin K_1 (phytonadione), 25 to 50 mg/day, and monitor the PT; in rare instances, as much as 150 to 200 mg/day may be necessary to correct the PT. It may also be necessary to continue treatment for several weeks or even months.[56] Patients should not be treated prophylactically with vitamin K_1 after an acute ingestion, because such treatment would mask the rise in PT for about 3 to 5 days or more, preventing early diagnosis. As a result, the patient would require prolonged follow-up even in the case of a subtoxic ingestion.

Vitamin K_1 may be given subcutaneously or, cautiously, by the I.V. route to patients with severe prolongation of the PT. However, because vitamin K_1 does not restore clotting factors immediately, patients who have active bleeding may require fresh frozen plasma or whole blood. Because coagulopathy after a superwarfarin overdose may last for weeks to months, high-dose oral vitamin K_1 therapy (5 mg/kg over 24 hours) may be necessary for outpatient therapy.[57]

Beta Blockers

Beta blockers are used for the treatment of hypertension, angina pectoris, migraine, and cardiac arrhythmias. Propranolol is the prototypical beta blocker but is also the most toxic [*see Table 10*].[58] All of these agents act competitively at beta-adrenergic receptors; at therapeutic doses, some have a degree of selectivity for $beta_1$- or $beta_2$-adrenergic receptors that is not apparent at high doses. Propranolol and a few of the other agents also have depressant effects on the myocardial cell membrane that are similar to those of quinidine and the tricyclic antidepressants.[59]

Beta blockade typically causes hypotension and bradycardia. Severe overdose may cause cardiogenic shock and asystole. Bronchospasm and hypoglycemia may also occur. In addition, propranolol overdose may cause widening of the QRS complex and CNS intoxication, including seizures and coma.[59] Most patients with beta-blocker poisoning manifest symptoms within 6 hours after an acute ingestion.[60]

Treatment

Treatment of overdose with a beta blocker includes aggressive gut decontamination. In cases of a large or recent ingestion, gastric lavage and the administration of activated charcoal and a cathartic agent should be initiated.

Hypotension and bradycardia are unlikely to respond to beta-adrenergic–mediated agents such as dopamine and isoproterenol; instead, the patient should receive high dosages of glucagon (5 to 10 mg I.V. followed by 5 to 10 mg/hr). Glucagon is a potent inotropic agent that does not require beta-adrenergic receptors to activate cells.[59,61] When glucagon fails, an epinephrine drip may be more beneficial in increasing heart rate and contractility than isoproterenol or dopamine. If pharmacologic therapy is unsuccessful, transvenous or external pacing should be used to maintain heart rate.[59,61] Use of hemodialysis in atenolol poisoning has been reported.[59]

Table 10 Toxicity of Common Beta Blockers[161]

Drug	*Usual Daily Dose (mg)*	*Cardioselective*	*Myocardial Cell Membrane Depression*
Acebutolol	400–800	+	+
Atenolol	50–100	+	–
Labetalol	200–800	–	+
Metoprolol	100–450	+	Variable
Nadolol	40–240	–	–
Propranolol	40–360	–	++

CALCIUM ANTAGONISTS

Calcium channel blockers are used for the treatment of angina pectoris, hypertension, hypertrophic cardiomyopathy, migraine, and supraventricular tachycardia. These agents have a relatively low toxic-to-therapeutic ratio, and life-threatening toxicity can occur after accidental or intentional overdose. Calcium antagonists block the influx of calcium through calcium channels and act mainly on vascular smooth muscle, resulting in vasodilatation, reduced cardiac contractility, and slowed AV nodal conduction and sinus node activity. The most commonly used calcium antagonists in the United States are nifedipine, verapamil, diltiazem, and amlodipine. Although each of these agents has a different spectrum of activity, this selectivity is usually lost in overdose.[59]

Diagnosis

Manifestations of intoxication with a calcium antagonist include hypotension and bradycardia. Bradycardia may result from AV block or sinus arrest with a junctional escape rhythm. The QRS complex is usually normal. Severe poisoning may cause profound shock followed by asystole. Overdose with sustained-release products, which are very popular, may be associated with delayed onset of toxicity.[62]

Treatment

Treatment of overdose of an orally administered calcium antagonist includes aggressive gut decontamination. Gastric lavage and administration of activated charcoal are recommended. For patients who have ingested a large dose of a sustained-release preparation, the physician should consider whole bowel irrigation[62] in combination with administration of repeated doses of activated charcoal; in such cases, the patient should be observed closely for possible delayed-onset effects.

Hypotension should be initially treated with boluses of fluid, vasopressors, and I.V. calcium chloride (10 ml of a 10% solution) or calcium gluconate (20 ml of a 10% solution).[12] Doses of calcium should be repeated as needed; in some case reports, as much as 10 g of calcium has been given.[63] Calcium administration may improve cardiac contractility but has less effect on AV nodal conduction or peripheral vasodilatation. Infusion of glucagon (5 to 10 mg I.V.) or epinephrine has been recommended for patients with unresponsive hypotension; in one reported case, cardiopulmonary bypass was also shown to be effective. In a verapamil-toxic canine model, the survival rate was higher with high-dose insulin therapy (i.e., insulin-dextrose infusion) than with high doses of epinephrine, calcium chloride, or glucagon. A small, uncontrolled case series of patients with calcium channel blocker poisoning showed improvement with high-dose insulin therapy,

but a prospective, controlled trial is still pending.[64] Hemodialysis is not effective.[59]

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless, nonirritating gas that is produced by the combustion of organic material. It is responsible for more than 5,000 deaths in the United States each year, most occurring from suicidal inhalation. Sources of carbon monoxide include motor vehicle exhaust, improperly vented gas or wood stoves and ovens, and smoke generated by fire. Children riding under closed canopies in the backs of pickup trucks have been poisoned from the exhaust, and campers have been poisoned by using propane stoves or charcoal grills inside their tents.[65] The blizzards that hit the eastern United States in the winter of 1996 produced reports of carbon monoxide poisoning associated with snow-obstructed vehicle exhaust systems.[66] In 2005, use of portable generators in hurricane-damaged areas of Florida led to increased cases of carbon monoxide poisoning.[67]

Tissue hypoxia, which occurs as a consequence of the high affinity of carbon monoxide for hemoglobin, is the major pathophysiologic disturbance in carbon monoxide poisoning: at a carbon monoxide concentration of only 0.1%, as many as 50% of hemoglobin binding sites may be occupied by carbon monoxide. In addition to reducing the oxygen-carrying capacity of the blood, carbon monoxide interferes with the release of oxygen to the tissues. Carbon monoxide may also inhibit intracellular oxygen utilization by binding to myoglobin and cytochromes.[68]

Diagnosis

Carbon monoxide poisoning produces the symptoms and signs commonly associated with hypoxia, such as headache, confusion, tachycardia, tachypnea, syncope, hypotension, seizures, and coma. Clinical manifestations depend on the duration and intensity of exposure: an acute, sizable exposure may produce rapid unconsciousness, seizures, and death, whereas prolonged, low-level exposure may cause vague and nonspecific symptoms such as headache, dizziness, nausea, and weakness. Mild cases may be mistakenly diagnosed as influenza or migraine headache. So-called classic features of carbon monoxide poisoning, such as cherry-red skin coloring and bullous skin lesions, are not always present. Survivors of severe carbon monoxide poisoning may be left with permanent neurologic sequelae. These sequelae can include gross deficits, such as a permanent vegetative state or parkinsonism, or more subtle deficits, such as memory loss, depression, and irritability. In some cases, delayed neurologic deterioration may occur after 1 to 2 weeks.[68,69]

Laboratory findings may include metabolic acidosis and cardiac ischemia on ECG. The oxygen tension is usually normal because carbon monoxide binds to hemoglobin but does not disturb levels of dissolved oxygen; therefore, the calculated oxygen saturation is falsely normal. Furthermore, indirect measurement of oxygen saturation by pulse oximetry is inaccurate because of the similar absorption characteristics of oxyhemoglobin and carboxyhemoglobin.[70] Thus, correct diagnosis depends on direct spectrophotometric measurement of oxyhemoglobin and carboxyhemoglobin in a blood sample or direct measurement of exhaled carbon monoxide. Carboxyhemoglobin levels greater than 20% to 30% are usually associated with moderate symptoms of intoxication, and levels greater than 50% to 60% are associated with a serious or fatal outcome. There is considerable variability, however, and levels do not always correlate with symptoms.[68]

Treatment

The victim of carbon monoxide poisoning should immediately be removed from the site of exposure and given supplemental oxygen in the highest available concentration. Oxygen competes with carbon monoxide for hemoglobin binding sites, and administration of 100% oxygen can reduce the half-life of carboxyhemoglobin to approximately 40 to 60 minutes, thereby restoring normal oxygen saturation within about 2 to 3 hours. It should be noted that it is difficult to deliver 100% oxygen unless the patient is endotracheally intubated. Hyperbaric oxygen (HBO) administered in a sealed chamber can deliver oxygen at a pressure of 2.5 to 3.0 atm and has been reported to speed recovery and reduce neurologic sequelae.[68,71] Proponents of HBO therapy assert that this treatment can reduce cerebral edema and quell lipid peroxidation and other postinjury mechanisms of cellular destruction.[68,72] However, hyperbaric chambers are not readily available, and until recently, the few clinical studies to have compared HBO therapy with 100% oxygen at ambient pressure produced conflicting or inconclusive results or were otherwise unsatisfactory.[73]

In Australia in 1999, a randomized, double-blind, placebo-controlled trial (using sham HBO treatments) compared HBO with normobaric oxygen in a large number of patients with significant carbon monoxide poisoning; the authors found that HBO provided no greater benefit than normobaric oxygen.[74] A more recent study of similar design from the United States found a small but statistically significant reduction in cognitive sequelae 6 weeks after treatment.[71] Proponents of HBO generally advise its use for patients who have a history of unconsciousness, a detectable neuropsychiatric abnormality on bedside testing, or a carboxyhemoglobin level greater than 25%.[68] Because of concerns about the higher affinity of carbon monoxide for fetal hemoglobin, the recommended threshold for treatment of young infants and pregnant women is usually lower.[75] However, there are no controlled studies evaluating HBO therapy in pregnancy. It also remains unclear whether HBO may be useful in patients presenting many hours after exposure or with milder degrees of poisoning.

In patients with carbon monoxide poisoning associated with smoke inhalation, consideration should be given to the potential role of other toxic gases produced during combustion, such as cyanide, phosgene, nitrogen oxides, and hydrogen chloride, as well as the possibility that inhaled soot or steam has caused direct thermal injury to the airway and respiratory tract.

COCAINE, AMPHETAMINES, AND OTHER STIMULANTS

The 2004 National Survey on Drug Use and Health reports that 5.7 million Americans used cocaine in the past year.[76] This figure is down from 5.9 million in 2003. In 2002, there were an es-

Table 11 Common Stimulant Drugs

Drug	*Street Names*
Cocaine	Coke, crack (free-base cocaine)
Methamphetamine	Speed, crystal, ice
3,4-Methylenedioxymethamphetamine (MDMA)	Ecstasy
Methylphenidate	Ritalin*
Methcathinone†	Cat

*Ritalin is the trade name, not the street name.
†An illegally synthesized ephedrine derivative.

Table 12 Corrosive Agents

Corrosive or Caustic Agent	*Comments*
Mineral acids (e.g., hydrochloric, sulfuric, nitric, and phosphoric acids)	Produce rapidly painful coagulation necrosis of skin and eyes; inhalation of mists or vapors can cause irritation, bronchospasm, and chemical pneumonitis
Hydrofluoric acid	Highly electronegative fluoride ion causes deep tissue injury, which may have a delayed onset; systemic absorption from the skin or after ingestion may cause fatal hypocalcemia or hyperkalemia[162,163]
Caustic alkalis (e.g., sodium, potassium, calcium, and ammonium hydroxides)	Injury is often progressive and deep because of tissue saponification and resulting liquefaction necrosis
Phenol (carbolic acid)	Liquid and vapor are rapidly absorbed across the skin, causing severe systemic toxicity (shock, convulsions, and coma)[164]; isopropyl alcohol may speed its removal from skin[165]
Paraquat	Ingestion causes severe corrosive injury; systemic absorption leads to progressive and ultimately fatal pulmonary fibrosis[166]

timated 199,198 cocaine-related emergency department visits.[1]

Cocaine and the amphetamines [*see Table 11*] stimulate the CNS and the sympathetic nervous system and may act directly on peripheral adrenergic receptors.[76,77] Although cocaine also has local anesthetic properties and may cause sodium channel blockade in high doses, the clinical manifestations and treatment of cocaine overdose are essentially the same as those of amphetamine overdose. These drugs can be taken orally or can be snorted, smoked, or injected. So-called crack cocaine is a crudely prepared nonpolar derivative of the hydrochloride salt that is more easily volatilized and is thus the preferred form for smoking. The combined use of ethanol and cocaine may create the highly potent metabolite cocaethylene, which has a longer half-life than does cocaine and may contribute to the development of delayed toxic effects.[77,78]

Another common drug of abuse, particularly among teenagers and young adults, is methylenedioxymethamphetamine (MDMA), or ecstasy. National surveys suggest a marked increase in the prevalence of MDMA use in the United States. In 1993, there were 168,000 new users of MDMA; in 2001, the number of new users had soared to 1.8 million.[79] The 2001 National Survey on Drug Use and Health reports that 3.2% of teenagers (aged 12 to 17) and 13.1% of young adults (aged 18 to 25) have used MDMA.[79] Additionally, MDMA-related emergency department visits increased significantly from 253 visits in 1999 to 5,542 visits in 2001 and then declined to 4,026 in 2002.[80] Although MDMA is an amphetamine derivative with psychoactive properties similar to those of the hallucinogen mescaline, MDMA toxicity appears to be related to its stimulant properties. The subjective effects of MDMA include euphoria, sexual arousal, enhanced sensory perception, increased endurance, and greater sociability.[81] Adverse reactions from MDMA abuse reported in the literature include hyperthermia, hyponatremia, seizures, hepatitis, cerebrovascular accidents, and cardiac arrhythmias.[81] As MDMA use rises, health care providers are likely to see more patients with adverse reactions from this drug.[82]

Very limited national data regarding abuse of prescription stimulants, particularly methylphenidate (Ritalin), indicate that rates of abuse in children and teenagers are declining. Past-year rates of abuse have been tracked only since 2001; the data indicate an overall decrease from 2001 to 2004 among eighth graders (2.9% to 2.5%) and 10th graders (4.8% to 3.4%). Among 12th graders, past-year rates of abuse fluctuated between 5.1% and 4.0%. Data show that the past-year rate of abuse of methylphenidate among young adults was 2.9% in both 2002 and 2003.[83] Methylphenidate toxicity is most commonly the result of therapeutic error in children treated with the drug.[84] Abuse of methylphenidate has been reported; a national survey indicated the prevalence among college students in the United States varies by region, ranging from zero to 25%.[85]

Diagnosis

Clinical manifestations of mild stimulation include euphoria, alertness, and anorexia. More severe intoxication causes agitation, psychosis, tachycardia, hypertension, and diaphoresis. The pupils are usually dilated. Severe poisoning may result in convulsions, hypertensive crisis (e.g., intracerebral hemorrhage or aortic dissection), and hyperthermia.[17,18] Consequences of severe hyperthermia include shock, brain damage, coagulopathy, and hepatic and renal failure.[22]

The differential diagnosis includes acute functional psychosis, acute exertional heatstroke, and intoxication with other drugs. Phencyclidine, a ketaminelike dissociative anesthetic, may produce stimulant effects, but victims of overdose often have a waxing-and-waning encephalopathy with periods of flaccid stupor or coma.[17] Anticholinergic agents (see above) may also cause dilated pupils, tachycardia, and agitation, but these toxins usually cause the skin to be dry and flushed; stimulants generally cause the skin to be pale, clammy, and diaphoretic.

Treatment

Mild or moderate intoxication with a stimulant can often be successfully managed by administering a sedative agent, such as diazepam or lorazepam, and by providing the patient with a quiet room. If hypertension is severe and does not improve after sedation, phentolamine (2 to 5 mg I.V. at 5- to 10-minute intervals) or nitroprusside (0.5 to 10 μg/kg/min) should be administered. For patients with tachycardia or ventricular arrhythmias, a short-acting beta blocker such as esmolol (50 to 100 μg/kg/min) is recommended, although it should be cautioned that beta blockers may worsen hypertension because of unopposed alpha-adrenergic effects of the stimulant drug.[18] Wide-complex dysrhythmias in cases of cocaine overdose should be treated with sodium bicarbonate.[76] Severe hyperthermia should be treated aggressively to prevent brain damage and multiorgan complications [*see* Hyperthermia, *above*].

Because acute myocardial infarction may occur even in young persons with normal coronary arteries, all patients with chest pain should be evaluated carefully for evidence of ischemia.[18] Other causes of chest pain in these patients may include mechanical trauma to the chest wall, pneumomediastinum from hard coughing or the Valsalva maneuver, or pectoral muscle ischemia.[18]

CORROSIVE AGENTS

A number of agents with caustic or corrosive properties [*see Table 12*] are used for a variety of purposes in industry, as cleaning agents in the home, and in hobbies. Exposure to these agents may occur accidentally or as a result of suicidal ingestion. In some cases, the corrosive effect of these agents is a direct result of the high concentration of hydrogen (H^+) or hydroxyl (OH^-) ions

and can be predicted from the very low or very high pH of the product. In other cases, toxicity may result from the product's oxidizing or alkylating or from other cytotoxic effects. Systemic toxicity can occur as a result of absorption across burned skin or after ingestion (e.g., in the case of hydrofluoric acid, phenol, or paraquat) [*see Table 12*].[86]

Diagnosis

Manifestations of toxicity usually occur immediately after exposure to the corrosive or caustic agent and include burning pain and erythema at the site of exposure. Immediate effects occur most commonly with acids. Injury caused by alkali burns can evolve over several hours and takes the form of a penetrating liquefaction necrosis. Burns may also be delayed in cases of exposure to hydrofluoric acid (hydrogen fluoride in aqueous solution); the toxicity of this agent is mediated through its fluoride component, which combines with calcium and magnesium ions. With hydrofluoric acid burns, pain and swelling may not be apparent until several hours after exposure, especially after exposure to relatively dilute solutions.

Treatment

Treatment of toxicity from corrosive or caustic agents must be initiated rapidly to reduce injury. Exposed areas should be flushed with copious amounts of plain water and any contaminated clothing removed (health providers must be careful not to become exposed while assisting victims). For patients whose eyes have been exposed to the agent, the physician should use an eyewash fountain or should splash water into the face, then pour water directly over the eyes from a pitcher or glass. Patients who have ingested a corrosive agent should drink one to two glasses of water. Although use of gastric lavage is controversial because of concerns about possible mechanical damage to the esophagus, our gastrointestinal consultants recommend gastric intubation with a small flexible tube as soon as possible after corrosive-liquid ingestion, to remove as much of the injurious material as possible. Neutralizing agents should not be administered in an attempt to normalize the pH; they may modify the pH too far in the opposite direction, and the heat of neutralization may cause thermal injury. There are a few exceptions to this rule; for example, after exposure to hydrofluoric acid, soaking the skin in a solution or gel that contains calcium (e.g., 2.5% calcium gluconate gel) or magnesium or in benzalkonium chloride may bind the toxic fluoride ion before it can be absorbed[87]; calcium is sometimes injected subcutaneously or by the intra-arterial route for deeper burns. For management of exposure to hydrofluoric acid, the physician should consult a regional poison-control center, a medical toxicologist, or a plastic or hand surgeon.

CYANIDE

Cyanide (the CN^- anion or a salt that contains this ion) is a highly toxic chemical that is used in a variety of industries, including electroplating, chemical synthesis, and laboratory analysis.[88] Cyanide is also released in the I.V. administration of nitroprusside. Acetonitrile, which is found in some glue removers for artificial fingernails, is metabolized to cyanide and has caused death in children.[88] Natural sources of cyanide (cyanogenic glycosides) include cassava, apricot pits, and several other plants and seeds. Hydrogen cyanide gas is generated from the combustion of many natural and synthetic materials that contain nitrogen and is a common component of the smoke generated by fire [*see* Smoke Inhalation, *below*].[89]

Cyanide is a highly reactive chemical that binds to intracellular cytochrome, blocking the utilization of oxygen. The resulting cellular asphyxia leads to headache, confusion, dyspnea, syncope, collapse, and death.[88,90] Although these effects occur rapidly after inhalation of hydrogen cyanide gas, symptoms of intoxication may be delayed for minutes after the ingestion of cyanide salts or even for hours after the ingestion of cyanogenic glycosides or acetonitrile.[88]

Diagnosis

A diagnosis of cyanide poisoning is based on a history of possible exposure (e.g., in a laboratory worker who attempts to commit suicide; in a person who has ingested laetrile, a cyanogenic glycoside; in a victim of smoke inhalation; or in a patient who has received a rapid high-dose infusion of nitroprusside) and the presence of characteristic symptoms. Any victim of smoke inhalation who has altered mental status should be suspected of having been poisoned with cyanide as well as with carbon monoxide. After cyanide ingestion, the victim may detect a smell of bitter almonds, but only about 50% of the general population has the ability to perceive this odor. Severe lactic acidosis is usually present. Because cyanide blocks the cellular utilization of oxygen, the oxygen content of venous blood may be elevated; a venous oxygen saturation of greater than 90% suggests the diagnosis.

Treatment

Once cyanide poisoning is suspected, immediate measures must be taken to prevent further exposure and to provide an antidote. For an ingestion, oral activated charcoal should be immediately administered; although the adsorption of cyanide to charcoal is relatively low, a standard dose of charcoal (e.g., 50 to 60 g) is sufficient to adsorb several hundred milligrams of cyanide salts. If charcoal is not available and there will be a delay before the patient reaches the hospital, emesis should be induced with ipecac. If ipecac is not available, emesis should be induced by mechanical gagging.

The antidotes for cyanide poisoning consist of nitrites, which oxidize hemoglobin to methemoglobin; in turn, methemoglobin binds free cyanide ions. If I.V. access is not immediately available, a pearl of amyl nitrite should be broken and the victim should inhale the contents. As soon as possible, sodium nitrite, 300 mg I.V., should be administered. The other antidote is sodium thiosulfate (12.5 g I.V.), which enhances the conversion of cyanide to the less toxic thiocyanate by the endogenous enzyme rhodanese. Although nitrites produce serious side effects (e.g., methemoglobinemia reduces the oxygen-carrying capacity, and vasodilatation may cause hypotension), sodium thiosulfate is relatively benign and can be used empirically as a single agent when the diagnosis is uncertain. Other potential antidotes include cobalt ethylenediaminetetraacetic acid (cobalt EDTA) and vitamin B_{12a} (hydroxocobalamin), but these agents have not been approved for use in the United States, and hydroxocobalamin, although used in the United States for the treatment of pernicious anemia, is not available in a concentrated high-strength form needed for antidotal treatment of cyanide poisoning.[88,91]

DIGITALIS GLYCOSIDES

Digitalis glycosides are found in a variety of plants, including foxglove, oleander, and rhododendron,[92] and have been used for centuries to treat heart failure. Digoxin is the most commonly prescribed digitalis glycoside. Digitalis poisoning may occur af-

Table 13 Dosing of Digoxin-Specific Antibodies

Type of Intoxication	*Dose Needed to Provide Complete Binding of Digoxin*
Acute ingestion*	Administer one vial (40 mg) for each 0.5 mg of digoxin expected to be absorbed (because bioavailability is 80%, multiply ingested dose by 0.8 to estimate absorbed dose)
Chronic intoxication†	Use the following formula to calculate the number of vials needed: $\frac{\text{Serum digoxin level (ng/ml)} \times \text{body weight (kg)}}{100}$

*Dose of digoxin-specific antibodies is based on the estimated amount of digoxin ingested.
†Dose of digoxin-specific antibodies is based on the steady-state serum digoxin level.

ter accidental or suicidal acute overdose, as a result of long-term accumulation (usually because of renal insufficiency or overmedication), or as a drug interaction. There have been many reports of elevated digoxin levels resulting from the interaction of digoxin with commonly used drugs, such as quinidine, amiodarone, and macrolide antibiotics.[93] Digitalis glycosides inhibit the sodium pump (Na^+,K^+-ATPase), which returns potassium to cells and increases the intracellular calcium concentration.[94]

Diagnosis

After an acute overdose, serum potassium levels are often elevated and AV nodal conduction is impaired, leading to varying degrees of AV block. Additionally, gastrointestinal symptoms of nausea, vomiting, and anorexia are often described after acute digitalis poisoning. With chronic poisoning, in contrast, ventricular dysrhythmias (e.g., ventricular ectopic beats or bidirectional ventricular tachycardia) predominate, and the potassium level is often normal or low, perhaps in part because of long-term coadministration of diuretic agents. The digitalis level is usually markedly elevated; however, if the sample is drawn within a few hours of overdose or within a few hours after receiving the last therapeutic dose, the result may be misleading because the drug would not have been fully distributed to tissues.[95]

Treatment

Management of acute digitalis poisoning includes gut decontamination with the oral administration of activated charcoal and, if the ingestion was large and occurred shortly before presentation, gastric lavage. Activated charcoal administered in multiple doses is effective in reducing deaths and life-threatening cardiac arrhythmias after yellow oleander poisoning.[96] This treatment has important implications for areas of the world where antidotal therapy with digoxin-specific antibodies is not available. Initially, sinus bradycardia or uncomplicated AV block should be treated with atropine (0.5 to 2 mg I.V.). A temporary pacemaker may be needed in patients with persistent symptomatic bradycardia; however, such patients should also receive digoxin-specific antibodies.

Digoxin-specific antibodies (e.g., Digibind, DigiFab) are indicated for patients with manifestations of severe intoxication (i.e., marked hyperkalemia and symptomatic dysrhythmias). These antibodies are derived from sheep and then cleaved so as to leave only the Fab fragment, which is small enough to be filtered and eliminated by the kidney after binding to digoxin. Extensive clinical experience with dixogin-specific antibodies has shown that they are safe and highly effective, with peak activity occurring within 20 to 30 minutes after administration.[7] The dose of digoxin-specific antibodies depends on the type of intoxication [*see Table 13*]. After acute ingestion, the serum level of drug does not predict the body burden because of ongoing tissue distribution[95]; therefore, the dose of digoxin-specific antibodies is calculated by estimating the amount of drug ingested. In patients with chronic poisoning in whom a steady-state digoxin level can be obtained, the body burden can be estimated on the basis of the serum level and the average apparent volume of distribution. When the ingested dose is not known or a steady-state level cannot be obtained, patients should be treated empirically: initially, one to five vials should be administered, depending on the severity of toxicity. It may also be appropriate to start with small doses and to titrate them to clinical effect in patients who have preexisting disease that requires residual digitalis effect (e.g., those with congestive heart failure or atrial fibrillation).

ETHANOL, METHANOL, AND ETHYLENE GLYCOL

Ethanol (grain alcohol) is probably the most widely used drug in the United States, and complications related to acute intoxication, as well as related medical illness and trauma, are commonly encountered. Ethanol-related illnesses account for nearly 20% of the national expenditure for hospital care, and ethanol is involved in about 50% of all fatal motor vehicle accidents.[97] Ethanol is frequently ingested with other drugs, both in suicide attempts and in recreational drug abuse. Ethylene glycol (antifreeze) and methanol (wood alcohol) are other alcohols that cause profound and often fatal poisoning when mistakenly ingested as substitutes for ethanol.

Ethanol

Diagnosis Acute ethanol intoxication produces an easily recognized state of inebriation that includes disinhibition, slurred speech, ataxia, stupor, and coma.[17] Loss of protective reflexes in the airway may permit pulmonary aspiration of gastric contents, possibly causing respiratory arrest in those who are in a deep coma. In most states, a blood ethanol level above 80 to 100 mg/dl is considered sufficient evidence to charge a driver of a car with the crime of driving while intoxicated. A level above 300 mg/dl is generally considered sufficient to cause deep coma and respiratory arrest; however, because tolerance to ethanol develops, persons with a long history of ethanol abuse who have ethanol blood levels above 300 mg/dl are often awake and even able to ambulate.[17] Acute ethanol ingestion can also cause hypoglycemia because of the inhibitory effect of ethanol on gluconeogenesis.

Treatment Treatment of ethanol intoxication usually consists of supportive care. The blood ethanol level decreases at an average (but variable) rate of about 20 mg/dl/hr,[17] and most patients are awake and ambulatory within 6 to 12 hours or less. The physician should protect the airway and, if necessary, intubate the trachea and assist ventilation. The patient should be evaluated for hypoglycemia, and glucose-containing fluids should be given as necessary; vitamin B_1, 100 mg I.V. or I.M., should be administered to malnourished patients or patients with chronic alcoholism. Hypotension, although uncommon, may result from vasodilatation and dehydration and usually responds to an I.V. bolus of fluid. Although such patients often come to medical attention because of falls, even those without a history of trauma should be examined for occult injuries (especially to the head,

neck, and abdomen) because inebriated patients often have such injuries. In addition, serious infections, vitamin deficiencies (especially of vitamin B_1 and folic acid), and metabolic abnormalities also occur frequently in patients with chronic alcoholism[18]; if any of these are present, they should be treated.

Methanol and Ethylene Glycol

Diagnosis Methanol or ethylene glycol poisoning produces an initial clinical picture that is similar to that of ethanol intoxication. However, these alcohols are gradually metabolized to highly toxic organic acids that can have disastrous effects [*see Table 14*]. After a delay of up to several hours, the patient develops severe metabolic acidosis and evidence of end-organ injury from the accumulation of the toxic acid metabolites. A diagnosis of methanol or ethylene glycol poisoning is based on the patient's history of exposure and the presence of severe metabolic acidosis. The osmolar gap is usually elevated, especially early after ingestion when the parent compounds are present, but toxic products can be present with a seemingly normal osmolar gap.[98] The serum lactate level is relatively low despite a large anion gap.[99]

Treatment If methanol or ethylene glycol poisoning is suspected, immediate measures should be instituted to reduce absorption, prevent metabolism, and remove the toxic acid metabolites.[99] If the ingestion occurred shortly before presentation (i.e., < 1 hour), gastric aspiration should be performed to remove as much of the ingested liquid as possible; activated charcoal does not efficiently adsorb the alcohols. Metabolism of the alcohols can be prevented by giving ethanol or fomepizole (4-methylpyrazole), which competitively inhibits the enzyme alcohol dehydrogenase. If ethanol is used, a loading dose of approximately 750 mg/kg orally or I.V. usually produces an ethanol level of about 100 mg/dl[99]; an infusion of 100 to 150 mg/kg/hr is given to maintain this level. An ethanol drip is difficult to manage, and the ethanol may contribute to obtundation. Fomepizole is easier to administer, has few side effects, and, if initiated early after ethylene glycol ingestion, may eliminate the need for dialysis (this is not the case for methanol). Although costly, fomepizole therapy may be less expensive than the combined costs of hemodialysis, intensive care, and serial blood work during an ethanol drip.[99] Administration of folic acid (50 mg I.V. every 4 hours), vitamin B_1 (100 mg I.M. or I.V. every 6 hours), and pyridoxine (50 mg I.V. every 6 hours) is also recommended to enhance the metabolism of the toxic organic acids. In addition, sodium bicarbonate should be given as needed to restore normal serum pH and enhance renal elimination of the toxic acid metabolites.

If the measured or estimated serum level of the toxic alcohol is greater than 50 mg/dl or if severe metabolic acidosis is present, hemodialysis is indicated to remove the parent compounds and their metabolites. During hemodialysis, the ethanol infusion is usually increased twofold, and fomepizole is administered every 4 hours to replace the respective drugs that are lost during the procedure.[99]

γ-HYDROXYBUTYRIC ACID

γ-Hydroxybutyric acid (GHB) is a naturally occurring four-carbon compound that was first synthesized in 1960. Since then, the drug has been used for various clinical purposes, including induction of general anesthesia, treatment of alcohol withdrawal and narcolepsy, and even as a protective agent during tissue ischemia.[100] In the United States, it has been available only under an FDA investigational new drug exemption for the treatment of narcolepsy. However, in the late 1980s, GHB gained popularity among some bodybuilders who believed it could enhance muscle mass through stimulation of growth hormone release. It is now promoted popularly as a sleep aid, a diet agent, and a euphorigenic drug. Its increasing use has been accompanied by a number of reports of severe and fatal effects. Its illegal recreational abuse has become a part of the underground drug culture (e.g., at rave parties and dance clubs). It has also been used to facilitate rape and assault because it produces rapid loss of consciousness. Innovative ways to continue GHB use despite FDA and Drug Enforcement Administration restrictions have included the sale of precursors of the drug such as γ-butyrolactone (GBL) and 1,4-butanediol, marketed as dietary supplements at health food stores and on the Internet under several trade names (e.g., Renewtrient and Revivarant). These precursors are metabolized to GHB in the body, and toxic effects are similar or identical to those of GHB.[101] After numerous reports of adverse reactions to these agents, including one death, the FDA asked manufacturers on January 21, 1999, to recall their GBL-containing products and warned consumers to avoid taking these products.[101]

Diagnosis

Clinically, patients poisoned by GHB or its analogues usually present with profound CNS and respiratory depression, with possible loss of laryngeal reflexes and apnea. Symptoms usually last less than 4 to 6 hours, and patients often have sudden awakening and agitation, particularly in response to painful stimuli (e.g., intubation).[102] Concurrent sinus bradycardia, myoclonic movements, and vomiting are common. Delirium and tonic-clonic seizures have been reported. There is an additive effect of GHB when it is taken in conjunction with sedative agents or al-

Table 14 Poisoning with Ethylene Glycol, Isopropyl Alcohol, or Methanol

Alcohol	*Metabolic Products*	*Treatment*
Ethylene glycol	Oxalic, hippuric, and glycolic acids cause severe anion-gap metabolic acidosis; calcium oxalate crystals precipitate in tissues and kidneys[167]	Fomepizole or ethanol infusion; perform hemodialysis if there is severe acidosis, if serum level > 20–50 mg/dl, or if osmolar gap > 10 mOsm/L
Isopropyl alcohol	Acetone causes characteristic odor; toxicity includes CNS depression, but there are no toxic acid by-products[168]	Isopropyl alcohol is a potent CNS depressant and gastric irritant, but its toxicity is usually managed supportively
Methanol	Formic acid causes severe anion-gap metabolic acidosis and visual disturbances that can lead to blindness and death[169]	Fomepizole or ethanol infusion; perform hemodialysis if there is severe acidosis, if serum level > 20–50 mg/dl, or if osmolar gap > 10 mOsm/L

cohol. GHB is absorbed within 10 to 15 minutes, and because of its short half-life of 27 minutes, plasma blood levels are undetectable within 4 to 6 hours of therapeutic ingestion.[100] Evidence suggests that GHB dependence may lead to severe withdrawal after sudden discontinuance.[100] Symptoms are similar to those of alcohol withdrawal but may last 7 to 14 days; these patients often require very large doses of benzodiazepines and barbiturates to control agitation.[103]

Treatment

There is no specific antidote for GHB. Therapy consists of airway protection, with rapid-sequence intubation if needed [*see* Initial Stabilization, *above*]. Because of the short half-life of GHB, patients without complications from GHB (e.g., prolonged hypoxia, aspiration, or untoward effects of mechanical ventilation) are often extubated and discharged from the emergency department within 3 to 7 hours.[102] Symptomatic bradycardia can be successfully treated with atropine.[102] Decontamination measures, such as gastric lavage and activated charcoal, are of little benefit because of GHB's rapid absorption, although it should be considered for large overdoses or if a coingestion is suspected. GHB withdrawal can be treated in the same manner as alcohol withdrawal, although physicians should recognize the potential need for higher doses of benzodiazepines and a longer treatment period.[104]

IRON

Iron poisoning is typically seen in children who accidentally ingest their parents' iron supplements, but intentional overdose occasionally occurs in adults.[105] Iron in large quantities is corrosive to the gastrointestinal tract, causes nausea and vomiting, and sometimes causes bloody emesis and diarrhea. Intestinal perforation occasionally occurs. Shock may result from volume loss and fluid shifts, as well as from iron-induced peripheral vasodilatation. In addition, free iron is cytotoxic, and coma, metabolic acidosis, and liver failure may develop from excessive, acute systemic absorption.[105]

Diagnosis

The diagnosis of acute iron poisoning may be based on a history of exposure or may be suspected in a patient with severe gastroenteritis and hypotension, especially if such a patient also has metabolic acidosis, hyperglycemia, and leukocytosis.[105] A plain x-ray of the abdomen (KUB view) may reveal radiopaque iron tablets. Serum iron levels in patients with severe poisoning are usually higher than 600 to 1,000 μg/dl, although lower levels may be seen if the sample is drawn late in the course of intoxication. In the past, it was common to estimate the quantity of free iron by subtracting the total iron-binding capacity (TIBC) from the serum iron level. However, it has since been shown that the TIBC is falsely elevated during iron poisoning, and this value is no longer considered useful for the purpose.[106]

Treatment

Treatment of acute iron overdose includes gut decontamination, I.V. administration of fluids, and, possibly, chelation with deferoxamine. Patients who are in shock should receive vigorous I.V. fluid replacement. Because activated charcoal does not bind iron, it should not be given unless an overdose of other drugs is also suspected. Gastric lavage may be useful in patients who have taken liquid iron preparations or chewable products; however, if intact tablets are seen on x-ray, it is unlikely that they can be removed through even the largest-bore gastric hose. Attempts to render the iron insoluble by gastric lavage with bicarbonate- or phosphate-containing solutions have proved ineffective or dangerous. Currently, the recommended method of gut decontamination in patients with large ingestions is whole bowel irrigation,[26,31] which is achieved by administering polyethylene glycol-electrolyte solution (e.g., GoLYTELY or Colyte), 1 to 2 L/hr by nasogastric tube for several hours, until the rectal effluent is clear and the x-ray shows no radiopacities.

Therapy with deferoxamine, a specific chelator of iron, is indicated in patients who have evidence of severe poisoning, but such therapy should not replace thorough gut decontamination and aggressive volume replacement.[105] The I.V. route is preferred, and an initial dosage of 10 to 15 mg/kg/hr should be given. Dosages as high as 40 to 50 mg/kg/hr may be given in particularly severe cases of poisoning. The iron-deferoxamine complex imparts an orange or vin rosé color to the urine that is sometimes used as evidence of the continued presence of chelatable (free) iron. Inasmuch as serum iron levels are readily available in most hospitals, the so-called vin rosé test is seldom used as an indication to continue therapy. Many clinicians stop administering deferoxamine as soon as the serum iron level is lower than 350 μg/dl, because prolonged infusions have been associated with acute respiratory distress syndrome (ARDS).[7]

ISONIAZID

Isoniazid is widely used in the treatment of tuberculosis. Long-term use of isoniazid has been associated with hepatitis and peripheral neuropathy [*see 4:VIII Chronic Hepatitis and 7:XIV Antimicrobial Therapy*]. Acute overdose of isoniazid is a well-known cause of seizures and metabolic acidosis.[107] Isoniazid causes acute toxicity by competing with pyridoxal 5´-phosphate (the active form of vitamin B_6), resulting in lowered γ-aminobutyric acid (GABA) levels in the brain. It also inhibits the hepatic metabolism of lactate to pyruvate. As little as 1.5 g of isoniazid may cause toxicity, with severe toxicity likely to occur after administration of 5 to 10 g.

Diagnosis

Acute overdose of isoniazid causes confusion, seizures, and coma; the onset is abrupt, often occurring within 30 to 60 minutes of ingestion. Lactic acidosis is often severe, and its severity is disproportional to the duration or intensity of seizure activity. Diagnosis is based on a history of isoniazid ingestion and should be suspected in any person who experiences the acute onset of seizures and who may be taking the drug (e.g., persons who have tuberculosis or AIDS and recent immigrants who test positive on the purified protein derivative [PPD] skin test). Results of testing for serum isoniazid levels are not generally available immediately, and routine toxicology screens do not ordinarily test for the drug.

Treatment

Activated charcoal should be administered to any person who is suspected of having isoniazid intoxication. Emesis should not be induced because of the risk of the abrupt onset of seizures and coma. Gastric lavage is appropriate in cases of large, recent ingestion. Seizures should be treated initially with diazepam, 5 to 10 mg I.V., or with lorazepam, 1 to 2 mg I.V. Vitamin B_6 is a specific antidote and should be given to all patients who have taken more than 3 to 5 g of isoniazid. In cases in which the amount of isoniazid ingested is unknown, the dose is 5 to 10 g I.V.; if the

amount is known, an equivalent gram-for-gram amount of vitamin B_6 should be given.[107] Administration of vitamin B_6 effectively stops resistant seizures and improves metabolic acidosis. It has also reportedly reversed isoniazid-induced coma.[108]

LEAD

Lead poisoning primarily occurs in the occupational setting, with exposure occurring over a period of months or years. However, lead is a ubiquitous metal found in the paint of older houses, car batteries and radiators, some pottery glazes and solders, and some folk medicines[109]; thus, it may be encountered by hobbyists, home-repair buffs, and those who use ceramic cookware.

Diagnosis

The clinical manifestations of lead poisoning are sufficiently variable and nonspecific that lead poisoning should be suspected in any patient who has multisystem illness, especially if the illness involves the neurologic, hematopoietic, and gastrointestinal systems.[109] Lead poisoning rarely results from a single ingestion, although such occurrences have been reported.[38] More commonly, exposure occurs repeatedly and gradually. Patients typically have cramplike abdominal pain or nausea and may have chronic systemic symptoms such as irritability, malaise, and weight loss. Other manifestations of lead poisoning include peripheral motor neuropathy (wristdrop) and anemia, which is often microcytic and accompanied by basophilic stippling. Lead encephalopathy, manifested by coma and seizures, is rare.

Chronic lead poisoning has been misdiagnosed as porphyria, in part because they both involve alteration of heme metabolism.[110] Diagnosis of lead poisoning is usually based on the lead level in whole blood. Symptoms generally occur in patients with lead levels above 25 to 40 μg/dl, but lower levels have been associated with impaired neurobehavioral development in children.[111] Lead levels above 80 μg/dl are often associated with severe overt toxicity. The free erythrocyte protoporphyrin (FEP) concentration, which is elevated (> 35 μg/dl) in persons with chronic intoxication, has been used to screen large populations for lead poisoning but is not sufficiently sensitive for the identification of low blood lead levels (< 30 μg/dl) in children.

Treatment

For patients with an acute ingestion of lead (e.g., a fishing weight, bullet, or curtain weight), a plain x-ray of the abdomen should be obtained. If the object is in the stomach, there is a risk that the action of stomach acid may create enough absorbable lead to cause systemic toxicity; therefore, the object should be removed by the use of cathartic agents, whole bowel irrigation, or endoscopy. Objects that clearly lie beyond the pylorus are likely to pass uneventfully into the stool, but confirmation of this supposition should be obtained by close follow-up with repeated x-rays and measurement of blood lead levels.[38]

Several chelating agents are available for the treatment of patients with acute or chronic intoxication who are symptomatic and have elevated blood lead levels.[111] The oldest chelating agent, dimercaprol, is reserved for patients with lead encephalopathy (but even this use is controversial). For less severe intoxication, the physician should administer I.V. calcium EDTA or oral succimer (meso-2,3-dimercaptosuccinic acid [DMSA]). Triple-chelation therapy with dimercaprol, EDTA, and oral succimer has been used in conjunction with whole bowel irrigation following an extremely high lead level in a 3-year-old child with encephalopathy.[111] A recent trial suggests that succimer does not provide any benefit in children with chronically elevated blood lead levels between 20 and 44 μg/dl.[112] However, the findings of this study, the indications for treatment, and the recommended agents and doses are controversial; the physician should consult with a specialist in occupational medicine or toxicology or contact a regional poison-control center for specific advice about the doses and side effects of these drugs.

Health care providers should be aware that the Occupational Safety and Health Administration (OSHA) has provided specific guidelines for monitoring and managing workers who have been exposed to lead [*see CE:VI Occupational Medicine*]; these guidelines stipulate that such workers be removed from exposure if a single blood lead level exceeds 60 μg/dl or if the average of a series of three successive periodic screening levels exceeds 50 μg/dl.[113] For further information, a regional OSHA office or an occupational medicine specialist should be consulted. (A directory of regional offices is available at the OSHA Web site, at http://www.osha.gov.) Finally, because household members of persons who have been occupationally exposed to lead may be contaminated by the poisoned individual, household members should also be evaluated for lead poisoning even if they are apparently asymptomatic, and measures should be taken to reduce or prevent further exposure.

LITHIUM

Lithium is a simple cation that is widely used for the treatment of manic-depressive illness and other psychiatric disorders. It is also used to elevate the white blood cell count in patients with severe leukopenia. Lithium is excreted renally, and severe intoxication usually results from drug accumulation caused by renal impairment or excessive overmedication. An acute single overdose, however, is less likely to result in severe poisoning.

Diagnosis

The usual therapeutic level of lithium is 0.6 to 1.2 mEq/L. Chronic intoxication can occur with levels only slightly above 1.2 mEq/L, but patients with acute overdose may remain asymptomatic despite having much higher levels early after ingestion of the drug.[114] Manifestations of lithium intoxication include confusion, lethargy, tremors, and muscle twitching. The ECG may show flattening of T waves, the presence of U waves, and prolongation of the QT interval. In severe cases, coma and convulsions may occur.[114] Symptoms may take several days to weeks to resolve, and some patients are left with permanent neurologic impairment.[115] Other toxic effects of lithium intoxication are nephrogenic diabetes insipidus and neuroleptic malignant syndrome [*see Table 5*]. These effects can also occur at therapeutic levels of the drug.

Treatment

Treatment of acute lithium overdose consists mainly of gut decontamination and fluid therapy. Because lithium is poorly adsorbed to activated charcoal, administration of this agent is not necessary unless the physician suspects that another drug has also been ingested. Gastric lavage may reduce the gastric burden of lithium. Whole bowel irrigation should be considered, especially if the patient has ingested a sustained-release form of the drug.[114] Limited experimental and anecdotal evidence suggests that administration of sodium polystyrene sulfonate reduces absorption and enhances elimination of lithium, although its role in acute lithium overdose remains to be established.[116]

Fluid therapy is an essential part of treatment of lithium intoxication. Volume should be restored with 1 to 2 L of normal saline; the I.V. administration of fluids should be continued at a rate sufficient to produce urine at a rate of about 100 ml/hr. The indications for hemodialysis in the setting of lithium toxicity are controversial. A recent review article recommends the following guidelines for hemodialysis: a lithium level greater than 6 mEq/L in any patient; a lithium level greater than 4 mEq/L in any patient on long-term lithium therapy (in contrast to an acute overdose); or a lithium level of 2.5 to 4.0 mEq/L in any patient with severe neurologic symptoms, renal insufficiency, hemodynamic instability, or neurologic instability.[114] However, a poison-control center–based study did not report any significant difference in patients with lithium toxicity in whom hemodialysis was recommended by the poison-control center but not performed and in those for whom hemodialysis was performed.[117] These authors recommended reserving hemodialysis for severe cases of lithium toxicity. Blood should be drawn at least 8 to 12 hours after the last dose of lithium is given to prevent misinterpretation, which can occur as a result of the serum level being falsely elevated before the drug is distributed in tissues. Serial lithium measurements should be obtained until the level clearly drops, to exclude ongoing absorption or rebound after hemodialysis. Consultation with a regional poison-control center, medical toxicologist, and nephrologist should be obtained early to help manage a lithium-toxic patient.

METHEMOGLOBINEMIA-INDUCING AGENTS

Methemoglobin is an oxidized form of hemoglobin that is incapable of carrying and delivering oxygen normally. A number of oxidant drugs and chemicals can convert hemoglobin to its oxidized form, causing methemoglobinemia.[118] These agents include local anesthetics (e.g., benzocaine and lidocaine), antimicrobial agents (e.g., chloroquine, dapsone, primaquine, and sulfonamides), analgesics (e.g., phenazopyridine and phenacetin), nitrites and nitrates (e.g., amyl nitrite, butyl nitrite, isobutyl nitrite, and sodium nitrite), and several miscellaneous drugs and chemicals (e.g., aminophenol, aniline dyes, bromates, chlorates, metoclopramide, nitrobenzene, nitrogen oxides, and nitroglycerin). Benzocaine-containing sprays used for topical anesthesia before certain procedures (e.g., endoscopy, intubation, and nasogastric lavage) are a common cause of methemoglobinemia.[119] Persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency and congenital methemoglobin reductase deficiency are more likely than persons without these conditions to accumulate methemoglobin after exposure to an oxidant.

Diagnosis

Methemoglobinemia causes cellular asphyxia. Symptoms of mild to moderate methemoglobinemia include headache, nausea, dizziness, and dyspnea. Methemoglobin levels as low as 15% can cause the patient to appear cyanotic despite having a normal oxygen tension. The blood usually has a dark or chocolate-brown appearance. Although pulse oximetry is abnormal, the reported drop in oxygen saturation does not correlate with the actual reduction in oxyhemoglobin saturation, and specific testing for methemoglobinemia should be performed.[120]

Treatment

Mild methemoglobinemia (methemoglobin levels < 15% to 20%) usually resolves spontaneously and requires no treatment. Patients who have more severe intoxication should be given the antidote methylene blue (1 to 2 mg/kg I.V. [0.1 to 0.2 ml/kg of a 1% solution] over several minutes).[118] The dosage may be repeated once. Although symptoms and signs usually resolve quickly, methemoglobinemia may recur with the administration of long-acting oxidants such as dapsone [*see 5:IV Hemoglobinopathies and Hemolytic Anemias*].[118]

OPIOIDS

The opioids and opiates include several synthetic and naturally occurring compounds that are widely used for their analgesic properties. Common opium derivatives include morphine, heroin, hydrocodone, and codeine. Synthetic opioids include fentanyl, methadone, and butorphanol. Preparations of hydrocodone or codeine for oral use commonly contain aspirin or acetaminophen, which may themselves be responsible for serious toxicity in an overdose. Opioids stimulate several receptors in the CNS, resulting in sedation and reduced sympathetic outflow.[6,7] Excessive opioid effect may cause coma and blunting of the respiratory response to hypercapnia. Buprenorphine is a mixed opioid agonist-antagonist that has been introduced as an alternative to methadone in outpatient drug-treatment programs. Its use in a patient addicted to opioids may precipitate acute withdrawal symptoms.[121] The opioids meperidine and dextromethorphan may cause serious rigidity and hyperthermia in persons who are taking MAO inhibitors or other serotoninergic drugs (e.g., selective serotonin reuptake inhibitors [SSRIs]).[122]

Diagnosis

Patients may have opioid intoxication as a result of unintentional overdose or attempted suicide. Signs of intoxication include lethargy or coma, pinpoint pupils, and respiratory depression. Acute noncardiogenic pulmonary edema may occur.[6] Seizures are not typical but may occur with acute propoxyphene overdose; repeated therapeutic doses of meperidine can also cause seizures, especially in persons with renal failure because of the accumulation of the metabolite normeperidine.

Diagnosis of opioid intoxication is usually not difficult in a person who is in a coma and has pinpoint pupils and apnea.[5,6] Paramedics may discover I.V. drug paraphernalia or empty prescription bottles at the scene. Exposure to other drugs, however, may complicate the clinical picture.

Treatment

The physician should immediately establish that the airway is not obstructed and that ventilation is adequate. Supplemental oxygen should then be administered as necessary. After these initial measures, the specific opioid antagonist naloxone should be given (0.2 to 2 mg I.V. or S.C.). A recent trial has shown similar results with subcutaneous and intravenous naloxone.[123] Persons who are suspected of long-term narcotic abuse should be started with smaller doses of naloxone to minimize the severity of an acute withdrawal reaction. Patients usually become fully awake within a few minutes after administration. If the initial dose is not effective, additional doses (up to 15 to 20 mg if opioid intoxication is strongly suspected) should be given until a satisfactory response is achieved. The plasma half-life of naloxone is about 60 minutes, which is shorter than that of most of the opioids whose actions it reverses; therefore, patients who respond to the antidote should be observed for at least 3 hours after the last dose for the recurrence of sedation. Traditionally thought to be an innocuous drug, naloxone has been associated with an approximately 1.6% complication rate. Com-

plications include asystole, seizures, pulmonary edema, and severe agitation.[6]

Oral ingestion of an opioid should be treated with activated charcoal. Gastric lavage should be considered in cases of large or recent overdose. There is no role for hemodialysis or other enhanced removal procedures in the treatment of opioid overdose.

ORGANOPHOSPHATES AND RELATED AGENTS

Organophosphates and carbamates are widely used as pesticides,[124] and several of the nerve agents (e.g., VX, soman, sarin) developed for chemical warfare[125] are potent organophosphates. All of these poisons inhibit the enzyme acetylcholinesterase, preventing the breakdown of acetylcholine at cholinergic synapses. Whereas the organophosphates may cause permanent damage to the enzyme, carbamates have a transient and reversible effect. Many of these agents are well absorbed through intact skin. Persons may be exposed accidentally while working with or transporting the chemicals or as a result of accidental or suicidal ingestion.

Diagnosis

Excessive activity of acetylcholine may occur at nicotinic, muscarinic, and CNS cholinergic receptors. The most common presenting symptoms of poisoning are abdominal cramps and vomiting accompanied by sweating and hypersalivation [*see Table 15*]. The patient usually has small or pinpoint pupils. Because of the mixed effects of poisoning on sympathetic ganglia and parasympathetic synapses, the heart rate may be either slow or fast. Life-threatening manifestations of acetylcholinesterase inhibition include muscle weakness with respiratory arrest, as well as severe bronchospasm. Significant volume loss may result from excessive sweating, salivation, vomiting, and diarrhea.[124]

Treatment

Contaminated clothing should be removed immediately and all exposed areas washed thoroughly with soap and water. Rescue personnel should take precautions to avoid secondary contamination from direct contact with the victim's skin, clothing, or vomitus. Xylene or other solvent vapors emanating from the victim are not life threatening to medical personnel but may cause dizziness, nausea, and headache. In patients who have ingested an organophosphate or a carbamate, gastric lavage should be performed with the use of a closed-container unit, and activated charcoal should be administered.

Specific therapy includes administration of atropine and pralidoxime (2-PAM). Atropine is not a physiologic antidote but can reverse excessive muscarinic stimulation, thereby alleviating abdominal cramps, bronchospasm, and hypersalivation. It does not reverse muscle weakness. All patients with organophosphate poisoning should also be given 2-PAM because it can chemically restore the enzyme acetylcholinesterase; in persons who go untreated, the organophosphate's binding to acetylcholinesterase may become permanent (the so-called aging effect). Because carbamates have a transient effect, 2-PAM therapy is not needed in patients who have been poisoned with these agents. However, because the exact product causing cholinergic excess is often not known initially or because the cholinergic excess may be the the result of a mix of organophosphate and carbamate, 2-PAM may be initiated empirically. Additionally, several case reports suggest that 2-PAM may be useful in carbamate poisoning.[126]

Table 15 Manifestations of Excessive Activity of Acetylcholine

Site of Activity	*Clinical Manifestations*
Postganglionic muscarinic receptors	Bradycardia; miosis; salivation; lacrimation; bronchorrhea; increased peristalsis; sweating
Autonomic ganglia	Tachycardia; hypertension
Skeletal muscle nicotinic receptors	Muscle fasciculations followed by weakness; neuromuscular paralysis
CNS cholinergic receptors	Agitation; seizures

The dosage of 2-PAM is 1 to 2 g I.V. initially, followed by a continuous infusion of 200 to 500 mg/hr, depending on the patient's response. The infusion should be continued until the patient can be weaned from the drug without experiencing recurrence of weakness or muscarinic manifestations. This process may take several days in persons who have been exposed to highly lipid-soluble agents such as fenthion or dichlorvos.[7] A so-called intermediate syndrome has been described in which some patients experience recurrent muscle weakness several days after initially successful treatment[127]; this syndrome may be caused by neurotoxic components of the agent, continued toxicity from a lipid-soluble product, or inadequate 2-PAM therapy.

SALICYLATES

Aspirin (acetylsalicylic acid) and other salicylates are widely used for their antipyretic, anti-inflammatory, and analgesic effects and can be found alone or in combination in a number of prescription and over-the-counter products (e.g., oil of wintergreen, Pepto-Bismol). Salicylates interfere with the metabolism of glucose and fatty acids; they also uncouple oxidative phosphorylation, leading to inefficient production of adenosine triphosphate, accumulation of lactic acid, and production of heat. Poisoning may result from an acute single ingestion (usually in a dose > 200 mg/kg) or from long-term overmedication.[128] Long-term poisoning occurs most commonly in elderly persons who regularly take large doses of aspirin (e.g., for osteoarthritis) and who gradually begin to take larger doses or in whom renal insufficiency develops. In such cases, the diagnosis of salicylism is often overlooked, and patients may be assumed to have sepsis, gastroenteritis, or pneumonia on admission to the hospital.[128]

Diagnosis

The most common initial manifestation of salicylate poisoning is hyperventilation, which occurs largely as a result of central stimulation of the respiratory drive and partly in response to metabolic acidosis. Measurement of arterial blood gases usually reveals respiratory alkalosis with predominant alkalemia and underlying metabolic acidosis. Other findings include tinnitus, confusion, and lethargy. Patients with severe intoxication may experience coma, seizures, hyperthermia, noncardiogenic pulmonary edema, and circulatory collapse. The serum salicylate level in such cases usually exceeds 100 mg/dl (1,000 mg/L), although patients with chronic intoxication may experience severe effects with much lower serum levels.[129]

Treatment

For patients with an acute ingestion, activated charcoal

should be administered and gastric lavage considered if the ingestion was large (e.g., > 10 to 15 g). Because salicylates cause pylorospasm and delay gastric emptying, lavage may be successful even after a delay of several hours. For a patient who has taken a massive ingestion, extra dosages of activated charcoal (50 to 60 g every 4 to 6 hours for the first 1 to 2 days) may be needed to achieve the desired 10-to-1 ratio of charcoal to drug. Massive ingestions, as well as those involving enteric-coated aspirin, may lead to prolonged or delayed absorption and the potential for catastrophic worsening after 1 to 2 days.[128] In such cases, close observation of the patient should be maintained, and measurement of the serum salicylate level should frequently be performed until the level clearly drops into the therapeutic range (10 to 20 mg/dl).

Enhanced elimination procedures can effectively reduce elevated salicylate levels. Alkalinization of the urine traps the ionized form of salicylate in the kidney tubules, increasing renal elimination.[120] To initiate alkalinization, the physician should add 100 mEq of sodium bicarbonate to 1 L of 5% dextrose in quarter-normal (0.225%) saline, then infuse the solution at 200 ml/hr while monitoring the pH of the urine (the goal is to achieve a pH of 7 to 8). It may be difficult to perform alkalinization in patients with volume and potassium deficits without first replacing these losses. Hemodialysis rapidly lowers serum salicylate levels and can restore fluid and electrolyte balances. Hemodialysis is recommended for patients who are unable to tolerate fluid challenges (e.g., as in cerebral edema or pulmonary edema) and those who have worsening renal insufficiency, severe metabolic acidosis, or a serum salicylate level greater than 100 mg/dl (1,000 mg/L).

SEDATIVE-HYPNOTIC AGENTS

The sedative-hypnotic agents include the barbiturates (e.g., phenobarbital, pentobarbital, butalbital, and amobarbital) and the benzodiazepines (e.g., alprazolam, diazepam, lorazepam, and triazolam), as well as several other drugs, such as meprobamate, glutethimide, ethchlorvynol, chloral hydrate, zolpidem, zaleplon, and buspirone. These drugs cause generalized depression of CNS activity and are commonly used to alleviate anxiety or to induce sleep. The mechanisms of action and pharmacokinetics are different for each drug group.[13,130,131]

Diagnosis

Overdose of a sedative-hypnotic drug causes lethargy, ataxia, and slurred speech. In patients with severe poisoning, coma and respiratory arrest may occur, especially when sedative-hypnotic drugs are combined with other depressants, such as ethanol. The blood pressure and pulse rate are usually decreased, the temperature may be low because of exposure and venodilatation, and the pupils are usually small (although they may be dilated in patients with glutethimide overdose). Patients who are in a deep coma may appear to be dead because they may have absent reflexes, fixed pupils, and even flat EEG tracings.[132] In patients with chloral hydrate overdose, ventricular ectopy and ventricular tachycardia may develop; these effects are caused by generation of the metabolite trichloroethanol, which, like other chlorinated hydrocarbons, can sensitize the myocardium to the effects of epinephrine.[133] In cases of phenobarbital overdose, blood levels of the drug can be obtained in most hospital laboratories, but in cases of overdose of most of the other sedative-hypnotic agents, blood levels are neither clinically useful nor readily available.

Treatment

An unobstructed airway should be maintained and supplemental oxygen should be administered. The trachea should then be intubated and assisted ventilation initiated, if necessary. Uncomplicated hypothermia should be treated with gradual passive external rewarming. I.V. crystalloids should be administered to patients with low blood pressure; if necessary, dopamine and other pressor agents should be given. For patients with ventricular arrhythmias caused by chloral hydrate overdose, propranolol (1 to 5 mg I.V.) or esmolol (25 to 100 μg/kg/min) should be given.[134] Activated charcoal should be administered. For cases of massive ingestion, gastric lavage should be considered.

Flumazenil is a specific benzodiazepine antagonist that has been proved effective in reversing the coma caused by benzodiazepine overdose. It has a rapid onset of action after I.V. administration (0.5 to 3.0 mg); because its effects last for only about 2 to 3 hours, resedation may occur. Flumazenil is contraindicated in patients with a known or suspected overdose of a tricyclic antidepressant and in patients who have been given a benzodiazepine for the control of status epilepticus, because flumazenil may induce seizures in these patients. It should also not be used in patients who have increased intracranial pressure and who are receiving benzodiazepines for sedation. The use of flumazenil in persons who have been taking large quantities of benzodiazepines for long periods may provoke an acute withdrawal syndrome.[5,7,8]

Enhanced removal procedures are rarely needed in patients with sedative-hypnotic overdose because most will recover with airway management, assisted ventilation, and other supportive measures. When supportive measures fail, hemodialysis can effectively reduce blood concentrations of phenobarbital.[134]

THEOPHYLLINE

Although no longer a first-line drug, theophylline is still occasionally used for the treatment of asthma and other bronchospastic disorders, congestive heart failure, and neonatal apnea. It is available in regular and sustained-release formulations for oral use. Aminophylline, the ethylenediamine salt of theophylline, is used for I.V. infusions. Theophylline intoxication may occur after an acute single overdose or as a result of long-term overmedication.[135] Chronic intoxication may also be caused by reduced theophylline metabolism resulting from the addition of an interfering drug (e.g., cimetidine or erythromycin) or from an intercurrent illness (e.g., congestive heart failure or liver failure). The normal elimination half-life, 4 to 6 hours, may be prolonged to more than 20 hours in theophylline overdose.

Diagnosis

Acute theophylline overdose causes vomiting, tremors, and tachycardia. Laboratory findings include hypokalemia, hypophosphatemia, and hyperglycemia. These metabolic effects, as well as tachycardia and vasodilatation, are thought to be mediated through excessive $beta_2$-adrenergic stimulation. If serum theophylline levels exceed 100 mg/L, seizures, hypotension, and ventricular arrhythmias are likely to develop.[135] The seizures are often refractory to anticonvulsant therapy. Serum drug levels may not peak for 16 to 24 hours after theophylline ingestion, especially if the drug was in a sustained-release formulation.

Chronic intoxication may develop gradually, with toxicity possibly occurring at serum drug levels that are much lower than those associated with acute overdose: seizures have been

reported to occur at levels as low as 14 to 35 mg/L.[135] Unlike the findings in acute overdose, hypokalemia and hypotension are not common.

Treatment

In cases of acute ingestion of theophylline, activated charcoal should be given. Gastric lavage should be considered for large ingestions (i.e., more than 15 to 20 tablets). However, it is unlikely that lavage will remove intact sustained-release tablets, and severe or fatal intoxication may ensue despite aggressive attempts at decontamination.[136] Although some toxicologists have suggested administering repeated doses of activated charcoal in combination with whole bowel irrigation for massive ingestions of sustained-release medications, this approach remains controversial.[136]

Hypotension should be treated with esmolol (25 to 100 μg/kg/min) rather than a beta-adrenergic agonist because the hypotension is probably caused by beta$_2$-adrenergic–mediated vasodilatation.[137] Seizures should be treated with phenobarbital (15 to 20 mg/kg I.V.) rather than with phenytoin, which is ineffective.[136] For patients with recurrent seizures and for those with serum theophylline levels of around 100 mg/L or greater, excess theophylline should be removed as quickly as possible by hemodialysis or hemoperfusion.[138] Administration of multiple repeated doses of activated charcoal [*see* Enhanced Elimination, *above*] can effectively shorten the elimination half-life of theophylline, but such administration is often not practical in the critically ill patient.

TRICYCLIC ANTIDEPRESSANTS AND RELATED COMPOUNDS

Tricyclic antidepressants, also known as cyclic antidepressants, were once a leading cause of seizures and death from acute drug overdose.[134] Although most of the newer SSRI antidepressants are much less toxic [*see Table 16*], tricyclic antidepressants are still commonly used for the treatment of depression, enuresis, and other disorders.

The toxicity of the tricyclic antidepressants is caused by various pharmacologic properties of this class of agents, including anticholinergic activity, inhibition of norepinephrine reuptake, alpha-adrenergic blockade, and, most important, depression of the fast sodium channel in cardiac cells (the so-called quinidine-like or membrane-depressant effect). This last property is responsible for prolongation of conduction and depressed cardiac contractility.[139] Ingestion of approximately 1 g of a tricyclic antidepressant is likely to produce severe toxicity.

Diagnosis

Initially, persons with tricyclic antidepressant overdose have anticholinergic signs, including tachycardia; dilated pupils; reduced peristalsis; muscle twitching; and dry, flushed skin. Lethargy and slurred speech are common. The abrupt onset of seizures, coma, and hypotension signals severe toxicity, which may occur within 30 to 60 minutes of ingestion or may be delayed because of slowed gut absorption. In patients with severe intoxication, the ECG shows a QRS complex that is usually wider than 0.12 second[139,140]; however, this finding may initially be absent if the drug has not been absorbed or in cases of overdose with amoxapine or another noncardiotoxic drug. In some patients, right-axis deviation of the terminal 40 msec of the QRS complex may represent early evidence of a conduction disturbance.[140] Death may result from profound depression of cardiac conduction and contractility; respiratory arrest; or complications of pulmonary aspiration, aspiration pneumonia, or hyperthermia (caused by muscle twitching and seizures coupled with the absence of sweating).

Table 16 Common Tricyclic and Other Antidepressants

Tricyclic antidepressants and related agents (may induce cardiotoxicity, including widening of the QRS complex)
- Amitriptyline
- Desipramine
- Doxepin
- Imipramine
- Maprotiline
- Nortriptyline

Newer-generation antidepressants (cardiotoxicity is unlikely but seizures may occur)
- Amoxapine
- Bupropion
- Fluoxetine
- Paroxetine
- Sertraline
- Trazodone
- Venlafaxine

Treatment

The physician should administer activated charcoal. Gastric lavage should be considered for patients with massive ingestions (e.g., > 4 to 5 g), especially if less than 1 hour has elapsed since the overdose. All patients should be monitored closely for at least 6 hours; any person with altered mental status, evidence of anticholinergic toxicity, or cardiac conduction abnormalities should be admitted to the hospital and monitored closely. The physician should maintain an unobstructed airway, intubate the trachea, and assist ventilation if needed.

Seizures should be treated with benzodiazepines and phenobarbital (see above). Physostigmine should not be administered, because it may cause seizures and can worsen cardiac conduction disturbances. Initially, hypotension should be treated with I.V. boluses of normal saline. If there is evidence of depression of the sodium channel (i.e., a wide QRS complex), sodium bicarbonate should be administered at a dosage of 50 to 100 mEq I.V.[11,139] Repeated doses may be given as needed, although the serum pH should be monitored for excessive alkalemia. If hypotension does not respond to administration of fluids and sodium bicarbonate, dopamine or norepinephrine should be given. Norepinephrine may be more effective than dopamine in some patients, possibly because of tricyclic antidepressant–induced depletion of norepinephrine, but in one study, no difference between these agents was found.[139] Partial cardiopulmonary bypass has been suggested for patients with refractory hypotension and agonal cardiac rhythm, although there is little likelihood of survival.[12] There is no known role for hemodialysis in this setting.

Food Poisoning

A variety of toxins may produce illness after consumption of fish, shellfish, or mushrooms. Illness caused by bacterial or viral contamination of food, including botulism, is discussed elsewhere [*see 7:V Anaerobic Infections*].

SEAFOOD

The mechanism of toxicity varies with each toxin [*see Table 17*]. In general, the seafood-associated toxins are heat stable; therefore, cooking does not render the food safe to eat. In some cases (e.g., ciguatera and paralytic shellfish poisoning [PSP]), the poisons are highly potent neurotoxins elaborated by dinoflagellates, which are then consumed by fish or concentrated by filter-feeding clams and mussels. Scombroid poisoning results from bacterial overgrowth in inadequately refrigerated fish (although the fish may look and smell fresh); scombrotoxin is a mixture of histamine and histaminelike compounds produced by the breakdown of histidine in the fish flesh. Tetrodotoxin is produced by microorganisms associated with the puffer fish (as well as the California newt and some species of South American frogs) and concentrated in various internal organs. Although the fish is deadly and ranks as the leading cause of fatal food poisoning in Japan, it is also considered a delicacy; extreme care is required in preparation of this fish by specially trained chefs to separate the edible muscle from the toxin-containing organs. Poisoning from saxitoxin (the culprit in PSP) has recently been reported in persons who ate puffer fish caught in waters near Titusville, Florida.[141]

Diagnosis

Signs and symptoms of seafood poisoning vary with the toxin [*see Table 17*]. Diagnosis is based on the clinical presentation and history of ingested seafood. In some cases, laboratory confirmation can be carried out with the assistance of the regional or state health department.

Treatment

In general, treatment is supportive. For neurotoxic poisonings such as PSP and tetrodotoxin, prompt medical attention may be required to prevent death from sudden respiratory arrest. Scombroid poisoning is often treated with H_1 and H_2 histamine blockers (e.g., diphenhydramine and cimetidine). For ciguatera poisoning, previous anecdotal reports have suggested benefit from mannitol, but a recent randomized, controlled blinded trial showed that mannitol did not relieve symptoms of ciguatera poisoning and resulted in more side effects than normal saline.[142] Ciguatera poisoning can produce chronic symptoms, which may resemble multiple sclerosis or chronic fatigue syndrome.[143] Improvement in chronic symptoms has been reported in patients treated with amitriptyline or fluoxetine[144,145]; polyneuropathy has responded to gabapentin.[146] Recurrence of symptoms, which may be worse than the initial attack, can be triggered by ingestion of fish or alcohol.

AMANITA PHALLOIDES MUSHROOMS

The *A. phalloides* mushroom ("death cap") has been known and feared for at least two millennia and continues to cause serious illness and death, although in recent years, mortality has declined because of the availability of orthotopic liver transplantation for patients with fulminant liver failure. This mushroom, as well as several others that contain the cellular toxin amanitin (also known as amatoxin), are found throughout Europe and the United States. Most victims are amateur or novice mushroom hunters who mistake this mushroom for another, edible species. The toxin is heat stable and is not destroyed by cooking. Once absorbed, it binds to RNA polymerase and inhibits cellular protein synthesis. Hepatocytes and rapidly dividing cells are most sensitive.

Diagnosis

Severe abdominal cramps, vomiting, and diarrhea begin about 8 to 12 hours or longer after a meal. Diarrhea can be so severe that it results in severe volume depletion and cardiovascular collapse. After apparent recovery from the gastrointestinal syndrome, patients can develop rapidly progressive hepatic failure.

Treatment

Treatment of suspected amatoxin poisoning includes aggressive fluid replacement and administration of activated charcoal by mouth to bind any unabsorbed toxin in the gut and to prevent enterohepatic reabsorption, which can be significant.[147] Patients who develop severe liver injury with encephalopathy are candidates for emergency liver transplantation. Various antidotes have been described over the years, including high-dose intravenous penicillin G, corticosteroids, thioctic acid, and silibinin (an extract of the milk thistle plant), but none have proved to be effective in controlled studies, and neither thioctic acid nor silibinin is available as a pharmaceutical in the United States.[147] (Milk thistle extract can be found in some stores selling dietary and nutritional supplements, however.)

MONOSODIUM GLUTAMATE

Monosodium glutamate (MSG) is a food additive used to enhance flavor and add body to prepared foods. It is also found as a component of hydrolyzed vegetable protein. Consumption of MSG can invoke, in susceptible persons, a syndrome originally

Table 17 Seafood Poisonings[170]

Type	*Onset*	*Common Sources*	*Syndrome*	*Treatment*
Ciguatera	1–6 hr	Barracuda, red snapper, grouper	Gastrointestinal upset, paresthesias, sensation of hot and cold reversal, itching, weakness, myalgias, orthostatic hypotension	Supportive; ?mannitol
Paralytic shellfish poisoning	30 min	Bivalve mollusks (mussels, clams), associated with algae bloom (red tide)	Gastrointestinal upset, paresthesias, ataxia, weakness, respiratory muscle paralysis, respiratory arrest	Supportive
Scombroid	Minutes to hours	Tuna, mahi-mahi, bonito, mackerel	Gastrointestinal upset, flushed skin, urticaria, wheezing	Antihistamines
Tetrodotoxin	30 min	Puffer fish (fugu), sunfish, porcupine fish	Vomiting, paresthesias, perioral tingling, muscle weakness, respiratory paralysis, respiratory arrest	Supportive

coined the Chinese-restaurant syndrome and now known as the MSG symptom complex. The syndrome, which begins about 15 to 30 minutes after ingestion, includes a burning sensation or pressure in the face, behind the eyes, and in the chest, neck, shoulders, forearms, and abdomen. Headache, syncope, and, rarely, cardiac arrhythmias have been described. Not everyone who ingests MSG experiences the reaction. The etiology of the syndrome is not clearly understood. Symptoms usually last no more than 2 to 3 hours, and there is no specific treatment.[148,149]

HERBAL REMEDIES AND DIETARY SUPPLEMENTS

In 2002, about 62% of adults in the United States reported using at least one form of alternative medicine within the previous year[150] [*see CE:XII Complementary and Alternative Medicine*]. Herbal products are not subject to FDA approval, because they do not undergo the scientific testing required of conventional therapies. They cannot be promoted specifically for treatment, prevention, or cure of a disease. However, the Dietary Supplement Health and Education Act of 1994 allows these products to be sold and labeled with statements describing their professed effects. With the increasing use and availability of herbal medications, poison-control centers and health care providers are commonly encountering patients with adverse effects from impure products, drug interactions, and intentional ingestions. Ginkgo biloba has been suggested to have antiplatelet effects, and cases of spontaneous hyphema and bilateral subdural hematomas have been reported.[151] The additional risk of warfarin must be considered in patients taking Ginkgo biloba. Ephedra (ma huang) is a common ingredient in herbal weight-loss products (herbal fen-phen), stimulants (herbal ecstasy), decongestants, and bronchodilators. The active moiety in ephedra is ephedrine and related alkaloids. Serious adverse reactions, including hypertension, seizures, arrhythmias, heart attack, stroke, and death, have been reported.[152] In 2004, the FDA declared dietary supplements containing ephedra to be unsafe and banned ephedra-containing supplements.[153] However, a federal judge reversed the ban in early 2005; the future of this substance remains uncertain. St. John's wort (*Hypericum perforatum*), touted as a natural antidepressant, has been shown to inhibit serotonin, dopamine, and norepinephrine reuptake and thus presents the possibility of interaction with MAO inhibitors and other serotoninergic drugs.[152]

Adverse events associated with most herbal products are largely undescribed, and there are few specific antidotes. Emergency and supportive measures should therefore be instituted as necessary [*see* Management of Common Complications, *above*]. To enhance research and knowledge in this area, all such events should be reported to poison-control centers and to the FDA's MedWatch Program (800-FDA-1088; http://www.fda.gov/medwatch).

Smoke Inhalation

Smoke inhalation injury is the most common cause of mortality among fire victims, accounting for up to 75% of deaths.[90] Fires produce heat and smoke, although the latter is the chief culprit in inhalation injuries.[154] Smoke comprises a varying mixture of particles and gaseous chemicals that are pyrolysis products of substances that become toxic only when burned.[155] Smoke components can be broken down into simple asphyxiants, chemical asphyxiants, and irritants. Simple asphyxiants (e.g., methane and carbon dioxide) displace oxygen, thus decreasing fraction of inspired oxygen (F_IO_2) and resulting in hypoxemia. Chemical asphyxiants (e.g., carbon monoxide, cyanide, and hydrogen sulfide) cause systemic toxicity and cellular hypoxia by interrupting transport or utilization of oxygen [*see* Specific Drugs and Poisons, *above*].

Irritant gases have a direct cytotoxic effect on the oropharynx and the respiratory tract. Toxicity depends on the physical and chemical properties of the gas, which are often divided into two major groups on the basis of their water solubility. Highly water-soluble gases (e.g., ammonia, acrolein, hydrogen chloride, and sulfur dioxide) are readily absorbed in the mucous membranes along the upper respiratory tract, causing local irritation of the eyes, nose, and throat. Compounds with intermediate solubility (e.g., chlorine and isocyanates) cause upper and lower respiratory tract injury. Substances that are less water soluble (e.g., phosgene and nitrogen dioxide) do not dissolve readily in the mucous membranes of the upper respiratory tract and can reach the distal airway, producing delayed-onset pulmonary toxicity.[90,155]

Diagnosis

Clinical symptoms vary with the location of tissue injury, which in turn depends on the solubility and the concentration of exposure. Manifestations of toxicity may include conjunctival irritation, rhinitis, oropharyngeal erythema and burns, coryza, hoarseness, stridor, wheezing, coughing, and noncardiogenic pulmonary edema. Onset of pulmonary edema may be delayed from 12 to 24 hours or longer when the patient has been exposed to low-solubility gases such as phosgene and nitrogen dioxide.[90]

Treatment

Management at the scene of the exposure should include evacuation of all persons from further exposure to the smoke. Rescuers should take precautions to avoid personal exposure and should use a self-contained breathing apparatus. Although the clinician rarely has access to information regarding the constituents of the smoke, initial treatment of all victims should focus on the airway [*see* Initial Stabilization, *above*]. All patients should receive supplemental oxygen in the highest concentration while arterial blood gas and carboxyhemoglobin levels are pending [*see* Carbon Monoxide, *above*]. For patients who do not require immediate airway protection (e.g., those who are without respiratory distress, coma, or stridor), a careful plan should be sought for identifying those at high risk for potential deterioration. Many authors recommend fiberoptic bronchoscopy to help identify supraglottic and subglottic airway injury.[90] An important caveat is that lack of upper airway injury (e.g., oropharyngeal burns or singed nasal hairs) neither precludes nor predicts future airway demise. Patients should be risk-stratified on the basis of history (e.g., closed-space fire, particular materials in the fire, loss of consciousness, or history of reactive airway disease) before final disposition. Patients with any sign of airway injury or clinically significant smoke inhalation should be observed overnight. A normal initial chest radiograph is not a reliable indicator of pulmonary injury.[156] If exposure to a low-solubility toxin is likely (e.g., phosgene or nitrogen dioxide), manifestation of pulmonary injury may be delayed for 12 to 24 hours. Bronchodilators should be used for bronchospasm, but unlike treatment of patients with asthma and chronic obstructive pulmonary disease, use of steroids has not been shown to be beneficial in patients with smoke inhalation.[90] Patients with suspected cyanide poisoning should receive sodium thiosulfate [*see* Cyanide, *above*].

Kent R. Olson, M.D., has served as a paid expert consultant to McNeil Con-

sumer Products, the makers of Tylenol-brand acetaminophen.

Manish M. Patel, M.D., has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

Mammalian Bites

EPIDEMIOLOGY

There were an estimated four and a half million cases of dog bites in the United States in 1994, the most recent year for which published statistics are available.[1] Over a lifetime, over half of all Americans are bitten by a dog or cat.[2] Although the majority of victims with bite wounds treat themselves, nearly 370,000 dog-bite victims required medical attention in an emergency department in 2001.[3] This is an increase of 10% to 15% over that reported for 1992 to 1994.[4] The highest incidence of dog-bite injuries is in boys 5 to 9 years of age (60.7 per 10,000 person-years).[4] Children are also more likely to be bitten on the face, head, and neck than are adults.[4] Infection, the most common complication of bite wounds, arises from microbes either on the victim's skin or in the mouth of the human or animal inflicting the bite wound. The relative risk of infection is determined by a number of factors, including the species of animal inflicting the wound, the location of the bite, the size and depth of the wound, host factors, and the type of wound care given.[5-7] Most infections that result from mammalian bites are polymicrobial, with mixed aerobic and anaerobic species.[8] Nonetheless, certain species tend to cause infections with characteristic bacteriologic pathogens. In addition, transmission of the rabies virus may occur through bites from mammals of certain species.

DOMESTIC ANIMALS

Dog Bites

Dogs are responsible for more bite wounds in patients who seek medical attention than all other animals combined.[9] Most bites are inflicted by animals known to the victim, with strays accounting for less than 10% of reported bite-wound injuries.[9] Wounds occur most frequently on the extremities, except in young children, in whom bite wounds to the face, head, and neck are most common.[4,10] Specifically, bite wounds to the hand occur in anywhere from one fifth to one half of reported cases; such wounds are associated with an increased risk of infection, particularly tenosynovitis, closed-space compartment infection, and septic arthritis.[11] Although deaths from dog attacks are rare, this tragic scenario occurs about 12 to 15 times a year in the United States (238 dog-bite–related deaths from 1979 through 1998). Pit-bull–type dogs and Rottweilers are responsible for over half of the reported deaths.[12]

The oral bacterial flora of dogs includes *Pasteurella multocida*, *Staphylococcus aureus, Capnocytophaga canimorsus, S. epidermidis, Streptococcus* species, and a number of anaerobes. Mixed aerobic and anaerobic infection is present in about half of infected dog bites.[8] The aerobic organisms most commonly isolated from infected dog bites include *Pasteurella*, *Staphylococcus*, and *Streptococcus* species.[8,13] The anaerobic organisms most commonly isolated from dog bites include *Fusobacterium, Bacteroides, Porphyromonas*, and *Prevotella* species.[8,13] Anaerobic organisms are significantly more common in cultures from abscesses than from other types of infection.[6]

Dog bites are unlikely to become infected, with infection rates usually reported to be on the order of 5% to 10%.[14,15] However, the risk of infection is higher in older persons and in persons with diabetes, vascular disease, chronic alcoholism, or immunosuppression. Infection risk is also higher in puncture wounds, in wounds on the hand or foot or over a joint, and in wounds associated with crush injuries.[11]

Dog bites infected with *Capnocytophaga canimorsus* may cause an overwhelming sepsislike picture associated with high fever, leukocytosis, disseminated intravascular coagulation (DIC), and multiorgan failure. This complication of dog-bite injuries is seen most commonly in immunocompromised patients (e.g., those with asplenia, alcoholism, or hematologic malignancy) and carries a 25% mortality.[11]

Globally, dogs are the major reservoirs for rabies.[16] In developed countries, however, vaccination programs have reduced the prevalence of canine rabies; for example, only 117 rabid dogs were reported in the United States in 2003.[17] Rabies is discussed in detail elsewhere [*see 7:XXXI Viral Zoonoses*].

Cat Bites

Cat bites are the second most common mammalian bites in the United States, accounting for 5% to 15% of all reported bites. About two thirds of all cat bites occur on the upper extremity. Cat bites are more often puncture wounds than tearing lacerations and often appear innocuous initially. However, the infection rate for cat bites is reported to be 15% to 30%, or almost triple that for dog bites.[18,19] *P. multocida* is the major pathogen associated with cat bites, being found in about three fourths of infected cat-bite wounds.[8] *P. multocida* infection progresses rapidly, with pain, swelling, and erythema usually occurring within 24 hours.[9] The types of anaerobic organisms found in cat bites are similar to those found in dog bites (see above), although anaerobic isolates are somewhat more common in cat bites. Penetration into deep tissues with resultant osteomyelitis or septic arthritis is more common with cat bites than dog bites.[13] Cat-scratch disease (CSD) is an infection arising from a rickettsia-like organism, *Bartonella henselae*; CSD is discussed in detail elsewhere [*see 7:XI Infections Due to Brucella, Francisella, Yersinia pestis, and Bartonella*].

Cats continue to outnumber dogs by more than 2 to 1 as the most common domestic rabid animal.[15,20] Overall, however, domestic animals account for only a small minority of animal rabies cases in the United States; about 90% occur in wildlife [*see 7:XXXI Viral Zoonoses*].

Ferret Bites

Ferrets have become increasingly popular as pets; a 1996 survey suggested that there are almost 800,000 ferrets in the United States.[21] Ferret attacks are uncommon but can result in severe injury, especially to infants and small children.[22,23] These attacks (in contrast to dog or cat bites) are usually unprovoked.[22,23]

The bacteriologic flora in ferrets has not been well studied. One study showed that facultative anaerobic gram-positive cocci were the predominant organisms, followed by *Pasteurella* and *Corynebacterium* species; few strict anaerobes were detected.[24]

Ferrets are clearly capable of contracting and carrying the ra-

bies virus.[25] However, it is not known how long infected ferrets can shed virus before showing clinical signs of disease, thus making quarantine recommendations problematic. Although there is an approved rabies vaccine for use in ferrets, its efficacy in preventing rabies is currently not known.[26] For ferret bites involving animals suspected of being rabid, current recommendations are to give the patient rabies postexposure prophylaxis immediately. For cases involving ferrets that are not suspected of being rabid, the recommendation is to withhold vaccination and to observe the animal for 10 days; the patient should be vaccinated only if the animal shows signs of rabies during that period.[27]

HUMAN BITES

Human bites are the third most common mammalian bite in the United States, accounting for approximately 5% to more than 20% of bite wounds seen in urban emergency departments.[11,18,28] Most human-bite wounds occur on the extremities, with an unusually high percentage being over the metacarpal-phalangeal joint secondary to a clenched fist contacting a tooth. Traditionally, human-bite wounds have had a reputation for frequent and severe complications. Current data, however, suggest an infection rate from human-bite wounds on the order of 10% to 50%, depending on the wound type and location.[11,16,28] Occlusional/simple bite wounds to areas other than the hand probably are no more at risk for infection than any other type of bite wound and minimally more than for nonbite lacerations.[11,16,17,29,30] However, human-bite wounds to the hand are associated with infection rates of almost 50%.[18] A clenched-fist injury is considered the most serious of all human-bite wounds.[1] These injuries may appear innocent at first but progress to serious infections that may include the joint, tendons, or various compartments of the hand. These injuries require meticulous wound care, appropriate antibiotic therapy, and consultation with a hand surgeon. Bacterial pathogens associated with human-bite wounds include a number of anaerobes similar to those recovered from dog and cat bites, but with a much higher percentage of β-lactamase producers.[19,31,32] The predominant aerobes are *Staphylococcus* and *Streptococcus* species. About 10% to 30% of human-bite wounds have been shown to contain *Eikenella corrodens,* a facultative anaerobe.[18,28,33,34] *E. corrodens* is present in 25% of clenched-fist injuries and often causes serious, chronic infections.[34] Besides bacterial infection, human bites can transmit the hepatitis B virus, HIV, herpes simplex virus, tuberculosis, and even syphilis.[11,13,28,35] Prophylactic therapy against hepatitis B or HIV should be considered for patients bitten by persons considered at high risk for these diseases.

NONDOMESTIC ANIMALS

Rats

Rat bites are uncommon, representing less than 2% of the bite wounds seen in one urban emergency department.[36] Although the list of potential pathogens that could be transmitted from rat bites is daunting, infections from rat bites, including rabies, are, in fact, very infrequent.[37] Rat-bite fever is a disease caused by *Streptobacillus moniliformis,* a gram-negative rod. It is associated with fever, chills, headache, myalgia, and rash and usually begins abruptly about 3 to 10 days after inoculation [*see 7:VII Lyme Disease and Other Spirochetal Zoonoses*].

Bats

Although bat bites typically produce only trivial trauma, bat bites were responsible for almost 75% of all human rabies cases reported in the United States since 1990 and for 90% of all cases acquired in the United States from 1981 through 1998.[37,38] Studies suggest that cleaning a bite wound with soap and a virucidal agent is effective in lowering the risk of rabies transmission.[39] Rabies prophylaxis is recommended for any bat exposures unless immediate brain testing of the animal can be performed.

Table 1 Bite Wounds Requiring Prophylactic Antibiotics

Wound characteristics	Puncture wounds Full-thickness wounds Hand or foot wounds Wounds requiring surgical repair Treatment delay (> 24 hr) Human bites* Cat bites*
Patient characteristics	Age > 50 yr Immunosuppression (e.g., asplenia, alcoholism, corticosteroid use) Diabetes mellitus Peripheral vascular disease

*There is debate, but many authors recommend prophylactic antibiotic treatment for virtually all human and cat bites because of the high rate of infection.

Other Mammals

Skunks, raccoons, and foxes are also important animal reservoirs of rabies in the United States.[38] Bites from raccoons, skunks, and foxes should be regarded as likely to be rabid until proved otherwise, and the use of rabies immune globulin and rabies vaccine is warranted, particularly if rabies is endemic to the area or the animal's behavior is deemed abnormal.[39]

Bite wounds from wild animals are rare; most occur from exposure at zoos or from owning or harboring exotic animals.[40] The incidence of serious injury from wild-animal attacks among the three million visitors to Yellowstone National Park is reported to be lower than the chance of being struck by lightning.[40]

Bite wounds from nonhuman primates are rare. In addition to transmitting bacterial infection, these bites may transmit *Herpesvirus simiae* or monkey B virus [*see 7:XXXI Viral Zoonoses*]. If left untreated, monkey B virus infection often causes encephalitis, resulting in death or permanent neurologic impairment.[41] Monkey B virus is enzootic in North African and Asian monkeys, including the macaque and rhesus. Thorough scrubbing of bites or scratches with soap or detergent and irrigation for 15 minutes have been shown to reduce the viral inoculum.[42]

TREATMENT

The goals of bite-wound care are to recognize and treat serious injury (e.g., nerve or tendon laceration), avoid infection (both local and systemic), and achieve a good cosmetic result. The treatment of mammalian-bite wounds begins with a history and physical examination. The history should include when and where the bite occurred, the events leading to the bite, what type of animal was responsible for the bite, and any background information on the animal. Any treatment rendered before arrival at the facility, as well as the patient's tetanus immunization history, should be documented.

A careful physical examination to assess for arterial or major venous injury and nerve, joint, bone, or tendon involvement should be performed and documented. The wound should be explored for foreign bodies, including teeth or tooth fragments.

Table 2 Common and Important Pathogens and Antibiotic Selection for Various Mammalian Bite Wounds

Animal	*Pathogen*	*Antibiotics*
Dog	*Staphylococcus, Streptococcus, Capnocytophaga canimorsus, Pasteurella multocida,* anaerobes	Amoxicillin–clavulanic acid, third-generation fluoroquinolones, doxycycline*
Cat	*P. multocida, Staphylococcus, Streptococcus,* anaerobes	Amoxicillin–clavulanic acid, third-generation fluoroquinolones, doxycycline*
Human	*Staphylococcus, Streptococcus,* anaerobes, *Eikenella corrodens*	Amoxicillin–clavulanic acid, third-generation fluoroquinolones
