The sequence and structure of MHC molecules have been extensively elucidated, and it has been determined that the polymorphic, or antigenic, portions of MHC molecules are quite small. In fact, the polymorphic portions frequently comprise only one to four amino acid substitutions encoded in regions of DNA nucleotide sequence hypervariability. A specific configuration in an MHC molecule resulting from particular substitutions of amino acids is called an epitope.

MHC class I antigens

MHC class I antigens consist of two polypeptide chains held together noncovalently. One chain is heavy (44 kd) and glycosylated, and it determines antigen specificity. The extracellular portion of this class I heavy chain is divided into three domains, des-

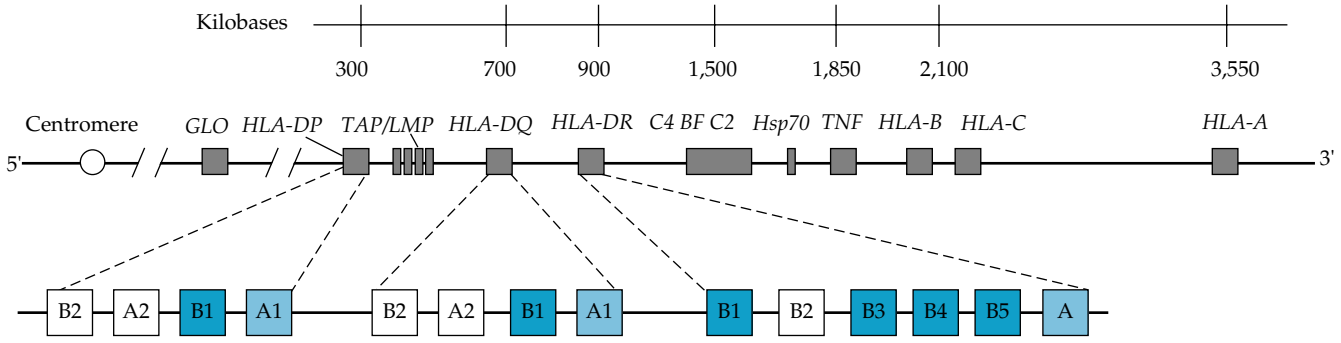

Figure 1 **The best-characterized loci of the human major histocompatibility complex (MHC), located in the *HLA* region of the short arm of chromosome 6, are depicted. Distances are shown in recombination units (centimorgans), as determined by crossover frequencies in family studies, and in kilobases, as determined by sequence analysis of fragments produced by DNAses having defined cleavage sites. MHC class II molecules are encoded in the *HLA-DP*, *HLA-DQ*, and *HLA-DR* genes, and MHC class I molecules are encoded by *HLA-B*, *HLA-C*, and *HLA-A* genes. A cluster of closely linked complement genes—*C4*, *BF*, and *C2*—lies in the center of the region. There are two structural genes for *C4*, interspersed with two genes for the adrenal enzyme 21-hydroxylase. Next is the heat shock protein gene, *Hsp70*, followed by the tumor necrosis factor (TNF) genes, *A* and *B*. The orientation of the complement cluster and the *TNF* cluster has not been established, but an expanded view of this area could be depicted as –(*C4-210HA-C4B-210HB-BF-C2*)–(*HSP70*)–(*TNFA-TNFB*). *GLO* is a marker gene for the enzyme glyoxylase. An expansion of the class II region is in the lower portion of the figure. Each class II molecule is a heterodimer of an α and a β chain, which are encoded in the *A* and *B* genes, respectively. Pseudogenes, which are not expressed on the cell surface, are shown in white boxes. *HLA-DP* and *HLA-DQ* have one expressed heterodimer, A1B1; *HLA-DR* has only one A chain but nine genes for B chains (four are shown in the figure). The principal expressed heterodimers for *HLA-DR* are AB1, AB3, AB4, and AB5. In the region between *HLA-DP* and *HLA-DQ* lie the closely linked *TAP1*, *TAP2*, *LMP2*, and *LMP7* genes. The *TAP* genes encode peptide transporters, whereas the *LMP* genes encode proteosomes that fragment proteins into peptides. This cytoplasmic system is believed to be responsible for production and delivery of peptides to MHC class I molecules before their movement to the cell surface.**

ignated α_1, α_2, and α_3. The other chain is a small (11.5 kd) protein known as β_2-microglobulin [*see Figure 2*]. Class I heavy chains are the gene products of three MHC loci, designated *HLA-A, HLA-B,* and *HLA-C* [*see Table 1*]. There are many alleles for each locus; therefore, considerable polymorphism exists. β_2-Microglobulin is encoded by a gene on chromosome 15. Both the β_2-microglobulin and the α_3 domain of the heavy glycosylated chain of MHC class I antigens demonstrate considerable structural similarity to the constant region of the heavy chain of IgG (C_H3).

MHC class I molecules have been crystallized, and their structure has been determined by x-ray diffraction to a resolution of 3.5 angstroms (Å).[1] Two of the heavy-chain domains, α_1 and α_2, are located at the membrane-distal portion of the heavy chain and form a groove along the top surface of the molecule. The sides of the groove are composed of α helices from the α_1 and α_2 domains, and the base is composed of eight antiparallel β-pleated sheets from these domains. The hypervariable (antigenic) regions are found mostly along the sides of the groove, but there is also variability in the β-pleated sheet region. The rest of the molecule shows minimal variability in relation to other molecules of the same *HLA* locus. In the crystals studied, the groove, which faces away from the cell membrane and is approximately 25 Å long and 10 Å wide, contains material representing processed antigen (i.e., peptide fragments). When peptides eluted from purified class I molecules are sequenced, they show patterns of amino acids, called motifs, that bind to particular sets of HLA class I molecules.[2] These findings helped confirm the hypothesis that MHC molecules bind and present processed antigens to responding T cells and that the T cell receptor (TCR) recognizes foreign antigen as a peptide in the context of self-antigen; that is, it binds to a surface composed of both MHC and a bound peptide.

MHC class I antigens can be expressed on all cell types except erythrocytes and trophoblasts and can be detected by staining with labeled antibodies. Striated muscle cells and liver parenchymal cells are normally negative for class I antigens (i.e., they lack class I molecules or express only a low density of class I molecules), but in inflammatory states, these cells may become strongly positive for class I antigens.

MHC CLASS II ANTIGENS

Some antibodies, elicited by immunizations with histoincompatible cells, react with a limited variety of cells, most notably B cells, monocytes, dendritic cells, and activated T cells. Normally, these cells are the only ones found to bear MHC class II antigens. As is the case with class I antigens, however, inflammatory states cause many tissues to express class II antigens.

Each MHC class II antigen consists of two membrane-inserted glycosylated polypeptides, designated α (34 kd) and β (28 kd), which are bound together noncovalently [*see Figure 2*]. The extracellular portion of the α chain is divided into two domains, designated α1 and α2; the extracellular portion of the β chain is also divided into two domains, β_1 and β_2. Class II antigens are encoded by the *HLA-D* region, which is divided into at least three subregions: *HLA-DP, HLA-DQ,* and *HLA-DR* [*see Figure 1*].

Crystallographic studies indicate that MHC class II molecules have a structure similar to that of MHC class I molecules, with the α_1 and β_1 domains forming a groove in which β-pleated sheets form the base and α helices form the sides.[3] As in MHC class I molecules, the hypervariable (antigenic) regions of MHC class II molecules are located primarily along the groove, which again indicates a molecular basis for TCR recognition of foreign antigen together with self-MHC.

Class II MHC antigens can be identified by the use of sera from multiparous women that react predominantly with B cells. A serum is first exposed to platelets from a pool of many persons, because platelets contain MHC class I, but not MHC class II, antigens and thus will absorb antibodies to class I antigens, leaving antibodies to class II antigens in the serum. The naming of genes from the HLA-D region is now based on knowledge of the biochemistry of expressed antigens and on a growing database of DNA nucleotide sequences. The gene encoding the HLA-DR α chain, for example, is called *DRA*. Similarly, the closely linked genes encoding the β chains have been named *DRB1* (encoding the β chains for DR1 through DR18), *DRB3* (encoding the β chain for DR52), *DRB4* (encoding the β chain for DR53), and *DRB5* (encoding the β chain for DR51). Because *DRB2* expresses no protein product, it is called a pseudogene. Each of the HLA-DR β chains associates with the common nonpolymorphic HLA-DRA α chain to form functional class II HLA-DR molecules. HLA-DRA α chains are always the same; the difference in *HLA-DR* antigenic alleles is accounted for by variations in the genes encoding the HLA-DR β chains. The *HLA-DQ* locus contains the genes *DQA1, DQB1, DQA2,* and *DQB2*. *DQA2* and *DQB2* are pseudogenes, whereas the products of *DQA1* and *DQB1*—that is, the α and β chains of HLA-DQ—are both polymorphic. *HLA-DP* gene organization is similar to that of *HLA-DQ* [*see Figure 1*].

NOMENCLATURE OF HLA ANTIGENS

The nomenclature of the *HLA* system is coordinated through the World Health Organization Nomenclature Committee for Factors of the HLA System.[4] The prefix for the gene name is *HLA*, followed by a hyphen, then a locus name (e.g., *DRB1, DQA2, C*). A specific allele (DNA sequence variant at a locus) is denoted by appending an asterisk to the gene name followed by a unique alphanumeric identifier for that allele. The alphanumeric identifier is composed of up to nine characters: AACCSSXXN, where AA is an integer that refers (when possible) to the serologic family of which the allele is a member; CC is an integer defining the nucleotide coding variant resulting in a unique peptide product; SS is an integer defining synonymous variants (different DNA sequence but same amino acid sequence) of a coding variant; XX is an integer defining variants outside the coding region. An N is appended to the identifier if the allele is a null or nonexpressed variant. Thus, *HLA-DRB1*030502* encodes a DR molecule that is serologically in the DR3 group and has a different amino acid sequence from *DRB1*0301, DRB1*0302, DRB1*0303,* or *DRB1*0304*. It also has a different nucleotide sequence from *DRB1*030501*, but has the same amino acid sequence, making it a synonymous variant.

FREQUENCY OF DIFFERENT HLA ALLELES

Two terms, haplotype and linkage disequilibrium, describe important associations between MHC genes. Haplotype refers to the set of closely linked genes on any one chromosome. Every person has two haplotypes of the MHC, one from each parent. Each haplotype has a particular set of antigens determined by the *HLA-A, HLA-B, HLA-C, HLA-DR*, and other loci.

The second term, linkage disequilibrium, refers to the observation that in a population, some HLA antigens coincide within a single haplotype much more frequently than expected. If discrete genes were distributed independently throughout the population, the frequency at which any two linked antigens encoded at different loci would occur within a haplotype is the product of their frequencies in the population. However, in whites, the

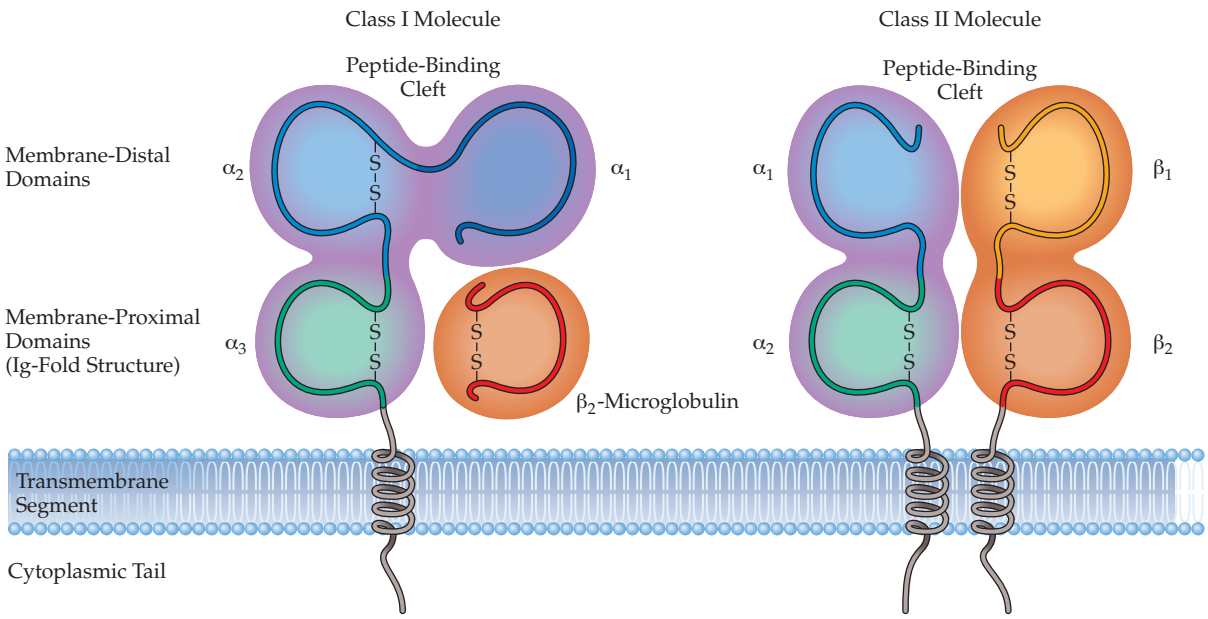

Figure 2 **MHC molecules are of two structural types with very similar peptide-binding sites on the membrane-distal surface. (*a*) MHC class I molecules consist of heavy chains made up of three polypeptide domains (α_1, α_2, α_3) and a noncovalently associated light chain, β_2-microglobulin. (*b*) MHC class II molecules are heterodimers of α and β chains with a very similar overall structure and peptide-binding surface.[20]**

HLA-A1 antigen and the HLA-B8 antigen are associated six to 21 times more often than would be predicted from their gene frequencies. Such linkage disequilibrium may occur because not enough evolutionary time has elapsed for the genes governing the antigens to be evenly distributed or because such an association results in a selective advantage to the individual. Recombination, or crossover, takes place during meiosis and occurs about 1.5% of the time between MHC class I and MHC class II loci. Over many generations, recombination leads to an equilibrium of linked alleles in a population unless selective pressures favor survival of certain haplotypes. A hypothetical example of such selection would be the survival of persons bearing HLA haplotypes that confer resistance to epidemics, such as smallpox and plague. Racial differences are reflected in marked variations in the frequencies of certain HLA antigens and haplotypes. Fewer, though often striking, examples of such differences are also observed in various ethnic groups.[5]

Role of MHC in Immune Response

THE MIXED LYMPHOCYTE REACTION

When lymphocytes from one person are cultured with those from another, the cells are stimulated to divide. This division, which can be measured from the rate of uptake of ^{3}H-thymidine into the cells, is called the mixed lymphocyte reaction (MLR). By preventing the division of one of the sets of cells by treatment with mitomycin or irradiation, it is possible to study the antigens on the membrane of the treated cells that stimulate this proliferative response. In humans, *HLA-DR* antigenic determinants are mainly responsible for evoking a primary MLR. HLA-DQ antigens play a lesser role, and HLA-DP antigens do not appear to be involved in the primary MLR. However, responding lymphocytes that have been primed by previous exposure to HLA-DQ or HLA-DP antigens proliferate vigorously when reexposed to the same antigen in a secondary MLR. The primary MLR is driven by the very high precursor frequency of naive cells having affinity to HLA-DRB1, not by primed memory cells.

ANTIGEN PROCESSING AND PRESENTATION

The breakdown of protein molecules into peptide fragments is an important part of the process by which antigens are presented to T cells and other immune effector cells. MHC molecules come to the cell surface with peptides already bound. Proteins are first degraded internally, and the peptide fragments are bound to MHC class I and MHC class II molecules within the cell. Class I molecules are expressed on virtually all tissues. Virally infected cells are recognized principally by class

Table 1 Antigens of the HLA System

	Antigen	*Number of Antigenic Specificities**	*Number of DNA Variants†*
Class I	HLA-A	22	290
	HLA-B	48	555
	HLA-C	9	140
Class II	HLA-DR (1-18)	17	356
	HLA-D	24 (cellular)	356
	HLA-DR (51-53)	3	76
	HLA-DQ	7	25 (DQA1)
			56 (DPB1)
	HLA-DP	6 (cellular)	20 (DPA1)
			106 (DPB1)

*Antigenic specificities are defined by reactivity with HLA-specific sera from multiparous women (serologic specificity) or by proliferative response of cells (cellular specificity).
†Variants at each locus; most variants result in a different expressed amino acid sequence.

Table 2 Cell-Mediated Lympholysis in a Mixed Culture

*Lymphocyte Antigens Matched between Responder and Stimulator Cells**		*Mixed Lymphocyte Culture Reaction*	*Cell-Mediated Lympholysis*
Class II	*Class I*		
Yes	Yes	No	No
No	No	Yes	Yes
No	Yes	Yes	No†
Yes	No	No	No
{ Yes / No }	{ No / Yes } ‡	Yes	Yes

*The stimulator cells that induce proliferation of the responder T cells in the mixed lymphocyte culture reaction also serve as the targets for the cytotoxic cells that develop from the responder population (as measured by the cell-mediated lympholysis assay).
†Low numbers of cytotoxic T cells may develop against class II antigens.
‡Stimulator cells from two individuals are mixed with responder cells from a single individual.

I–restricted T cells, usually those with a cytotoxic function. In contrast, class II–directed T cells are restricted to antigen-presenting cells of the immune system (i.e., B cells, macrophages, dendritic cells, or Langerhans cells) that are principally concerned with defense against external infectious agents. Because class II–positive cells also carry class I molecules, they may act as antigen-presenting cells for both exogenous and endogenous proteins [*see 6:IV Cell-Cell Interactions, Cytokines, and Chemokines in Immune Response Mechanisms*].

Exogenous and endogenous antigens reach the cell surface by different pathways. Exogenous proteins are taken up into endosomes or lysosomes, where they are catabolized. Peptides from exogenous proteins are generally bound to MHC class II molecules, and the class II–peptide complexes are then brought to the surface for presentation to T cells. Peptides from endogenous proteins (e.g., secretory proteins or products of viral infection) appear to be complexed in the endoplasmic reticulum to MHC class I molecules. Genes called *LMP*, which are also located in the MHC region, encode proteins that are responsible for breaking down proteins into small peptides (eight to 10 amino acids long); closely linked *TAP* genes encode chaperones that transport peptides across intracellular membranes [*see Figure 1*].[6-8] This system delivers peptides of intracytoplasmic origin to newly formed class I molecules. As noted, certain peptide sequence motifs are known to be characteristic of peptides eluted from purified molecules of a given MHC allele.[9,10] These findings indicate that the allelic sequence differences at the margins of the peptide-binding groove determine which peptide sequences will bind. Class I–bound peptides are usually nine amino acids long, with residues at particular locations that have similar charge or hydrophobicity (e.g., at positions 1, 3, and 9) for different groups of *HLA* alleles. In addition, a number of synthetic peptides representing immunogenic portions of infectious agents or other foreign proteins align on similar common motifs. Peptides eluted from purified HLA-DR class II molecules are variable in length, up to 25 residues, and have a minimal length of 13 to 14 amino acids. The motifs for DR1 represent a positively charged residue at position 1, a hydrogen bond donor at position 6, and hydrophobic residue at position 10.[11] Prediction of binding affinity for a given HLA sequence is becoming common practice for development of peptide vaccines and studies of the specific immune response to protein antigens.[10,12]

CLONAL SELECTION OF T CELLS

The corecognition of MHC and peptide fragments of an antigen bound in the groove of the class I or class II molecules appears to require that the binding surface of the TCR and the binding surface formed by MHC plus peptide be attached at multiple points [*see 6:III Adaptive Immunity: Antigens, Antibodies, and T Cell and B Cell Receptors*]. Each T cell clone is specific for a self-MHC–peptide complex and generally does not have sufficient affinity for MHC or peptide to bind well to either component alone. There is extensive evidence that the development of the T cell repertoire in the thymus begins during the fetal period and continues well into adult life as new precursor cells from the bone marrow mature in the thymus. In this process, many potential clones are destroyed and others are selected to mature. The selected T cell clones then leave to populate the rest of the body. The MHC of the host plays the major role in selection: T cell clones that are strongly autoreactive to self-MHC molecules are eliminated, leaving clones with weak affinity to self-MHC to survive. Because the surviving clones have a large variety of T cell receptor rearrangements [*see 6:III Adaptive Immunity: Antigens, Antibodies, and T Cell and B Cell Receptors*], the individual retains the necessary repertoire of T cell clones that can recognize self-MHC plus peptide. The successful crystallization of a complex consisting of a human TCR, its viral peptide, and the HLA-A2 molecule that binds it has revealed the configuration and extent of the binding surface between the TCR and the MHC-peptide surface. The axis of the TCR is diagonal to that of the MHC helices, so that it covers a large portion of both α helices and the peptide between them. Although the extensive MHC polymorphisms increase the likelihood that a particular peptide fragment will be bound so that it can be recognized by T cells, a given individual has a small repertoire of such MHC binding sites compared with the rich combinatorial possibilities in the TCR gene complex. The inheritance of multiple *HLA* loci from two parents, however, increases the potential for recognizing a greater number of different self-MHC–peptide complexes and therefore increases the likelihood that at least some persons will survive a given infection.

The alloresponse, which is the immune response mounted against another individual's cells, is a special case. Except for direct activation of T cell subsets with bacterial superantigens (e.g., staphylococcal exotoxins), the in vitro proliferation of T cells in the MLR is the most vigorous antigen-specific response known because it does not require the priming that is needed to induce proliferation to microbial antigens. Transplantation is, of course, a technological artifact and would not have been encountered during evolution; only pregnancy has the potential for exposing the cells of one person to those of another having different *HLA* haplotypes. The allobarrier could have made pregnancy difficult or impossible except for the presence of several imperfectly defined mechanisms at the placental level that protect the fetus from rejection. The existence of such mechanisms suggests that the need for MHC polymorphisms is most important and requires special protection at the maternal-fetal interface.

Alloreactive T cells are known to either indirectly perceive allo-MHC peptides presented on self-MHC molecules or directly recognize intact allo-MHC molecules that hold a self-peptide.[13] Because a number of peptides derived from endogenous proteins occupy MHC binding sites at all times, such self-peptides need not be polymorphic or unique to an individual. The functional significance of the indirect, as well as the direct, pathways in transplantation has been established. It has been shown in an-

imal models that immunization with synthetic allopeptides alone can cause accelerated graft rejection,[14,15] whereas administration of such peptides by the oral or intrathymic route can increase tolerance for alloantigens. Also, priming to allopeptides presented by self-MHC molecules is a feature of rejection activity in human transplant recipients.[16]

GENERATION OF CYTOTOXIC T CELLS

The MLR leading to the generation of cytotoxic T cells requires two distinct types of responding T cells. The process begins with the stimulating cell—a B cell, dendritic cell, or monocyte—which has both MHC class I and MHC class II molecules on its surface. The class II molecule stimulates subsets of responding T cells to proliferate and become helper T cells. This subset is marked by the CD4 antigen. The class I molecule sensitizes a second subset of T cells, which become cytotoxic T cells if stimulated by the proliferating helper T cells. One of these stimulatory signals is mediated by the lymphokine interleukin-2 (IL-2). This second T cell subset is marked by the CD8 antigen. Cytotoxic T cells that develop against cells that differ only in their class II antigens bear the CD4 marker. The two stimuli—the one that induces helper T cell proliferation and the one that sensitizes T cells to become cytotoxic—can be delivered by different cells [*see Table 2*]. This type of cell interaction and cooperation is thought to mirror in vivo events that lead to graft rejection by cytotoxic T cells, showing why it is desirable to have both class I antigen and class II antigen compatibility between donor and recipient cells.

It was formerly thought that CD4+ T cells were simply helper lymphocytes and that CD8+ T cells were either cytotoxic or suppressor lymphocytes, but these functional divisions do not appear to be clear-cut. Ongoing molecular studies indicate that the CD4 surface molecule is closely associated with the TCR and guides interaction between T cells and antigen-presenting cells by binding to a nonpolymorphic region of MHC class II molecules [*see 6:III Adaptive Immunity: Antigens, Antibodies, and T Cell and B Cell Receptors*]. Similarly, the CD8 molecule binds to MHC class I molecules on antigen-presenting cells. CD4 and CD8 molecules also increase the strength with which the TCR complex binds to the antigen-MHC complex. In addition, these surface molecules participate in signaling activation of the adherent T cell.

Immune Response Genes

As previously mentioned, many lines of evidence indicate that MHC class II molecules are the expressed products of immune response (Ir) genes; in other words, immune responsiveness can be a direct function of antigen presentation. If an antigen fragment is not bound to a class II molecule, a person's immune system is unable to recognize it. Certain diseases in animals—including virally induced forms of leukemia, mammary tumors, and lymphocytic choriomeningitis—have been linked to polymorphism of MHC class II genes. However, the ability of specific HLA antigens to confer susceptibility to clinically important infectious agents has rarely been suggested (see below). It is likely that evolution has resulted in selection of MHC alleles that are capable of binding at least some portions of antigenic molecules on infectious agents. In addition, the duplication of class II genes with expression of HLA-DR, HLA-DQ, and HLA-DP sets of molecules increases the likelihood that a response can be initiated in a given case. In particular, polymorphisms on both α and β chains of HLA-DQ and HLA-DP provide considerable variation in binding configurations, especially

Table 3 Diseases Showing Positive HLA Antigen Association(s)[22]

Type	*Disease*	*Serologic HLA Antigen*	*Relative Risk**
Rheumatologic	Ankylosing spondylitis	B27	90.0
	Reiter syndrome	B27	37.0
	Acute anterior uveitis	B27	8.2

*Relative risk = $\frac{\text{(\% antigen-positive patients) (\% antigen-negative control subjects)}}{\text{(\% antigen-negative patients) (\% antigen-positive control subjects)}}$

when αβ dimers are composed of chains inherited from both parents; for example, $\alpha_{mother}/\beta_{father}$ may provide a peptide-binding molecule not present in either parent. There are also many non-MHC influences on immune responsiveness; none of these have yet been well characterized clinically.

Studies in humans have also suggested the ability of the MHC to suppress immunologic responses to environmental agents, such as streptococcal infection, schistosomiasis, and leprosy, as well as antigens from cedar pollen and hepatitis B vaccine. For example, the in vitro IgE response to cedar pollen antigen is suppressed by T cells of persons bearing HLA-DQ3, but the mechanisms of such T cell–mediated suppression are ill defined.[17,18]

COMPLEMENT FACTOR GENES

Several complement proteins are encoded by genes that are linked to the MHC. These proteins include C2 and factor B (Bf), which are closely linked and also similar in structure, suggesting gene duplication. In addition, two loci for C4 (*C4A* and *C4B*) are closely linked to C2 and Bf. The C2 deficiency associated with systemic lupus erythematosus is associated with the *HLA-A25, B18* haplotype. Indeed, researchers have found extended haplotypes in which the same *HLA-B, HLA-DR, HLA-DQ*, and complement types are found in apparently unrelated persons with the same disease. These circumstances could result from a mutation occurring in a common ancestor. Alternatively, there may be selective pressures to keep in close proximity genes that produce proteins that act together.

NONIMMUNOLOGIC FUNCTIONS OF MHC GENES

MHC genes are possibly also important in a variety of nonimmunologic cell-cell interactions. In 1976, a study showed that when a male mouse was presented with two females in estrus that were genetically identical except in portions of the MHC, the male would most often choose to mate with the female of an MHC type different from his own.[19] Further experiments showed that the male discriminated between MHC types by sense of smell. The advantage most apparent in this example of opposites attracting is that the heterozygosity of genes in the region that encodes for MHC ensures a wider range of immune defenses for the hybrid progeny of such matings. There is no evidence that humans can sense HLA antigens, however.

Disease and the Major Histocompatibility Complex

HLA-ASSOCIATED DISEASE

Many diseases have been associated with certain MHC antigens [*see Table 3*]. Such associations per se show only that the MHC molecules or some other genes closely linked in the HLA region have an influence on initiation or expression of disease. A relative risk of 5, for example, means only that there is a fivefold increase in the likelihood of disease in a person with a particular HLA antigen, compared with someone who does not have that antigen. It indicates nothing about the frequency of the disease itself, which may be rare or common. One explanation for such associations is that the disease in question is related to a deficiency in the immune response to a particular causative organism. There is increasing evidence, however, that organ-specific HLA-associated diseases—such as type 1 diabetes mellitus, multiple sclerosis, Graves disease, the glomerulonephritides, celiac disease, ankylosing spondylitis, and rheumatoid arthritis—have a major component of autoimmunity.

In animal models in which appropriate breeding studies have been done, it has been demonstrated that autoimmune states depend on five to 15 randomly segregating genes, one of which is in the MHC. Polygenic etiology of human autoimmunity is very likely, and the HLA components may be useful targets for intervention, particularly in diseases in which HLA presentation of an immunogenic self-peptide is a key event. Also, with the development of inflammation, de novo expression of HLA class II molecules on tissue cells may provide the immune stimulus for perpetuation of the autoimmune process. For example, patients with thyroiditis show aberrant expression of HLA-DR on thyroid cells, providing a possible mechanism by which thyroid antigen could be presented to T cells.

There has been some progress in discerning which diseases may be directly related to immunogenic peptide presentation. Analysis of the sequences of genes encoding MHC class II molecules from patients with type 1 diabetes mellitus suggests that inheritance of particular HLA alleles is important in determining susceptibility to this disease, involving a T cell–mediated autoimmune response to pancreatic islet cell antigens. Resistance to type 1 diabetes mellitus is strongly associated with the presence of aspartate at position 57 of the *HLA-DQB* chain. In persons with the *HLA-DR2* haplotype, for example, the relative risk for the disease drops to 0.2 [*see Table 3*]. *HLA-DR2* is in linkage disequilibrium with *HLA-DQB* alleles, such as *DQB1*0602*, encoding aspartate at position 57. In contrast, when aspartate is not present at position 57, particularly in persons with the *HLA-DR3* or *HLA-DR4* haplotype, there is an increased risk of type 1 diabetes mellitus. Amino acid residue 57 on the HLA-DQB chain would lie toward one end of the groove; aspartate at that position may influence binding of a peptide to this class II molecule, causing reduction of helper T cell responses or activation of suppressor T cell responses to pancreatic islet cell antigens. Many studies in certain ethnic groups have shown that the greatest susceptibility to type 1 diabetes mellitus is related to *HLA-DQ*. The *DQA/DQB* heterodimer *DQA1*0301/DQB1*0201* is associated with the highest risk. What is of interest here is that this heterodimer is uncommon, occurring mostly in persons who have inherited the *DQA* gene from one parent and the *DQB* from the other. Whereas *DQA1*0301* and *DQB1*0201*, usually found with *DR4* and *DR3* haplotypes, respectively, separately increase the risk for type 1 diabetes mellitus, together they provide the highest risk of disease. As noted previously, the formation of a heterodimer from the products of genes inherited from both parents does occur with the HLA-DQ molecule. The hypothesis is that this "new" peptide-binding site will be most effective in the presentation of pancreatic islet cell autoantigen. Definition of the binding motifs of this site may provide a clue to the antigen. There are additional and independent effects of *HLA-DR*—particularly the *DR4* alleles, some of which are associated with enhancement and others with suppression of the risk for diabetes. Amino acid differences in the hypervariable regions of MHC class II molecules have also been associated with such autoimmune disorders as pemphigus vulgaris and rheumatoid arthritis.

The association of narcolepsy with *HLA-DR2* (*DRB1*1501*) is more than 90%, but the highest association is with *HLA-DQA1*0102/DQB1*0602*. The HLA effect is dominant, not recessive, and there is no indication of an immunologic defect in affected persons. An abnormality in a peptide neurotransmitter or its receptor has been postulated, but the relation to the *HLA-D*–region genes remains elusive.

About 80% to 90% of celiac disease is associated with *HLA-DQA1*0501/DQB1*0201*. The peptide-binding groove of this

molecule is known to bind a peptide of wheat protein gliadin, which is a potentiating if not etiologic factor in this disease.

Although an HLA molecule may determine specificity to a particular autoantigen, it is possible that genes controlling other factors (e.g., the production of antigen receptors, specific subsets of regulatory cells, or helper and suppressor molecules) are responsible for a general tendency toward an abnormal immune response. Additional study of the peculiar role of the HLA system in autoimmunity may well reveal mechanisms of autoimmune disease that are currently unknown.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VII IMMUNOGENETICS OF DISEASE

Edgar L. Milford, m.d.
Charles B. Carpenter, m.d.

Differences in genetic makeup from individual to individual have long been recognized to have physiologic consequences in both health and disease. The recent ability to do high-throughput sequencing of genes has revealed that many genes have variants that are present in a significant proportion of the population. Inherited variants of specific genes, either alone or in combination with other genes, may confer a differential risk of disease or of rejection of transplanted tissue.

Genetic Polymorphism

The fundamental basis of genetic polymorphism in a population is variation of the nucleotide sequence of DNA at homologous locations in the genome. These differences in sequence can result from mutations involving a single nucleotide or from deletions or insertions of variable numbers of contiguous nucleotides. Each of these variants presumably occurred in a single ancestor in the distant past. Most new mutations are extinguished through random genetic drift and never become established in the population at any significant frequency. When the gene frequency of a mutation becomes established at more than 1% to 2%, it is often given the more dignified appellation of allele.

Allelic variants can occur anywhere in the genome. Some are found within coding regions of genes, and others are located in introns or gene regulatory regions. However, still others are found in areas that are not closely linked to any known expressed gene.

Equilibrium, Disequilibrium, Genotypes, and Haplotypes

There can be multiple polymorphic nucleotide positions in or near an expressed gene on the same chromosome. In such cases, it is desirable to know whether specific variants at each of the polymorphic positions are independent of the variants at the other positions. If examination of a population shows that the variants at the different positions occur independently of one another, the system is said to be in Hardy-Weinberg equilibrium.[1] If certain variants at one of the positions are statistically associated with specific variants at another of the linked positions, the system is said to exhibit linkage disequilibrium.[1]

Hardy-Weinberg equilibrium can be reestablished over many generations through recombination events. The closer the polymorphic loci are to each other on the chromosome, the less likelihood there is of a recombination and the more likely it is for the specific alleles at the two linked loci to be inherited en bloc as a haplotype. For example, if there are two polymorphic positions within a gene, each of which has two alleles, a given individual will have up to four definable alleles. These alleles are inherited as two parental haplotypes, each of which carries one allele from each of the two loci. Most methods used to type individuals cannot organize the genotype into haplotypes without additional information. The common assays simply define the genotype at each of the two polymorphic positions. Extensive population studies permit sophisticated maximum-likelihood estimates of haplotype frequencies within the population.[2] These studies, combined with confirmatory cloning and sequencing studies of individual DNA strands, often reveal that some theoretically possible haplotypes never occur, whereas others can be assumed when a specific allele is present (because of linkage disequilibrium) [*see Figure 1*]. The ability to deduce haplotypes provides a much higher degree of specificity to the analysis of genetic polymorphism, because the haplotype more accurately defines a larger inherited region of DNA.

Types of Genetic Polymorphism

Single-nucleotide polymorphisms (SNPs) are allelic variants that have been generated as the result of conversion of one nucleotide to another at a homologous position. When present within a coding region (exon) of a gene, the expressed product may or may not have a single amino acid difference, depending on the resulting codon change. In some cases, the change can lead to either a nonsense codon or a stop codon, which halts the transcription process and results in the production of a truncated peptide. SNPs that are located in regulatory regions of an expressed gene can alter the transcription efficiency of that gene but not the protein sequence [*see Figure 2*].

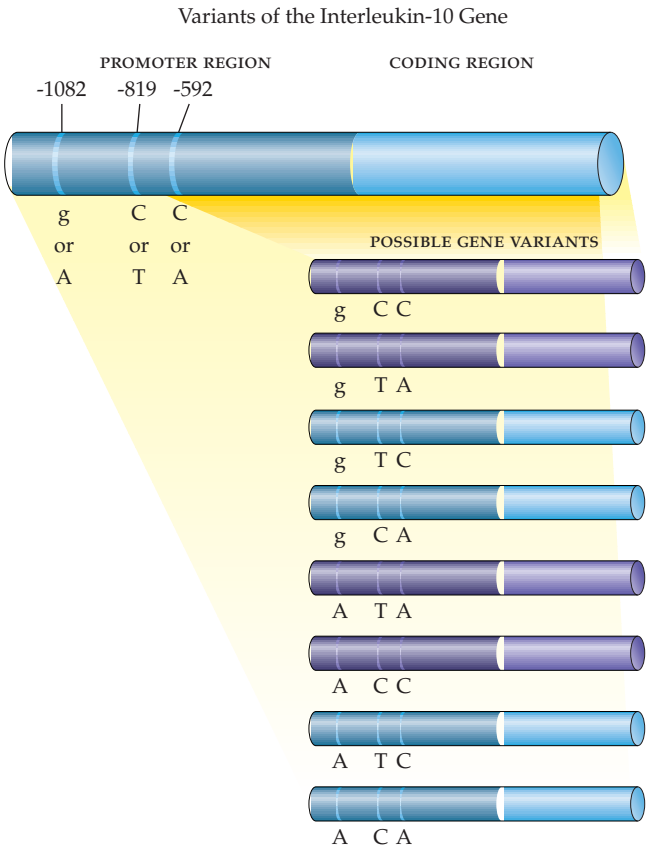

Figure 1 **Single-nucleotide variants occur at positions –1082, –819, and –592 in the promoter region of the interleukin-10 (IL-10) gene. Although eight variants are theoretically possible, only three of these potential IL-10 variants (in purple) are actually observed in large population studies. This is a consequence of strong linkage disequilibrium between the variants at those three positions.**

Deletion or insertion mutants have also been found in functional genes, sometimes at frequencies that merit their inclusion as alleles. Again, the consequence of a deletion depends on the precise location of the deletion; whether it produces a nonsense frameshift; and whether it alters the function of the expressed product. Angiotensin-converting enzyme (ACE) represents a gene that has a deletion variant in which a 278-base-pair segment of intron 16 is excised. This deletion variant is associated with increased ACE levels.

Another class of allelic variance in association with a particular gene is short tandem repeat (STR) polymorphism. Short sequences of two to four base pairs at a given location can be duplicated back-to-back a specific number of times and inherited as a genetic variant. Because such variation would usually result in a nonsense codon, these STRs are almost always located in noncoding regions. The interferon gamma (IFN-γ) gene has such an STR within intron 1, in which the (CA) dinucleotide motif is repeated a variable number of times. The allele with $(CA)_{12}$—that is, with 12 repeats of the CA motif—is associated with high IFN-γ production [*see Figure 3*].

METHODS OF DETECTION OF GENETIC POLYMORPHISM

DNA-based genotyping methods are rapid, accurate, and economical. SNPs can easily be detected, with a high degree of specificity and sensitivity. The assays depend on amplification of the polymorphic locus in question to produce sensitivity in the setting of a background of sample genomic DNA. Specificity is ensured by using tailored oligonucleotides that are complementary to the DNA sequence of the allele one wants to detect.

One strategy for typing is to use polymerase chain reaction to amplify a segment of DNA that includes the polymorphic position and a moderate amount of flanking DNA on both the 3′ and 5′ sides of the polymorphic position. This is done with primers that are complementary to conserved sequences in either side of the desired segment to be amplified. This yields an amplicon of known size that contains inherited alleles and is present in an amount that can be tested for the presence of specific alleles without significant interference from genomic DNA. The amplicon can then be probed, using a set of fluoresceinated or radiolabeled oligonucleotides, each of which is complementary to the DNA sequence of one of the possible alleles. This method is often referred to as site-specific oligonucleotide probe (SSOP) testing.

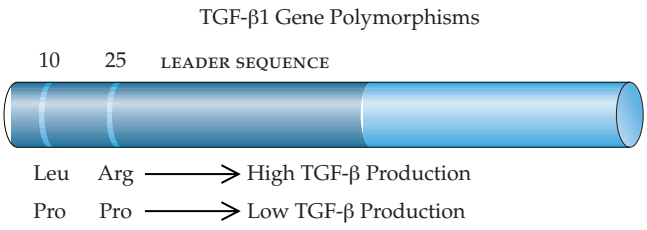

Figure 2 **Single-nucleotide polymorphisms have been identified in the gene for transforming growth factor–β1 (TGF-β1). Each polymorphism involves two alleles in the leader sequence of the gene. These biallelic nucleotide substitutions produce codon changes that result in alternative amino acids. Leu10 is in linkage disequilibrium with Arg25, and Pro10 is in linkage disequilibrium with Pro25. The Leu10Arg25 variant is associated with high TGF-β1 production, whereas the Pro10Pro25 variant is associated with lower production. This may be the consequence of different efficiency of posttranslational modification for the two variants, which differ only in the leader amino acid sequence.**

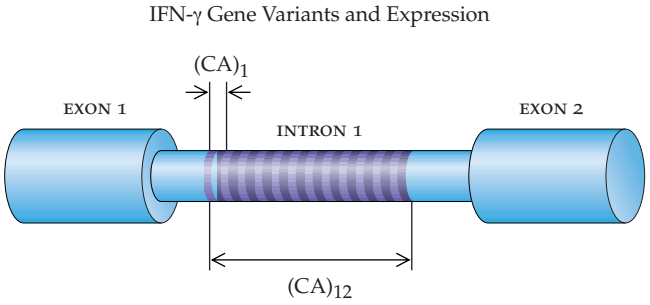

Figure 3 **Illustration of a short tandem repeat (STR) polymorphism within intron 1 of the interferon gamma (IFN-γ) gene. STR polymorphisms in this intron differ according to the number of repetitions of the cytosine-arginine (CA) motif. The allelic variant with 12 tandem repeats [(CA_{12})] is associated with higher IFN-γ production.**

Another strategy for SNP typing, which does not require two steps, is called site-specific priming (SSP). This method takes advantage of the fact that the 3′ terminal base of a primer is where DNA synthesis commences during each cycle of PCR. For synthesis to proceed, the 3′ base must be closely bonded to its complementary base on the template DNA. Therefore, the terminal 3′ base of the primer can be used to render the PCR reaction itself exquisitely sensitive to the identity of the base that is on the template. For detection of SNPs, one can craft a set of PCR primers that are complementary to the alleles to be detected, with the terminal 3′ base of one of the primers located at the polymorphic position. The second PCR primer is usually complementary to a conserved segment of DNA and positioned to yield a product of a convenient size. If an allele is present, use of the appropriate set of primers will produce an amplicon. The amplicon can be separated from genomic DNA by simple agarose gel electrophoresis and identified by ethidium bromide staining under ultraviolet light, and the expected size can be confirmed.

Both SSOP and SSP can be modified to detect deletion or insertion variants. With SSP, using primers that flank the deletions or insertions, amplicons of characteristic sizes are produced. SSOP can confirm the presence or absence of the deletions or insertions through the use of probes that include the junctions of the deleted or inserted regions.

RELEVANCE OF GENETIC POLYMORPHISM IN HUMANS

Historically, polymorphisms in several genetic systems have been recognized as a barrier to transfusion and transplantation. The ABO blood group antigens were among the earliest genetically determined glycoproteins that exhibited mendelian inheritance and had biologic relevance in humans.[3] Mismatch for the ABO antigens is a risk factor not only for transfusion reactions but also for solid-organ transplantation because of the prominent expression of these antigens on the vascular endothelium.

The major histocompatibility complex (MHC)—so called because of its prominent role in rejection of allogeneic tissue—is a primary barrier to transplantation of solid organs, tissue, and hematopoietic stem cells. This closely linked cluster of highly polymorphic genes, grouped on the short arm of chromosome 6, encodes cell surface molecules (human leukocyte antigens [HLA]). The normal role of the MHC is presentation of endogenous and exogenous peptide antigen fragments to T cells,

thereby initiating an immune response against the molecule (or pathogenic organism) from which the peptide was derived.[4] The extreme variability of molecular structure in the MHC antigens permits a wide range of different peptides to be presented by autologous human antigen-presenting cells, although some persons may have a specific repertoire of MHC antigens that do not present certain antigens effectively. The focused immunogenicity of MHC molecules and the variability of these molecules from person to person render them prominent targets for the immune response in the context of solid-organ and bone marrow transplantation. In cases in which live allogeneic cells are the target of the immune response, the apparent target is the nonself MHC molecule itself. Freedom from rejection and, in the case of bone marrow transplantation, graft versus host disease (GVHD) is improved with HLA matching of donor and recipient.

Innate and Adaptive Responses

It has become abundantly clear that the selective (adaptive) immunologic response, which is important in organ transplantation, tissue transplantation, and defense against certain microorganisms, is closely associated with the innate cellular and humoral pathways of nonspecific tissue injury, inflammation, hypoxia, and healing. Macrophages, for example, play a central role in the response to hypoxia, trauma, bacterial invasion, and inflammation caused by exogenous toxins, but they are also important in the processing and presentation of antigen to the specific immune system. Natural killer (NK) cells, which constitute approximately 10% of human mononuclear cells, are thought to be important mediators of innate immunity. Their cytolytic activity is regulated by inhibitory receptors, called killer immunoglobulin-like receptors (KIRs).[5] Class I MHC molecules are ligands for the KIRs—in particular, genetically determined epitopes on HLA-B and HLA-C molecules that have limited polymorphism.[5] In bone marrow transplantation, recipients who present the appropriate class I ligands to donor NK cells will downregulate the NK response. This is thought to decrease both GVHD and graft versus tumor activity.

Humans also have innate humoral immunity against a number of glycoprotein antigens. This so-called natural antibody is thought to have protective effects against a wide range of bacterial products. At the same time, the humoral immune system is able to mount a robust adaptive response to an astonishingly broad spectrum of specific antigens, if challenged to do so. The genes responsible for the adaptive immune response are highly polymorphic, but they are found only in specific subsets of T cells with antigen receptor genes that are rearranged during thymic development and in B cells that undergo somatic mutation in response to antigenic challenge. Specific germline variant alleles of the T cell receptor for antigen (before somatic mutation) are also associated with differential susceptibility to a number of immunologically mediated conditions, including renal allograft rejection and several rheumatic diseases, such as rheumatoid arthritis.[6]

Other Polymorphic Genes Involved in Organ and Tissue Injury

Variants of genes can influence organ and tissue physiology, directly induce diseases, or render the person more susceptible or resistant to a pathologic state. Variants that directly induce a profound disease state are usually rare in the population, because the disease may cause death before the person can reproduce. Variants or mutations that cause severe early disease are not discussed in this subsection. Polymorphic variants of loci that have a more subtle effect on disease susceptibility are more likely to become established in the population at frequencies of 1% or more (i.e., to become alleles). Several patterns can be appreciated with these alleles. Variant alleles may exhibit a gene-dose effect, with heterozygotes having an intermediate influence, between that of the normal genotype (the so-called wild type) and the homozygous variant genotype. In other cases, a variant allele appears to have a dominant influence; presumably, these variants are able to achieve significant frequency in the population because the condition they produce does not substantially decrease reproduction. The disease phenotype that is a measurable physiologic consequence of a particular genotype may be a downstream effect that depends on multiple influences, including the genotype in question, interaction with other genes, and environmental exposure.

Loci that encode cytokines, chemokine receptors, costimulatory molecules, and components of physiologically important pathways such as the angiotensin system are all concrete examples in which genetic polymorphism influences pathophysiology. These examples can be used to highlight some ways in which determination of individual genotype can assist in assessing risk of disease.

Cytokines and chemokines are secreted proteins and glycoproteins that act as important signaling devices in both the innate and the adaptive responses. They serve variously as chemoattractants and as inducers or suppressors of leukocyte, endothelial cell, platelet, fibroblast, and myocyte function. They have a particularly notable effect on cells that bear the appropriate receptors. Cytokines and chemokines often represent a common pathway that links the classical immune pathway and other pathways of tissue injury and repair, such as those involved in ischemia, trauma, and toxic damage.[7]

Costimulatory molecules such as CTLA-4 are expressed on the cell membranes of T cells and serve as ligands for complementary molecules on antigen-presenting cells [*see 6:IX Immunologic Tolerance and Autoimmunity*]. The engagement of costimulatory molecules with their ligands can augment or suppress the magnitude of the immune response induced by the recognition of antigen via the T cell receptor.[8,9] Soluble CTLA-4 has been used to block antigen-dependent T cell activation by competitive blockade of normal cell membrane–bound interaction.

Functional Consequences of Specific Genetic Variants

CYTOKINE POLYMORPHISMS

Variants in the genes that govern the production of cytokines such as interleukin-10 (IL-10), tumor necrosis factor–α (TNF-α), and transforming growth factor–β (TGF-β) can help determine whether a person has high or low levels of these cytokines.[10] The cytokine network is thought to play an important role both in rejection of allografts and in tolerance,[11] and a number of clinical effects of these polymorphisms in cytokine genes have now been described [*see Tables 1 and 2*].

TGF-β has two well-studied dimorphic positions within the leader sequence of the gene [*see Figure 2*]. These polymorphisms are in linkage disequilibrium; only two variants of the TGF-β gene have been described, rather than the four theoretically possible combinatorial variants. TGF-β is considered to be

Table 1 Cytokine Genetic Polymorphisms and Their Pathophysiologic Effects[9,31-59]

Locus	*Position*	*Genotype*	*Pathophysiologic Effect*
CTLA4	Microsatellite	Allele 3 and allele 4	Increased rejection, liver/kidney transplants
IFN-γ	Microsatellite	Allele 2 (12 CA repeat)	Increased production
IFN-γ	Microsatellite	Allele 2 (12 CA repeat)	Increased production
IFN-γ	Microsatellite	Allele 2 (12 CA repeat)	Increased acute rejection, kidney transplants
IFN-γ	Microsatellite	Allele 3 homozygotes	Increased GVHD, bone marrow transplant patients
IFN-γ	T+874A	T allele	Increased production
IL-10	-1082A	A allele	Low producer
IL-10	-1082A	A/A homozygotes	Increased frequency in Wegener granulomatosus
IL-10	-1064	Low producer	Increased GVHD, bone marrow transplant patients
IL-10	-1082, -819, -592	Low producer	Increased rejection, pediatric heart transplant patients
IL-10	-1064	High producer	Increased graft survival, renal transplants
IL-10	-1082A	High producer	Increased rejection, if high TNF genotype
IL-10	-1082A	High producer	Increased rejection episodes, renal transplants
IL-10	-1082A	Recipient high; donor low	Increased rejection, renal transplants
IL-4	-590T	Recipient and donor low	Decreased rejection, renal transplants
IL-6	-174C	G allele	Increased acute GVHD, bone marrow transplants
TGF-β1	Arg25Pro	A/A homozygotes	Increased production
TGF-β1	Arg25Pro	Arg	Increased in patients with fibrotic lung disease
TGF-β1	Arg25Pro	A/A homozygotes	Progression of renal insufficiency, heart transplant patients
TGF-β1	Arg25Pro	A/A homozygotes	Decreased gingival hyperplasia with cyclosporine
TGF-β1	Arg25Pro	A/A homozygotes	Increased coronary vasculopathy, heart transplants
TGF-β1	Arg25Pro	Arg	No correlation with renal transplant rejection
TGF-β1	Leu10Pro	Leu	Progression of renal insufficiency, heart transplant patients
TGF-β1	Leu10Pro	L/L homozygotes	Decreased renal dysfunction, heart transplant patients
TGF-β1	Leu10Pro	Pro	Association with dilated cardiomyopathy
TGF-β1	Leu10Pro	Pro/Pro	Increased gingival hyperplasia with cyclosporine
TNF-α	-308A	High A/A or A/G	Increased rejection and creatinine, renal transplants
TNF-α	-308A	High A/A or A/G	Increased GVHD and mortality, bone marrow transplant patients
TNF-α	-308A	High A/A or A/G	Increased rejection, renal transplants
TNF-α	-308A	Low producer	Decreased acute rejection, pediatric heart transplants
TNF-α	-308A	A allele	Sixfold to sevenfold higher production
TNF-α	-308A	A allele	Risk factor renal transplants, if HLA-DR mismatch
TNF-α	-308A	A allele	Increased rejection, pediatric heart transplants
TNF-α	-308A	A allele	Increased frequency in primary sclerosing cholangitis
TNF-α	-308A	A allele	Increased mortality, heart transplant patients
TNF-α	-308A	A allele	Increased rejection, renal transplants
TNF-α	-308A	A allele	Increased hepatitis C recurrence after liver transplants
TNF-α	-308A	A allele	Decreased plasma TNF levels
TNF-α	-308A	A/A homozygotes	Increased rejection, liver transplants
TNF-α	-308A	A/A homozygotes	Increased acute rejection, liver transplants
TNF-α	Microsatellite	High producer	Increased rejection, cardiac transplants (low IL-10 subset)
TNF-α	Microsatellite	High producer	Increased acute GVHD, bone marrow transplant patients
TNF-α	Microsatellite	a9	Increased in rejection, renal transplants, in patients with HLA-B35
TNF-α	Microsatellite	d3/d3 homozygotes	Increased GVHD grade III/IV
TNF-α	Microsatellite	d4	Decreased in rejection, renal transplants, in patients with HLA-B44
TNF-α	NcoI	Low recipient	Increased infection, renal transplants
TNF-α	-308A	A allele	Nonischemic cardiac dysfunction

Note: Some of these gene variants appear to have paradoxical effects, depending on the investigator and the assay system.
GVHD—graft versus host disease IFN—interferon IL—interleukin TGF—transforming growth factor TNF—tumor necrosis factor

a major mediator of fibrosis in kidney and lung allografts.[12,13] Specific variants of the TGF gene that result in high production of TGF-β (so-called high-producer genotypes) are associated with poor outcome in lung transplants: 98% of patients with chronic rejection are homozygous for the high-producer TGF-β genotype represented by Leu at position 10 and Arg at position 25. Moreover, fibrosis develops in the lung grafts of 93% of those with homozygous high-producer TGF-β genotype but only in 7% of those with heterozygous (high/low) producer genotype.[12] TGF-β also mediates the gingival hypertrophy induced by the immunosuppressive agent cyclosporine. Increased gingival hypertrophy has been reported in patients with the low-producer TGF-β genotype, represented by Pro at both position 10 and position 25. Because the two variants differ only in the leader amino acid sequence, the different production levels may be the consequence of different efficiency of posttranslational modification.

ANGIOTENSIN SYSTEM POLYMORPHISMS

The renin-angiotensin system is a metabolic-hormonal pathway that plays a critical role in blood pressure homeostasis and salt and water balance. In the renin-angiotensin pathway, the

Table 2 Renin-Angiotensin System and Chemokine Polymorphism and Pathophysiology[26,60-72]

Locus	*Position*	*Genotype*	*Pathophysiologic Effect*
ACE	Deletion variant	I/I or I/D	Favorable function trend, pediatric renal transplants
ACE	Deletion variant	D	Favorable renal function, bone marrow transplant patients
ACE	Deletion variant	D/D homozygotes	Favorable renal function, renal transplants
ACE	Deletion variant	D	Increased cardiac allograft vascular disease
ACE	Deletion variant	D/D homozygotes	Increased risk of renal failure, pediatric kidney transplants
ACE	Deletion variant	D/D homozygotes	Inreased risk of renal failure, high-risk renal transplants
ACE	Deletion variant	D	Increased frequency in systemic lupus erythematosus
ACE	Function	Function	ACE inhibitor suppresses IL-12, IFN-γ
ACE	Deletion variant	D/D homozygotes	Increased ACE levels
ACE	Deletion variant	D/D homozygotes	Increased blood pressure with salt administration
ACE	Deletion	D	Increased risk of renal dysfunction, renal transplants
AGT	Met235Thr	Met vs Thr	No function association, pediatric renal transplants
AGT	G → A,-6	A/A	Increased risk of renal dysfunction, renal transplants
AT1	A1166C	A vs C	No function association, pediatric renal transplants
AT1	Function	Function	Activation of NF-κB via IL-12 and IFN-γ
AT1	A1166C	C	Increased blood pressure, renal transplant patients
CCR2	V64I	I	Less acute rejection, renal transplants
CCR2	Expression	Expression	High expression in renal transplants during rejection
CCR5	A59029G	A/A homozygotes	Less acute rejection, renal transplants
CCR5	Expression	Expression	High expression in renal transplants during rejection
CXCR3	Expression	Expression	High expression in heart biopsy infiltrates

Note: Some of the gene variants appear to have paradoxical effects, depending on the investigator and the assay system.
ACE—angiotensin-converting enzyme IFN—interferon IL—interleukin

prohormone angiotensinogen (AGT) is converted to angiotensin I by renin. Angiotensin-converting enzyme then catalyzes the conversion of angiotension I to angiotensin II [*see Figure 4*]. Angiotensin II is one of the most potent vasoconstrictive human hormones. In addition, angiotensin II has indirect inflammatory and fibrotic effects, which are distinct from its physiologic vasoconstrictive role. These indirect effects appear to be mediated by cytokines. Angiotensin II promotes the secretion of a number of inflammatory cytokines, including TGF-β, platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), IL-6, IL-12, TNF-α, and IFN-γ.[14-17] There are two receptors for angiotensin II, type 1 (AT1) and type 2 (AT2). AT1 receptors mediate the major vasoconstrictive activity of angiotensin II but also appear to be involved in angiotensin II–dependent augmentation of immune activation and stimulation of TGF-β production. The AT2 receptors are implicated in remodeling; may promote angiotensin II–dependent apoptosis; and have some functions that oppose the AT1 receptor, including vasodilation and increased production of nitric oxide.[18,19]

Several of the genes encoding members of the renin-angiotensin pathway exhibit polymorphisms that influence function. Genomic variants of the genes encoding AGT, ACE, AT1, and AT2 have been described.[20] There is evidence that the AGT(A/A) and ACE(D/D) variants result in increased angiotensin II activity; in turn, the angiotensin II can interact differentially with receptors of different genotypes and influence ultimate pathophysiology. A deletion variant of the ACE gene (D14091-14378) and a single-nucleotide polymorphic variant of the AGT gene (G → A, -6) are correlated with increased peripheral ACE activity and AGT levels, respectively.[21,22] Both genotypes confer increased susceptibility to hypertension, and ACE(D14091-14378) also worsens ischemic heart disease and progression of intrinsic renal insufficiency [*see Table 2*].[23] An analysis of ACE polymorphism in diabetes revealed that the ACE(D) allele is highly associated with diabetic nephropathy.[24]

Of the different classes of white blood cells, T cells contain the highest level of ACE, approximately 28-fold more than

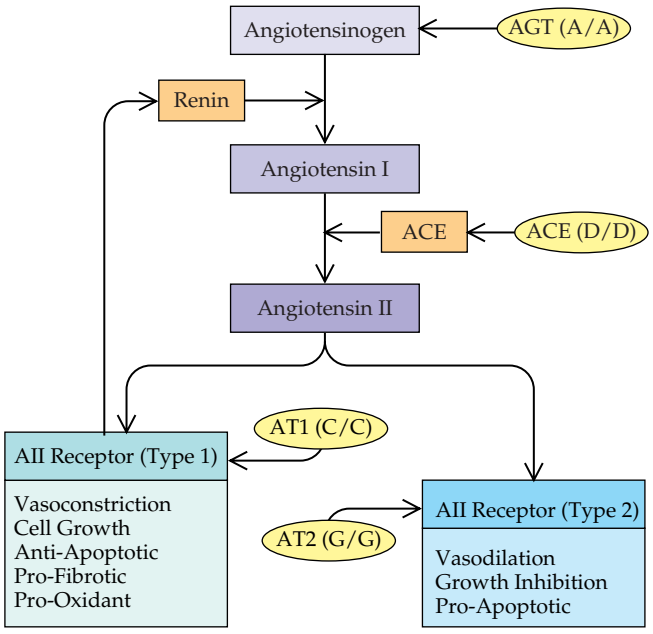

Figure 4 **The renin-angiotensin system is illustrated, along with proven variants of genes responsible for its components. The variant genes indicated are thought to result in a quantitative increase in function in the system. The final hormone, angiotensin II (AII), has a variety of vasoactive, inflammatory, or anti-inflammatory effects, which appear to be dependent on the receptor that is engaged. (ACE—angiotensin-converting enzyme; AGT—angiotensinogen; AT1—angiotensin type 1 receptor; AT2—angiotensin type 2 receptor)**

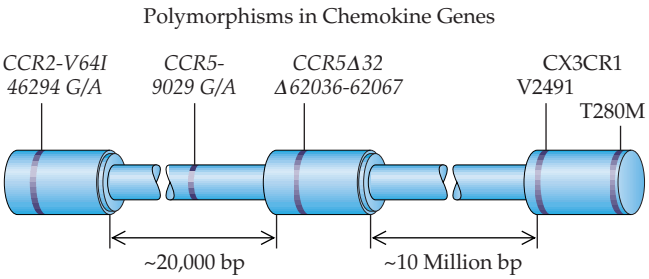

Figure 5 **Locations of chemokine receptor genes and variant positions associated with those genes are shown. The CCR2, CCR5, and CX3CR1 genes are located on the same chromosome. CX3CR1 has two variable positions within the coding region. The location of the deletion variant of CCR5 and the location of the G-to-A variant of CCR5 in the 5′ promoter region of the gene are illustrated. The CCR2 gene has a G-to-A variant located within the coding region.**

monocytes. Indeed, immunologically competent T cells appear to be the major cell type expressing ACE in blood.[25] The ACE expression can vary up to 100-fold during the differentiation of T cells. Monocytes express angiotensin II, the final product of the angiotensin synthetic pathway. Monocyte angiotensin II appears to mediate recruitment of inflammatory cells during renal damage through the synthesis of monocyte chemoattractant protein-1.[26]

A variant of the AT2 gene (A → G, 1332) has been associated with congenital anomalies of the kidney and urinary tract. These developmental abnormalities are preceded by delayed apoptosis of undifferentiated mesenchymal cells surrounding the urinary tract during key ontogenic events.[27] In kidney transplant recipients, specific variants of the ACE and AGT genes are correlated with poor clinical outcomes. Renal transplant patients who have either the ACE(D14091-14378) or the AGT homozygous (G → A, -6)/(G → A, -6) variant have poorer renal transplant function at 3 years, as well as more rapid progression of transplant failure, defined as an increase of serum creatinine levels over time. Diastolic blood pressure in these patients was also significantly higher as a function of the AT1(A → C, 1166) C gene dose. The pathophysiologic reasons for the association between specific angiotensin system gene polymorphisms and renal transplant outcomes are not well understood. Further work is needed to reveal the degree to which this association is a function of hypertensive organ damage or modulation of the immunologic response mediated by angiotensin.

CHEMOKINE RECEPTOR POLYMORPHISMS

Chemokines are molecules with a variety of functions, some of which influence the recruitment of inflammatory cells to sites of injury. Three of the genes encoding chemokine receptors are located on one chromosome. CCR2 and CCR5 are located within 20,000 base pairs of each other; CX3CR1 is located 10 million base pairs away from CCR5 [*see Figure 5*].

The leukocyte chemokine receptor CCR5 is expressed on monocytes, as well as on helper T cells involved in augmentation of the immune response (T_{H1} subset)[28] [*see 6:X Allergic Response*]. CCR5 is a coreceptor for entry of HIV-1 into macrophages. CCR5 binds the inflammatory chemokines RANTES (regulated on activation, normal T cell expressed and repeated), macrophage inflammatory protein (MIP)-1α, and MIP-1β, whereas CCR2 and CX3CR1 are receptors for the chemokines monocyte chemoattractant protein (MCP)-1 and fractalkine, respectively. Antagonists of CCR5, such as met-RANTES, prolong renal allograft survival in MHC-incompatible mice. Furthermore, prolonged heart transplant survival is achieved if the recipient is a homozygous CCR2 or CCR5 knockout. In humans, a 32-base-pair deletion of the CCR5 gene (CCR5 Δ32) renders the gene nonfunctional. There is also a polymorphic single-nucleotide variant of CCR5, CCR5-9029(G → A), which is located in the promoter region of the gene. The G variant is associated with defective transcription. Gene variants of some of these chemokine receptors have been associated with different rates of HIV disease progression.[29] The CCR5 Δ32 variant is associated with lower incidence and severity of asthma and rheumatoid arthritis.[30] Patients with homozygosity for CX3CR1-V2491I(G → A), CX3CR1-T280M(C → T), and CCR5-9029(G → A) have higher HIV progression rates. In contrast, patients with CCR2V64I(G → A) and CCR5(Δ32) exhibit slower progression of HIV, presumably because of reduced binding of the virus to target cells.

In renal transplant patients, the A/A homozygous genotype of the CCR59029(A → G) polymorphic locus is associated with significantly lower incidence of acute rejection episodes in the first posttransplant year. Although this could be explained by a protective effect of A/A homozygosity, it might instead be from a dominant detrimental effect of the G variant, given that both A/G heterozygotes and G/G homozygotes have been found to have similarly high rejection frequencies, which were twice that of patients with A/A genotype.[14]

Practical Applications of Genotyping Polymorphisms

The genetic polymorphisms discussed in this subsection represent but examples of the many inherited variants of physiologically important genes that influence susceptibility to disease. These variants can act alone, in conjunction with variants at other loci, or through interaction with environmental factors to increase or decrease disease incidence or severity. The cytokine genes, chemokine genes, and genes of the renin-angiotensin system are important modulators of the immune response and, in the case of the renin-angiotensin axis, of hypertension and vascular disease. Knowledge of a patient's genotype may assist physicians in assessing prior risk of a pathophysiologic outcome and in tailoring therapy. Clinical trials may, in some cases, be better interpreted by knowledge of participant genotypes, because certain genotypes may impart differential incidence of disease and responsiveness to pharmacologic agents.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

VIII DEFICIENCIES IN IMMUNOGLOBULINS AND CELL-MEDIATED IMMUNITY

FRED S. ROSEN, M.D.

Immunoglobulin Deficiency Syndromes

Insufficient production of one or more kinds of antibodies characterizes the immunoglobulin deficiency syndromes [*see Table 1*].[1,2] Patients with these deficiencies are subject to recurrent pyogenic infections, such as otitis media, sinusitis, and pneumonia. Repeated episodes of pneumonia can lead to chronic obstructive pulmonary disease. For many of these deficiencies, the genetic basis has now been defined. The primary care physician's role in these disorders is to suspect the diagnosis under the appropriate clinical circumstances—often, unusual susceptibility to certain infections in a patient with a family history of the same—and to order the preliminary laboratory studies. Definitive diagnosis and management is typically the responsibility of the immunologist. Control of the infections to which these patients are susceptible is principally managed by the intravenous administration of large doses of γ-globulin.

X-LINKED AGAMMAGLOBULINEMIA

X-linked agammaglobulinemia, also known as congenital agammaglobulinemia or Bruton disease, was the first immunodeficiency disorder to be described, in 1952.

Genetics and Pathogenesis

The gene responsible for X-linked agammaglobulinemia is located on the long arm of the X chromosome (Xq21.33–q22).[3-5] This gene, termed *btk*, is a member of the *src* family of oncogenes and encodes a unique tyrosine kinase.[4-8] It probably plays a critical role in the maturation of B cells: pre–B cells are present in normal numbers in the bone marrow of males with X-linked agammaglobulinemia, but they do not develop into mature B cells.[2] Because the genes governing the structure of immunoglobulins are on autosomal chromosomes, the mechanism of the disorder must also involve a defect in a regulatory gene.

In patients with X-linked agammaglobulinemia, the lymphoid organs are characterized by a lack of germinal follicles, B cells, and plasma cells. On bone marrow studies, pre–B cells (which contain immunoglobulin μ heavy chains in their cytoplasm and therefore can be identified by immunofluorescence staining with antiserum to the μ chain) are present in normal numbers.

Diagnosis

Clinical manifestations Because infants are born with IgG from their mother in their blood, boys who have X-linked agammaglobulinemia do not start to show the effects of the disorder

Table 1 Primary Specific Immunodeficiencies Involving Antibodies

Designation	*Usual Phenotypic Expression*		*Presumed Level of Basic Cellular Defect*	*Known or Presumed Pathogenetic Mechanism*	*Inheritance*
	Antibody Deficiencies	*Cellular Abnormalities*			
X-linked agammaglobulinemia	All immunoglobulins	↓ B cells	Pre–B cells	Mutations in the gene for Bruton's X-linked tyrosinase (*btk*)	X-linked
Common variable immunodeficiency	All immunoglobulins	Faulty B cell maturation	Immaturity of B cells	↓ Helper T cell function Intrinsic B cell defect Underproduction of B cells Autoantibodies to B cells	Unknown
Selective IgA deficiency	IgA	↓ IgA plasma cells ± ↑ IgA^+ B cells	Terminal differentiation of IgA^+ B cells impaired	Unknown	Usually unknown (autosomal recessive more common than autosomal dominant); frequent in families of patients with common variable immunodeficiency
Ig deficiencies, with increased IgM	IgG, IgA, and IgE	↓ IgG and IgA plasma cells ↑ IgM and IgD plasma cells ± ↑ IgM^+ B cells	Failure of immunoglobulin class switching	X-linked form: mutations in the gene for the CD40 ligand Autosomal recessive form: activation-induced cytidine deaminase	X-linked, autosomal recessive, or unknown
Selective deficiency of IgG subclasses	One or more IgG isotypes	↓ Plasma cells ± ↓ T cells	Unknown	Unknown	Unknown
κ-Chain deficiency	IgG(κ)	↓ $κ^+$ B cells	Unknown	Point mutation at 2p11	Autosomal recessive
Transient hypogammaglobulinemia of infancy	IgG and IgA	↓ Plasma cells B cells normal	Impaired terminal differentiation of B cells	↓ Helper T cells	Frequent in heterozygous individuals in families with various severe combined immunodeficiencies

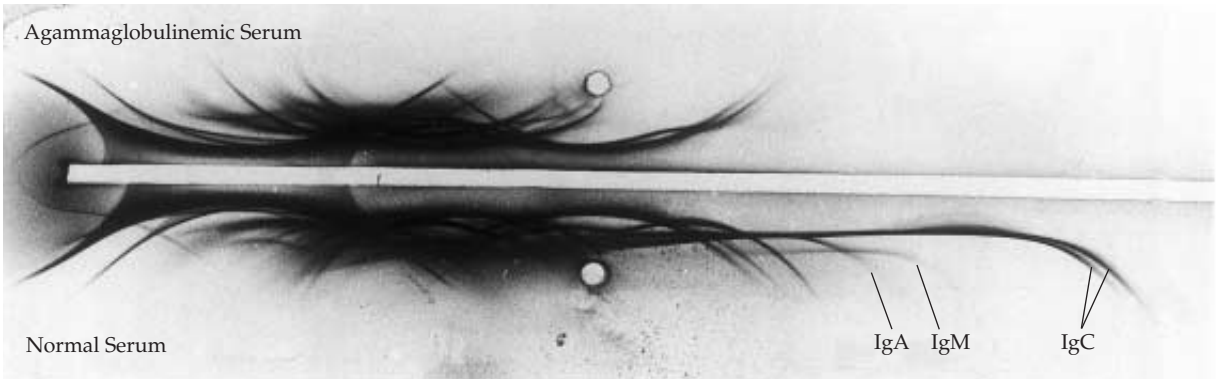

Figure 1 **When an immunoelectrophoretic pattern of agammaglobulinemic serum is compared with 6a normal serum pattern, the absence of IgA, IgM, and IgG—characteristic of the disorder—is clearly demonstrated.**

until 6 to 15 months of age. They then demonstrate unusual susceptibility to infections by pyogenic organisms (e.g., otitis media, sinusitis, and pneumonia from *Haemophilus influenzae*, pneumococci, streptococci, staphylococci, and meningococci). Those infections are more frequent and more severe in boys with X-linked agammaglobulinemia than in normal children, and recurrent infection by the same organism is common. Frequently, the infections are slow to respond to antibiotics. Recurrent pulmonary infections often lead to bronchiectasis and pulmonary insufficiency. Affected males have normal resistance to the common viral diseases, fungi, and most gram-negative organisms, but some have developed polio after receiving oral polio vaccine. About one third of patients have symptoms that resemble rheumatoid arthritis, including swollen and painful joints. A severe late complication is a fatal syndrome similar to dermatomyositis but with central neurologic involvement, as well. This syndrome is gradual in onset, usually starting in the second or third decade of life. In several patients with this syndrome, echoviruses have been cultured from the blood, stool, and cerebrospinal fluid.[9]

Laboratory testing Diagnosis begins with measuring the serum level of each class of immunoglobulin [*see Figure 1*]. Patients with X-linked agammaglobulinemia usually have less than 100 mg/dl of IgG (normal levels are 614 to 1,295 mg/dl), and they have levels of IgA, IgM, IgD, and IgE that are extremely low or undetectable. Such findings should prompt referral of the patient to an immunologist.

In patients with X-linked agammaglobulinemia, analysis of white blood cells by flow cytometry reveals a lack of B cells. These patients are unable to mount an antibody response to antigen challenge, such as routine diphtheria-pertussis-tetanus (DPT) or *H. influenzae* vaccination, and they cannot neutralize the toxin in a Schick test (intradermal injection of diphtheria toxin). In contrast, cell-mediated immune functions, such as delayed hypersensitivity–mediated skin reactions and graft rejection, are essentially normal, and the T cells respond in vitro to phytohemagglutinin and produce lymphokines normally.

Screening All subsequent male offspring of the mother or maternal aunts of a patient with X-linked agammaglobulinemia should be screened for mutations of the *btk* gene. Because the defect is limited to B cells, female carriers of the gene can be detected by analysis of X-chromosome inactivation in B cells.[10,11] In female carriers, pre–B cells in which the X chromosome bearing the normal gene has been inactivated will not develop into B cells; therefore, all mature B cells will bear an active X chromosome containing only the normal gene.

Treatment

Preparations of 5% or 10% γ-globulin solution are now used as replacement therapy for agammaglobulinemia. Parents can be reassured that these preparations pose no risk of transmitting HIV or other viral infection. Intravenous administration of these preparations is well tolerated; large doses can be given without discomfort or pain. Infants do not require permanent intravenous access.

Dosages of γ-globulin are adjusted according to the patient's health. The minimal effective dosage of intravenous γ-globulin is 300 mg/kg a month; however, higher doses, such as 500 mg/kg a month, are usually optimal.[12] Dividing the monthly dosage of γ-globulin and administering it at 1-week or 2-week intervals is preferable, because it maintains higher immunoglobulin levels. The γ-globulin is infused at a rate of 3 ml/min or slower. Side effects may include headache, shaking chills, flank pain, fever, and hypotension. These can be ameliorated by giving an antihistamine or methylprednisolone before the infusion.

Bacterial infections in patients with X-linked agammaglobulinemia require vigorous antibiotic treatment. Antibiotics should be given in prolonged courses (e.g., 2 weeks) at full doses.

Prognosis The prognosis is very good for patients whose condition is diagnosed and treated early. A recent study of 31 patients with X-linked agammaglobulinemia found that early and prolonged γ-globulin replacement therapy is effective in preventing bacterial infections and pulmonary insufficiency. Viral infections still developed, however, and one patient died of enteroviral meningoencephalopathy.[13]

COMMON VARIABLE IMMUNODEFICIENCY

Common variable immunodeficiency (CVID) is so called because it accounts for over 50% of cases of immunodeficiency and because patients present with variable clinical manifestations and somewhat inconsistent laboratory findings; disease course varies, as well.

Etiology and Pathogenesis

The cause of CVID is unknown. CVID does not appear to be genetically transmitted—apparently the germ cells are not in-

volved—although some family clusters have been seen. CVID affects males and females equally.

A variety of pathogenetic mechanisms underlie CVID.[2] These include (1) B cells that do not respond to stimulatory signals from T cells, (2) B cells that can synthesize but cannot secrete immunoglobulins, (3) the absence of helper T cells (required for normal B cell function), and (4) the presence of autoantibodies to B cells. In a few cases of CVID, B cells cannot be detected. All patients show markedly low serum levels of all immunoglobulins.

Diagnosis

Clinical manifestations Onset of CVID can occur at any age, but it usually occurs after puberty. Patients have the same heightened vulnerability to infections as those with X-linked agammaglobulinemia; also, there is chronic involvement of the sinuses and respiratory tract.

CVID is associated with several autoimmune diseases, such as rheumatoid arthritis, idiopathic thrombocytopenia, hemolytic anemia, neutropenia, and, predominantly, pernicious anemia. Infectious diarrhea and malabsorption syndrome are common. CVID is also associated with severe malabsorption syndrome caused by gluten-sensitive enteropathy. It is unclear whether CVID is a cause or an effect of these disorders. Chronic lung disease that produces bronchiectasis is common in CVID; this condition should be differentiated from cystic fibrosis, chronic allergy, and α_1-antitrypsin deficiency. In contrast to X-linked agammaglobulinemia, CVID is often marked by considerable enlargement of regional lymph nodes and splenomegaly.

Laboratory tests IgG levels in patients with CVID are generally lower than 250 mg/dl, and other immunoglobulins are also markedly decreased. B cells are usually present, but they do not mature normally into plasma cells, which synthesize and secrete immunoglobulins. Tests of cell-mediated immunity also demonstrate defects.

Lymphoid hyperplasia may occur in the gut of patients with CVID. This can be visualized by barium contrast x-ray of the upper GI tract, which is indicated in CVID patients with GI symptoms.

Treatment

Treatment of CVID is essentially the same as that of X-linked agammaglobulinemia: replacement γ-globulin therapy and vigorous use of antibiotics during acute infections. Diarrhea in these patients is frequently caused by *Giardia lamblia* infection, which can be rapidly controlled with quinacrine hydrochloride or metronidazole.[11] Special care must be taken if steroids are used as therapy for the associated autoimmune diseases, because these agents may heighten susceptibility to infection.

Prognosis

Patients with CVID can have a normal life span. Women with the disease can carry a normal pregnancy to term and have normal babies. Although those babies will lack maternal IgG and the passive immunity it confers in the first months of life, they do well without treatment with γ-globulin.

SELECTIVE IMMUNOGLOBULIN DEFICIENCIES

Selective IgA Deficiency

Epidemiology Selective IgA deficiency is one of the most common immunodeficiencies in whites, occurring in one in 600 to 800 persons in this population. It does not occur in Africans and almost never occurs in Asians.

Genetics and pathogenesis The genetics of IgA deficiency are unclear. Data on inheritance are conflicting, with some suggesting autosomal dominant inheritance and others suggesting autosomal recessive inheritance.

A few patients lacking serum IgA have secretory IgA, and some patients have monomeric IgM in their secretions. B cells bearing surface IgA are present, indicating that the defect is probably in the terminal differentiation of IgA-secreting cells. In vitro, IgA-bearing cells can be stimulated by mitogens to produce IgA.[14]

Diagnosis Many patients with IgA deficiency are surprisingly healthy. Nevertheless, IgA deficiency is associated with many clinical syndromes. Patients most often come to medical attention because of recurrent sinus and pulmonary infection by bacteria and viruses. These patients also show a higher incidence of autoimmune, GI, allergic, connective tissue, and malignant diseases. Some patients with IgA deficiency produce antibodies to bovine proteins, suggesting that IgA in the gut normally helps prevent absorption of foreign antigens. IgA deficiency is found in about 70% of patients with ataxia-telangiectasia (see below).

The serum IgA level is less than 5 mg/dl (normal, 60 to 309 mg/dl). Other immunoglobulin levels are normal. Although patients with IgA deficiency usually also have defects in T cell function, most of these patients have normal cell-mediated immunity.

Treatment There is currently no satisfactory means of supplying adequate levels of IgA. Sinus and pulmonary infections in IgA-deficient patients are treated by standard means.

Complications In extremely rare instances, patients with IgA deficiency produce IgE antibodies to IgA and will have anaphylactic reactions when given immunoglobulin.[15] Immunoglobulin replacement therapy should be avoided in such patients; blood transfusion can also precipitate an anaphylactic reaction. Patients who require blood should receive red cells from an IgA-deficient donor because anaphylactic reactions may occur even if the red blood cells are washed three times.

Immunoglobulin Deficiency with Elevated IgM

The combination of markedly elevated IgM levels and deficiency of other immunoglobulins is termed the hyper-IgM syndrome. The IgM in these patients is heterogeneous; thus, it is polyclonal and does not emerge from malignant cells.

In 70% of hyper-IgM cases, the syndrome is X-linked; in the remainder, it is autosomal recessive and affects both males and females. The X-linked form of the hyper-IgM syndrome results from a genetic defect in the CD40 ligand, which is found on the surface of activated T cells.[16-18] Normally, this ligand interacts with the CD40 molecule on the B cell surface, inducing isotype switching. The autosomal recessive form of the hyper-IgM syndrome results from a genetic defect in an enzyme called activation-induced cytidine deaminase (AID).[19] This enzyme is involved in RNA editing, but its precise role in immunoglobulin class switching is unknown.

Diagnosis Patients with hyper-IgM syndrome show increased susceptibility to infection similar to that seen in X-linked

agammaglobulinemia (see above). Immunoglobulin assays show an elevated level of IgM (350 to 1,000 mg/dl); the IgD level may also be elevated. IgA is usually undetectable, and the IgG level is normally less than 100 mg/dl. Many plasma cells, as well as lymphocytoid and plasmacytoid cells structurally similar to those of Waldenström macroglobulinemia, are seen in the gut, lymphoid organs, and blood. These plasma cells stain with fluorescein-labeled antibodies to IgM. In the X-linked form of hyper-IgM syndrome, lymph nodes are small and contain no germinal centers. In AID deficiency, lymph nodes are enlarged and contain germinal centers. Lymph node biopsy is not usually obtained for clinical diagnosis, however.

Treatment Treatment for hyper-IgM syndrome is the same as that for X-linked agammaglobulinemia (see above).

Selective Deficiencies of IgM or the Subclasses of IgG

Selective IgM deficiency is rare. This deficiency may precede the onset of CVID. Patients with selective deficiencies of the IgG subclasses have a decrease in total IgG, the degree of which depends on the subclass involved. The decrease is most profound in the case of IgG1 deficiency because almost three quarters of IgG molecules belong to this subclass. Some patients with IgG deficiency are unable to mount an antibody response to certain antigens. Patients with IgG2 deficiency are especially prone to infection by bacteria with a large amount of surface polysaccharide, such as pneumococci and *H. influenzae*. The diagnosis is confirmed by quantitation of the IgG subclasses and administration of a polysaccharide-antigen vaccine (typically, pneumococcal vaccine); patients with IgG deficiency will fail to produce antibodies in response to vaccination. Patients with selective deficiencies of the IgG subclasses respond to intravenously administered γ-globulin.

Deficiencies of Cell-Mediated Immunity

Extreme susceptibility to opportunistic infection is the most important clinical feature of deficiencies of cell-mediated immunity, or T cell deficiencies. Such deficiencies, which manifest as impairment in delayed hypersensitivity, may be inherited or may be secondary to another disorder [*see Table 2*]. The acquired immunodeficiency syndrome is discussed elsewhere [*see 7:XXXIII HIV and AIDS*].

In general, patients with T cell deficiencies have more frequent and more severe infections than do patients who have pure B cell deficiencies [*see Table 3*].[2] Patients with deficiencies of cell-mediated immunity cannot cope with a number of ordinarily innocuous organisms, such as *Candida albicans* and *Pneumocystis carinii*, and are especially susceptible to enteric bacteria, viruses, and fungi. Live attenuated vaccines are dangerous in these patients: vaccination for smallpox or administration of bacillus Calmette-Guérin (BCG) has led to rapid death.

Determining the defects of cell-mediated immunity requires testing in a specialized immunology laboratory. An extensive array of tests is available at such laboratories [*see Table 4*]. The choice of tests and the order in which they are performed depend on the particular case.

Table 2 Conditions Associated with Impaired Delayed Hypersensitivity

Primary deficiencies of cell-mediated immunity [*see Table 3*]
Chromosomal abnormalities: Bloom syndrome, Down syndrome, Fanconi syndrome
Infections: HIV (AIDS), lepromatous leprosy, Epstein-Barr virus (X-linked lymphoproliferative syndrome), chronic mucocutaneous candidiasis, secondary syphilis, and many other viral and parasitic diseases
Neoplasms: thymoma, Hodgkin disease and other lymphomas, any advanced malignant disease
Connective tissue diseases: systemic lupus erythematosus, advanced rheumatoid arthritis
Physical agents: burns, x-irradiation
Other conditions: sarcoidosis, malnutrition, aging, inflammatory bowel disease, intestinal lymphangiectasia
Iatrogenic causes: chemotherapy, postsurgery, x-irradiation therapy

CONGENITAL THYMIC HYPOPLASIA

Pathogenesis

Congenital thymic hypoplasia (DiGeorge syndrome) results from the lack of normal development of the third and fourth brachial, or pharyngeal, pouches, which leads to abnormality in the great vessels and to the absence of the thymus and the parathyroids. Congenital thymic hypoplasia is not inherited; rather, it is thought to result from an intrauterine accident occurring before the eighth week of pregnancy. The absence of the thymus leads to deficiency in cell-mediated immunity.

Diagnosis

Clinical manifestations Patients with congenital thymic hypoplasia have distinctive facial features, including low-set ears, a shortened philtrum, and ocular hypertelorism. Hypocalcemia from associated parathyroid deficiency is a universal finding and often results in neonatal tetany. There can be a right-sided aortic arch or tetralogy of Fallot or many other cardiac malformations.

Laboratory tests The T cell defect in children with congenital thymic hypoplasia varies from mild to profound. Severely affected children do not exhibit delayed hypersensitivity reactions; their lymphocytes do not respond to mitogens or antigens in vitro, nor do they produce lymphokines. The lymph nodes lack paracortical lymphocytes. Plasma cells are present, however, and immunoglobulin levels are normal. Although patients with congenital thymic hypoplasia produce specific antibodies when they are immunized with various antigens, the antibody response is not quite normal, because secondary responses are lacking.

As the patient ages, T cell function improves; and usually by the time the child is 5 years of age, skin testing reveals no abnormality in cell-mediated immunity. However, the abnormal T cell phenotype—as indicated by a higher than normal ratio of $CD4^+$ to $CD8^+$ T cells—persists for life. Karyotyping reveals microdeletions at chromosome 22q11 in approximately 90% of patients.

Treatment

Thymus transplantation should be undertaken in those infants with congenital thymic hypoplasia who experience frequent infections. Transplantation of fetal thymus results in rapid acquisition of normal T cell function, which is thought to be secondary to production of a thymic hormone secreted by the thymic epithelium. Rejection appears not to be a problem.

Table 3 Classification of Primary Specific Immunodeficiencies Involving Cell-Mediated Immunity

Designation	*Usual Phenotypic Expression*		*Presumed Level of Basic Cellular Defect*	*Known or Presumed Pathogenetic Mechanism*	*Inheritance*	*Main Associated Features*
	Functional Deficiencies	*Cellular Abnormalities*				
Congenital thymic hypoplasia (DiGeorge syndrome)	CMI, impaired antibody	↓ T cells	Thymocytes	Embryopathy of third and fourth pharyngeal pouch areas	Usually not familial	Hypoparathyroidism Abnormal facies Cardiovascular abnormalities
Severe combined immunodeficiency	CMI, antibody	- T cells, + B cells	LSC	Mutation in γ chain of IL-2R, IL-4R, IL-7R, IL-11R, IL-15R, *JAK3*, or IL-7 receptor α chain	X-linked or autosomal recessive	—
		- T cells, - B cells		Mutation in *RAG1* or *RAG2*	Autosomal recessive	
Adenosine deaminase (ADA) deficiency	CMI, antibody	↓ T cells, ± B cells	LSC or early T cells	Metabolic effects of ADA deficiency	Autosomal recessive	—
Purine nucleoside phosphorylase (PNP) deficiency	CMI ± antibody	↓ T cells	T cells	Metabolic effects of PNP deficiency	Autosomal recessive	Hypoplastic anemia
Reticular dysgenesis	CMI, antibody, phagocytes	↓ T cells, ↓ B cells, ↓ phagocytes	HSC	Unknown	Autosomal recessive	Neutropenia
Wiskott-Aldrich syndrome	Antibody to certain antigens (mainly polysaccharides), CMI (progressive)	↓ T cells, ↑ B cells (progressive)	HSC	Mutations in *WASP* gene	X-linked	Thrombocytopenia Eczema Lymphoreticular cancers
Immunodeficiency with ataxia-telangiectasia	CMI, antibody (partial)	↓ T cells, ↓ plasma cells (mainly those cells producing IgA, IgE, ± IgG)	Defective checkpoints in T and B cell division	Mutations in *ATM* gene	Autosomal recessive	Cerebellar ataxia Telangiectasia Chromosomal abnormalities Raised serum α-fetoprotein levels
MHC class II deficiency	CMI ± antibody	None	T cells, B cells, and antigen-presenting cells	Defects of promoter proteins	Autosomal recessive	Intestinal malabsorption
CD3 deficiency	CMI	None	T cells	Mutations in CD3-ε or CD3-γ	Autosomal recessive	—
CD8 deficiency	CMI	↓ $CD8^+$ T cells, normal number of $CD4^+$ cells	Early T cells	Mutations in *ZAP* genes	Autosomal recessive	—

CMI—cell-mediated immunity LSC—lymphocytic stem cell HSC—hematopoietic stem cell

SEVERE COMBINED IMMUNODEFICIENCY

Severe combined immunodeficiency disease (SCID) is characterized by marked depletion of cells that mediate both humoral and cellular immunity—B cells and T cells, respectively. SCID is fatal if left untreated.

Several variants of SCID have been identified. They are designated as T^-B^- or T^-B^+, depending on whether B cells are normal or increased (B^+) or absent (B^-). In addition to the extent of B cell involvement, the variants also differ in the site of the basic cellular defect, the pathogenetic mechanism, and the mode of inheritance [*see Table 3*].

Genetics and Pathogenesis

T^-B^+ SCID may be transmitted as either an X-linked or an autosomal recessive trait. The specific genetic defect responsible for the X-linked form of T^-B^+ SCID results from mutations in the γ chain of the interleukin-2 receptor (IL-2R),[20] whose gene is localized to the long arm of the X chromosome at Xq13.[21] This γ chain is also found in the receptors for IL-4, IL-7, IL-11, and IL-15.[22] Engagement of the IL-7 receptor by IL-7 is required for T cell maturation, so precursor T cells in these patients do not mature.

When any of those receptors, or IL-2R, are engaged by its ligands, a cytoplasmic tyrosine kinase (Janus-family tyrosine kinase, or JAK3) bound to the γ chain is activated. The gene encoding JAK3 is on an autosome, not the X chromosome. Thus, autosomal recessive T^-B^+ SCID is caused by mutations in the *JAK3* gene.[23,24]

T^-B^- SCID is inherited in an autosomal recessive manner. About half of the cases are caused by a deficiency in the enzyme adenosine deaminase (ADA),[25] and another large fraction results from mutations in the recombination-activating genes *RAG-1* and *RAG-2*.[26] These recombinase enzymes are required for the gene rearrangements that occur before T cell receptor or immunoglobulin synthesis. Other patients with autosomal recessive T^-B^- SCID lack the enzyme purine nucleoside phosphorylase (PNP).[27]

ADA deficiency leads to an accumulation of adenosine, adenosine triphosphate (ATP), and deoxy-ATP (dATP). It has

Table 4 Laboratory Tests Used to Determine Deficiencies of Cell-Mediated Immunity

Skin test: 24- to 48-hr reaction to *Candida*, *Trichophyton*, PPD
Response to nonspecific mitogens: phytohemagglutinin, concanavalin A, pokeweed mitogen
Response to specific mitogens: diphtheria, tetanus, *Candida*
Response to alloantigens: mixed lymphocyte reaction
When responses to alloantigens and nonspecific and specific mitogens are negative: repeat tests while stimulating cells with IL-2
Enumerate T cells with monoclonal antibody to CD3, with or without a cell sorter
Enumerate T cell subsets with monoclonal antibody to CD4 for helper T cells and with monoclonal antibody to CD8
Enumerate T cells positive for Ia (class II) antigens (which measures the number of activated T cells)
Quantitate IL-2 receptors with monoclonal antibody TAC
Quantitate IL-2 and interferon-gamma synthesis
Enumerate NK cells with monoclonal antibodies Leu-7 and Leu-11
Assay NK cell activity using cell line K-562
Assay cytotoxic T cell activity using cell lines of cloned T cells
Enumerate monocytes with monoclonal antibody Mo-1
Assay for IL-1 production by stimulated monocytes
Determine serum level of anti–T cell antibodies
Determine if antibody to HIV is present
HLA typing
Assay erythrocytes for adenosine deaminase and purine nucleoside phosphorylase activity
Detect thymus shadow on x-ray

Note: All patients with defects in cell-mediated immunity should receive all tests listed, except the last three, for optimal examination. The last three tests are for patients suspected of having severe combined immunodeficiency or congenital thymic hypoplasia. HLA typing is needed for prospective recipients of bone marrow transplants.
IL-1—interleukin-1 IL-2—interleukin-2 PPD—purified protein derivative of tuberculin NK—natural killer

been shown that dATP poisons ribonucleotide reductase, an enzyme required for DNA synthesis. Thus, lymphocytes lacking ADA cannot divide until the dATP overload is decreased or removed. In a similar manner, lymphocytes that lack PNP accumulate guanosine, guanosine triphosphate (GTP), and deoxy-GTP, causing metabolic abnormalities that resemble those seen in ADA deficiency. SCID caused by ADA or PNP deficiency can be diagnosed prenatally by amniocentesis because fibroblasts in the amniotic fluid also show the enzymatic defect.

CD8 deficiency is a rare form of SCID that results from mutations in the *ZAP-70* gene.[28,29] ZAP-70 is a tyrosine kinase that binds to the CD3 chain and is involved in signal transduction from the T cell receptor (the TCR-CD3 complex). $CD8^+$ T cells fail to mature, and mature $CD4^+$ T cells fail to function as a result of the mutations in *ZAP-70*.

Another variant of SCID is reticular dysgenesis, a severe combined immunodeficiency with a generalized granulocyte deficiency. Newborns with this disease lack granulocytes in the blood and bone marrow and die of infection within the first few days of life.

Diagnosis

Clinical manifestations Chronic pulmonary infections, diarrhea, moniliasis, and failure to thrive are the most common manifestations of SCID. The lymph nodes are small to absent despite chronic infections, which usually begin at 3 to 6 months of age.

Laboratory tests Complete blood counts show a low number of lymphocytes. There is absence of a thymic shadow on chest x-ray. (Autopsy in fatal cases has revealed an embryonic thymus that resembles the thymus at 6 weeks of gestation, before invasion with lymphocytes.) Tests for cutaneous delayed hypersensitivity and contact sensitization and in vitro assays of blood lymphocytes are negative, demonstrating the absence of T cells, a phytohemagglutinin response, and lymphokine production. Antibody levels are usually low, although occasionally the IgM level is normal; and sometimes, a myeloma component is seen.

Treatment

Hundreds of cases of SCID have been successfully treated by transplantation of bone marrow cells.[30] By 3 to 8 months after receiving the bone marrow, these patients show normal delayed hypersensitivity and T cell function and are no longer abnormally susceptible to infection.

Immunologic reconstitution with bone marrow cells should be attempted only in specialized centers where comprehensive histocompatibility typing and intensive 24-hour care can be given. If the donor and the recipient are not exceedingly well matched, fatal graft versus host disease (GVHD) will ensue. Even an HLA-mismatched blood transfusion can produce fatal GVHD in such patients: the patient is immunocompromised and thus cannot reject the injected cells, but the histoincompatible cells that have been administered recognize the patient's cells as foreign and react against them.

The manifestations of GVHD include fever, diarrhea, depression of the bone marrow, splenomegaly, and an erythematous rash on the face, trunk, and extremities. The reaction eventually leads to death. GVHD can be avoided by irradiating the blood before transfusion.

It is possible to establish grafts of half-matched (haploidentical) parental marrow in infants with SCID. GVHD can be avoided in those cases if the parental marrow is depleted of T cells before transplantation by passage over lectin columns or by treatment with anti–T cell monoclonal antibody plus complement.

Patients with ADA deficiency have also been treated successfully with infusions of purified adenosine deaminase modified with polyethylene glycol. The ADA gene has been cloned and inserted into a retroviral vector.[31] In a few ADA-deficient children, this vector has been transfected into peripheral blood lymphocytes, which were then reinfused. This gene therapy procedure has corrected the immunodeficiency in these patients, although it must be repeated periodically.[32] Successful gene therapy has also been carried out in X-linked SCID by transducing a Maloney virus vector bearing the gene for the common γ chain into bone marrow cells. Sustained responses have been reported in four of these patients: T cell number and function normalized in these patients, as did B cell function, and infusions of γ globulin were no longer required.[33]

WISKOTT-ALDRICH SYNDROME

An X-linked recessive disease, Wiskott-Aldrich syndrome (WAS), results from a mutation that has been mapped to the Xp11.3–p11.22 region of the X chromosome. The *WAS* gene has been cloned.[34,35]

The lymphoid system of a patient with WAS appears anatomically intact at birth. Starting in the first months of life, however, there is a decrease in T cells in the paracortical areas of the lymph nodes and a polyclonal expansion of B cells. The T cells in these patients respond poorly to mitogens. The protein encoded by the *WAS* gene appears to be involved in signal transduction that

leads to reorganization of the cytoskeleton when lymphocytes are stimulated, which results in defective collaboration between T cells and B cells. Lymphocytes have a markedly abnormal appearance when visualized by scanning electron microscopy. Platelets are abnormally small and few in number.[36] Certain missense mutations in the *WAS* gene lead to a mild disease called X-linked thrombocytopenia.[37]

Diagnosis

Clinical manifestations WAS is characterized by eczema, easy bruising, increased susceptibility to infection (both pyogenic and opportunistic), and bloody diarrhea. These manifestations appear in the first months of life. An increased incidence of hematopoietic malignancies is seen, starting in the second or third decade of life.

Laboratory testing Patients with WAS have normal levels of IgG, high levels of IgE and IgA, and low levels of IgM. Severe thrombocytopenia is universal. Tests of cell-mediated immunity [*see Table 4*] show a variety of abnormalities: WAS patients lack isohemagglutinins and are unable to make antibodies to polysaccharides. They respond to some protein antigens but not to others; in addition, they may exhibit anergy and may not display positive results to skin tests for the usual bacterial or fungal antigens.

Treatment

WAS patients have been treated with marrow transplantation after receiving irradiation or busulfan and antilymphocyte serum to destroy residual lymphocytes; they have then shown normal immune and platelet functions. In WAS patients who do not receive a bone marrow transplant and who experience severe bleeding from thrombocytopenia, splenectomy may be considerably beneficial.[38]

IMMUNOLOGIC DEFICIENCY WITH ATAXIA-TELANGIECTASIA

Ataxia-telangiectasia (A-T) is a disease associated with defects in cell-mediated immunity and with immunoglobulin deficiencies. It is inherited as an autosomal recessive trait. The gene for A-T (*ATM* for A-T mutated) maps to the chromosomal region 11q22.3.[39,40] Normally, the gene appears to function in repair of breaks in double-stranded DNA. Patients with A-T have a disorder of the cell-cycle checkpoint pathway that results in an extreme hypersensitivity to ionizing radiation. Consequently, frequent chromosomal breaks, inversions, and translocations are observed. Postmortem examination may disclose abnormalities in the thymus, which is small and deficient in lymphocytes. There also may be an abnormality in lymph node structure.

Diagnosis

Clinical manifestations A-T presents as a progressive neurologic disease that begins in early childhood. It is characterized by cerebellar ataxia, starting at 18 months of age, followed by increasing tremor and deterioration of mental function. By 5 years of age, progressive telangiectasia is seen in the vessels of the bulbar conjunctiva and is later visible on the skin. The immune deficiencies in these patients leads to recurrent sinus and bronchial infections and subsequent bronchiectasis. An unusually high incidence of lymphoid malignant disorders has been reported in patients with A-T.[41]

Laboratory testing About 70% of patients with A-T have a severe deficiency in IgA. On tests of cell-mediated immunity [*see Table 4*], some A-T patients are anergic and fail to show delayed hypersensitivity responses to common microbial antigens. They may also have abnormal in vitro cell-mediated immune responses and may tolerate allografts.

Treatment and Prognosis

No satisfactory treatment for A-T is currently available. Persons with A-T who survive into their second decade may fail to mature sexually. A-T patients usually die of lymphoid malignancies or other causes by the end of their second decade.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

IX IMMUNOLOGIC TOLERANCE AND AUTOIMMUNITY

Paul Anderson, m.d., ph.d.

A central concept of immunology is that autoimmune reactions are injurious to the host. Around 1900, Paul Ehrlich postulated that the immune system acquires a state of tolerance to self-antigens; as a corollary to that, he proposed that the breakdown of tolerance would lead to self-destruction, a condition he described as "horror autotoxicus."[1] Subsequent work by mid–20th-century researchers such as Ray Owen,[2] Macfarlane Burnet,[3] and Peter Medawar[4] established the basic mechanism for the development of immunologic tolerance. In recent years, many important advances have been made in our understanding of tolerance at the molecular and cellular levels. These advances are beginning to transform the clinical management of autoimmune diseases and may lead to therapies that prevent rejection of transplanted organs.

Tolerance

Tolerance is defined as a state of immunologic unresponsiveness to antigens, whether self or foreign. Antigens are recognized by specific receptors expressed on the surface of T cells and B cells. Binding of an antigen to the receptor can either activate or inhibit these immune effector cells. The molecular and cellular factors that determine whether receptor ligation induces immunity or tolerance are beginning to be unraveled.

Mechanisms of Tolerance

Tolerance results from one of three inhibitory influences on T and B cells: (1) clonal deletion, in which antigenic recognition leads to the activation-induced death of specific lymphocytes; (2) clonal anergy, in which lymphocytes are not killed but are rendered unresponsive to the recognized antigen; and (3) T cell–mediated suppression, in which regulatory T cells actively inhibit an immune response to an antigen. Several factors help determine which of those responses will occur.

Immature lymphocytes are more susceptible to induction of tolerance than are mature lymphocytes. Tolerance can be induced in immature lymphocytes either centrally or in the periphery. Central tolerance is acquired when immature lymphocytes encounter antigens in the organs that generate these cells: the thymus (T cells) and the bone marrow (B cells).

T cells recognize antigens that have been processed into peptides and presented in a complex with major histocompatibility complex (MHC) molecules (self-MHC–peptide complexes). Consequently, immature T cells must be screened for their ability to recognize self-MHC. This screening takes place in the thymus gland. T cells bearing receptors that recognize self-MHC are subjected to the processes of positive and negative selection [*see Figure 1*].[5] Positive selection occurs when T cells bearing receptors with a moderate affinity for self-MHC–peptide complexes receive survival and maturation signals after receptor ligation. Once these cells mature, they are exported to the periphery. Negative selection occurs when T cells bearing receptors with a high affinity for self-MHC–peptide complexes undergo activation-induced death. The thymus gland is capable of presenting many self-antigens that are normally expressed outside of the thymus or during restricted developmental stages.[6,7] This allows the elimination of most T cells bearing high-affinity receptors for self-MHC–peptide complexes and plays a major role in preventing autoimmunity in peripheral organs. The promiscuous expression of peripheral antigens in thymic epithelial cells is regulated by the autoimmune regulator (AIRE). This transcriptional modulator is mutated in persons with autoimmune polyglandular syndrome type 1 (APS-1), which is characterized by mucocutaneous candidiasis in association with autoimmune tissue damage that variably targets the parathyroid, adrenal glands, ovaries, and other tissues.[6-8] The severity of this syndrome highlights the critical importance of central tolerance to immune homeostasis.

Because positive selection allows the maturation of T cells bearing receptors capable of low-affinity interactions with self-MHC–peptide complexes, potentially self-reactive T cells are normally found in peripheral lymphoid organs. Peripheral tolerance prevents these cells from inducing autoimmune disease.

Peripheral tolerance is achieved in one of three ways.[9] Perhaps the most common mechanism is the failure of T cells bearing low-affinity receptors to recognize self-antigen in the periphery. In this situation, the potentially self-reactive T cell is not activated and remains functionally naive. These cells are functional, however, as is shown by the fact that they can be activated by immunization with self-antigen delivered in the presence of immune adjuvants (e.g., complete Freund adjuvant, which contains microbial products that strongly activate the immune system at many levels). Failure to respond to self-antigen may simply re-

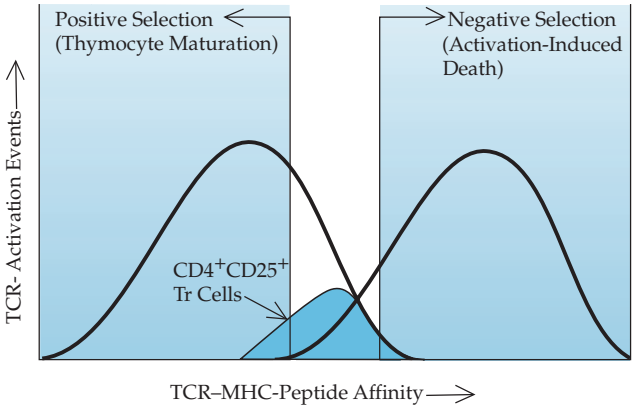

Figure 1 **In the thymus, tolerance is induced through positive and negative selection of immature T cells. The fate of a particular T cell depends on the affinity of its receptor (TCR) for complexes of major histocompatibility complex (MHC) and self-peptides. After ligation, T cells whose receptors have low affinity for self-MCH–peptide complexes receive survival and maturation signals and are exported to the periphery (positive selection); T cells with high affinity undergo activation-induced death (negative selection).**

$CD4^+$ regulatory T cells (Tr) that express CD25 have intermediate affinity for self-MCH–peptide complexes. This subpopulation of T cells matures in the thymus gland; suppression of their activation takes place in the periphery.

flect a receptor-binding affinity that is below the threshold for T cell activation.

T cells bearing receptors with high affinity for a self-antigen can also remain in an unactivated state if that self-antigen is sequestered from immune effector cells. An example of an antigen that is sequestered from the immune system is myelin basic protein. Because T cells do not normally circulate through the central nervous system, potentially self-reactive cells can persist in an unactivated state in the periphery. Similarly, pancreatic islet cells are normally sequestered from the immune system. In transgenic mice, recombinant proteins expressed on pancreatic islet cells are ignored by high-affinity T cells specific for the recombinant protein. This appears to result from the failure of naive T cells to contact islet cells in the absence of inflammation. In contrast, T cells do become activated in an antigen-specific manner in transgenic mice that express the same recombinant protein in hepatocytes. It therefore appears that circulating lymphocytes contact different tissues in different ways.

A second mechanism of peripheral tolerance involves the elimination of self-reactive T cells by apoptosis. This process is analogous to clonal deletion in the thymus (i.e., negative selection). An example of peripheral deletion is the ability of superantigens (bacterial proteins that bridge selected T cell receptors and selected MHC molecules in an antigen-nonspecific manner) to induce the activation and subsequent death of T cells[10] [*see 7:XXX Sepsis*]. Whether peripheral deletion plays an important role in tolerance to self-antigens is not known, however.

A third mechanism of peripheral tolerance involves the acquisition of anergy after ligation of the T cell receptor complex.[11] This antigen-nonresponsive state can be induced in several distinct ways. The most extensively characterized mechanism of anergy induction occurs when the T cell receptor is ligated in the absence of costimulation. In the classic studies of Schwartz and colleagues, T cell clones that were activated by MHC-peptide complexes incorporated into artificial lipid bilayers were rendered nonresponsive to subsequent challenge with peptide-pulsed antigen-presenting cells (APCs).[12] It was subsequently shown that once a T cell has bound with an antigen, the cell requires a so-called second signal delivered by one or more costimulatory molecules to be primed for an immune response. T cells express several surface molecules that can transmit this second signal. These costimulatory receptors are engaged by ligands expressed on the surface of APCs. T cells that are activated in the absence of costimulation acquire defects in the transcriptional control pathways for the production of interleukin-2 (IL-2), an important T cell autocrine growth factor.[13] In vitro anergy can often be overcome by supplying exogenous IL-2 to anergic T cells.

Costimulatory signals can be delivered to T cells by soluble factors or cell surface molecules expressed on APCs. The most potent costimulatory signals are delivered when CD28,[14] CD154,[15] or both are ligated on the surface of T cells [*see Figure 2*]. Blockade of costimulatory signals by monoclonal antibodies or recombinant receptor antagonists confers potent immunosuppression and allows the acceptance of skin, cardiac, and pancreatic allografts in rodents.[16] Simultaneous blockade of the CD28 and CD154 pathways is significantly more immunosuppressive than blockade of a single costimulatory pathway. The ligand for CD154 is CD40, a protein expressed on the surface of activated B cells, dendritic cells, and macrophages.[15] The ligands for CD28 (B7-1, B7-2, and related proteins[14]) are expressed on the surface of APCs, such as dendritic cells, monocytes, and B cells. Their expression is induced when APCs are activated in the course of microbial infection. This property heightens the immune response in the setting of perceived danger (i.e., microbial infection). B7-1 and B7-2 have overlapping immunostimulatory roles: mice lacking either protein are only partially deficient in generating an immune response to foreign antigen.[14] Additional costimulatory molecules that are involved in fine tuning the immune response include B7 homologues expressed on APCs (e.g., B7-H1, B7-H2, B7-H3, and B7-DC) that bind to ligands expressed on T cells (ICOS, PD-1, and possibly others).[14]

Ligation of CD28 induces the expression of CTLA-4 (cytotoxic T lymphocyte–associated protein 4), a structurally related protein that turns off activated T cells.[17,18] By this mechanism, the activated T cell initiates a program that will ensure its elimination at the conclusion of the immune response. Compared with CD28, CTLA-4 has a higher affinity for B7-1 and B7-2.[14] The importance of the negative regulatory influence of CTLA-4 is dramatically observed in CTLA-4–null mice. These animals develop a fatal lymphoproliferative syndrome from the uncontrolled activation of self-reactive T cells.[19]

Given the central importance of CD28-B7 interactions in T cell activation and the ability of costimulatory blockade to prevent allograft rejection, it might seem paradoxical that NOD mice (a strain that develops spontaneous diabetes) lacking either CD28 alone or both B7-1 and B7-2 have more severe diabetes.[20] The reason for this appears to be that CD28-B7 interactions are required for the maturation of self-reactive regulatory T cells (Tregs). Tregs, which are generated within the thymus gland, form a distinct class of regulatory T cells that play a major role in ensuring tolerance to self-antigens in the periphery. Just as APS-1 provides a clinical demonstration of the importance of central tolerance to normal immune function, the immune dysregulation, polyendrocrinopathy, enteropathy, and X-linked syndrome (IPEX) dramatically demonstrates the importance of Tregs in the maintenance of self-tolerance.[21] IPEX patients have mutations in the FOXP3 transcription factor that is essential for the maturation and function of Tregs. These patients exhibit hyperactivation of T cells that are reactive with self-antigens, resulting in polyendocrinopathy, inflammatory bowel disease, and allergy.

In rodents, FOXP3-dependent Tregs comprise a subset of peripheral blood $CD4^+$ T cells that express CD25, a subunit of the IL-2 receptor.[22] The selective removal of $CD4^+$ and $CD25^+$ T cells from BALB/c mice results in the development of T cell–mediated autoimmune thyroiditis, gastritis, and diabetes. The $CD4^+$ and $CD25^+$ Treg cells that mature in the thymus gland bear receptors that have an intermediate affinity for self-MHC–peptide complexes [*see Figure 1*]. In the periphery, antigen exposure confers the ability to suppress the activation of $CD4^+$ and $CD25^+$ T cells in an antigen-independent, cell contact–dependent manner. Although these cells secrete IL-10, a potent anti-inflammatory cytokine, their suppressive activity is cytokine independent. $CD4^+$ and $CD25^+$ T cells can suppress graft versus host disease in allotransplants, and they can prevent autoimmune disease in several different animal models. Consequently, these cells probably play an essential role in maintaining peripheral tolerance to self-antigens.

Although T cells play a dominant role in the maintenance of immune tolerance, non–T cells are also important in this process. Natural killer T (NKT) cells are specialized effectors of innate immunity that are activated by endogenous or microbe-derived lipids bound to CD1.[23] Activated NKT cells express

large amounts of interferon gamma and IL-4, allowing them to have profound effects on the immune response. Results in animal models have implicated NKT cells in the suppression of autoimmune disease.[24] Several autoimmune mouse strains (e.g., NOD, MRL-lpr/lpr, and SJL/J) have reduced the numbers of NKT cells as compared with nonautoimmune strains. In these models, adoptive transfer of NKT cells can ameliorate disease. Moreover, activation of NKT cells by the natural product α-galactosylceramide prevents autoimmune disease in several murine models. Although the role of NKT cells in human autoimmune disease remains to be determined, these results show that components of the innate immune response can have profound effects on discrimination of self from nonself [*see 6:II Innate Immunity*].

Autoimmunity

Despite the multiple and redundant mechanisms that exist to ensure immunologic tolerance to self, autoimmune phenomena are relatively common. In some cases, autoimmune responses accompany a normal immune response to a microbial pathogen. Thus, the appearance of rheumatoid factor (anti-immunoglobulin antibodies) in the serum of patients with bacterial endocarditis is relatively common. In general, these autoantibodies are not pathogenic. Their appearance probably results from antigen-nonspecific activation of T cells and B cells bearing low-affinity receptors for self-antigens that are normally held in check by mechanisms of peripheral tolerance. The ability of bacterial products (e.g., lipopolysaccharide) to function as immune adjuvants appears to overcome these repressive influences.

Molecular Mimicry

Clinical observations have established a link between certain microbial infections and specific autoimmune syndromes. Examples include streptococcal infection and rheumatic fever, *Borrelia burgdorferi* infection and Lyme arthritis, *Trypanosoma cruzi* infection and Chagas disease, and B4 coxsackievirus infection and type 1 diabetes mellitus.[25] These associations suggest that the immune response to a specific microbial peptide may be redirected toward a similar self-peptide, a phenomenon known as molecular mimicry. Although this is an appealing hypothesis, definitive evidence for molecular mimicry has yet to be demonstrated in any of these diseases. The strongest evidence, to date, for molecular mimicry comes from the molecular analysis of the immune response to the tick-borne spirochete *B. burgdorferi*. About 10% of infected patients develop persistent synovitis, despite the eradication of the spirochete by antibiotic therapy.[26] Most patients with treatment-resistant Lyme arthritis have the HLA-DRB1*04041 or HLA-DRB1*0101 major histocompatibility alleles, implicating antigen presentation in disease pathogenesis. These same HLA alleles confer an increased relative risk for rheumatoid arthritis and, perhaps, for synovial disease in general. Treatment-resistant Lyme arthritis is associated with a cellular and humoral immune response to the *B. burgdorferi* outer-surface protein OspA, and a computer algorithm predicted that an immunodominant OspA epitope (OspA165-173) should bind to HLA-DRB1*0401. This prediction was confirmed experimentally, and indeed, most patients with treatment-resistant Lyme arthritis have T cells that recognize this immunodominant epitope. The computer algorithm also predicted that a peptide epitope encoded by leukocyte function–associated antigen–1α (LFA-1α) would bind to HLA-DRB1*0401. This binding was confirmed experimentally, and most patients with treatment-resistant Lyme arthritis have T cells that weakly respond to the LFA-1α peptide epitope. The LFA-1α peptide does not bind to HLA-DRB1*0101, however, indicating that this mechanism cannot explain all cases of treatment-resistant Lyme arthritis. Moreover, it remains to be proved that T cells reactive with LFA-1α are necessary and sufficient for the onset of treatment-resistant Lyme arthritis.[27]

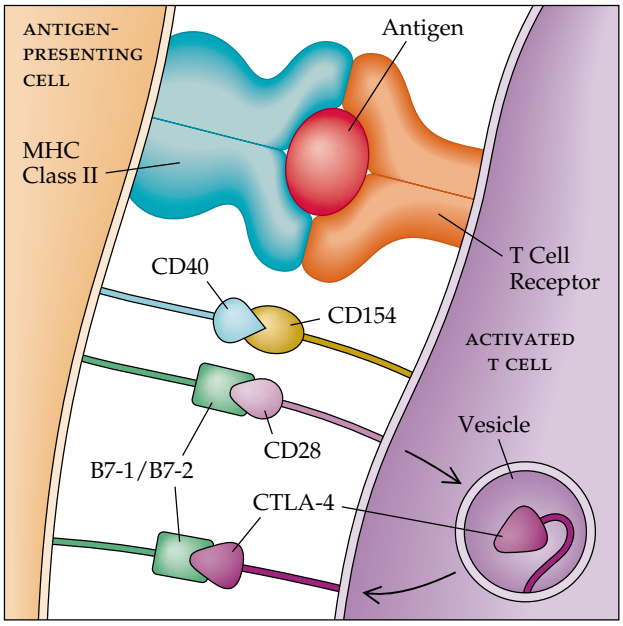

Figure 2 **Activation of T cells begins when the T cell receptor binds with a complex of an MHC molecule and a peptide expressed on the surface of an antigen-presenting cell (APC). Activation is completed by a second signal generated by the ligation of costimulatory molecules expressed on the cell surface of the APC. B7-1/B7-2 interacts with CD28 on the T cell, and CD40 interacts with CD154.**

In unactivated T cells, CTLA-4 (a relative of CD28) is a component of intracellular vesicles. After CD28 ligation, CTLA-4 moves to the cell surface and binds with B7-1/B7-2, generating negative signals that turn off the immune response.

Identification of Autoantigens

A common feature of autoimmune diseases is the appearance of autoantibodies in the serum. In some cases, these autoantibodies are directly pathogenic: the clinical syndrome is produced when the antibody binds to its target antigen. The molecular pathogenesis of these autoimmune conditions can be determined with some precision. Unfortunately, the molecular defects that allow the bypass of tolerance to the disease-inducing autoantigen are less well understood.

Pathogenic Autoantibodies

Myasthenia gravis Nearly all patients with myasthenia gravis have autoantibodies to acetylcholine receptors (ACRs) on skeletal muscle [*see 11:III Diseases of Muscle and the Neuromuscular Junction*]. However, the degree of neuromuscular blockade seen in this disease does not always parallel the serum levels of anti-ACR antibodies. The antibodies are polyclonal and bind to several distinct epitopes on the ACR. Although these antibodies can directly inhibit ACR function, they can also promote the endo-

cytosis and accelerated degradation of the ACR or activate complement-mediated destruction of the postsynaptic surface.[28] The supposition that these anti-ACR antibodies have direct pathogenic effects is supported by the fact that injection of ACR antibodies can induce myasthenic weakness in animals and that plasmapheresis is an effective treatment in some patients. Some patients with myasthenia gravis have a coincident thymoma, and thymectomy can be an effective treatment in such patients, suggesting that defects in thymic selection of maturing T cells may play a role in the autoimmune response to the ACR. This could involve impaired negative selection of $CD4^+$ helper T cells reactive with ACR-derived peptides or impaired generation of Tregs specific for ACR-derived peptide epitopes.

Pemphigus Pemphigus vulgaris and bullous pemphigoid are autoimmune skin diseases characterized by the presence of serum autoantibodies that react with adhesion molecules found at the dermoepidermal basement membrane zone [*see 2:IX Vesiculobullous Diseases*]. In pemphigus vulgaris, a common target antigen is desmoglein 3, a desmosomal adhesion molecule. In bullous pemphigoid, common target antigens are two major hemidesmosomal proteins of 180 kd and 230 kd. Several lines of evidence have implicated autoantibodies targeting these proteins in the pathogenesis of pemphigus. First, autoantibodies are consistently present in patients with pemphigus, levels of those antibodies correlate with disease activity, and the removal of the antibodies by plasmapheresis results in improvement of symptoms. Second, serum from patients with pemphigus vulgaris causes pemphigus-like lesions in mice. Third, newborns of mothers with pemphigus have transient disease resulting from transplacental transmission of maternal antibody.

Autoimmune endocrinopathies Autoantibodies reactive with hormone receptors can contribute to endocrine disorders. High levels of antibody reactive with the peripheral insulin receptor can result in insulin-dependent diabetes mellitus. Paradoxically, low levels of antibody may stimulate the insulin receptor by mimicking insulin, resulting in hypoglycemia.

Autoimmune disease of the thyroid is associated with antibodies directed toward three antigens: microsomal thyroid peroxidase, thyroglobulin, and the thyroid receptor for thyroid-stimulating hormone (TSH). Antibodies to the TSH receptor may mimic the action of TSH, thereby resulting in Graves disease [*see 3:I Thyroid*]. Another apparent autoimmune disease of the thyroid, Hashimoto thyroiditis, is associated with antibodies to the TSH receptor, but the pathogenic role of the antibodies in this disease is unclear. Less commonly, antibodies to the TSH receptor may block the action of TSH and cause hypothyroidism. A pathogenic role for the other two classes of antithyroid autoantibodies has not been established.

Antiphospholipid syndrome The antiphospholipid syndrome (APS) consists of recurrent thrombosis, fetal loss, and thrombocytopenia in association with antibodies to cardiolipin or other negatively charged phospholipids, along with abnormalities of certain clotting tests caused by an inhibitor referred to as the lupus anticoagulant [*see 5:XIV Thrombotic Disorders*]. APS can be primary or secondary; secondary APS is usually associated with systemic lupus erythematosus (SLE) or its variants. The antiphospholipid antibodies do not bind to phospholipids alone but to a complex of phospholipids and the plasma proteins β_2-glycoprotein I and prothrombin. These antibodies induce the expression of adhesion molecules on endothelial cells that promote the binding of monocytes and platelets as the first step in a thrombotic cascade.

Nonpathogenic Autoantibodies

Autoantibodies reactive with intracellular targets can serve as markers of specific autoimmune diseases. For example, antibodies reactive with citrullinated peptides are specific markers of rheumatoid arthritis, antibodies reactive with the mitochondrial enzyme 2-oxo acid dehydrogenase are specific markers of primary biliary cirrhosis, and antibodies reactive with the Smith small nuclear ribonucleoprotein (snRNP) complex are specific markers of SLE. Although these autoantibodies are unlikely to be pathogenic, their presence is highly correlated with specific autoimmune diseases. An understanding of the process that promotes the disease-specific bypass of tolerance to a selected antigen is likely to shed light on the pathogenic mechanism underlying individual autoimmune syndromes. An important insight into the mechanism by which tolerance is abrogated in an antigen-specific manner came with the realization that the targets of many autoantibodies found in the serum of patients with autoimmune disease are proteins that are modified in cells undergoing apoptotic cell death.[29] During apoptosis, myriad intracellular proteins, nucleic acids, and lipids are subjected to enzymatic and nonenzymatic modification. These modifications include protease cleavage, phosphorylation, transglutamination, ubiquitination, citrullination, and isoaspartylation.[30] It has been proposed that these modifications create neo-epitopes to which the immune system has not been tolerized.

Although proteins that are modified during apoptosis are preferred targets of the autoantibodies found in the serum of patients with autoimmune disease, it is clear that apoptosis per se is not sufficient to break tolerance to these self proteins. Apoptosis is a ubiquitous process, yet most persons do not develop autoimmune disease. Apparently, the necessary additional element is delay in the execution of the apoptotic program or the clearance of the apoptotic cell. This phenomenon has been demonstrated in mice that lack the first component of complement. C1q functions as an opsonin that binds to apoptotic cells and promotes their clearance by professional phagocytes (neutrophils and macrophages). In the absence of C1q, the clearance of apoptotic corpses is delayed. Delayed clearance of apoptotic cells somehow increases their immunogenicity.[31]

A similar phenomenon occurs when the execution of the apoptotic program is delayed. For example, influenza virus–induced apoptosis in macrophages has been shown to increase the immunogenicity of viral proteins.[32] This phenomenon requires the phagocytosis of infected macrophages by dendritic cells. By a process of cross-priming, the dendritic cell can then present antigens derived from the infected macrophage in a highly efficient manner. Because influenza virus encodes several genes that function to inhibit apoptosis (e.g., *NS1*), virus-induced apoptosis requires many hours to complete. During this delay, the virus replicates within the infected cell, and the virus-infected cell expresses stress-response proteins (heat shock proteins [HSPs]), including HSP70 and HSP90. These HSPs function as natural adjuvants that can deliver peptides to class I MHC molecules expressed by APCs.[33] The generation of modified peptides and the induction of HSPs may account for the increased immunogenicity of apoptotic cells and the generation of autoantibodies reactive with proteins that are modified during apoptotic cell death.

In this model, the autoantibodies that serve as markers of specific autoimmune diseases are generated when the target cell undergoes delayed or aberrant apoptosis. This implies that the primary insult to the target tissue is produced by a stimulus that induces aberrant cell death and modification of the specific autoantigen. Such a process may be initiated by specific environmental factors (e.g., viruses, toxins, or ultraviolet radiation).

The autoantibodies that directly and indirectly contribute to the pathogenesis of autoimmune disease are produced by differentiated B cells. A reduced activation threshold for B cells has been implicated in the pathogenesis of SLE.[34] Moreover, increased activation of B cells may contribute to the predisposition to lymphoma observed in some autoimmune diseases.[34] Finally, preliminary results suggesting therapeutic efficacy of B cell–depleting monoclonal antibodies in patients with rheumatoid arthritis and SLE indicate that B cells play an important role in the pathogenesis of autoimmune disease.[35,36]

GENETICS OF AUTOIMMUNITY

Systemic autoimmunity is a multigenic trait that is significantly influenced by environmental factors. For example, the concordance rate for SLE in monozygotic twins is only 30%, indicating that both genetic and environmental factors contribute to disease onset. The specific genes that promote autoimmunity can be identified in two ways. Most of the genes currently known to promote autoimmunity have been discovered using case-control association methodologies.[37] These studies have linked the expression of specific HLA haplotypes to specific autoimmune diseases. In a similar fashion, case-control studies have linked defects in both classical pathway complement components (C1q, C2, and C4) and Fc receptor alleles to the development of SLE. In families in which two or more members have SLE, genetic linkage analysis has been applied in an attempt to identify disease-susceptibility loci. These studies have identified several chromosomal loci with significant linkage to human SLE.[37] It is likely that future studies will identify a cohort of genes that, alone or in combination, contribute to the autoimmune diathesis.

Studies of transgenic mice that either lack or overexpress specific genes have identified three groups of genes that encode distinct classes of proteins that modify susceptibility to autoimmune disease. Absence of these genes results in autoimmunity. The first group of genes encode proteins involved in the initiation or execution of apoptotic cell death. These proteins include dedicated death receptors and their ligands. Specific members of this family (e.g., Fas and tumor necrosis factor type I [TNF RI]) are required for the clonal elimination of activated T cells after an immune response to microbial infection. Mice lacking either Fas or its ligand develop lymphadenopathy and splenomegaly from the accumulation of previously activated T cells. In some strains of transgenic mice (e.g., MRL), but not in others (e.g., BALB/c), failure to eliminate activated T cells results in an autoimmune disease that resembles SLE. Thus, the absence of Fas or Fas ligand (FasL) promotes the phenotypic expression of an autoimmune diathesis that is intrinsic to the MRL strain (a genetic phenomenon known as epistasis). Although defects in Fas or FasL are not linked to autoimmunity in patients with SLE, mutations in either Fas or FasL produce the autoimmune lymphoproliferative syndrome (ALPS), an autosomal dominant condition characterized by lymphadenopathy, splenomegaly, and autoantibody production.[38] ALPS is also caused by mutations in caspase-10, a component of the effector arm of the apoptotic death program. Thus, ALPS is an autoimmune disease that results from defective execution of an apoptotic program in activated T cells. The importance of the apoptotic program in determining susceptibility to autoimmune disease is further demonstrated by the autoimmune syndromes observed in mice lacking BIM, a pro-apoptotic protein, or overexpressing BCL-2, an anti-apoptotic protein.

The second group of genes encode proteins involved in the recognition, clearance, or elimination of apoptotic cells. These include proteins that serve as opsonins to promote the phagocytosis of apoptotic cells (e.g., C1q, IgM, SAP/CRP), as well as phagocyte receptors that promote the recognition and ingestion of apoptotic cells (e.g., Mer).

The third group of genes encode proteins that set the threshold for lymphocyte activation. Increased activation of T cells or B cells is likely to disrupt normal mechanisms of tolerance, resulting in autoimmunity. Examples include costimulatory lymphocyte surface molecules (e.g., CD22, PD-1), kinases and phosphatases involved in lymphocyte activation (e.g., Lyn, Cbl-b), and transcription factors (e.g., Foxo3a) that promote lymphocyte activation. These animal studies reveal that genes involved in the regulation of apoptosis or lymphocyte activation are proven modifiers of autoimmune disease in mice and are candidates for the modulation of autoimmunity in humans.

Genome-wide linkage mapping has identified mutations in NOD2 as an etiologic factor in familial Crohn disease, an autoimmune inflammatory process that targets the intestinal mucosa.[39] NOD2 is a cytosolic protein that recognizes muramyl dipeptide (MDP), a metabolite of bacterial peptidoglycan.[40] Recognition of MDP promotes the oligomerization of NOD2, which results in activation of NF-κB and caspase-1—signaling events that lead to the secretion of inflammatory cytokines. Selected patients with Crohn disease possess mutant NOD2 that is unable to promote MDP-mediated activation of NF-κB. The mechanism by which ineffective recognition of bacterial products leads to intestinal inflammation remains to be determined.

ORGAN-SPECIFIC VERSUS SYSTEMIC AUTOIMMUNITY

For many years, organ-specific immunity was thought to result from the activation of lymphocytes bearing receptors specific for a tissue-restricted antigen. In rare cases of molecular mimicry, this may be the case. However, it now appears that the target of an autoimmune attack can shift from one tissue to another in response to defined or undefined genetic modifiers. For example, persons with APS-1 develop various combinations of autoimmune thyroiditis, parathyroid disease, and type 1 diabetes mellitus.[41] Although the factors that determine which tissues become targets of autoimmune attack have not been identified, the fact that different tissues are affected in different persons suggests that unique, tissue-specific autoantigens may not be the primary triggers of disease.

The concept that organ-specific autoimmunity need not be driven by a tissue-specific autoantigen is supported by observations made in two different animal models of autoimmunity. In NOD mice whose MHC locus is replaced with that of another strain, autoimmune thyroiditis develops instead of diabetes.[20] This result suggests that the NOD strain harbors an autoimmune diathesis that can manifest itself as different types of organ-specific autoimmunity. In support of this concept, NOD mice lacking the costimulatory molecule B7-2 develop autoimmune peripheral neuropathy, rather than diabetes.[20] Although the mechanism by which individual tissues are selected for im-

mune attack is not known, these results strongly suggest that factors other than tissue-restricted autoantigens can be the primary determinant of organ-specific autoimmune disease.

Another instructive example of organ-specific autoimmunity that arises in the absence of a defined, tissue-restricted autoantigenic trigger is the inflammatory arthritis that develops in the F1 progeny of K/B×NOD mice.[42] The K/B strain expresses a transgenic T cell receptor that recognizes a self-peptide derived from glucose-6-phosphate isomerase (GPI) presented in the context of Ag7, a class II MHC molecule from the NOD strain. In K/B×NOD mice, T cells bearing the transgene provide help for B cells encoding immunoglobulins that bind to GPI. GPI is an enzyme expressed in all cells, yet anti-GPI antibodies somehow provoke a symmetrical, inflammatory arthritis involving diarthrodial joints in these mice. Although the mechanism by which anti-GPI antibodies provoke arthritis is not fully understood, this model illustrates the potential for an immune response that is directed at a ubiquitous antigen to trigger organ-specific autoimmunity.

One way in which organ-specific autoimmunity can be induced in the absence of a tissue-specific autoantigen is by the pathologic overexpression of inflammatory cytokines. Thus, overexpression of tumor necrosis factor–α (TNF-α) in transgenic mice is sufficient to induce a symmetrical polyarthritis that resembles rheumatoid arthritis.[43] This appears to result from the ability of TNF-α to initiate an inflammatory cytokine cascade within the cells that make up the synovium. The importance of TNF-α in the pathogenesis of rheumatoid arthritis has been dramatically validated by the clinical efficacy of TNF blockers such as infliximab and etanercept[44] [*see 15:II Rheumatoid Arthritis*]. In an analogous fashion, BAFF/Blys, a TNF-α–related protein that promotes the survival and differentiation of B cells, has been proposed to participate in the induction of SLE-like autoimmune syndromes.[45,46] Transgenic mice engineered to overexpress BAFF/Blys develop hypergammaglobulinemia and autoimmune symptoms because of the survival of autoreactive B cells that would normally be deleted from the B cell repertoire. These observations suggest that neutralization of TNF family members may play an important role in the treatment of selected autoimmune diseases.

X ALLERGIC RESPONSE

Pamela J. Daffern, m.d.
Lawrence B. Schwartz, m.d., ph.d.

Definition of Allergic Response

The word anaphylaxis was coined in 1902 by Charles Richet, in order to contrast the condition with prophylaxis. Richet described anaphylaxis as "the peculiar attribute which certain poisons possess of increasing instead of diminishing the sensitivity of an organism to their action.…"[1] One hundred years later, we understand anaphylaxis as the extreme of a spectrum of events mediated by immunoglobulin E (IgE). Persons with IgE-mediated disorders have a genetic propensity to form IgE antibodies against otherwise innocuous environmental antigens (allergens); this propensity is termed atopy (from the Greek *atopos*, meaning "out of place"). In atopic persons, IgE mediates a wide range of reactions, including dermatitis, rhinitis, asthma, urticaria, angioedema, and anaphylaxis.

Confusion arises over the misapplication of the term allergy to describe any untoward reaction to food or medications or to perceived environmental exposures. This confusion is further complicated by the fact that both IgE-mediated and non–IgE-mediated forms of rhinitis, asthma, and atopic dermatitis occur, often in the same person.

In the nonatopic person, exposure to allergen results in immunologic tolerance or neglect, whereas in atopic persons, exposure results in sensitization. On reexposure to the allergen, atopic persons mount an immunologically mediated inflammatory response in the target organ. Other environmental factors—such as tobacco smoke, air pollution, respiratory virus infection, and lack of exposure to certain microbes in childhood—may also promote an allergic inflammatory response.

Epidemiology of Atopic Disorders

Up to 30% of the United States population may be affected by allergic rhinoconjunctivitis, asthma, or atopic dermatitis. This high incidence of atopic disease may reflect societal factors. Fetal development takes place in an intrauterine environment that favors atopic sensitization[2]; the maternal immune system suppresses cell-mediated immune responses in order to prevent rejection of the fetus. Thus, the neonate may enter the world with T cells that are already primed by common environmental and food allergens that have crossed the placenta. It has been proposed that microbial exposure and infections during infancy shift the immune response away from the allergic pattern to a protective immune response.[3] Specifically, after macrophages or dendritic cells ingest microbes, T cells produce cytokines that promote non-IgE responses by B cells. Therefore, the increasing prevalence of atopic disorders in countries that have adopted a Western lifestyle, including overuse of antibiotics, has been attributed to a lack of microbial antigen stimulation.

Humoral and Cellular Mechanisms of Allergic Inflammation Associated with Immediate Hypersensitivity

antigen-presenting cells and sensitization

All persons encounter environmental antigens that are capable of inducing an allergic response. Soluble antigens, such as allergens, undergo endocytosis by professional antigen-presenting cells (APCs), which include dendritic cells, such as epidermal Langerhans cells; macrophages; and B cells.[4] However, only dendritic cells and Langerhans cells are able to prime naive T cells and thus are responsible for the sensitization phase.[5,6] Once primary sensitization has been achieved, monocytes and B cells amplify the process. B cells bind allergen through immunoglobulin receptors specific for the allergen, as opposed to nonspecific endocytic pathways used by other APCs. The internalization of antigen results in two processes. The first is general activation of the APC: this includes upregulation of major histocompatibility complex (MHC) and accessory molecules. The second process is fusion of the endocytic vesicle with lysosomes, which results in the formation of specialized antigen-processing vesicles in which antigens are hydrolyzed into protein fragments. The linear peptides that result are incorporated into the antigen-binding groove of a class II human lymphocyte antigen (HLA) molecule during its transport to the cell surface.

In general, APCs will co-express a heterogeneous assortment of allergen-derived peptides and HLA class II molecules on their surface. The efficiency with which processed allergen peptides bind to the HLA class II molecules presumably depends on variations in the HLA loci; these variations are genetically determined. The binding efficiency in turn influences the predisposition of the person to develop allergy to or tolerance of a particular antigen. The APC loaded with processed antigen/HLA class II complexes presents this complex to $CD4^+$,$CD8^-$ helper T cells. The genetically determined binding efficiency of an HLA-derived molecule to an antigen also may influence how T cells develop when exposed to that complex.[7] In addition, the quantity of interleukin-12 (IL-12) produced by APCs also influences the type of T cell response.[5]

t cells and mediation of allergic inflammation

The helper T cell response is influenced not only by APCs but also by the age of the person and by the amount, type, duration, and route of allergen exposure.[7,8] Also, the cytokine milieu during lymphocyte differentiation determines the type of effector function of the helper T cell [*see Table 1*].

For example, bacterial DNA sequences have immunostimulatory regions containing deoxycytidine-phosphate-deoxyguanosine (CpG) repeats. CpG repeats are recognized as foreign by pattern recognition receptors called Toll-like receptor-9 (TLR-9) on APCs.[9,10] These CpG repeats stimulate macrophages and dendritic cells to secrete inflammatory cytokines, including IL-12 and IL-18. These cytokines then induce T cells and natural killer (NK) cells to produce interferon gamma (IFN-γ), a cytokine known to promote nonallergic, protective responses.

Table 1 Cytokines Involved in IgE-Mediated Allergic Inflammation

Cytokine	*Source*	*Function*
IL-3	T_{H2} cells,* mast cells, basophils, eosinophils	Promotes granulocyte and macrophage maturation; eosinophil activation and survival
IL-4	T_{H2} cells,* mast cells, basophils	Promotes differentiation of T_{H0} to T_{H2} cells; antagonizes differentiation of T_{H0} to T_{H1} cells; IgE isotype switching
IL-5	T_{H2} cells,* mast cells, eosinophils	Promotes eosinophil development, activation, and survival
IL-13	T_{H2} cells,* mast cells, basophils	IgE isotype switching, eosinophil activation
GM-CSF	T_{H2} cells and activated macrophages,* endothelial and epithelial cells	Promotes granulocyte and macrophage maturation, eosinophil activation, and survival
TNF-α	Monocytes/macrophages,* mast cells	Promotes chemotaxis and activation of leukocytes and vascular endothelium

*Major source.
GM-CSF—granulocyte-macrophage colony-stimulating factor IL—interleukin TNF—tumor necrosis factor

This pattern of response by helper T cells is termed a T_{H1} response, because it is associated with differentiation of naive helper T (T_{H0}) cells into mature T_{H1} cells. Similarly, the helper T cells of persons without atopy respond to presentation of potentially allergenic peptides by ignoring them or by producing IFN-γ and directing the production of allergen-specific IgG1 and IgG4 antibodies.[11]

In contrast, helper T cells of atopic persons respond to processed aeroallergens by forming IL-4, IL-5, and IL-13 and by directing the production of allergen-specific IgE antibodies. This type of helper T cell response is termed a T_{H2} response. IL-4 and IL-13 share a number of functions, because both cytokines signal through the IL-4Rα/IL-13Rα heterodimer.[12] However, only IL-4 is able to induce the differentiation of T_{H0} cells to T_{H2} cells and to antagonize the differentiation of T_{H0} cells to T_{H1} cells, resulting in IgE-mediated allergic inflammation. In contrast, both IL-12 and IFN-γ induce the differentiation to T_{H1} cells; T_{H2} cell differentiation is inhibited by IFN-γ. Differentiation to T_{H1} cells results in cell-mediated immunity and inflammation.[13] Therefore, the differentiation of T_{H0} cells to either T_{H1} cells or T_{H2} cells appears to be the crucial event that determines which type of immune response will follow.

GENETICS AND THE DEVELOPMENT OF ATOPY

Research has begun to identify specific genetic variants that contribute to the development of the atopic state. For example, a mutation of the IL-12R beta$_2$-chain gene has recently been shown to impair signaling through IL-12. Because IL-12 is a potent inducer of IFN-γ production and because IFN-γ downregulates IgE production (see above), this mutation results in increased IgE production in atopic persons.[14] Polymorphisms in the gene for STAT-6, a transcription factor selectively regulated by IL-4 and IL-13 (cytokines that upregulate IgE production), have also been described.[15] These genetic variations in STAT-6 also appear to be associated with a predisposition to atopy. Finally, an asthma gene (*ADAM-33*) associated with bronchial hyperresponsiveness but not atopy was recently defined by genetic-linkage analysis of affected sibling pairs. The *ADAM-33* gene product, a membrane metalloprotease, may function to modulate the response to cytokines in the lung by solubilizing cytokine membrane receptors, but its precise role still needs to be determined.[16] Like other allergies, however, asthma involves environmental factors. For example, the predisposition to asthma is modified by the presence of allergens and endotoxins.[17]

IgE SYNTHESIS

Once allergen is processed by APCs and presented to T_{H2} cells, a specific sequence of events must follow for IgE production by B cells to occur [*see Figure 1*]. The switch from IgM or IgG production to IgE production by B cells occurs in the genome and requires two signals.[18] The first signal is delivered through the IL-4Rα chain by either IL-4 or IL-13.[12] Signaling through these cytokine receptors initiates transcription from the germline promoter site of the constant portion of the heavy chain of IgE. The IgE heavy-chain gene is located downstream of the IgG and IgM heavy-chain genes and replaces IgG or IgM on the immunoglobulin molecule. The second signal is delivered through activation of the cluster differentiation 40 (CD40) receptor on B cells.[19] Signaling through CD40 activates the recombinases necessary to remove the upstream IgG or IgM heavy-chain constant region and replace it with the corresponding region of IgE. This process switches the type of antibody being produced without altering its antigenic specificity. Stimulation of B cells through CD40 also stimulates growth, differentiation, and survival of these cells.[20]

The ligand for CD40 (CD154, CD40L) is expressed not only on T cells but also on mast cells and basophils. Importantly, all of these cells also secrete IL-4, IL-13, or both, and therefore could potentially play a role in directing B cell production of IgE. However, it seems likely that T cells are responsible for initiating the switch to antigen-specific IgE production. Mast cells and basophils may then amplify deviation of immune responses toward IgE production after the primary IgE sensitization has occurred.[19] It seems likely that binding to CD40 on B cells by mast cells and basophils would enhance polyclonal (i.e., not antigen-dependent or specific) IgE production by B cells, because mast cells and basophils are not dedicated APCs. IgE antibody secreted by B cells circulates briefly, having a serum half-life of 2 to 3 days, before binding to IgE receptors.

IgE RECEPTORS AND REGULATION OF IgE

Receptors for IgE (FcεR) are expressed on various cells.[21] The high-affinity receptor for IgE, FcεRI, has two forms that differ by the presence or absence of a beta chain. The beta chain is present in the high-affinity receptor found on mast cells and basophils.[19] The presence of the beta chain amplifies the cellular signaling that occurs when IgE bound to FcεRI is cross-linked by allergen. Its presence also increases the amount of IgE receptor on the surfaces of mast cells and basophils by up to sixfold.[22]

Levels of FcεRI on the surface of basophils have been shown to correlate with serum IgE levels in various IgE-associated diseases.[23,24] The high-affinity receptor lacking the beta chain is also expressed on monocytes, Langerhans cells, dendritic cells (i.e., APCs other than B cells), activated eosinophils, and epithelial cells.

The low-affinity IgE receptor, FcεRII, bears structural homology to C-type lectins, but not to FcεRI. (Lectin receptors recognize pathogens and also function as adhesion receptors and signaling molecules.) FcεRII, also known as CD23, is expressed on B and T cells, monocytes, eosinophils, and platelets.[25] CD23 expression is increased by IL-4 and IL-13, and increased CD23 expression would presumably facilitate allergen uptake and presentation to T cells by APCs.[26] Furthermore, B cells from allergic asthmatic patients exposed to allergen have increased CD23 expression.[27] Whether allergic inflammation is initiated when IgE is bound to FcεRII is not clear. However, the solubilized form of CD23 may play a regulatory role in IgE synthesis.[26,28]

When a sensitized individual is exposed to allergen, the allergen binds to IgE receptors on mast cells and basophils. If multivalent, the allergen will cross-link a critical number of cell-bound IgE receptors, leading to cellular activation, secretion of mediators, and production of the symptoms characteristic of early-phase allergic responses.[28]

Clearly, treatment that interferes with IgE activation of mast cells and basophils may be beneficial. Omalizumab, a recombinant, humanized monoclonal antibody directed against the Fcε portion of IgE, has recently been developed.[29] Important features of this anti-IgE molecule are (1) it does not bind IgE already attached to FcεRI, and therefore does not cause anaphylaxis; (2) it does not activate complement; and (3) it has a much longer half-life than IgE. In phase III trials, omalizumab was administered by subcutaneous injections given every 2 or 4 weeks to patients with allergic rhinitis or with allergic asthma of varying severity.[30,31] All studies showed dramatic reductions in free IgE levels that were dependent on omalizumab dose as well as baseline IgE levels.[32] As levels of serum IgE decreased, so did surface expression of FcεRI on basophils. Moreover, the posttreatment level of free IgE directly correlated with reduced symptom scores, reduced use of rescue medication, and improved quality of life. For asthma, significant reductions in asthma exacerbations, in hospitalizations for asthma, and in the dose of inhaled or oral steroids were also found. A recent phase II trial of omalizumab in peanut-sensitive children showed a decreased sensitivity to oral peanut challenges.

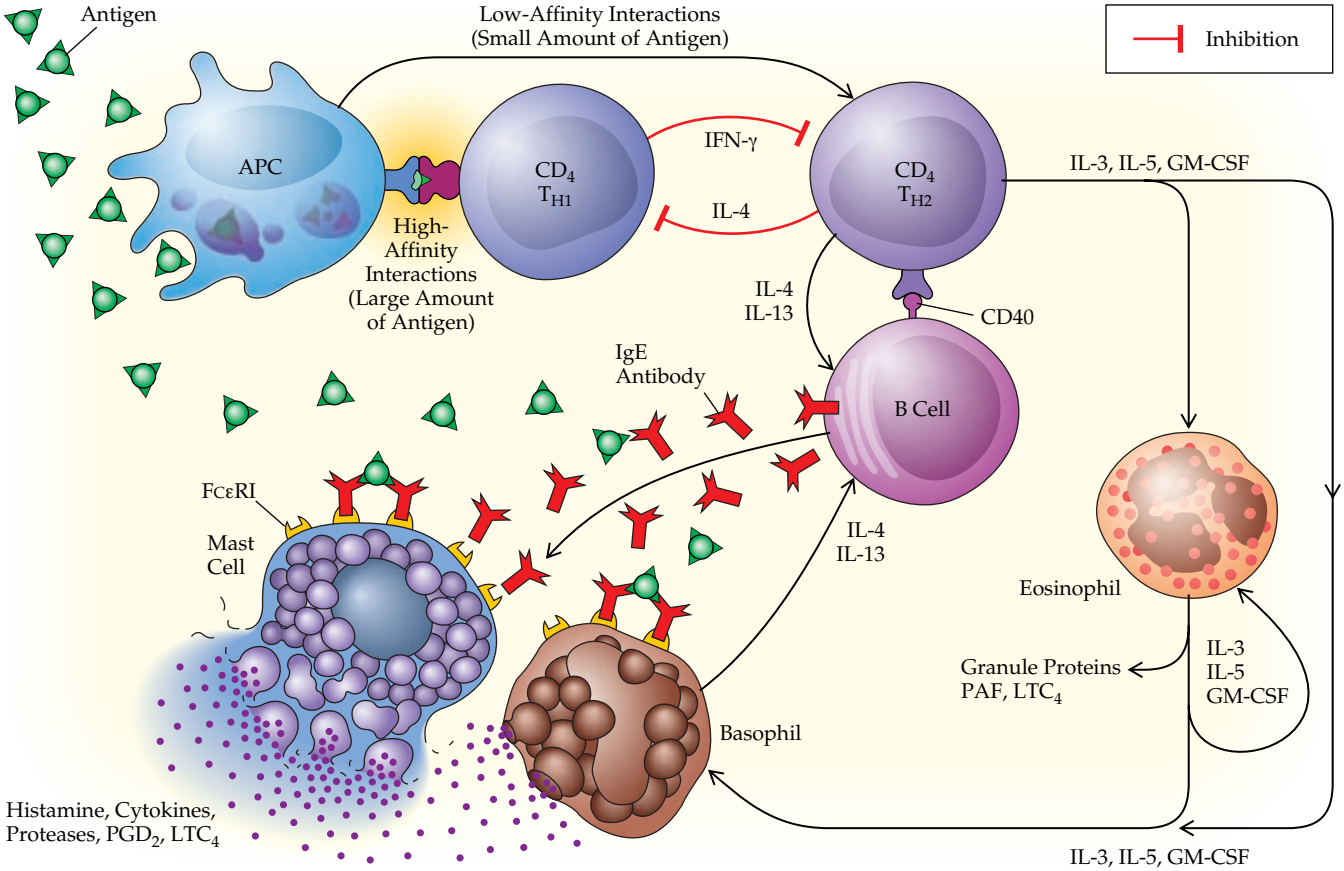

Figure 1 **Inflammatory mechanisms in allergic inflammation. Antigen is taken up by antigen-presenting cells (APCs), processed, and then presented to $CD4^+$ helper T cells (T_H). The strength of interactions between APCs and helper T cells and the quantity of antigen present determine the type of T cell response. Production of interferon gamma (IFN-γ) during T_{H1} responses downregulates T_{H2} responses, whereas interleukin-4 (IL-4) production by T_{H2} inhibits T_{H1} responses. IL-4 is also critical for switching B cell antibody production to IgE. Signaling through cluster differentiation 40 (CD40) on the B cell is also required for IgE production. Other T_{H2} cytokines, such as IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) lead to eosinophil (Eos) and basophil (Baso) production and activation. IgE binds to high-affinity receptors on basophils and mast cells (FcεRI); cross-linking by allergen initiates mediator release. (CpG—deoxycytidine-phosphate-deoxyguanosine; LTC_4—leukotriene C_4; PAF—platelet-activating factor; PGD_2—prostaglandin D_2)**

Eosinophils share a common origin with basophils: a single bone-marrow–derived myeloid progenitor cell has the capacity to give rise to a mixed colony of eosinophils and basophils or to pure colonies of either cell type.[33] A common origin for eosinophils and basophils is further supported by the presence of Charcot-Leyden crystal (CLC) protein and major basic protein (MBP) in both cell types. Eosinophil development is uniquely dependent on the presence of IL-5, a cytokine whose chief source is the T_{H2} helper cell.[34] Along with IL-5, other T cell cytokines—IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF)—promote maturation, activation, and prolonged survival of eosinophils.[33] However, only IL-5 potently stimulates the bone marrow to produce eosinophils. In vitro, a low dose of IL-3 favors the development of basophils from progenitors, whereas a high dose of IL-3 favors the development of eosinophils. In contrast, other cytokines may inhibit the growth of eosinophil progenitors. Transforming growth factor–β (TGF-β) contributes to eosinophil apoptosis in vitro and influences progenitor development toward the basophil pathway.[35] IFN-α inhibits progenitor cells in vitro and has been used for treatment of certain patients with eosinophilia refractory to treatment with prednisone.[36]

Eosinophils dwell primarily in tissue. Circulating eosinophils have a short half-life and represent only about 1% of the total number of eosinophils in the body. Epithelial surfaces of mucosal tissues that are exposed to the external environment are heavily inhabited by eosinophils, whereas other tissues are normally devoid of eosinophils.[33] The epithelial tissues of the respiratory tract produce GM-CSF, which is capable of prolonging eosinophil survival in vitro for up to 14 days.

Cell Surface Receptors

Two overlapping populations of circulating eosinophils are thought to represent differing states of eosinophil activation.[37] Nonallergic individuals have greater numbers of eosinophils of normal density and fewer numbers of low-density activated eosinophils. The reverse is true for patients with disorders leading to eosinophilia. This heterogeneity suggests that priming of eosinophils by various cytokines may lead to changes in expression of surface receptors and mediator release [*see Table 2*]. For example, both high-affinity receptors (FcεRI) and low-affinity receptors (FcεRII) for IgE have been found on peripheral blood eosinophils from patients with hypereosinophilic syndrome. However, eosinophils derived from normal donors or from patients with allergy fail to stain with a panel of monoclonal antibodies directed against IgE receptors.[38] Similar differences have been observed for IgG receptors (FcγR) on eosinophils. Freshly isolated eosinophils express FcγRIIb, a low-affinity IgG receptor that may inhibit mediator release when cross-linked.[34] Both FcγRI and FcγRIII can be induced on eosinophils in vitro when these cells are cultured with IFN-γ, which, in contrast to FcγRIIb, may result in activation. Sera from patients with hay fever contain allergen-specific IgG1 and IgG3, which cause eosinophils to degranulate in vitro in an allergen-dependent manner.[39] Surface receptors for IgA are also present on eosinophils and provide a potent stimulus for release of granule proteins in vitro. The presence of secretory IgA (sIgA) together with eosinophils at mucosal surfaces suggests that IgA-dependent activation also occurs in vivo.[40]

Receptors for complement (C3a and C5a); the lipid mediators platelet-activating factor (PAF), leukotriene C_4 (LTC_4), and LTB_4; and numerous cytokines and chemokines bind to and activate eosinophils.[33,34] Chemokines of the C-C family play an important chemotactic role for eosinophils. Chemokines of this large family have adjacent cysteine residues (C-C) and have the same receptors. A particular C-C chemokine receptor, CCR3, is found abundantly on eosinophils but not on neutrophils.[41] CCR3 binds at least four chemokines that play crucial roles in the homing of eosinophils to epithelial tissues and that activate eosinophils to release mediators. Another mechanism, which leads to preferential accumulation of eosinophils rather than neutrophils at sites of allergic inflammation, relates to differences in expression of surface adhesion molecules. Eosinophils and neutrophils share several selectins and integrins that initiate the rolling of circulating cells along the endothelium, as well as the subsequent firm adhesion, diapedesis, and transmigration of these cells through the vessel wall. However, eosinophils—but not neutrophils—express an integrin, very late antigen (VLA)-4, whose ligand on endothelial cells (VCAM-1) is upregulated by IL-4 and IL-13, cytokines that are present during T_{H2} responses; consequently, these cytokines promote adherence of eosinophils, but not neutrophils, to endothelium.[42]

Table 2 Receptors on Eosinophils

IgE receptors	Lipid-mediator receptors
FcεRI (high affinity)	Leukotriene (LT) receptors
FcεRII (low affinity)	LTC_4
IgA receptor	LTB_4
Complement receptors	Platelet-activating factor (PAF)
C3a	Chemokine receptors
C5a	CCR3
	Others

Mediators

An array of inflammatory mediators are produced when eosinophils are activated. Preformed mediators are stored in granules and rapidly released once eosinophils are activated. Major basic protein (MBP) is the principal constituent of the granule proteins.[43] Other granule proteins include eosinophil peroxidase (EPO), eosinophil-derived neurotoxin (EDN), and eosinophil cationic protein (ECP). MBP, ECP, and EPO have been shown to damage parasites in vitro; in patients with eosinophil-associated diseases, these proteins are present in high concentrations that can cause toxicity to autologous cells and tissues. Unfortunately, MBP and EPO cause ciliostasis and detachment of respiratory epithelial cells in vitro, and they may contribute to epithelial damage and inflammation in allergic respiratory disorders.[43] However, in one study, treatment of asthmatic patients with anti–IL-5 monoclonal antibody resulted in the selective elimination of eosinophils from the airway, but airway hyperreactivity or the airway response to inhaled allergen were not affected. This leaves open the question of the precise role that eosinophils play in the pathogenesis of atopic asthma.[44] Proteases present in the eosinophils may contribute to airway damage by degrading collagen.[45]

Lipid mediators are rapidly generated by eosinophils after appropriate stimulation. PAF production may lead to activation of platelets, neutrophils, and smooth muscle cells, and thereby induce bronchoconstriction and amplify inflammation. The major eicosanoid product of eosinophils is LTC_4, from which LTD_4 and LTE_4 are derived. These sulfidopeptides are extremely potent at contracting airway smooth muscle, stimulating mucus produc-

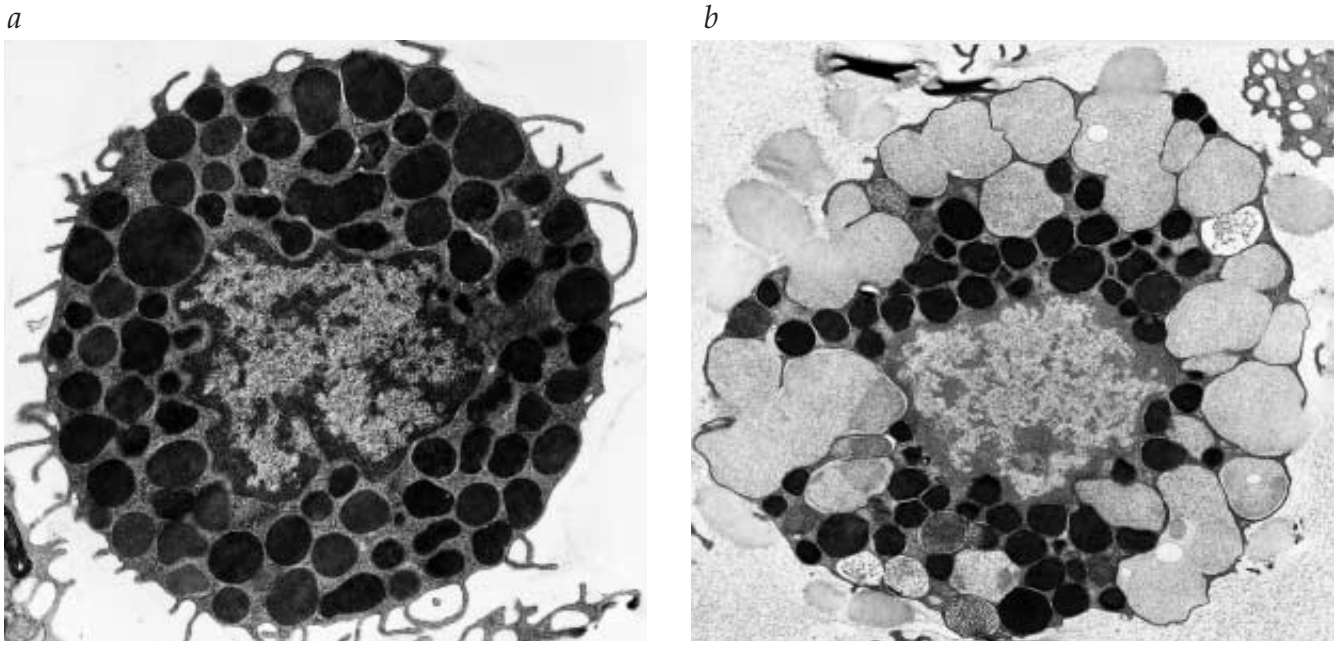

Figure 2 **(*a*) Before introduction of antigen, a sensitized mast cell contains many osmotic granules. (*b*) Sixty seconds after treatment with antigen, the peripheral granules have enlarged, neighboring granules have fused, and expulsion of granules from the mast cell has begun.**

tion, causing capillary leakage, and promoting chemotaxis of eosinophils.

Numerous cytokines have been identified as potential eosinophil products. Some may function in an autocrine or paracrine manner to activate or prime eosinophils. Others enhance eosinophil development and survival. In addition, eosinophils produce cytokines that regulate immune responses. However, eosinophils elaborate a considerably smaller quantity of cytokines than do lymphocytes. Therefore, the importance of the eosinophil-derived cytokines to allergic inflammation is unclear. Some cytokines that have been demonstrated in vitro have been confirmed in vivo by identifying the protein product in eosinophils infiltrating affected tissues. For example, eosinophils from nasal polyp tissue stain for TGF-β1 and could contribute to the structural pathology.[46] Exposure of allergic patients to allergen revealed eosinophils in nasal mucosal tissues that stain for IL-5 protein; however, much larger contributions of IL-5 are anticipated from T cells in the same tissue.[47]

MAST CELLS AND BASOPHILS AS EFFECTORS OF THE ALLERGIC RESPONSE

Microscopy of mast cells and basophils reveals intensely staining metachromatic granules [*see Figure 2*]. Other common features shared by these cells include the presence of high-affinity receptors for IgE, the release of histamine after cross-linking of the FcεRI by allergen, and common intracellular signaling pathways.[48] There are also numerous differences between the two cell types. Basophils generally complete their maturation in the bone marrow, circulate in the blood, and then are recruited to sites of inflammation.[49] Mast cells that complete their maturation in the bone marrow appear to remain there, whereas those found in peripheral tissues develop from progenitor cells that seed these tissues. Mature mast cells in peripheral tissues may reside there for many months, retaining antigen-specific IgE for periods that exceed the lifespan of IgE in the circulation. Mast cells are strategically distributed in tissues or at mucosal surfaces that interface with the external environment; they are also in proximity to blood vessels and nerves.[50]

All mast cells contain tryptase in their granules; its release is characteristic of mast cell degranulation. However, several additional features further distinguish two types of mast cells [*see Figure 3*].[51] Mast cells of the T type (MC_T cells) are normally the predominant type of mast cell found in the mucosa of the small intestine and in the alveolar wall and epithelium of the respiratory tract. MC_T cells are identified morphologically by a scroll-rich granule structure; they contain tryptase but not chymase, cathepsin G, or mast cell carboxypeptidase. The numbers of MC_T cells in respiratory epithelium are increased in allergic airway inflammation, making them more accessible to inhaled allergens. In a study in asthmatics, increased mast cells predominantly of the MC_{TC} type were localized to the airway smooth muscles but were not present in control subjects or in patients with eosinophilic bronchitis.[52]

In contrast, the MC_{TC} type of mast cell is the dominant type of mast cell in the dermis, conjunctiva, blood vessel walls, and small-intestinal submucosa. Morphologically, MC_{TC} cells display a lattice/grating, scroll-poor granule structure. In addition to tryptase, TC-type mast cells contain chymase, cathepsin G, and mast cell carboxypeptidase. The development of both mast cell types requires stem cell factor (SCF), the ligand for the Kit (tyrosine kinase) receptor. Factors that regulate the recruitment, development, or survival of one mast cell type over the other are not known. Lineage-committing growth factors such as GM-CSF may divert hematopoietic progenitor cells that are capable of forming mast cells when exposed to SCF alone to non–mast cell lineages.[53]

Mediators

Mast cells and basophils form histamine by decarboxylation of histidine. They then store the histamine in their granules. Degranulation releases the histamine, which then interacts with histamine receptors on various tissues. Histamine induces smooth-

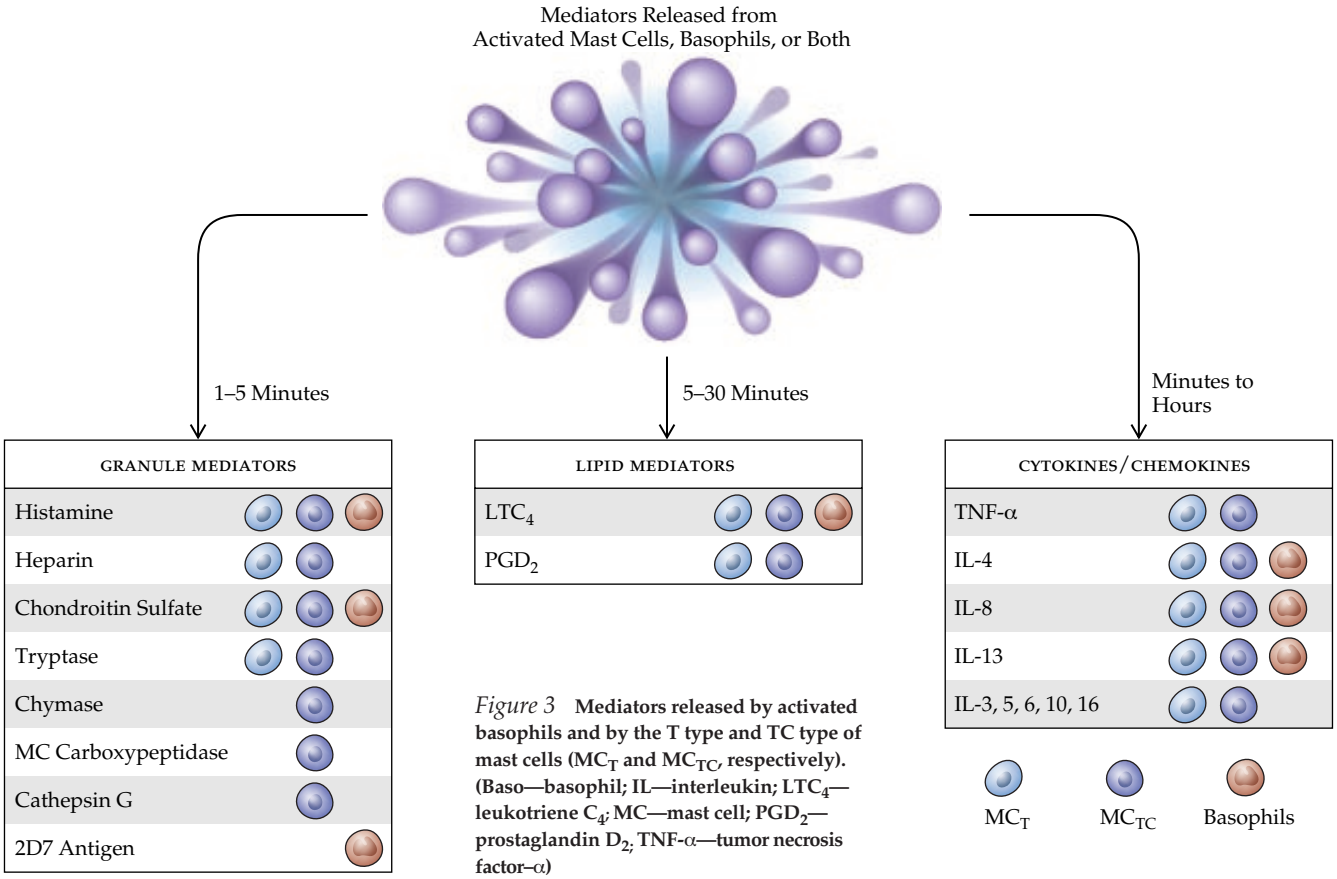

Figure 3 **Mediators released by activated basophils and by the T type and TC type of mast cells (MC_T and MC_{TC}, respectively). (Baso—basophil; IL—interleukin; LTC_4—leukotriene C_4; MC—mast cell; PGD_2—prostaglandin D_2; TNF-α—tumor necrosis factor–α)**

muscle contraction, increases mucous secretion in the airway, and stimulates nerve fibers. In addition, it enhances vascular permeability and dilates blood vessels, which results in hypotension if a critical number of cells degranulate. Chondroitin sulfates are proteoglycans that are present in the granules of both basophils and mast cells; heparin proteoglycan is stored exclusively in all mast-cell secretory granules. Both chondroitin sulfate and heparin proteoglycans play a role in packaging of histamine, proteases, and carboxypeptidases in the granules.[54] Heparin is also involved in the processing of chymase and tryptase to catalytically active enzymes. Neutralization of the acidic granule pH during degranulation facilitates the dissociation of histamine from the protease-proteoglycan macromolecular complex.[55] Consequently, histamine appears in the serum within minutes of induction of systemic anaphylaxis by allergen-dependent cross-linking of IgE on mast cells and basophils. Not surprisingly, peak plasma levels of histamine occur 5 minutes after insect-sting–induced anaphylaxis begins and decline to baseline within 20 minutes. Because they are relatively transient, these elevations in histamine levels in plasma are difficult to utilize for the clinical determination of anaphylaxis as a cause of hypotension. However, tryptase diffuses into, and is removed from, the circulation more slowly than histamine. Tryptase levels peak in the circulation 15 minutes to 2 hours after mast-cell degranulation and decline with a half-life of about 2 hours. Peak levels during insect-sting–induced anaphylaxis correlate closely to the drop in mean arterial blood pressure, which is an important measure of clinical severity. For that reason, serum or plasma tryptase levels have recently been recognized as a clinically useful marker for the diagnosis of systemic anaphylaxis.[55]

Prostaglandin D_2 (PGD_2) is a newly synthesized cyclooxygenase product of arachidonic acid produced by MC_T and MC_{TC} cells, but not by basophils. PGD_2 causes airway smooth muscle to contract, blood vessels to dilate, and platelets to remain unaggregated. In one study of patients with systemic mastocytosis and recurrent episodes of cardiovascular collapse that did not respond to antihistamines, therapeutic success was achieved with cyclooxgenase inhibition that diminished PGD_2 production.[56] LTC_4 is produced by both mast cells and basophils, as well as by eosinophils, and it is a potent mediator of airway smooth muscle contraction and mucus secretion. Effects of LTC_4 are blocked by 5-lipoxygenase inhibition and by leukotriene receptor antagonists.

Mast cells secrete a diverse array of cytokines, including TNF-α, GM-CSF, SCF, and interleukins 3, 4, 5, 6, 10, 13, and 16.[50] TNF-α can reside preformed in mast cell granules and is also synthesized and secreted after mast cell activation. TNF-α causes chemotaxis and activation of many leukocytes, as well as activation of vascular endothelium. IL-4 and IL-13 are central to T_{H2} differentiation, IgE isotype switching, and induction of the adhesion receptors VCAM-1 on endothelium and VLA-4 on eosinophils. Basophils do not synthesize TNF-α and generally produce fewer cytokines than do mast cells. However, activated basophils synthesize more IL-4 and IL-13 on a per-cell basis than any other cell type. In tissues with allergic inflammation that are challenged with allergen, basophils appear to be the predominant source of antigen-specific production of IL-4 and IL-13.[49]

As with eosinophils, a subpopulation of low-density (so-called hypodense) basophils can be detected in peripheral blood samples. This subpopulation is more sensitive to the effects of

glucocorticoids than the higher-density basophils. However, functional differences in the hypodense basophils have not been characterized, as they have for eosinophils. Recently, basophil-specific markers have been developed.[57] The monoclonal antibodies named 2D7 and BB1 detect basophil-specific antigens in secretory granules and should prove useful for more precise assessment of basophil involvement in human allergic diseases. For example, substantial numbers of basophils can now be detected in skin and respiratory tissues during the late-phase response to an allergen challenge, and these cells account for a major portion of the IL-4–containing cells in such tissues. Basophils appear to be similar to eosinophils in expression of numerous cytokines and chemokine receptors, including CCR3. Exposure of basophils to most CC chemokines leads to histamine release.

Pamela J. Daffern, M.D., has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

Lawrence B. Schwartz, M.D., Ph.D., has a licensing agreement with the Pharmacia Corporation for a tryptase assay kit.

XI DIAGNOSTIC AND THERAPEUTIC PRINCIPLES IN ALLERGY

Mitchell H. Grayson, m.d.
Phillip E. Korenblat, m.d., f.a.c.p.

By definition, allergy is an untoward physiologic event mediated by immune mechanisms, usually involving the interaction of an allergen with the allergic antibody, IgE. Common illnesses mediated in this manner include allergic asthma and rhinitis, Hymenoptera hypersensitivity, and certain other causes of anaphylaxis. In addition, a significant proportion of drug, food, and skin reactions are allergic in origin.

Allergic diseases in general, and asthma in particular, have been increasing in prevalence in high-income societies.[1] Although there are undoubtedly many reasons for this increase, one is described in the so-called hygiene hypothesis, which posits that greater exposure to infectious agents (and bacterial endotoxins in particular) early in life reduces the likelihood of subsequent allergy.[2] This hypothesis, which requires further proof of causality, acknowledges an etiologic role for both genetic and environmental factors in allergy: a child with a hereditary predisposition to atopy is more likely to develop clinical allergy if raised in a relatively aseptic environment.

History

In allergic illnesses, the importance of a careful and thorough medical history cannot be overstated. The clinician must dissect the allergic reaction to understand the nature of the event and identify the antigen that was responsible for the reaction. Formal diagnosis of allergy has three elements: characterization of the allergic reaction, correlation with antigen exposure, and demonstration of IgE specific for the suspected allergen. The history is essential for the first two elements, and for practical purposes, the history can sometimes obviate the third element.

The history should begin with a review of the patient's symptoms and their temporal pattern. If the presenting symptoms include wheezing, the clinician should remember the time-honored statement that all that wheezes is not asthma. Furthermore, all that is asthma is not allergy [*see 14:II Asthma*].

The presenting symptoms must match the set of features that characterize the suspected allergic illness. For example, patients with perennial allergic rhinitis typically present with sneezing, rhinorrhea, nasal itching, and nasal congestion. Postnasal drainage is not the only symptom of this disease, so postnasal drainage alone—even with evidence of antigen exposure and the presence of specific IgE antibodies—typically would not support the diagnosis of allergic rhinitis.

A central aspect of the history is to establish a link between the time and site of exposure to the presumed allergen and the development of allergic symptoms. Seasonal allergic events are often so characteristic that the diagnosis can be made solely on the basis of the presenting symptoms and their correlation with environmental exposure to the allergen; laboratory evidence may not be needed for the diagnosis. Similarly, symptoms that develop immediately after exposure to animals or their dander often do not need additional supporting evidence for diagnosis.

In the United States, the presence of airborne pollen may vary both temporally and geographically.[3] In general, early spring is characterized by the presence of tree pollen, and late spring is accompanied by grass pollen. Ragweed and other weed pollens are prevalent in the fall, usually until the first hard frost. Mold spores can be found indoors year-round, except possibly in very dry areas. Outdoor mold spores peak during the summer and fall months, and they diminish when snow covers the landscape [*see Table 1*].

Illnesses such as asthma or rhinitis that occur on a perennial basis, if allergic, should correlate with environmental exposure to a perennial allergen (e.g., dust mites, indoor mold spores, animal dander, or cockroach antigen). Such exposure most often takes place in the household, but the possibility of exposure to allergens in the workplace should not be forgotten. It should be noted that in some warm climates (e.g., that of the southern United States), the pollen season may be nearly year-round and, thus, may be a cause of perennial symptoms.

Allergic reactions to ingested substances typically include skin eruptions, abdominal discomfort, or respiratory symptoms. Severe and life-endangering reactions involving the cardiovascular or respiratory system, or both, may also occur. The list of ingested substances said to cause allergic reactions is seemingly endless. However, foods (particularly peanuts, tree nuts, shellfish, and seeded fruits) and medications are the most common triggers of this type of allergic reaction [*see 6:XVI Food Allergies*]. Again, the history is essential to establishing a particular substance as the probable cause of an allergic reaction.

The family history is important. Allergic predisposition is genetically mediated, so patients with allergies often report that family members have similar problems. However, in a patient who has both a personal and a family history of angioedema, the disorder may be inherited but not allergic: hereditary angioedema results from the absence of the C1 esterase inhibitor.

Physical Examination

The physical examination of a patient with a suspected allergic illness requires an in-depth focus on the involved organ system or systems. In atopic dermatitis, the skin findings may include patches of lesions that are pruritic, erythematous, papular,

Table 1 Inhaled Aeroallergens That Cause Rhinitis, Conjunctivitis, and Asthma

- Pollens (tree, grass, and weed pollens)
- Dust mites (*Dermatophagoides* species)
- Animal proteins (cat, dog, horse, guinea pig, gerbil, mouse, and rat proteins)
- Fungal spores (*Alternaria*, *Aspergillus*, *Penicillium*, and *Cladosporium* species)
- High-molecular-weight proteins (e.g., as derived from insects, insect venoms, and latex)
- Low-molecular-weight inorganic and organic chemicals (e.g., toluene diisocyanate and plicatic acid)

scaling, crusting, vesicular, or lichenified—qualities that may occur alone or in combination. Lesions are usually characterized by periodic exacerbations, and it is important to examine these lesions for pyogenic infections.

The distribution of allergic dermatitis lesions varies with the age of the patient. In infants, the dermatitis begins to appear by the sixth to eighth week of life. At this age, the eruptions ordinarily involve the scalp, face (especially the cheeks), ears, and extensor surfaces of the extremities. The trunk, buttocks, and anogenital regions may also be involved. The dermatitis may continue into childhood. Alternatively, allergic dermatitis may first develop at about 2 years of age. Dermatitis in childhood is often found in the antecubital and popliteal fossa, on the neck, and at the flexor and extensor areas of the wrist. In adolescents and adults, the lesions frequently involve the neck and the flexural areas but may occur anywhere on the skin.[4]

Typical urticarial lesions are pruritic, transient (individual lesions resolve within 24 hours), erythematous, and raised; they comprise a wheal with a surrounding erythematous flare. Urticaria can be confused with skin lesions of vasculitis. The presence of hemorrhage or a lesion that lasts longer than 24 hours should raise the specter of urticarial vasculitis. Skin biopsy may be required to differentiate urticarialike lesions.

The hallmarks of allergic rhinoconjunctivitis are bilateral erythema and edema of the conjunctiva, watery ocular discharge, and, often, mild periorbital edema.[5] Allergic shiners (bluish discoloration just below the eye orbits) may be observed. Patients with allergic rhinitis may also have an extra fold in the lower eyelids (Dennie-Morgan lines). On the exterior portion of the nose, a crease may be present as a result of continued upward rubbing of the tip of the nose (the so-called allergic salute). Examination of the nasal cavity often reveals watery secretions and edematous, bluish nasal turbinates that partially occlude the nasal passages [*see 6:XII Allergic Rhinitis, Conjunctivitis, and Sinusitis*]. Translucent nasal polyps may be observed, but these are not necessarily a hallmark of allergy; they can be seen in both allergic and nonallergic patients.

The chest examination often may reveal no abnormalities. However, a methodical examination is warranted. The clinician should observe specifically for cyanosis and the use of accessory muscles for respiration. In addition, auscultation is indicated for a prolonged expiratory respiratory phase or for inspiratory and expiratory wheezing. If wheezing is present, it is important to confirm that the sounds emanate from the lungs and not the trachea. All too often, extrathoracic obstruction is missed on the physical examination.

Although cardiovascular findings are not commonly associated with allergic diseases, it is important to remember that hypotension, tachyarrhythmia, and—particularly if the patient is using a beta-adrenergic blocking medication—bradycardia may be seen in cases of anaphylaxis.

Table 2 Time before Skin Testing to Stop Antihistamines*

Antihistamine (Trade Name)	*Days*
Azelastine	7
Cetirizine (Zyrtec)	7
Chlorpheniramine	3
Desloratadine (Clarinex)	7
Diphenhydramine	3
Fexofenadine (Allegra)	7
Loratadine (Claritin)	7

*Note: Other medications (e.g., tricyclic antidepressants) may also have antihistaminic activity.

Assays of IgE

Because allergic diseases result from the interaction of an allergen with specific IgE, analysis for specific IgE in a patient with clinical allergy is a major diagnostic consideration. Specific IgE can be identified both by in vivo methods (skin testing) and in vitro methods (e.g., radioallergosorbent testing [RAST]).[6]

SKIN TESTING

Epicutaneous Testing

The most rapid and sensitive test for allergy is skin testing. This in vivo method depends on mast cell–bound or basophil-bound IgE specific for the allergen being tested. Because a positive test requires degranulation of mast cells or basophils and subsequent histamine release, antihistamines will interfere with the outcome. In general, patients should discontinue antihistamines 1 week before skin testing, although certain antihistamines can be discontinued 3 days beforehand [*see Table 2*]. Corticosteroids do not inhibit this immediate-phase response, and hence, their use is not a contraindication for skin testing.

Skin testing should be performed by a qualified allergist. Initial testing is performed by pricking the epidermis with a small amount of the specific allergen. In patients with IgE specific for the allergen, a wheal-and-flare response will develop at the site within 20 minutes. The areas of edema and erythema are then measured. The results are often reported as wheal size over flare size (both in millimeters) or, alternatively, identified on an arbitrary scale of 1 to 4+, correlating to the size of the wheal, the flare, or both. Histamine is used as a positive control, and because some patients develop hives in response to any strong pressure on the skin (dermatographism), saline is used as a negative control.

Intradermal Testing

If the results of epicutaneous skin testing are negative but the patient's symptoms strongly suggest an allergic etiology, intradermal testing can be performed. This involves injecting 0.02 ml of a dilute allergen solution (usually a 1:100 or 1:1,000 dilution of the concentrated extract) into the dermis. As with epicutaneous testing, the skin is observed for the development of a wheal and flare within 20 minutes. Grading of the results is similar to that for epicutaneous testing.

Intradermal testing has a higher sensitivity but a lower specificity than epicutaneous testing. This means that intradermal testing produces more false positives but fewer false negatives than epicutaneous testing. Although the relevance of isolated positive intradermal tests for aeroallergens is debated, intradermal testing is crucial for the evaluation of drug and insect allergy.

Compared with epicutaneous testing, intradermal testing exposes the body to a significant antigen load and, therefore, poses a higher risk of a systemic reaction. For that reason, intradermal testing is contraindicated in patients who have not had a prior negative result on epicutaneous testing. It is not surprising that five of the six skin-testing fatalities reported from 1945 to 1987 occurred in patients who underwent intradermal testing with-

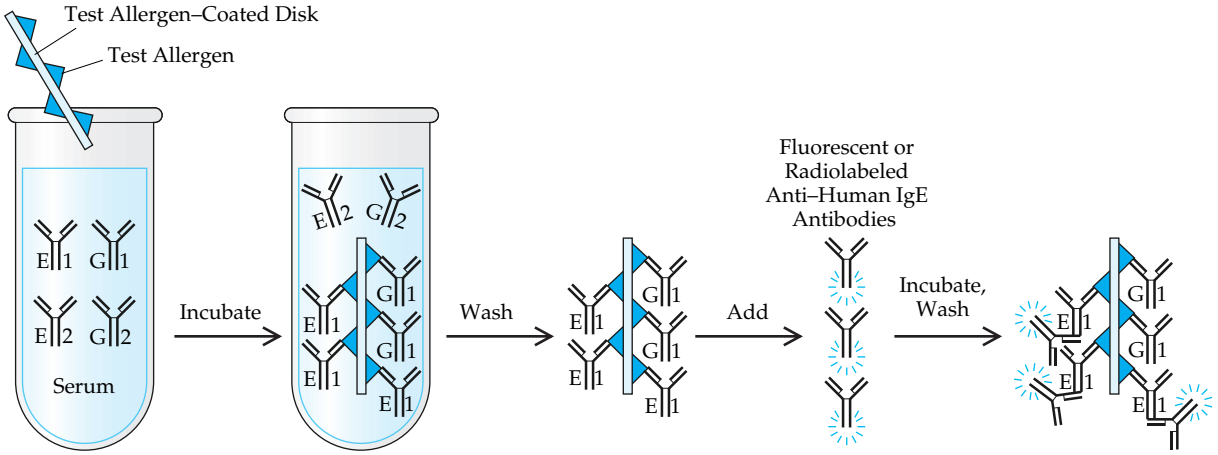

Figure 1 **The radioallergosorbent test (RAST). A solid-phase disk coated with the test allergen is incubated with the patient's serum. IgE and IgG antibodies to the test allergen (E1 and G1, respectively) will bind with the allergens on the disk, whereas IgE and IgG antibodies to other allergens (E2 and G2, respectively) will remain free in the serum. After the free antibodies have been washed away, the disk is incubated with antibodies against human IgE that have been labeled with a radioactive or a fluorescent tracer. The tagged anti–human IgE antibodies will then bind IgE attached to the disk; a second washing then removes any unbound tagged antibody. The level of radioactivity or fluorescence is then proportional to the amount of specific IgE against the antigen (E1). IgG against the antigen (G1) does not react with the tagged antibody and therefore is not counted in this test.**

out previous epicutaneous testing.[7] Food allergens should never be used for intradermal testing, because they are associated with a high rate of false positive irritant responses. Furthermore, some foods (e.g., peanuts and shellfish) are such potent antigens that they could provoke severe systemic reactions if injected intradermally.

Inaccurate or incorrect skin-testing results can occur for a variety of reasons. For example, the use of low-potency extracts can lead to false negative results, as can certain patient factors, such as (1) age (wheals are small in infants, increase until age 50, and then decline), (2) race (whites produce smaller wheals than African Americans[8]), and (3) antihistamine use (including drugs with antihistaminic properties, such as tricyclic antidepressants). In addition, skin-testing results depend on vascular leak; medications such as adrenergic agents can inhibit this response, leading to false negatives. False positives most often result because of irritant reactions, dermatographism, or a nonspecific reaction from a nearby strong reaction (a so-called bystander reaction).

RADIOALLERGOSORBENT TESTING

RAST and other in vitro tests measure the concentration of nonspecific and allergen-specific IgE in the patient's serum. Because these tests do not depend on IgE-mediated histamine release for their interpretation, they are not adversely affected by the use of antihistamines and other medications (except for anti-IgE, omalizumab [see below]). Although there are circumstances in which high levels of nonspecific IgE can be found, determination of nonspecific IgE is generally of little value, because IgE concentrations vary substantially and there is significant overlap between patients with atopic disease and patients with nonatopic disease. However, the determination of allergen-specific IgE can be useful, especially in patients in whom skin testing cannot be performed (e.g., because of skin disease or inability to stop using antihistamines).

RAST is the most common method of determining allergen-specific IgE in the serum [*see Figure 1*]. This test involves adding the patient's serum to a solid phase (usually a disk) coated with the allergen to be tested. Antibodies in the patient's serum that are specific for the allergen will bind to the solid phase. After the disk is washed, to remove the unbound antibodies to other allergens, antibodies against human IgE that have been tagged with a radioactive isotope are added. The disk is then washed again, to remove unbound tagged anti-IgE. The level of radiation that is present after washing the disk is directly proportional to the quantity of allergen-specific IgE in the patient's serum. Comparing these values with known standards allows for the determination of allergen-specific IgE. Gaining in popularity is the CAP-RAST system, which is a test for specific IgE that incorporates a solid phase consisting of an encapsulated hydrophilic carrier (in the shape of a cup or "CAP") to which antigen is covalently bonded. This allows for better allergen attachment and much more accurate quantification of specific IgE than can be obtained with traditional RAST testing. Furthermore, CAP-RAST testing is usually performed with fluorescently labeled anti-IgE, as opposed to the radiolabeled anti-IgE in traditional RAST testing. Although the CAP-RAST method is different from traditional RAST testing, some laboratories may refer to both of these modalities as RAST tests.

Although RAST results generally correlate with allergic sensitivity, RAST is more likely than skin testing to produce false positive results. As such, the sensitivity of RAST is lower than that of skin testing. Therefore, skin testing is still the preferred method of identifying the allergens to which a person is sensitive.

INTERPRETATION OF IgE TEST RESULTS

Regardless of the modality used to test for IgE, all results must be correlated with the clinical findings. Only tests whose results fit with the patient's symptoms should be considered relevant for explaining those specific symptoms. In other words, a positive result is useful for therapeutic intervention only if the patient has symptoms when exposed to the allergen, and a negative test is useful only if the patient has no symptoms on exposure to the allergen. An example would be a patient who has a positive skin test to a tree pollen yet has no symptoms in the spring but instead has symptoms in the fall, in a region devoid of tree pollen at that time of the year. Even if tests for weeds and

molds were negative, this seasonality of symptoms would still suggest that a fall pollen or untested mold spore is to blame for the symptoms rather than trees, as the testing would suggest. A positive skin test in the absence of exposure or symptoms, however, does not mean that the patient will not develop symptoms to the antigen at some time in the future. In general, the clinician should use the clinical history to guide all testing modalities, rather than using the testing to try to identify unknown triggers.

Treatment

ENVIRONMENTAL CONTROL

The most effective therapeutic intervention for atopic disease is complete removal of the offending allergen or allergens from the patient's environment [*see Table 3*]. For example, environmental control for a patient who is allergic to dust mites would include encasing the pillows and mattress in dust-mite–proof covers, washing all bedding in hot (> 130° F) water weekly, and lowering the ambient humidity in the house to below 45%. Some authorities also recommend the removal of bedroom carpet as an additional control for dust-mite exposure; this recommendation is controversial, however. For pet-allergic patients, the pet should be removed from the household or, at a minimum, should be kept out of the bedroom at all times. Pollen-sensitive individuals will benefit from staying in air-conditioned environments during the time of year when the offending pollen is prevalent.

Table 3 Environmental Control for Allergy Management

General measures
Eliminate irritants, especially cigarette smoke, from home
Keep relative humidity at 45% or less by using air conditioners and dehumidifiers
Specific measures
Pollens: use air conditioner and keep windows of house and car closed; during peak pollen season, avoid outside activities
Molds: outdoor molds can be excluded by keeping windows closed; use exhaust fan in bathroom and kitchen to keep humidity at 50% or less
Dust mites: cover mattresses, box spring, and pillows with impermeable cases; all bedding should be washed in hot water (> 130° F) once a week; if possible, remove carpet; keep the humidity at 45% or less
Feathers: replace feather pillow with Dacron (washable) pillow and wash regularly
Pets: remove the pet from the home; if the patient does not agree to remove the pet, the pet should not be permitted in the bedroom; in addition, to decrease antigen shedding, the pet should be bathed twice weekly

PHARMACOLOGIC AGENTS

Although environmental control measures constitute the primary treatment for atopic disease, such interventions are sometimes impossible to carry out or do not completely eliminate the allergen and, therefore, do not fully resolve the disease. This is the point at which pharmacotherapy should be added. The medications used in allergic disease are targeted to various components of the allergic cascade [*see Figure 2*]. These medications include antihistamines and decongestants, anti-IgE, long-acting and short-acting bronchodilators, corticosteroids (both topical and systemic), leukotriene receptor antagonists, and theophylline. Although cromolyn and nedocromil sodium have an established tradition of use and favorable safety profiles, their minimal efficacy does not justify their inclusion on this list.

Antihistamines and Decongestants

Antihistamines block the action of histamine at its receptor.[9] Although there are at least four histamine receptors, most allergic symptoms have been attributed to the H_1 receptor. Symptoms mediated by histamine include pruritus, nasal itching, conjunctivitis, and the wheal-and-flare response.

H_1 receptor antagonists can be divided into two broad categories on the basis of their ability to cross the blood-brain barrier and cause sedation. The classic antihistamines, which cause more sedation, include over-the-counter drugs such as diphenhydramine and chlorpheniramine, as well as prescription medications such as cyproheptadine and hydroxyzine. These medications are potent antihistamines, but their usefulness is limited by their central nervous system side effects. Of particular significance is that CNS effects have been shown to last beyond the sedative effects of these medications, leading to decreased reaction time. Therefore, the recommended choice for long-term therapy is a second-generation or third-generation (active metabolite) antihistamine, which will produce minimal sedation. Examples of such agents include over-the-counter loratadine and the prescription drugs cetirizine (Zyrtec), desloratadine (Clarinex), and fexofenadine (Allegra). Also available as a nasal spray is azelastine (Astelin).

Antihistamines do not have a significant effect on nasal congestion. For intermittent congestion, a systemic decongestant may be used. Since phenylpropanolamine (PPA) was taken off the market because of its association with increased frequency of strokes, pseudoephedrine has been the only systemic decongestant available in the United States. Nevertheless, although decongestants provide some relief of the sensation of nasal fullness, they do not alter the underlying etiology.

Anti-IgE Therapy

The allergic response requires the presence of IgE. A newly approved therapeutic modality in the United States is omalizumab, a humanized anti-IgE monoclonal antibody that is administered subcutaneously on a biweekly to monthly schedule and can reduce serum unbound IgE to undetectable levels. This molecule consists of the hypervariable region from a mouse antibody against human IgE that is genetically grafted onto a human IgG molecule—hence the term humanized. Clinically, omalizumab has been shown to significantly reduce symptom scores in patients with allergic rhinitis, as well as to relieve symptoms and modestly improve airway function in patients with moderate to severe asthma.[10-12] This medication has the ability to block the allergic cascade at its initiation and has not been associated with significant side effects.

The appropriate end points for omalizumab therapy remain uncertain. Standard measures of allergic sensitivity are not useful in patients who are taking omalizumab: skin testing will produce negative results, and total IgE will be elevated because IgE is bound to the anti-IgE medication in circulation. Current data support continued administration for a minimum of 12 weeks. Patients with low pulmonary functions, patients who have had emergency department visits within the preceding year, and patients on high-dose inhaled corticosteroids are the most likely to respond to therapy with anti-IgE.[13] The relatively high cost of this medication in the United States may limit its usefulness.

Bronchodilators

Both short-acting and long-acting bronchodilators are available for treatment of asthma. Short-acting bronchodilators relieve bronchoconstriction but have no effect on the underlying inflammatory process, whereas long-acting bronchodilators not only provide symptomatic relief of bronchoconstriction but also may have slight anti-inflammatory properties. Unfortunately, over time there is loss of potency of bronchodilators when they are used alone (subsensitivity). This loss of potency does not occur, however, when bronchodilators are combined with an inhaled corticosteroid. Given the lack of sufficient anti-inflammatory activity and the subsensitivity of bronchodilators, the recommended use of these medications is in combination with an inhaled corticosteroid rather than as monotherapy.[14,15]

Corticosteroids

Corticosteroids inhibit the production of inflammatory cytokines and chemokines, thus reducing the inflammation and cellular recruitment to sites of disease. These medications play a major role in the treatment of allergic disease. They may be given locally (topically) or systemically (orally).

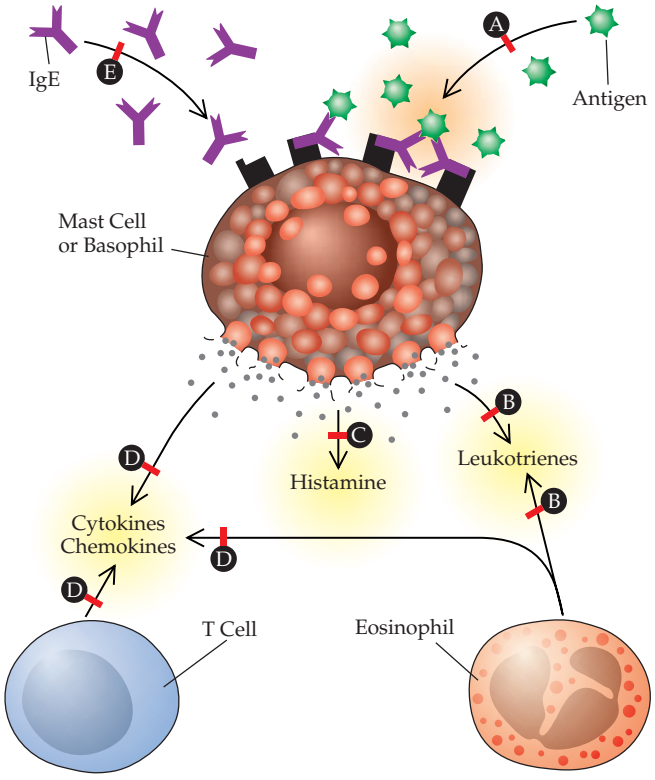

Figure 2 **Mechanisms of action of medications used in allergic diseases. Environmental control (A) minimizes exposure to the antigen to which the patient has specific IgE. If the antigen is present, it binds with specific IgE; cross-linking of the antigen-bound IgE on the surface of a mast cell or basophil starts the allergic cascade, with release of leukotrienes, histamine, cytokines, chemokines, and other mediators such as prostaglandins and proteases (not shown). Leukotriene antagonists (B) block the action of leukotrienes; antihistamines compete with histamine at H_1 receptors; corticosteroids (D) inhibit the production of inflammatory cytokines and chemokines. Anti-IgE therapy (e.g., omalizumab) (E) works by directly reducing the amount of IgE in the body. It is unclear at which sites immunotherapy and cromolyn and nedocromil sodium exert their anti-inflammatory action.**

Topical corticosteroids Topical corticosteroids are capable of potent anti-inflammatory effects and are a mainstay of allergic therapy. These medications, which are inhaled for asthma or taken intranasally for rhinitis, have the ability to abrogate the inflammatory response and interfere with multiple aspects of the allergic cascade. However, unlike antihistamines, which provide rapid relief (within 1 to 2 hours), topical corticosteroids may require 3 to 5 days of therapy before full relief is realized. In rhinitis, steroids can relieve the congestion and raise the threshold for the development of symptoms to allergen exposure.[16,17] Significant systemic effects are uncommon with inhaled or intranasal corticosteroids given at the usual recommended doses.

Oral corticosteroids Oral corticosteroids are potent at resolving and preventing most allergic disease. Unfortunately, the usefulness of chronic systemic corticosteroid use is limited by the potentially devastating side effects of these agents, which include weight gain, abnormal fat deposition, adrenal suppression, cataracts, type 2 diabetes mellitus, and osteoporosis.

In general, oral corticosteroids are prescribed only for short bursts and do not require a taper, because therapy for less than 2 weeks is not associated with adrenal suppression. Longer courses are reserved for patients whose condition has been refractory to all other standard therapies.

Leukotriene Antagonists

Leukotriene antagonists (either receptor antagonists or 5-lipoxygenase inhibitors) also have anti-inflammatory properties.[18] Leukotrienes are found at sites of allergic inflammation. Although corticosteroids affect many other inflammatory pathways, they do not seem to have a clinically significant impact on the generation and release of leukotrienes. These molecules are capable of inducing further inflammation by causing the release of additional mediators, as well as the recruitment of inflammatory cells to sites of allergic disease. Consequently, leukotriene antagonists are used in the treatment of both asthma and allergic rhinitis.[19]

Theophylline

Although generally not viewed as a major therapeutic option because of their narrow therapeutic window and significant side effects, methylxanthines still have some usefulness in asthma care. Recent asthma treatment guidelines suggest theophylline (at a serum concentration of 5 to 15 μg/ml) to be an alternative treatment in mild and moderate persistent asthma.[20] The addition of low-dose theophylline (5 to 10 μg/ml) to inhaled corticosteroids has shown benefit in asthma, with a lower risk of side effects than with higher theophylline doses.[21] As a result, methylxanthines remain worthy of consideration as part of the therapeutic regimen, especially in patients for whom cost is an issue.

IMMUNOTHERAPY

Immunotherapy, or allergy shots, involves injecting increasing doses of the offending antigen or antigens in an attempt to attenuate the specific allergic response. Clinical trials have shown that immunotherapy is successful in treating allergic rhinitis with or without associated asthma.[22,23] An immunotherapy extract is prepared on the basis of skin-testing results. The patient then receives increasing doses subcutaneously on a weekly or twice-weekly schedule for about 5 months. After this so-called build-up phase, the patient is maintained on a stable dose that is administered weekly to monthly for several years. Usual-

ly, patients achieve maximal benefit after being on the maintenance dose for 1 year. The duration of treatment is still under investigation; therefore, the discontinuance of immunotherapy must be determined on an individual basis.

Immunotherapy is usually reserved for those patients in whom environmental and pharmacologic interventions have been less than fully successful. The only patients for whom immunotherapy is almost always indicated are those who have systemic symptoms from venom (Hymenoptera) allergy. Immunotherapy is often indicated for allergic rhinitis or asthma that is clearly associated with sensitivity to specific allergens.[24] It is also used in children, because some data suggest that early treatment of allergic rhinitis with immunotherapy may prevent the subsequent development of asthma.[25] Because of the small but real risk of anaphylaxis, immunotherapy should be given only in a medical office or in another carefully screened location, where personnel and supplies are readily available to treat reactions. Similarly, patients with an FEV_1 (forced expiratory volume in 1 second) of less than 70% of predicted or those having an asthma exacerbation should not be given immunotherapy because of the risk of developing even worse bronchospasm. Currently, there is no role for immunotherapy in the treatment of food allergies.

Standard immunotherapy (also known as conventional high-dose immunotherapy) should not be confused with other invalidated and inappropriate methods of immunotherapy. These techniques, which should be avoided, include skin-titration testing and treatment (the Rinkel method), subcutaneous provocation and neutralization, and sublingual provocation.[6]

XII ALLERGIC RHINITIS, CONJUNCTIVITIS, AND SINUSITIS

Raymond G. Slavin, m.d.

Allergic rhinitis, conjunctivitis, and sinusitis are closely related disorders. Allergic rhinitis and conjunctivitis share the same causes and pathophysiology; sinusitis typically occurs as a complication of allergic rhinitis.

Allergic Rhinitis

Allergic rhinitis is an allergic inflammatory response in the nose. It can be classified as seasonal or perennial, depending on the allergens triggering the reaction.

EPIDEMIOLOGY

Allergic rhinitis is the most common atopic disorder in the United States. It affects about 24 million Americans—an estimated 8% of the population—with an equal distribution between males and females.[1] The prevalence of allergic rhinitis varies by age: 32% of patients are 17 years of age or younger, 43% are 18 to 44 years of age, 17% are 45 to 64, and only 8% are 65 years of age or older. The costs of treating allergic rhinitis (and indirect costs of the disorder, such as lowered productivity and time lost from work or school) are substantial. The total direct health care cost of treating allergic rhinitis is estimated at $3.4 billion.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

The airborne allergens responsible for allergic rhinitis can be divided into seasonal (trees, grass, weeds, and mold) and nonseasonal or perennial (house dust mites, pets, insects).[2] These aeroallergens land on the nasal mucosa, are processed by antigen-presenting cells, and are then presented to helper T cells. In genetically predisposed persons, this interaction promotes the generation and release of cytokines that induce B cells to produce antigen-specific IgE. The IgE attaches to receptors on mast cells and basophils, and the patient is thereby sensitized. On subsequent exposure, the allergen bridges IgE molecules, resulting in release of mediators, most notably histamine.[3] Histamine causes increased epithelial permeability, vasodilatation, and stimulation of a parasympathetic reflex. As a result, acetylcholine is released, resulting in marked hypersecretion of mucus and increased blood flow. Activation of centers in the central nervous system results in sneezing.

DIAGNOSIS

Clinical Manifestations

Symptoms of allergic rhinitis may include paroxysms of sneezing, nasal congestion, clear rhinorrhea, and itching of the nose and palate. Distinct temporal patterns of symptom production may aid diagnosis. For example, seasonal allergic rhinitis symptoms typically appear during a specific time of the year when aeroallergens are abundant in the outside air. Symptoms of rhinitis that occur whenever the patient is exposed to a pet with fur suggest IgE-mediated sensitivity to that species.[4] Allergic rhinitis may result in fatigue and significant disability.

Physical Examination

The patient with allergic rhinitis may appear uncomfortable, exhibiting mouth breathing. Children in particular may have so-called allergic shiners (dark rings under the eyes). Allergic shiners develop because the edematous nasal tissue compresses the veins that drain the eyes, leading to pooling of blood under the orbits. On the bridge of the nose, a so-called allergic crease may be present—a result of continued upward rubbing of the tip of the nose (the so-called allergic salute). On nasal examination, the mucosa typically appears pale and swollen, with a bluish-gray appearance when the mucosal edema is severe. Many patients have a normal examination, although they often may be sneezing and have rhinorrhea with mucosal edema. The other physical findings tend to be present in the more severely affected patients.

Laboratory Testing

Although a careful history is the most important step toward the diagnosis of allergic disease, skin testing may be useful in pinpointing the offending allergen [*see 6:XI Diagnostic and Therapeutic Principles in Allergy*]. The simplicity, ease and rapidity of performance, low cost, and high sensitivity of skin tests make them preferable to in vitro testing.[5]

DIFFERENTIAL DIAGNOSIS

The two nasal conditions most commonly confused with allergic rhinitis are infectious rhinitis and perennial nonallergic rhinitis (vasomotor rhinitis). Infectious rhinitis is characterized by constitutional symptoms and purulent rhinorrhea. A nasal smear shows a preponderance of neutrophils, whereas in allergic rhinitis, eosinophils predominate. Perennial nonallergic rhinitis is more frequent in women and is precipitated by such nonspecific factors as changes in temperature, humidity, and barometric pressure; strong odors; alcohol; and cigarette smoke. Nasal congestion frequently shifts from side to side and is often alleviated by exercise.[6]

TREATMENT

Therapy for allergic rhinitis comprises three elements: first, minimizing contact with the allergen (environmental control); second, pharmacotherapy; and third, immunotherapy, which is reserved for selected patients. Together, these treatments ensure an excellent prognosis for allergic rhinitis.

Environmental Control

Reducing or completely avoiding the offending allergen is a vital part of allergy management [*see 6:XI Diagnostic and Therapeutic Principles in Allergy*]. In the case of seasonal allergies, keeping the doors and windows closed and the air conditioning on will reduce the aeroallergen burden manyfold.[7] Measures to avoid house dust mites should focus on the patient's bedroom and include encasing the mattress, box spring, and pillows in occlusive covers; weekly washing of bedding at 130° F or hotter, dehumidification to less than 50%; and removal of reservoirs, such as carpeting. Removal of pets is the optimal approach for pet-sensitive patients. If the patient will not part with the pet,

weekly washing of the animal will reduce airborne levels of its allergen.[8] Also, patients with allergic rhinitis appear to be more sensitive to nonspecific irritants, such as cigarette smoke.[9]

Pharmacotherapy

Oral antihistamines are effective in reducing itching, sneezing, and rhinorrhea from allergic rhinitis. A major limitation of the first-generation (classic) antihistamines has been sedation. The second-generation antihistamines—cetirizine (Zyrtec), fexofenadine (Allegra), and loratadine (Claritin) and its metabolite desloratadine (Clarinex)—produce significantly less sedation. In patients with nasal congestion, an antihistamine-decongestant combination can be used.[10] An intranasal antihistamine spray (Astelin) has also proved to be efficacious. In severe cases, a short course of oral corticosteroids may be needed.

The most effective medications for controlling symptoms of allergic rhinitis are nasally inhaled corticosteroids.[11] They include beclomethasone (Beconase), budesonide (Rhinocort), flunisolide (Flonase), mometasone (Nasonex), and triamcinolone (Nasacort). These agents are generally not associated with significant systemic side effects. Local side effects (e.g., nasal irritation and a burning sensation) are minimized if patients are instructed to direct the spray toward the ear and away from the septum.

Leukotriene receptor antagonists have been approved for use in allergic rhinitis and can be considered as a component of combination therapy, particularly if there is associated asthma.

Omalizumab (Xolair) is a recombinant, humanized, monoclonal anti-IgE antibody for treatment of moderate to severe asthma. It has been shown to significantly reduce serum IgE and to have beneficial effects on allergic rhinitis.[12] However, its cost and the present indication by the Food and Drug Administration only for asthma preclude its routine use in allergic rhinitis.

Immunotherapy

Allergen immunotherapy is highly effective in controlling symptoms of allergic rhinitis. It should be considered in patients with severe symptoms that cannot be controlled by other treatment modalities and in those with comorbid conditions such as asthma. Immunotherapy may prevent worsening of asthma or possibly prevent its development.[13] The effectiveness of symptomatic medications, particularly intranasal corticosteroids, has made immunotherapy less necessary.

COMPLICATIONS

There is good evidence that poorly managed allergic rhinitis can result in otitis media[14] and sinusitis.[15] Rhinitis and asthma frequently coexist.[16] More than that, rhinitis appears to be a risk factor for development of asthma,[17,18] and treatment of rhinitis can improve coexisting asthma.[19] Prevention of asthma is an especially important goal in patients with a family history of asthma or atopic disease and early sensitization to aeroallergens.[20]

Allergic Conjunctivitis

Allergic conjunctivitis is the ocular counterpart of allergic rhinitis, and the two often occur together. Approximately 70% of patients with allergic conjunctivitis have an associated atopic disease, such as allergic rhinitis, asthma, or atopic dermatitis.

EPIDEMIOLOGY

Seasonal and perennial allergic conjunctivitis are the most prevalent forms of ocular allergy. Most reports agree that allergic conjunctivitis affects up to 20% of the world's population.[21]

ETIOLOGY AND PATHOGENESIS

Allergic conjunctivitis is triggered by the same aeroallergens and results from the same pathophysiologic processes as allergic rhinitis [*see* Allergic Rhinitis, Etiology and Pathophysiology, *above*].

DIAGNOSIS

Clinical Manifestations

Patients with allergic conjunctivitis present with itching of the eyes, accompanied by tearing and a burning sensation. The reaction is usually bilateral, although unilateral conjunctivitis may occur in a patient who has had direct hand-to-eye contact with an allergen such as dog or cat dander.

The periocular tissues are usually swollen and reddened. The conjunctiva is injected, with mild to moderate chemosis, and there is a ropy mucous discharge in the tear film.

Laboratory Tests

Although examination of the ocular discharge in allergic conjunctivitis typically reveals large numbers of eosinophils, this test is almost never done. Instead, allergic conjunctivitis is generally diagnosed clinically. As with allergic rhinitis, skin testing may be performed to identify the offending allergen or allergens [*see* Allergic Rhinitis, Laboratory Testing, *above*].

DIFFERENTIAL DIAGNOSIS

The eye condition that is most likely to be confused with allergic conjunctivitis is infectious conjunctivitis (viral or bacterial). Patients with infectious conjunctivitis complain of matting of the eyelids, with a clear to mucopurulent ocular discharge. The conjunctiva is deeply red, and although a burning sensation is common, itching is not as profound as in allergic conjunctivitis. Vernal conjunctivitis, which may also be confused with allergic conjunctivitis, is a severe, bilateral recurrent condition of the eye often occurring in the spring. It is marked by intense pruritus and a typical cobblestone appearance of the upper eyelid.

TREATMENT

Because allergic conjunctivitis results from the same allergens as allergic rhinitis, environmental control measures and immunotherapy are also the same [*see* Allergic Rhinitis, Treatment, *above*].

Drug treatment for allergic conjunctivitis typically begins with a topical over-the-counter antihistamine-decongestant combination such as antazoline-naphazoline (Vasocon-A) or pheniramine-naphazoline (Naphcon-A).[21] The next line of therapy would include a selective H_1 receptor antihistamine, a category that includes ketotifen (Zaditor), epinastine (Elestat), levocabastine (Livostin), azelastine (Optivar), and olopatadine (Patanol). Ketotifen, epinastine, and olopatadine also have mast cell-stabilizing properties. A meta-analysis confirms the benefit of topical mast cell stabilizers and antihistamines over placebo for the treatment of allergic conjunctivitis.[22] An additional therapeutic option is a nonsteroidal anti-inflammatory agent such as ketorolac (Acular).[21] For the most severe cases of allergic conjunctivitis, the clinician may consider giving corticosteroid eyedrops—loteprednol etabonate (Lotemax) or rimexolone (Vexol)—for 2 to 3 weeks. Long-term use of these agents has been

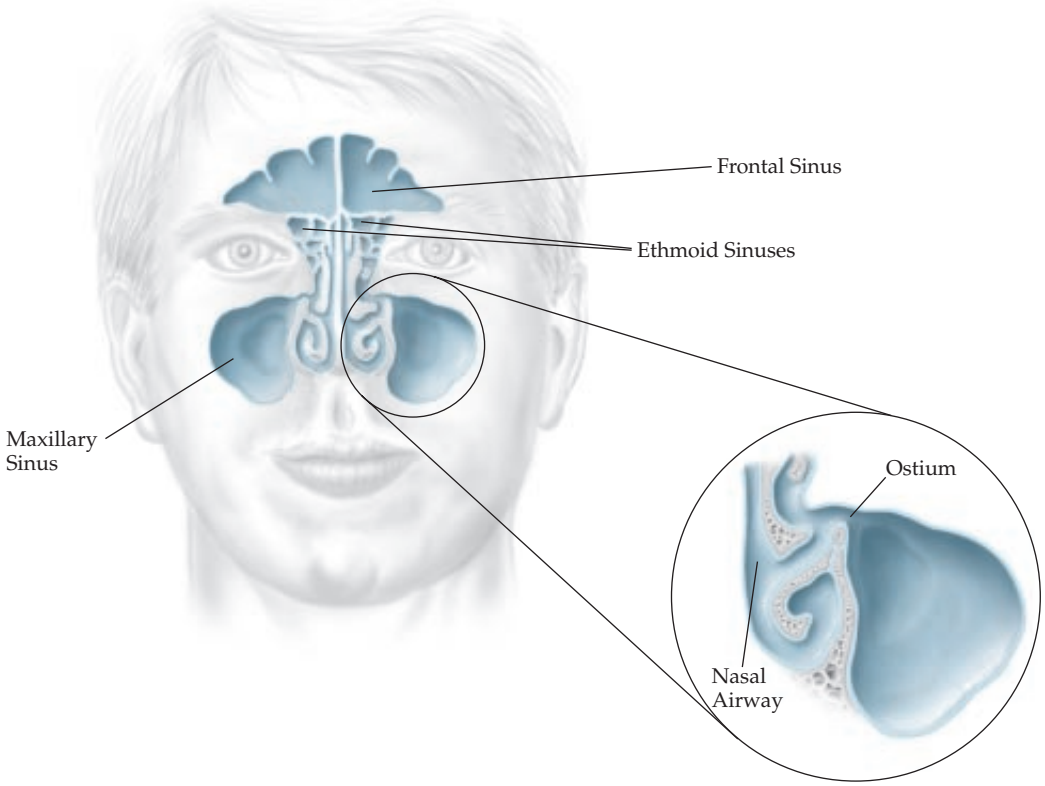

Figure 1 **The paranasal sinuses drain into the nasal passages via narrow ostia. The ostium through which the maxillary sinus drains is on the superior medial wall of the sinus, and hence the maxillary sinuses drain against the force of gravity. Edema of the nasal mucosa from allergic rhinitis can obstruct the ostia, and the resulting accumulation of mucus within the sinuses promotes bacterial infection.**

associated with the development of glaucoma, cataracts, and secondary infection and hence should be managed by an ophthalmologist.

Sinusitis

DEFINITION AND CLASSIFICATION

It has been suggested that the term rhinosinusitis may be more accurate than the term sinusitis, for the following reasons: (1) rhinitis typically precedes sinusitis, (2) sinusitis without rhinitis is rare, (3) the mucosa of the nose and sinuses are contiguous, and (4) symptoms of nasal discharge are prominent in sinusitis.[23]

Rhinosinusitis is classified as acute, recurrent acute, subacute, and chronic. Acute sinusitis is defined as inflammation of the sinuses for less than 4 weeks. Subacute sinusitis, lasting from 4 to 8 weeks, is the development and manifestation of minimal to moderate signs of sinus inflammation without an overt upper respiratory tract infection (URI) or abrupt onset of symptoms. Chronic sinusitis is defined as persistent sinus inflammation for more than 8 weeks. An operational definition of chronic sinusitis is persistent inflammation, documented with imaging techniques, continuing for at least 4 weeks after initiation of appropriate medical therapy in the absence of an intervening acute episode.

EPIDEMIOLOGY

Rhinosinusitis is the most frequently reported chronic disease in the United States, affecting 16% of the adult population. Chronic rhinosinusitis accounts for 11.6 million physician office visits a year, and the overall direct cost in the United States is estimated to be $4.3 billion annually.[24]

In one study of patients with rhinosinusitis, a 36-item health survey showed significant worsening in several domains, including bodily pain, general health, vitality, and social functioning. Comparison with other chronic diseases (e.g., chronic obstructive pulmonary disease, heart failure, angina, and back pain) revealed significantly worse bodily pain and social functioning in patients with sinusitis.[25]

PATHOGENESIS

The paranasal sinuses are composed of the ethmoid, frontal, maxillary, and sphenoid sinuses [*see Figure 1*]. Microorganisms, pollutants, irritants, and other foreign particles that escape the filtering apparatus of the nose are trapped in the mucus of the sinuses. The steady beating of the cilia that line the sinuses moves mucus out of the sinuses and into the nasal passages via the drainage ostia. This ongoing clearance of the sinuses is important for maintaining health.

The key factors that predispose an individual to rhinosinusitis are local [*see Table 1*]. The most common of these are viral URIs and allergic rhinitis. Edema of the nasal mucosa, which is characteristic of acute infectious or allergic rhinitis, results in obstruction of the ostia, decreased ciliary action in the paranasal sinuses, and increased mucus volume and viscosity. The subsequent accumulation of mucus in the sinus provides an environment for secondary bacterial infection and the conversion of mucus to mucopus.

Cultures from both adults and children with acute sinusitis grow predominantly aerobic organisms, with the heaviest yield being *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella* (formerly *Branhamella) catarrhalis.* Although the role of viruses and bacteria in causing acute infectious sinusitis is well established, the role of microbial infection in chronic sinus disease is much less clear. It was once believed that anaerobic organisms were responsible for instances of chronic sinusitis, but aerobes have now been implicated as the major cause. A noninfectious form of chronic rhinosinusitis, sometimes referred to as chronic hyperplastic eosinophilic rhinosinusitis, is marked by a preponderance of eosinophils and mixed mononuclear cells and by a paucity of neutrophils. It is often associated with nasal polyps, asthma, and aspirin sensitivity.[26]

DIAGNOSIS

Clinical Manifestations

Acute sinusitis The most important clinical clue to the diagnosis of acute sinusitis is the failure of symptoms to resolve after a typical cold. The previously clear nasal discharge becomes yellow or green. Fever persists and chills may develop. Pain is often felt in the cheek, or it may be referred to the forehead. The discomfort is often worse on bending over or straining. If the ostium of the maxillary sinus is blocked, pain may be severe and felt in the teeth.

On physical examination, thick, purulent, green or deep-yellow secretions are seen in the nose on the side of the diseased sinus. Because the maxillary sinus is most frequently involved, purulent secretions will be seen most often in the middle meatus, which is the drainage site of the maxillary sinus [*see 7:XIX Bacterial Infections of the Upper Respiratory Tract*]. The middle meatus may be hidden by the middle turbinate, so it may be necessary to shrink the turbinate with a topical decongestant. Once this is accomplished, the nose, particularly the middle meatus, can be examined thoroughly not only for pus but also for underlying problems, such as nasal septal deviation, spurs, and polyps. Frequently, a streak of pus is visible along the lateral wall of the oropharynx. When the diagnosis of sinusitis is in doubt, referring the patient to an otolaryngologist for fiberoptic nasopharyngoscopy can be helpful, because this technique affords a better opportunity for visualization of the drainage ostia of infected sinuses.

Table 1 Factors Predisposing to Sinusitis

Upper respiratory infection	Allergic rhinitis Anatomic variants Septal deviation Haller cells (infraorbital ethmoid cells) Hypertrophied adenoids Nasal polyps, chronic mucosal thickening Nasal or sinus tumors
Foreign bodies	Cigarette smoke Swimming and diving; barotraumas Rhinitis medicamentosa Cocaine abuse Nasal intubation Periapical abscess in a protruding tooth Dental extraction or injections

Chronic sinusitis If mucopus is not evacuated, acute sinusitis may enter a subacute or chronic phase. Chronic maxillary sinusitis may exist alone, but it is usually associated with chronic ethmoid and frontal sinusitis. The lack of pain or systemic symptoms makes chronic sinusitis difficult to diagnose on history alone. A patient may complain of dull pressure in the face or head. Chronic sinusitis generally presents as persistent, sometimes unilateral nasal stuffiness, hyposmia, purulent nasal and postnasal secretions, sore throat, fetid breath, and malaise. The secretions often pool in the hypopharynx at night, and the patient complains of increasing postnasal drainage with resultant cough and, sometimes, wheezing. On physical examination, a patient with chronic sinusitis may display an edematous and hyperemic nasal mucosa bathed in mucopus. Nasal polyps may accompany chronic sinusitis.

Nasal Smear and Sinus Culture

Nasal culture does not give an adequate picture of the organisms responsible for sinusitis. Microscopic examination of nasal secretions, however, may be of great diagnostic value. In instances of sinusitis, one sees sheets of polymorphonucleur neutrophils and bacteria. This is unlike viral URIs, in which polymorphonuclear neutrophils are scanty, or allergic rhinitis, in which a high percentage of eosinophils may be seen. Antral puncture provides a true specimen of the microbiology of the sinus cavity and is generally performed by an otolaryngologist when it is important to determine the pathogen (e.g., if fungal infection is suspected).[27]

Radiology

Two imaging modalities are used for the diagnosis of sinusitis: plain x-rays and computed tomography. In adults, plain films of the sinuses that show mucosal thickening greater than 8 mm, an air-fluid level, or opacification have been shown to correlate with positive bacterial cultures on antral punctures. In children older than 1 year, abnormal findings on maxillary sinus radiographs are generally related to inflammation of the upper airway. Crying has not been shown to be a cause of abnormalities on sinus radiographs in these children.[28]

The diagnostic value of plain films is controversial. Some authorities advise against plain radiographic studies, particularly for diagnosing chronic sinusitis. Conventional radiographs can depict changes of acute sinusitis in maxillary, ethmoid, frontal, and sphenoid sinuses but cannot delineate the status of individual ethmoid air cells or the osteomeatal complex, nor can they accurately show the extent of inflammatory disease in affected patients. For these reasons, CT is the radiographic modality of choice for examining the paranasal sinuses. Coronal CT scans demonstrate the osteomeatal complex and detect subtle disease that is not shown on plain films. The cost of CT scans used to be prohibitive, but through improved technology and the use of limited slices, the price has been reduced to the point where it is quite close to that of plain films in most centers. A limited four-slice coronal CT scan of the sinuses provides much more information than plain films do, and compared with full CT, four-slice coronal CT provides the increased information at a much reduced radiation dose and cost.[29]

Transillumination and ultrasonography are used in the diagnosis of sinusitis. Both are subject to great error, however, and cannot be recommended at the present time.

Ancillary Laboratory Tests

Other laboratory tests may have to be considered in some cases of treatment-resistant sinusitis. Underlying allergy can be determined by appropriate skin testing after a careful history has identified likely allergens. Immunologic testing may be indicated, because patients with refractory sinusitis may have immune dysfunction.[30] Associated immunodeficiency is diagnosed by serum immunoglobulin levels and by antibody responses to specific antigens such as pneumococci, diphtheria, and tetanus. Other considerations in medically resistant sinusitis include cystic fibrosis, fungal infection, and anatomic abnormalities.

DIFFERENTIAL DIAGNOSIS

The condition most often misdiagnosed as rhinosinusitis is a viral URI, which is the most important predisposing cause of acute rhinosinusitis. Rhinosinusitis is probably present if the URI symptoms do not resolve in 3 to 6 days; if the secretions, particularly postnasal secretions, turn yellow or green and persist throughout the day; and if the patient notes fullness of the head and discomfort in the face and teeth.

TREATMENT

Concern has been raised about the overdiagnosis of rhinosinusitis and unnecessary treatment with antibiotics of uncomplicated viral upper respiratory infection. More strict criteria for the use of antibiotics are symptoms for 10 to 14 days or severe symptoms, such as fever with purulent nasal discharge, facial pain or tenderness, and periorbital swelling.[31,32]

The antibiotic of choice for treatment of acute sinusitis is ampicillin or amoxicillin. An appropriate dosage of amoxicillin for acute sinusitis in the adult is 875 mg twice a day for 10 to 14 days. In patients with penicillin sensitivity, trimethoprim-sulfamethoxazole (one double-strength tablet twice a day) is an adequate alternative. More and more cases of β-lactamase–producing organisms are being reported. In penicillin-resistant sinusitis, recommended antibiotics include amoxicillin with clavulanic acid (Augmentin), the quinolones (e.g., levofloxacin [Levaquin]), and telithromycin (Ketek). Antibiotic treatment for chronic sinusitis should be continued for at least 2 weeks. If the patient reports feeling better by the last day of the regimen but still has purulent nasal discharge, the antibiotic can be continued for another 5 to 7 days.

Ancillary treatments for sinusitis, including oral decongestants and mucus thinners, have been advocated, but there are no controlled studies showing their effectiveness. The addition of intranasal corticosteroids may be modestly beneficial in the treatment of patients with recurrent acute or chronic rhinosinusitis.[33]

In some cases of chronic resistant sinusitis, surgical treatment must be considered. A wide array of surgical procedures are available, but functional endoscopic sinus surgery (FESS) has emerged as the technique of choice.[34]

COMPLICATIONS

Complications of sinusitis have decreased in incidence since the introduction of antibiotics. The complications most commonly encountered are cellulitis, abscess, and cavernous sinus thrombosis (all involving the orbit); epidural or subdural abscess; mucocele formation; and osteomyelitis.[35] It is evident in both children[36] and adults[37] not only that there is an association between sinusitis and asthma but also that sinusitis is an important trigger for asthma. In a patient who has both sinusitis and asthma, the asthma will be difficult to manage until the sinusitis is brought under control by either medical or surgical means.

PROGNOSIS

The prognosis for patients with sinusitis should be excellent if the diagnosis is made accurately and promptly and an appropriate antibiotic is administered for a sufficient period of time. Consultation with a specialist should be sought in the following situations:

- If there is a need to clarify the allergic or immunologic basis for sinusitis.
- If sinusitis is refractory to the usual antibiotic treatment.
- If sinusitis is recurrent.
- If sinusitis is associated with unusual opportunistic infections.
- If sinusitis significantly affects performance and quality of life.

Consultation is also appropriate when concomitant conditions are present that complicate assessment or treatment, including chronic otitis media, bronchial asthma, nasal polyps, recurrent pneumonia, immunodeficiencies, aspirin sensitivity, allergic fungal disease, granulomas, and multiple antibiotic sensitivities.

The author has received grants for clinical research from Genentech, Inc., and for educational activities from AstraZeneca Pharmaceuticals LP and has served as a consultant for Dey, Inc., and Aventis.

XIII URTICARIA, ANGIOEDEMA, AND ANAPHYLAXIS

VINCENT S. BELTRANI, M.D.

Definition

Urticaria (hives), angioedema, and anaphylaxis are the prototypical manifestations of mast cell activation. The common denominator in these conditions is the release of potent inflammatory mediators from activated mast cells[1] [*see 6:X Allergic Response*]. Urticaria and angioedema are effected primarily by activation of cutaneous mast cells, which are preferentially located around capillaries, lymphatics, appendages, and nerves in the skin. Massive activation of mast cells in the intestinal tract, respiratory tract, and central nervous system produces the multisystemic, potentially catastrophic symptom complex of anaphylaxis.

Although the three conditions have common features and may occur in various combinations, they are more easily understood when discussed individually.

Urticaria

Urticaria is a cutaneous eruption that consists of erythematous, pruritic wheals. Although urticaria is typically transient, it can be persistent, with lesions occurring for weeks to months.

EPIDEMIOLOGY

Urticaria is a common problem, with 15% to 23% of the general population experiencing at least one episode in their lifetime.[2,3] The precise prevalence of urticaria may never be known. Many patients experience transient episodes of hives and do not report them to a health care provider because of their readily identifiable cause, inconsequential nature, and spontaneous resolution. If the papular urticaria that develops after an arthropod bite is included in the spectrum of urticarial lesions, urticaria must be considered a virtually universal human experience.

ETIOLOGY

Injecting histamine into the skin will produce the so-called triple response of Lewis—a prototypical hive. This response comprises the following: (1) erythema, the clinical manifestation of vasodilatation; (2) a wheal, the result of vascular leakage; and (3) pruritus, caused by activation of dendritic itch receptors on nonmyelinated C fibers (neurons) in the epidermis [*see Table 1*]. A fourth feature of intradermally injected histamine is its spontaneous dissipation within 1 hour. Urticaria lasting longer than 1 hour is not caused solely by histamine. Multiple inflammatory mediators have been identified in the effluent of urticarial lesions, and some of these vasoactive mediators (e.g., prostaglandin D_2 and platelet-activating factor) have produced urticaria—with and without pruritus—lasting longer than 1 hour when injected subcutaneously.

PATHOGENESIS

Because histamine plays a leading role in the pathogenesis of urticaria, tracing the source and mechanism of histamine release is the key to understanding urticarial lesions. Most of the body's histamine is stored in tissue mast cells; much smaller amounts are present in basophils and CNS neurons. Mast cells at different anatomic locations, and even at a single site, can vary substantially in mediator content, sensitivity to agents that induce activation, quantity of mediator released, and response to pharmacologic agents.[1] Agents having the ability to initiate the release of mediators from mast cells are called secretagogues. There is debate regarding whether the number of cutaneous mast cells in patients with persistent urticaria increases[4] or remains unchanged.[5] However, it has been generally agreed that these cells have a lower threshold for mediator release. Thus, a more appropriate label for chronic or idiopathic urticaria would be twitchy mast cell syndrome.

A practical categorization of urticaria is a three-part classification based on the etiology and mechanism of mast cell degranulation [*see Table 2*]. The first category comprises cases with an identifiable cause; the second, idiopathic cases; and the third, mastocytosis. Mastocytosis encompasses a wide spectrum of clinical conditions, characterized by a localized or diffuse increase in mast cells in the skin or internal organs. Most cases of mastocytosis are transient, which suggests that this disorder represents a hyperplastic response to abnormal stimuli rather than a true neoplastic process.

DIAGNOSIS

The diagnosis of urticaria is made almost exclusively from an appropriate, complete history. The history should include questions about substances or circumstances that may trigger the urticaria; the clinical features of the urticaria, including its duration, the presence and degree of pruritus, and whether the urticaria is localized or generalized; underlying illnesses; any previous diagnostic procedures or therapy for the condition; and family history of urticaria. A personal or family history of atopy should also be noted. Although the occurrence of urticaria with identifiable triggers is increased in atopic patients, whether the incidence of atopic disease is higher in patients with idiopathic urticaria remains debatable.[6,7]

Many patients presenting with IgE-induced urticaria can identify the cause of their generalized, very pruritic, explosive hives. By merely avoiding that trigger, they remain symptom

Table 1 Pathologic Changes in Urticaria and Their Associated Mediators

Symptom	*Pathologic Event*	*Mediators*
Wheal	Vascular permeability	Histamine (H_1) Prostaglandin D_2 Platelet activating factor Bradykinin Leukotrienes C4, D4, E4
Flare	Vasodilatation	Histamine (H_1) Prostaglandin D_2 Platelet activating factor Bradykinin Leukotrienes C4, D4, E4
Pruritus	Sensory nerve stimulation	Histamine (H_1)

Table 2 Classification of Urticarial Lesions

- Identifiable cause
  - Immunologic
  - Nonimmunologic (e.g., cyclooxygenase pathway, opiates)
  - Physical urticaria
    - Aquagenic urticaria
    - Cholinergic urticaria
    - Cold urticaria
    - Contact urticaria (e.g., jellyfish, nettles)
    - Delayed pressure
    - Dermatographism
    - Solar urticaria
    - Vibratory urticaria
- Nonidentifiable cause (idiopathic)
  - Persistent — occurring almost daily
  - Episodic — recurrent, with days of no hives between episodes
  - Associated with an underlying disease
    - Anaphylaxis (IgE-induced)
    - Anaphylactoid (non–IgE-induced)
    - Bullous pemphigoid
    - Erythema multiforme
    - Leukocytoclastic vasculitis
    - Serum sickness (via immune complexes)
    - Systemic lupus erythematosus
    - Viral syndrome (via immune complexes)
- Mastocytosis
  - Mastocytoma
    - Urticaria pigmentosa
    - Diffuse cutaneous mastocytosis
    - Telangiectasia macularis eruptiva perstans (TMEP)
  - Systemic mastocytosis

free. These patients are at greater risk of developing fatal anaphylactic reactions, with or without urticaria.

Common Triggers of Urticaria

Before concluding that urticaria is idiopathic, the clinician must complete a systematic review of possible mast cell secretagogues. These include immunologic and nonimmunologic activators, as well as some whose mechanism is unknown [*see Table 3*].

Drugs Drugs are probably the most easily recognized of the identifiable causes of urticaria because the symptoms usually appear within 36 hours of administration of the drug.[8] The penicillins, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), and sulfa drugs are most commonly involved, but virtually any drug may elicit urticaria. When urticaria develops within 1 to 2 weeks after initiation of therapy with a drug that is known to cause urticaria, that drug must be suspected.

Drugs can cause urticaria via immunologic and nonimmunologic mechanisms. The best understood mechanism involves drug-specific IgE antibodies. These IgE-induced reactions typically arise within 2 weeks after a drug is started, are not dose-related, occur from seconds to minutes after administration of the drug, and may herald an anaphylactic episode [*see Figure 1*].[8] Non-IgE reactions to drugs (e.g., aspirin or other NSAIDs, opioids, and vancomycin) can occur on first exposure or from hours to days after ingestion, are dose related, and may herald an anaphylactoid reaction.[9]

Although urticarial reactions to aspirin and other NSAIDs are rarely induced through IgE, they occur most frequently in atopic persons.[10] Angioedema, with or without urticaria, is the most common symptom of NSAID hypersensitivity. Respiratory symptoms are not more likely to occur in patients who develop an urticarial reaction from an NSAID. Some cyclooxygenase-2 (COX-2) inhibitors, especially rofecoxib, are relatively safe in patients who experience urticaria or angioedema from standard NSAIDs.[11] Patients whose history suggests a non-IgE drug reaction should not undergo routine skin testing and radioallergosorbent testing (RAST) [*see 6:XI Diagnostic and Therapeutic Principles in Allergy*].

Drug-specific IgE antibodies can be detected by skin testing, but penicillin is the only antibiotic for which reliable skin-test reagents have been developed. Standardized antigens for penicillin include penicilloyl-poly-L-lysine (penicilloyl polylysine), which is considered the major determinant and is commercially available, and several investigational minor determinants. With these reagents, numerous studies have documented the presence of penicillin-specific IgE antibodies in patients who have experienced penicillin-induced urticaria. In contrast, IgE antibodies to other antibiotics have not been demonstrated routinely in patients who have experienced an antibiotic-induced urticaria. Although it is possible that these reactions are not IgE mediated, it is more likely that the IgE antibodies have not been detected because the patients had antibodies directed against a drug metabolite not used in the testing.[12] Consequently, the diagnostic test for confirming drugs (other than the penicillins) as an identifiable cause of an individual's urticaria is to carefully rechallenge the patient, under direct medical su-

Table 3 Mast Cell Secretagogues

Immunologic activators (act on receptors)	IgE antigens (e.g., foods, drugs, latex) IgG directed against IgE (autoimmunity) Anti-FcεRI (IgE receptor) antibodies Lectins (e.g., strawberries, conconavalin A) Neuropeptides (e.g., substance P, somatostatin) Complement activators (C3a, C5a) Radiocontrast media Blood products Cytokines IL-1, IL-3, IL-6 Granulocyte-macrophage colony-stimulating factor Histamine-releasing factors (HRF) c-*kit* ligand
Nonimmunologic activators	Ionophores (opiates, adrenocorticotropic hormone [ACTH], compound 48/80) Arachidonic acid metabolic pathway inhibition (nonsteroidal anti-inflammatory drugs) Direct effect on cell Opiates (e.g., morphine, codeine) Radiocontrast media Peptides Jellyfish, lobster, eosinophil major basic protein (EMB), polymyxin B, defensins Irradiation Dextran Physical contact (pressure, light, water)
Mechanism unknown	Alcohol, amphetamine, bradykinin, ciprofloxacin, papaverine, rifampin, thiamine, thiopental, tolazoline, vancomycin

Figure 1 **Generalized, symmetrical, very pruritic urticaria appeared within 10 minutes of an intramuscular injection of penicillin G in this boy. The reaction is polymorphic, with papular urticaria evolving to larger, evanescent urticarial plaques that appear annular because of central clearing. The patient in this photograph subsequently demonstrated a positive prick test to the penicillin allergen penicilloyl polylysine.**

pervision, several weeks after the original episode has resolved. In practice, this is rarely done unless the drug in question is absolutely required to treat a disease.

Foods Foods and additives are the second most easily recognized IgE-induced trigger. Symptoms usually appear within 1 hour after ingestion, and in 80% of these cases, GI symptoms (e.g., cramps, diarrhea, and nausea and vomiting) also occur. Respiratory or, less frequently, cardiovascular symptoms may also accompany or precede cutaneous reactions.[13]

Foods are a common cause of urticaria.[14,15] Although studies of different populations of patients with urticaria provide estimates of the prevalence of food-induced urticaria, prevalence in the general population is unknown. Determining prevalence is complicated by the fact that even in patients with histories of adverse reactions to foods, only about 60% or fewer have reproducible reaction to foods.[16]

Urticarial reactions to foods may result from exposure by ingestion, injection, contact, or inhalation. Eggs, peanuts, milk, nuts, soy, wheat, fish, and shellfish are the foods most often implicated in allergic reactions, but IgE-mediated reactions to numerous other foods and to contaminating substances in foods, such as molds or antibiotics, have been reported.[17] Certain foods, such as egg white, strawberries, and shellfish, have been shown to contain substances that liberate histamine directly through a nonimmunologic mechanism.[18] Urticaria can also result from the ingestion of foods that contain large amounts of histamine, either naturally or as a result of spoilage (e.g., scombroidosis) [*see 8:I Management of Poisoning and Drug Overdose*].

Some children who experience urticaria after exposure to certain foods such as milk, eggs, soy, or wheat early in life may later tolerate these foods without difficulty. Loss of sensitivity to foods such as peanuts,[19] nuts, or fish may occur less frequently.[20]

The diagnostic tools available to determine whether foods play a role in the production of urticaria in a patient include the history, physical examination, skin testing or RAST, diet and symptom diaries, elimination diets, and food challenges. Although slightly less sensitive than skin-prick test, RASTs for specific IgE antibodies are more widely available; they require only a serum sample and are performed by commercial laboratories, and therefore, they are practical in most primary care practices. As with skin tests, a negative result is very reliable in ruling out an IgE-mediated reaction to a particular food, but a positive result has low specificity.[21] Many patients have positive skin tests and RASTs to several members of a botanical or animal species, indicating immunologic cross-reactivity, but very few patients have symptomatic intrabotanical or intraspecies cross-reactivity. The practice of avoiding all foods within a botanical family when one member is suspected of provoking allergic symptoms generally appears to be unwarranted.[21]

Occupational and hobby exposures Contact urticarial reactions are seen in certain occupational situations, such as health care workers (latex induced) and food handlers (shellfish). Atopic individuals are at a higher risk of developing these immediate-type contact reactions, which may present as pruritus, urticaria, or anaphylaxis.

Latex or natural-rubber latex hypersensitivity is a fairly common identifiable IgE-induced cause of urticaria [*see 2:V Contact Dermatitis and Related Disorders*]. These patients may experience localized urticaria at the contact area, generalized urticaria with angioedema, or urticaria with systemic involvement (including anaphylaxis). The diagnosis is made from a history of exposure and confirmed by a skin-prick test or RAST.

Systemic illness Urticaria occurs in a variety of autoimmune and infectious diseases. Urticaria is rarely the sole symptom of an underlying disease, however. If the history and physical examination do not suggest an underlying problem, routine laboratory testing is not indicated.

Generalized, urticarial lesions that persist for longer than 24 hours or that burn or sting more than they itch may be a manifestation of rheumatoid arthritis, systemic lupus erythematosus, or other rheumatic disease. Lesions associated with rheumatic illness usually do not blanch on diascopy and may leave ecchymosis and eventually hyperpigmentation. Patients who present in this manner should be assessed for rheumatic disease [*see 15:I Introduction to Rheumatic Diseases*].

Approximately 5% to 10% of patients with chronic urticaria have been reported to have antithyroid antibodies but are clinically and biochemically euthyroid.[22,23] For that reason, autoimmune thyroid serologic studies have been recommended for patients with chronic urticaria.[24] There is only anecdotal evidence that treating these patients with exogenous thyroid hormone leads to significant improvement of their urticaria, however.[25,26]

Changes in mast cell reactivity apparently can be part of the immune response to infection. Urticaria reportedly can be a feature of streptococcal pharyngitis, otitis media, infectious mononucleosis, and hepatitis (a slightly higher incidence of

hepatitis C antibodies has been reported in patients with urticaria, but whether there is a causal relationship is questionable). Pathogens reportedly associated with urticaria include coxsackievirus, *Mycoplasma*, fungi, and *Candida*. A causative relationship of urticaria with *Helicobacter pylori* has not been confirmed.[27,28] Extensive searches for occult focal infections (e.g., sinusitis) as the cause of urticaria are consistently unsuccessful.[29]

A number of parasitic infestations produce transient urticaria.[30] The urticaria in these patients usually appears from the second to the sixth week of infestation. Random examinations of stool for ova and parasites rarely, if ever, prove positive in patients with urticaria who do not have typical symptoms of parasitic infestation.

Psychological factors Emotional stress can influence mast cell and IgE activity, resulting in the release of vasoactive mediators and exacerbations of chronic urticaria.[31] However, there is no good evidence that psychological factors by themselves can cause urticaria, so urticaria without an identifiable cause should not be dismissed as a psychosomatic illness.

Neoplasms Lymphomas and carcinomas may promote urticaria (paraneoplastic syndrome), but urticaria in patients with neoplasms is usually coincidental. In most cases, the malignancy is known; current evidence does not warrant routinely subjecting patients with unexplained urticaria to an exhaustive evaluation for an occult neoplasm.

Chronic urticaria may occur as part of Schnitzler syndrome, which also includes a monoclonal IgM gammopathy, intermittent fever, joint or bone pain, lymphadenopathy, leukocytosis, and an elevated erythrocyte sedimentation rate (ESR). In 15% of cases, Schnitzler syndrome evolves to lymphoplasmocytic malignancy.[32]

Genetic factors Several of the physical urticarias can be familial. Examples include urticaria induced by cold, heat, light, water, and vibration (see below), as well as urticaria associated with erythropoietic protoporphyria. The Muckle-Wells syndrome is a form of familial urticaria associated with deafness and amyloidosis.[33]

Localized Urticaria

Papular urticaria, some of the physical urticarias, and contact urticaria are the entities to consider when urticaria is restricted to a limited area of the body. Dermatographism, cold urticaria, delayed pressure urticaria, solar urticaria, and aquagenic urticaria are localized wheals produced by specific physical stimuli (i.e., stroking of the skin, cold, sustained pressure, ultraviolet light, and water, respectively).

Papular urticaria Papular urticaria consists of 4 to 8 mm wheals or firm papules, often in grouped clusters and especially on areas of exposed skin. Papular urticaria that is very pruritic, persists longer than typical hives, and is located on exposed parts of the body is often caused by insect bites (fleas, bedbugs, scabies, and other mites). The pattern of the eruption corresponds to the biting habits of the offending insect (e.g., mosquito bites often comprise three quasilinear lesions—referred to as breakfast, lunch, and supper), and the seasonal occurrence corresponds to the peak prevalence of that insect. IgE and IgG antibodies against mosquito antigens have been detected in human sera,[34] but there have been no reported cases of anaphylaxis or death associated with hypersensitivity to mosquitoes. Arthropod bites are the only known cause of bulla on papular urticaria. Papular urticaria persists for 2 to 10 days and may leave postinflammatory hyperpigmentation. Occasionally, healed lesions may recrudesce when fresh crops appear.[35]

Figure 2 **Dermatographism elicited by gentle stroking of the skin of the back.**

Dermatographism Firm stroking of the skin may elicit a wheal and erythema in 5% of a healthy population, but only in a minority of these persons does it also cause any pruritus (so-called symptomatic dermatographism) [*see Figure 2*]. The etiology of dermatographism is uncertain, but passive transfer tests are sometimes positive. Dermatographism (Darier sign) is a common finding in patients with idiopathic urticaria and may be associated with other conditions. For example, dermatographism can be elicited in more than 90% of patients with mastocytosis.[36] Confirmation of mastocytosis always requires biopsy, however. The elicitation of symptomatic dermatographism in patients with urticaria supports the use of both H_1 and H_2 receptor antagonists, which may more effectively reduce wheal size and duration of urticaria.[37]

Delayed pressure urticaria Urticaria that results from localized, continuous (4 to 6 hours) pressure is seen most often in patients with persistent urticaria without an identifiable cause.[38] It may be associated with systemic complaints such as myalgias, arthralgias, and fever. It responds best to aspirin or NSAIDs and poorly to antihistamines.

Cold urticaria The lesions of cold urticaria develop 5 to 30 minutes after exposure to cold and can be caused by wind, bathing, contact, or eating cold foods or drinking cold liquids.[39] Although the urticaria may appear during the period of exposure, more often it develops upon rewarming of the skin. The urticaria usually lasts approximately 30 minutes and resolves spontaneously.

Cold urticaria is often idiopathic and acquired. Patients with these lesions usually have a positive response to an ice-cube–challenge test.[40] Rare forms of acquired cold urticaria include delayed, localized, and reflex cold urticaria. In delayed cold urticaria, lesions develop several hours after exposure; localized cold urticaria lesions occur only at sites of injections or bites; and reflex cold urticaria lesions present as widespread whealing in response to a fall in core body temperature.

Much rarer than acquired forms of cold urticaria is familial cold urticaria. In this autosomal dominant disorder, lesions appear 30 minutes after exposure to generalized cooling, rather than to local application of cold, and may persist for up to 48 hours.

Solar urticaria Solar urticaria is a rare idiopathic disorder in which erythema heralds a pruritic wheal that appears within 5 minutes after exposure to a specific wavelength of light and dissipates within 15 minutes to 3 hours after onset [*see Figure 3*].[41,42] Solar urticaria is usually provoked by light in the visible spectrum, although the specific wavelength that leads to mast cell degranulation may vary from patient to patient. The severity of the reaction depends on the duration of the exposure, the intensity of the irradiation, and the light spectrum.[43] These reactions are believed to result from the development of an antigenic photoproduct, which then triggers an IgE-mediated response. Patients should usually be referred to an allergist or dermatologist for provocative testing.

Aquagenic urticaria Urticaria that appears 2 to 30 minutes after water immersion, regardless of its temperature or source (seawater or tap water) has been reported in a few patients.[44] These pruritic, follicular, cholinergic-like wheals can be reproduced by applying wet compresses to the patient's back for at least 30 minutes. It is believed that aquagenic urticaria occurs when sensitized mast cells are activated by a water-soluble antigen that diffuses through the epidermis, causing the release of acetylcholine and histamine.

Vibratory urticaria Urticaria that follows massage and vigorous toweling has been described in a single family.[45]

Contact urticaria Immediate contact reactions can appear on normal or eczematous skin within minutes to an hour after exposure. The reaction then will disappear within a few hours. Itching, tingling, or burning accompanied by erythema are the mildest form of contact reactions. They are often caused by cosmetics, fruits, and vegetables. Generalized urticaria after a local contact is a rare phenomenon, but it can occur with some allergens.[46]

Contact reactions may have either immunologic or nonimmunologic mechanisms. Immunologic mechanisms require prior sensitization to the causative agent. The respiratory and gastrointestinal tracts are typically the routes of sensitization, but sensitization to natural latex and some foods may occur through the skin. The substances causing immunologic immediate contact reactions are usually proteins. Foods most commonly involved are fish, shellfish, and wheat flour. Most cases of protein contact dermatitis develop after the person has handled food products for a protracted period. Symptoms usually appear within 30 minutes after direct cutaneous contact with the offending agent.[47] Specific IgE antibodies against the causative allergen can be found by skin testing or RAST.

Figure 3 **Solar urticaria.**

Figure 4 **Lesions of generalized urticaria tend to be symmetrical and sometimes have a halo of pallor surrounding the wheal.**

Most immediate contact reactions are nonimmunologic and occur without previous sensitization. These reactions remain localized. The pathophysiology of nonimmunologic immediate contact reactions has not been established, but it may involve direct influence on dermal vessel walls or a non-IgE release of inflammatory mediators. A list of chemicals that cause occupational allergic contact dermatitis can be found on the Internet at http://www.haz-map.com/allergic.htm.

Generalized Urticaria

The clinical features and natural history of generalized urticaria are as varied and unpredictable as the etiology. Generalized lesions tend to be numerous and symmetrical. Characteristically, they are intensely pruritic, especially at onset. Except for cholinergic papular urticaria, little information about the etiology can be obtained from the morphology. Individual lesions fade completely within 24 hours. Occasionally a halo of pallor surrounds the wheal [*see Figure 4*].

Cholinergic urticaria The lesions of cholinergic urticaria are highly distinctive, consisting of 2 to 3 mm scattered papular wheals surrounded by large, erythematous flares. These lesions are extremely pruritic, and they may affect the entire body but often spare the palms, soles, and axilla.[48] Precipitating stimuli include exercise, warm temperature, ingestion of hot or spicy foods, and possibly emotional stress. The condition often remits within several years but can last for more than 30 years. The diagnosis can be made by provocation with exercise or a hot bath. Cholinergic urticaria can be aborted by the prompt application of cold water or ice to the skin, and a refractory period of up to 24 hours can be induced by a hot bath.

Table 4 H_1 Antihistamines Available for Treatment of Urticaria

Chemical Group	*Agents*	*Antihistaminic Activity*	*Sedation*	*Anticholinergic Activity*	*Cost*
Ethanolamine derivatives	Diphenhydramine	+	++/+++	++	$
	Clemastine	+	++	+	$
Ethylenediamine derivatives	Tripelennamine (PBZ)	++	+	+	$
Piperidine derivatives	Azatadine	+	+	+	$$
	Cyproheptadine	+/++	+/++	+	$
	Fexofenadine (Allegra)*	++/+++	0	0	$$$
	Loratadine (Claritin)*	+/++	0	0	$$$$
Piperazine derivatives	Hydroxyzine	+++	++	+	$
	Cetirizine (Zyrtec)	+++	+/0	0/+	$$$$
Propylamine derivatives	Acrivastine	++	0/+	0	$$$
	Brompheniramine	+	+	+	$
	Chlorpheniramine	+/++	+	+	$
	Dexchlorpheniramine	+/++	+	+	$$
Phenothiazine derivatives	Promethazine	++/+++	+++	++	$
	Trimeprazine	++	+/++	++	$
Tricyclic antidepressants	Doxepin	+++++	+++	+++	$
	Amitriptyline	+++++	+++/++++	+++	$

*Considered second-generation antihistamines, which are nonsedating (Zyrtec less so) and have other anti-inflammatory properties besides being antihistaminic.

Physical Examination

Recognition of urticaria does not usually present a problem. Unfortunately, except for the contact and physical urticarias, the examination does not facilitate identification of the cause. Episodes of angioedema occur in half the patients presenting with persistent urticaria. The individual swellings of angioedema always last longer than an individual hive and are almost always nonpruritic.

Laboratory Evaluation

The use of laboratory tests in patients with urticaria should be directed toward confirmation of diagnoses suggested by the history and physical examination. Routine laboratory testing should not be performed, because it has consistently proved disappointing for the identification of an etiology. A skin biopsy is indicated if the diagnosis of urticaria is in question. A biopsy should be performed on any urticaria that lasts more than 24 hours, is only mildly pruritic or nonpruritic, is associated with vesicles or bullae, or does not respond to appropriate therapy. The subtleties of the histologic variances demand interpretation by a dermatopathologist.

TREATMENT

Eliminating or avoiding the triggers of mast cell activation is the basis of treatment for urticaria. However, this strategy may be impractical in patients with persistent idiopathic urticaria, which usually has multiple triggers. Any underlying disease should be treated. Idiopathic urticaria is managed symptomatically. Fortunately, the hyperreactive state in patients with idiopathic urticaria eventually resolves spontaneously.

H_1 Receptor Antagonists

When used appropriately, antihistamines can offer significant relief to most patients with urticaria. The more the skin lesions resemble the triple response of Lewis, the better they respond to antihistamine treatment. Urticarial vasculitis and delayed pressure urticaria are resistant to antihistamines. Antihistamines compete with histamine for H_1 receptor sites on effector cells and thereby prevent, but do not reverse, responses mediated by histamine alone. There are eight recognized chemical groups of H_1 receptor antihistamines; all effectively compete for H_1 receptor sites [*see Table 4*]. Among these groups are tricyclic antidepressants, which also have potent antihistaminic activity.

The choice of antihistamine is based on its effectiveness, frequency of administration, and side-effect profile. The dose of the agent selected should be increased to tolerance; if adequate relief is not achieved at the maximal tolerated dose, a drug from another group can be added. Patients do not all respond in the same way to agents from each group. Most of the so-called first-generation (sedative) antihistamines are virtually equivalent in effectiveness, with the major differences being the degree of sedation or anticholinergic effects. Activation of H_1 receptors in the brain is responsible for alertness; inhibiting these sites with antihistamines results in sedation. Second-generation (nonsedating) antihistamines tend not to cause drowsiness, because they cross the blood-brain barrier poorly.[49] Many patients find the itching and urticaria to be most troublesome in the evening and at night, so a useful strategy is to combine sedating antihistamines given at bedtime with nonsedating antihistamines during the day. This combination is effective, promotes compliance, and is economical. Tachyphylaxis has not been noted with H_1 receptor antagonists.

Because other mediators besides histamine are involved in urticaria, antihistamines are not a panacea. Also, none of the antihistamines have the ability to displace histamine from the H_1 receptor site, so the best clinical results are attained when the antihistamines occupy those receptors before the arrival of histamine; hence, round-the-clock dosing is necessary for patients with persistent symptoms.

An effective cocktail for persistent urticaria is fexofenadine (180 mg) or loratidine (10 mg) in the early morning and cetirizine (10 to 20 mg) in the early evening. If this is insufficient, the tricyclic antidepressant doxepin, 10 to 50 mg, can be added at bedtime. (A single dose of doxepin suppresses the histamine-induced wheal and flare for 4 to 6 days.[50]) This cocktail controls symptoms in more than three quarters of patients with persistent urticaria. Prednisone, 0.5 to 1.0 mg/kg/day, should be used only for patients with refractory idiopathic urticaria or with urticarial vasculitis. The goal of treatment should not be to attain a hive-free status but, rather, to minimize compromise of the patient's quality of life from both the disease and its treatment.

In urticaria with an identifiable cause, antihistamines are discontinued once the substance is gone from the body. In persistent urticaria, antihistamines can be sequentially discontinued when patients have been completely free of hives for at least 96 hours. At that point, the morning dose of nonsedating antihistamines can be discontinued. If the patient is still symptom free after another 96 hours, the doxepin dosage can begin to be reduced and, lastly, the cetirizine can be discontinued.

H_2 Receptor Antagonists

Human skin has H_2 receptors as well as H_1 receptors. H_2 receptors are present on the cutaneous arterioles, and their activation can result in vasodilatation (noted as flushing). For that reason, combining H_2 antagonists with H_1 antagonists can be helpful in patients who have prominent flushing, dermatographism, or angioedema.[51] The available evidence does not justify the routine addition of H_2 antagonists to H_1 antagonists in patients with persistent urticaria or urticarial vasculitis.

Beta Agonists

Beta agonists increase intracellular levels of cyclic adenosine monophosphate (cAMP), thereby reducing mediator release by mast cells and promoting vasoconstriction of cutaneous vasculature. Any explosive, generalized urticaria demands the subcutaneous administration of 0.2 ml of aqueous epinephrine 1:1000 (which has combined alpha-agonist and beta-agonist properties), in addition to H_1 antagonists and H_2 antagonists (e.g., doxepin, 10 mg). This is the treatment of choice for anaphylaxis (see below).

Oral beta agonists have been tried for chronic urticaria and angioedema in conjunction with H_1 antagonists and H_2 antagonists. Terbutaline (2.5 to 5.0 mg q.i.d.) deserves a trial in patients not responding to standard treatment. Some studies have demonstrated efficacy, and others have found none.[52,53]

Corticosteroids

Because corticosteroids do not inhibit cutaneous mast cell degranulation, they have no effect on acute urticaria. However, these agents are often used in patients with persistent urticaria whose symptoms are disabling and unresponsive to maximum standard therapy.[54] In these cases, steroids are given in a pulse dose to break the cycle of a resistant episode. The recommended starting dosage of prednisone for persistent urticaria is 0.5 to 1.0 mg/kg/day. This dosage should not be reduced until the patient shows definite clinical improvement.

A protocol for steroid therapy for patients with persistent urticaria has been recommended by the Parameters of Care Committee of the American Academy of Allergy, Asthma and Immunology.[55] Daily steroids are recommended only during the first 1 or 2 weeks for patients with persistent urticaria who have had no relief for a protracted period. The goal is then to utilize an alternate-day regimen with a gradually decreasing dosage over a period of months. Patients should be started on a daily dose of prednisone, 0.5 to 1.0 mg/kg (while continuing the maximum antihistamine regimen). If the symptoms become tolerable, the prednisone dose is decreased by 5 mg every 1 to 3 days until 25 mg a day is reached. The patient's progress is then reassessed every 1 to 2 weeks. Once the patient's condition stabilizes, the dose is decreased by 2.5 to 5 mg every 2 to 3 weeks. When the lowest dose is reached, alternate-day therapy may be tried. Usually, the alternate-day dose is 1.5 times the daily dose. Should some rebound occur on the off day, the alternate-day treatment can be given in divided doses (at 8 A.M. and at 5 P.M.). Once a maintenance dose is reached, the dose of prednisone should be reduced by 1 mg every 1 to 2 weeks.

Other Agents

There are recent reports of success using the anabolic steroid stanozolol for chronic urticaria,[56] aquagenic urticaria,[57] familial cold urticaria,[58] and cholinergic urticaria. Nifedipine, 20 mg three times daily, has been reported effective for chronic urticaria.[59] This treatment deserves further evaluation. Patients with chronic urticaria are advised to avoid aspirin and all NSAIDs, yet there are anecdotal reports of patients with urticaria who benefit from these drugs. Indomethacin has been used successfully in the management of urticarial vasculitis.[60]

Cyclosporine has proved effective in some cases of chronic idiopathic urticaria refractory to antihistamines, as well as in urticarial vasculitis and solar urticaria.[61] Doses used are 2.5 to 6 mg/kg daily. Higher doses can cause elevation in the blood urea nitrogen (BUN) and serum creatinine levels, but these have returned to normal on discontinuance of the drug.

Leukotriene antagonists have been combined with antihistamines for the management of allergic rhinitis and have been noted to be more effective than the antihistamine alone. Therefore, many allergists have tried this combination for urticaria, with some anecdotal success. There is nothing in the literature to support its use, however, and in my experience, the use of a leukotriene antagonist with an antihistamine offers no advantage for persistent urticaria without angioedema.

PROGNOSIS

Except for IgE-induced urticaria, which may progress to fatal anaphylaxis, the prognosis for the other urticarias is benign, although prolonged episodes of these disorders can be extremely bothersome. To date, there is no evidence that the natural history of any of the urticarial syndromes, whether induced by an identifiable cause or idiopathic, is influenced by treatment. Almost all cases of persistent urticaria eventually resolve, however; even the majority of cases of IgE-induced urticarias (especially those without anaphylaxis) are rarely permanent. Chronic urticaria tends to last longer in elderly persons than in younger ones. Studies of chronic (persistent) idiopathic urticaria have found that with or without treatment, 50% of cases will resolve within 6 to 12 months of onset; 20%, within 12 to 36 months; and another 20%, within 36 to 60 months. Less than 2% of cases persist for 25 years or longer. Over 50% of patients will have at least one recurrence.[62] Interestingly, although anaphylactic or anaphylactoid reactions have been noted in patients with identifiable causes of urticaria, there have been no reports of these reactions ever occurring in patients with persistent urticaria without an identifiable

cause. More than 50% of patients with idiopathic urticaria can be made comfortable with appropriate antihistamine therapy. Immunosuppression with corticosteroid dependence occurs in fewer than 5% of patients.

Angioedema

Angioedema is an episodic, asymmetrical, nonpitting swelling of loose tissue (usually skin) [*see Figure 5*]. It is usually nonerythematous and nonpruritic, and it may be painless. Angioedema rarely lasts less than 2 hours, and it frequently persists for 24 hours or longer. It may occur together with urticaria. Angioedema involving the face can be disfiguring during its course. Laryngeal swelling from angioedema may compromise the airway, leading to stridor and even asphyxiation. Gastrointestinal involvement can cause crampy abdominal pain, followed by watery diarrhea. Most cases of angioedema are a reaction to a food or a drug, but some episodes have no identifiable trigger. There are both hereditary and acquired forms of angioedema.

EPIDEMIOLOGY

It is estimated that approximately 10% of the population will experience at least one episode of angioedema.[63] Angioedema occurs episodically in 50% of patients with urticaria. Of patients who have angioedema as their primary disorder, approximately 20% will also experience episodes of urticaria.[64]

ETIOLOGY

Angioedema can be induced by a variety of mechanisms, including IgE, inhibition of the cyclooxygenase pathway of arachidonic acid metabolism, activation of the kinin-forming system, and activation of complement. In some patients, none of these mechanisms can be identified; these cases are labeled idiopathic.

IgE

IgE-induced angioedema resembles IgE allergy and is typically provoked by foods or drugs. It tends to occur in atopic persons and can be confirmed by prick skin testing or RAST.

Cyclooxygenase Inhibition

There is increasing evidence that the inhibition of the enzyme cyclooxygenase causes the de novo release of leukotrienes, an inflammatory mediator derived from arachidonic acid, in response to injury. Of particular interest in the skin is leukotriene B_4, which can induce neutrophil chemotaxis and increase vascular permeability.[65] Aspirin and other NSAIDs directly inhibit the ability of cyclooxygenase to decrease the formation of prostaglandins and thromboxanes, but not leukotrienes, from arachidonic acid. Angioedema (with or without urticaria) may occur in 100% of patients with hypersensitivity to aspirin or other NSAIDs.[11] Interestingly, not all patients who are hypersensitive to aspirin react to other NSAIDs,[66] and in one study, only 3% of patients sensitive to both aspirin and other NSAIDs reacted to the COX-2 inhibitor rofecoxib.[67]

Activation of the Kinin-Forming System

Bradykinin increases vascular permeability. Angiotensin-converting enzyme (ACE) inhibitors inhibit the kininase enzymes required for degradation of bradykinin, and the resulting elevation in bradykinin levels may lead to angioedema.[68] Angioedema has been reported in approximately 0.1% to 0.5% of patients who take ACE inhibitors.[69] However, because these agents are so widely used, ACE inhibitor–induced angioedema is relatively common.

Figure 5 **Angioedema of the tongue is evident in this photograph of a 54-year-old man. This episode, the patient's fifth, was unresponsive to epinephrine, antihistamines, and prednisone; his sixth episode required intubation for 92 hours, after which the angioedema resolved spontaneously.**

Angiotensin II receptor blockers (ARBs), such as losartan and valsartan, do not increase bradykinin levels. Nevertheless, rare instances of angioedema have been reported with the use of ARBs.[70]

Complement Activation

Increased susceptibility to angioedema can result from either an inherited defect in C1-esterase inhibitor (C1-INH) activity or an acquired deficiency of C1-INH. The inherited form of the disease, known as hereditary angioedema, is rare. There are two principal types of hereditary angioedema: type 1, which accounts for 80% to 85% of cases and is caused by decreased production of C1-INH, and type 2, in which normal or elevated amounts of functionally deficient C1-INH are produced.[71] A third, very rare form of hereditary angioedema that may be X-linked has recently been described in women.[72]

Acquired angioedema results from increased metabolism or destruction of C1-INH. Two types of acquired angioedema have been described. Type 1, which is caused by excessive activation of complement and subsequent consumption of C1-INH, typically occurs in patients with rheumatologic disorders and B cell lymphoproliferative diseases. Patients with type 2 produce autoantibodies against C1-INH, leading to its inactivation.[73,74]

PATHOGENESIS

Angioedema is consistently described as a variant of urticaria in which the subcutaneous tissues, rather than the dermis, are mainly involved. However, unlike urticaria, which seems to be mediated primarily by histamine, angioedema seems to be mediated primarily by bradykinin and leukotrienes. Anecdotal evidence indicates that although urticaria can be elicited with a histamine prick or intradermal injection, the injection of histamine deeper in the dermis does not produce angioedema. On the other hand, there are patients whose angioedema will dissipate with the administration of antihistamines (especially the combination of H_1 and H_2 receptor antagonists).[75] These obser-

vations suggest that several vasoactive mediators are capable of producing angioedema.

Unfortunately, angioedema is almost never biopsied, so there are no documented pathologic descriptions of the disorder. The histopathology is always included with urticaria, and its morphology seems to be assumed. Teleologically, the vasodilatation and vascular leakage occur deeper in the skin, and the specific cellular infiltrate, if any, remains uncertain.

DIAGNOSIS

Diagnosis of angioedema is usually straightforward. Cellulitis, edematous states, trauma (stings), and fasciitis occasionally are considerations in the differential diagnosis. Insights into causes and mechanisms of induction are derived primarily from the history.

The history in a patient with angioedema—especially one who has had repeated episodes—should include the following questions: (1) Is the angioedema always, sometimes, or never associated with urticaria? (2) Is the swelling pruritic? (3) Are there accompanying gastrointestinal symptoms (e.g., pain, nausea and vomiting, or diarrhea)? (4) Is the patient taking any medications? (5) Can the patient identify any apparent triggers for the angioedema?

Patients with IgE-induced angioedema are most likely to present with concomitant urticaria. This form of angioedema may be pruritic and may progress to an anaphylactic reaction. Typically, IgE-induced angioedema occurs within 30 minutes after contact with the IgE antigen. It is most likely to occur in atopic patients. Gastrointestinal symptoms may occur but are uncommon. IgE-induced angioedema often occurs as a drug reaction, with β-lactam antibiotics being the most common trigger.

Cyclooxygenase inhibitors (i.e., aspirin or other NSAIDs) are more apt to cause nonpruritic angioedema. NSAID-induced angioedema is occasionally accompanied by urticaria.

Angioedema induced by ACE inhibitors is nonpruritic and rarely occurs with urticaria. No sex predominance has been noted in patients without gastrointestinal tract involvement, but all patients with GI involvement have been women.[76]

Complement-activated angioedema is never pruritic and is not accompanied by urticaria. In 20% to 25% of patients with hereditary angioedema, there is no family history of the disease (these cases may represent new mutations).[77] Therefore, a positive family history of hereditary angioedema is not a prerequisite for the consideration of this disorder in the differential diagnosis when typical symptoms are present. Symptoms of hereditary angioedema are usually mild or nonexistent during childhood, typically first manifesting during the second decade of life. Acquired angioedema usually develops during or after the fourth decade of life.

Hereditary and acquired angioedema have similar clinical presentations. Episodes can occur without provocation, but some episodes may be associated with trauma, medical procedures, emotional stress, menstruation, oral contraceptive use, infections, or the use of medications such as ACE inhibitors.[71] Manifestations include marked edema of the skin and lining of hollow visceral organs. GI tract involvement results in varying degrees of intestinal obstruction, with severe abdominal pain, nausea, and vomiting. Despite the absence of fever and leukocytosis, these cases are often mistaken for an acute abdomen, which occasionally leads to unnecessary surgical exploration of the abdomen. Typically, the attacks last about 2 to 5 days before resolving spontaneously.

Laboratory Tests

IgE-induced drug reactions are readily identifiable with skin-prick tests or RAST. In complement-activated angioedema, a low level of the complement component C4 is a constant finding and therefore represents a sensitive screening test. A normal level, especially during an attack, rules out both hereditary and acquired angioedema. In patients with suspected complement-activated angioedema, confirmation of the diagnosis can be obtained by measuring antigenic levels of C1-INH, which are low in 85% of patients, or functional levels, which are low in 100% of patients. Hereditary forms of complement-activated angioedema can be distinguished from acquired forms by measurement of C1q complement—levels of which are normal in hereditary forms but decreased in acquired forms.

TREATMENT

Discontinuance of the causative agent is an obvious initial step in angioedema. Emergency measures are necessary to secure the airway if there is airway obstruction by a swollen tongue, uvula, or epiglottis. Monitoring the airway in these patients until the angioedema resolves is imperative. Subcutaneous epinephrine should be given and is helpful in most types of angioedema, except those associated with low levels of C1-INH. Aerosolized epinephrine sprayed on the swollen mucous membrane may at times be helpful.

Antihistamines (both H_1 and H_2 receptor antagonists) are indicated for IgE-induced angioedema (see above). Idiopathic angioedema has been split into those presentations that respond to antihistamine therapy and those that do not.[78] Doxepin (see above) should be given to all patients with idiopathic angioedema, but results are often disappointing if this agent is administered without epinephrine. Leukotriene inhibitors counteract the vasodilation produced by leukotrienes and can reduce the edema.

Intramuscular or intravenous glucocorticoids (prednisone, 0.5 to 1 mg/kg/day, or methylprednisolone, 0.4 to 0.8 mg/kg/day) can be used as adjunctive treatment. However, the anti-inflammatory action of these agents does not affect the underlying cause of the inflammation, and they require hours to take effect. Injectable C1-INH concentrate has been developed and is effective in treating patients with hereditary angioedema,[79] but it is difficult to obtain.

To prevent future episodes of angioedema, patients should avoid identified triggers. ACE inhibitors are contraindicated in patients with idiopathic or C1-INH deficiency, and ARBs should be used only with extreme caution. Patients with idiopathic angioedema should undergo an annual general medical evaluation to identify any underlying occult disease.

Anaphylaxis

Anaphylaxis is an explosive, massive activation of mast cells, with release of their inflammatory mediators in the skin, respiratory tract, and circulatory system resulting in urticaria, wheezing, and hypotension.

The term anaphylaxis has been restricted to IgE-mediated mast cell and basophil activation. Anaphylactoid reactions, although similar in presentation, result from non–IgE-dependent mechanisms and are less likely to have a fatal outcome.[80] For practical purposes, however, it does not matter whether the patient is having true anaphylaxis or an anaphylactoid reaction, because the clinical manifestations and the treatment of these two types of reactions are identical.

EPIDEMIOLOGY

The authors of all epidemiologic reports regarding anaphylaxis believe the incidence to be underestimated because of failure to report or recognize every episode. A Dutch study estimated that only 4% to 8% of anaphylactic reactions were reported.[81] From the combined results of reported series, several significant conclusions can be drawn: First, the occurrence of atopy in anaphylaxis patients can be as high as 53%.[82] Second, the incidence of females predisposed to anaphylactic episodes can be as high as 61%.[83] Third, when the cause of anaphylaxis is found, food and drugs head the list, with peanuts and shellfish being the most common offending foods and NSAIDs and antibiotics being the most common drug offenders.[84] Fourth, cutaneous symptoms are by far the most common manifestation.[85] Fifth, the risk of anaphylaxis in hospitalized patients is reported to be 196 per million population, with the risk being highest in women and in persons younger than 30 years.[86]

ETIOLOGY

A number of substances are known to cause anaphylactic and anaphylactoid reactions [*see Table 5*]. IgE-mediated anaphylaxis is caused by agents that act as haptens (e.g., β-lactam antibiotics) or by complete antigens (e.g., venoms, foods, allergen extracts). Anaphylatoxins (C3a and C5a) often mediate reactions to human plasma and blood products. The nonimmunologic mast cell activators include radiocontrast media, opiates, and some muscle relaxants. Other anaphylactoid-inducing agents include those agents that modulate arachidonic acid metabolism (i.e., aspirin and other NSAIDs). In a number of cases, the mechanism that leads to anaphylactic or anaphylactoid reactions is unknown (i.e., idiopathic, exercise, and cold urticaria or cholinergic urticaria with anaphylaxis; mastocytosis; and some drug-induced reactions).[87] Patients with idiopathic persistent urticaria or episodic urticaria do not experience anaphylaxis.

PATHOGENESIS

Any of the mast cell secretagogues [*see Table 3*] have the potential to induce an anaphylactic or anaphylactoid reaction. Activation of the mast cell through the FcεRI receptor by an antigen releases the greatest amount of histamine. The physiologic responses to the release of inflammatory mediators include smooth-muscle spasm in the bronchi and GI tract, vasodilatation, increased vascular permeability, and stimulation of nociceptor nerve endings.

DIAGNOSIS

The classic symptoms of anaphylaxis include flushing, urticaria, angioedema, pruritus, bronchospasm, and abdominal cramping with nausea, vomiting, and diarrhea. Hypotension and shock can result from intravascular volume loss, vasodilatation, and myocardial dysfunction. Symptoms usually begin within 5 to 30 minutes after the causative agent is introduced into the body and within 2 hours after it is ingested. The shorter the latent period, the more ominous the prognosis. In rare cases, symptoms can be delayed in onset for several hours. These are called late reactions. The biphasic reaction, which includes both immediate and late reactions, tends not to be recognized and therefore is more likely to result in a fatal outcome. Least common is the protracted reaction, in which the immediate reaction persists for hours.

Table 5 Estimated Incidence or Prevalence of Acute Anaphylactic Reactions[91]

Cause	*Incidence/Prevalence*
General cause	1 per 2,700 hospitalized patients
Insect sting	0.4%–0.8% of United States population
Radiocontrast medium	1 per 1,000–14,000 procedures
Penicillin (fatal outcome)	1.0–7.5 per million treatments
General anesthesia	1 per 300 inductions
Hemodialysis	1 per 1,000–5,000 sessions
Immunotherapy (severe reactions)	0.1 per million injections

Table 6 Grading System for Anaphylaxis

Group	*Clinical Manifestations*
I	Pruritus, flushing, urticaria, or angioedema
II	Pruritus, flushing, urticaria, or angioedema Nausea, dyspnea, tachycardia, or hypotension
III	Pruritus, flushing, urticaria, or angioedema Nausea, dyspnea, tachycardia, or hypotension Bronchospasm and shock
IV	Respiratory arrest Cardiac arrest Other manifestations may be present

Clinical Manifestations

At the onset of anaphylaxis, patients often initially experience a sense of impending doom, accompanied by generalized pruritus and flushing. Almost all patients with anaphylaxis present with cutaneous manifestations that include pruritus, flushing, urticaria, or angioedema.

Anaphylaxis is graded by its clinical presentation [*see Table 6*]. Cases with signs and symptoms limited to the skin are designated as group I. Group II comprises cutaneous manifestations plus nausea, dyspnea, tachycardia, or hypotension; group III includes all the manifestations of groups I and II plus bronchospasm and true shock. Group IV consists of respiratory arrest, cardiac arrest, or both, with or without other manifestations.

Physical Examination

Cutaneous involvement Flushing, urticaria, and angioedema have been reported in 88% to 100% of patients experiencing anaphylaxis. Pruritus, especially of the scalp, soft palate, palms, soles, and anogenital areas, usually heralds an impending anaphylactic or anaphylactoid reaction or may be the only cutaneous signs of the episode. Conjunctival pruritus, injection, and edema are not unusual.

Respiratory involvement Nasal congestion (occurring in up to 56% of patients), rhinorrhea (16%), laryngeal edema, dyspnea (47%), bronchospasm (24% to 47%), cough, and hoarseness may all be part of the anaphylaxis syndrome.

Cardiovascular involvement Tachycardia and hypoten-

sion are common cardiovascular manifestations of anaphylaxis. Uncommon findings include bradycardia (6%), angina (6%), syncope, palpitations, and cardiac arrest (2% to 14%).

Gastrointestinal involvement GI symptoms, including nausea, vomiting, diarrhea, abdominal cramps, and bloating occur in 30% of patients with anaphylaxis.

Neurologic involvement Dizziness or syncope (33%), headache (up to 15%), and seizures (1.5%) may be among the presenting symptoms of anaphylaxis.

Laboratory Evaluation

Anaphylaxis is a clinical diagnosis. Laboratory studies are rarely helpful. Postmortem testing may help clarify the diagnosis in cases of so-called sudden death or in patients who are dead on arrival at the emergency department.

If a patient is seen shortly after an episode, plasma histamine, urinary histamine, or serum tryptase may be helpful in confirming the diagnosis. Plasma histamine levels rise within 10 minutes, but they fall again within 1 hour. Serum β-tryptase levels peak by 1 hour and may remain elevated for as long as 5 hours. However, a negative histamine and tryptase study does not completely rule out the diagnosis of anaphylaxis. Skin testing and RAST for the causative agent (e.g., food, Hymenoptera venom, latex, or drug), if indicated, should be performed 4 to 6 weeks after the episode for greatest sensitivity.

TREATMENT IN THE FIELD

The essential steps in the treatment of anaphylaxis are (1) prevention, (2) recognition, (3) prompt therapy, and (4) early transport to an emergency care facility.

Prevention

Prevention depends on recognition of persons at risk. Use of oral rather than parenteral medications should always be considered in patients at high risk for anaphylaxis. This includes patients with atopy or those with a possible history of allergic reactions to drugs. If drugs are administered parenterally, such patients should remain in a medically supervised area for at least 30 minutes afterward. Patients with known food or drug allergies must read labels to avoid the foods or drugs to which they are allergic. Severely food-allergic patients must be especially careful when dining out and may wish to avoid eating in restaurants altogether. Patients with a history of anaphylactic reaction to Hymenoptera venom should be given information on avoiding future stings and should be referred to an allergist for consideration of venom immunotherapy [*see 6:V Allergic Reactions to Hymenoptera*]. Patients with a history of anaphylaxis should always carry an epinephrine autoinjector (Epi-Pen).

Recognition

Immediate diagnosis of a developing reaction is imperative. Because of the risk of respiratory and cardiovascular collapse, the patient's airway, breathing, and circulation (the so-called emergency ABCs) must be rapidly assessed.

Prompt Initiation of Therapy

Anaphylaxis can rarely be overtreated. Treatment must be expeditious and appropriate. A protocol and supplies for prompt treatment should be in place at every medical office or facility. A protocol for diagnosis and management of anaphylaxis has been developed by the Joint Task Force on Practice Parameters.[88] The supplies should include oxygen, aqueous epinephrine, injectable antihistamines, intravenous or intramuscular glucocorticoids, oropharyngeal airways, and I.V. fluids. If the clinical assessment even suggests an anaphylactic reaction, it is best to call 911 and initiate therapy.

Whenever possible, decrease the absorption of the antigen. With insect bites and stings on an extremity, for example, apply a tourniquet above the injection site to block venous return and remove the insect stinger. Inject epinephrine (1:1000) locally.

Give supplemental oxygen, 6 to 8 L/min, and administer epinephrine (1:1000) subcutaneously or intramuscularly. The epinephrine dose is 0.2 to 0.5 mg in adults and 0.01 mg/kg in children. If the patient is in cardiopulmonary arrest, epinephrine (1:10,000) should be administered intravenously, in a dose of 0.1 to 1.0 mg for adults and 0.001 to 0.002 mg in children. Patients and their caregivers should recognize that more than one dose of epinephrine may be required.[89]

Intravenous H_1 antihistamines (e.g., diphenhydramine, 50 mg) and H_2 antihistamines (e.g., ranitidine, 50 mg, or cimetidine, 300 mg) should be given. If the patient can swallow, H_2 antihistamines can be given orally. Bronchospasm may be treated with aerosolized beta-adrenergic agonists (albuterol). Severe bronchospasm may require endotracheal intubation or cricothyrotomy. Respiratory failure can occur with or without upper airway compromise. Persistent hypoperfusion and ischemia may lead to myocardial infarction, cerebral ischemia, or renal failure.

Once the acute reaction is under control, systemic corticosteroids (e.g., hydrocortisone sodium phosphate, 100 mg every 2 to 4 hours) may be administered. The patient can be transferred to the emergency department.

PROGNOSIS

Most patients experience only a single episode of anaphylaxis,[82] but some patients have three or more episodes.[90] Death from anaphylaxis is uncommon. Complications are also unusual; most patients recover completely. However, respiratory failure from severe bronchospasm or laryngeal edema can cause hypoxia, which if prolonged could lead to brain injury. Hypotension and hypoxia may lead to cardiac ischemia or arrhythmias.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XIV DRUG ALLERGIES

Mark S. Dykewicz, m.d.
Heather C. Gray, m.d.

Adverse drug reactions are the most common iatrogenic illnesses, occurring in 1% to 15% of drug courses. Most adverse drug reactions result from nonimmunologic or unknown mechanisms (e.g., toxic overdose, toxic side effects, intolerance). Approximately 6% to 10% of drug reactions are caused by proven or suspected immunologic mechanisms mediated by specific antibodies, sensitized T cells, or both.[1] Immunologic reactions develop in patients who have become sensitized by previous exposure or continuous exposure to the same or an antigenically related drug. Although identification of antibodies or sensitized T cells directed against the drug helps confirm the diagnosis of immunologic drug reactions, diagnosis usually is based on clinical presentation.[2] This chapter provides an overview of pathogenesis, discusses recognition of both common and uncommon patterns of allergic drug reactions, and explains the application of diagnostic tests and management techniques.

Pathogenesis

Hypersensitivity drug reactions can be influenced by intrinsic properties of the drug, its administration, and the host. Drug factors that increase risk include a higher molecular weight, the ability of the drug or its reactive metabolites to readily bind to self-proteins to form antigenic hapten-protein conjugates, higher dose, parenteral (as opposed to oral) administration, and repeated exposure to the drug. Host factors that increase risk include adult age, female gender, concurrent infections, and HIV infection.[3]

Although β-lactam antibiotics covalently bind to self-protein carriers to form antigenic conjugates, many non–β-lactam antibiotics require enzyme systems, such as cytochrome P-450, to form reactive products that then bind with self-protein carriers. Consequently, testing with a parent drug may not identify sensitivity to reactive intermediate products. Rashes from sulfonamides are more likely in patients who are slow acetylators, because these patients preferentially metabolize sulfa drugs by alternative oxidative pathways that produce highly reactive metabolites that bind to self-protein carriers.

Classification of Drug Reactions

Classifying drug reactions on the basis of either the temporal relation between drug exposure and adverse manifestations or the presumptive immunologic mechanism may aid in evaluation and management. Temporally, drug reactions are classified as immediate, accelerated, or delayed. Immediate reactions occur within 1 hour and include anaphylaxis. Accelerated reactions, such as urticaria and angioedema, occur within 72 hours of administration. Delayed reactions, which occur 72 hours or more after administration, include urticarial and nonurticarial skin rashes; serum sickness–like reactions; fever; and a variety of cardiopulmonary, hematologic, hepatic, renal, and vasculitic effects.

The Gell and Coombs classification system defines four basic immunologic mechanisms for drug reactions [*see Figure 1*]. However, some clinical presentations may involve several mechanisms, and not all immunologic mechanisms conform to the Gell and Coombs classification. Type I (anaphylactic) reactions occur when drug antigen cross-links adjacent IgE antibodies that are bound to the surfaces of mast cells or basophils, with consequent cell activation and release of mediators such as histamine, tryptase, and leukotrienes. Common causes of type I reactions include antibiotics, vaccines, allergen extracts, and

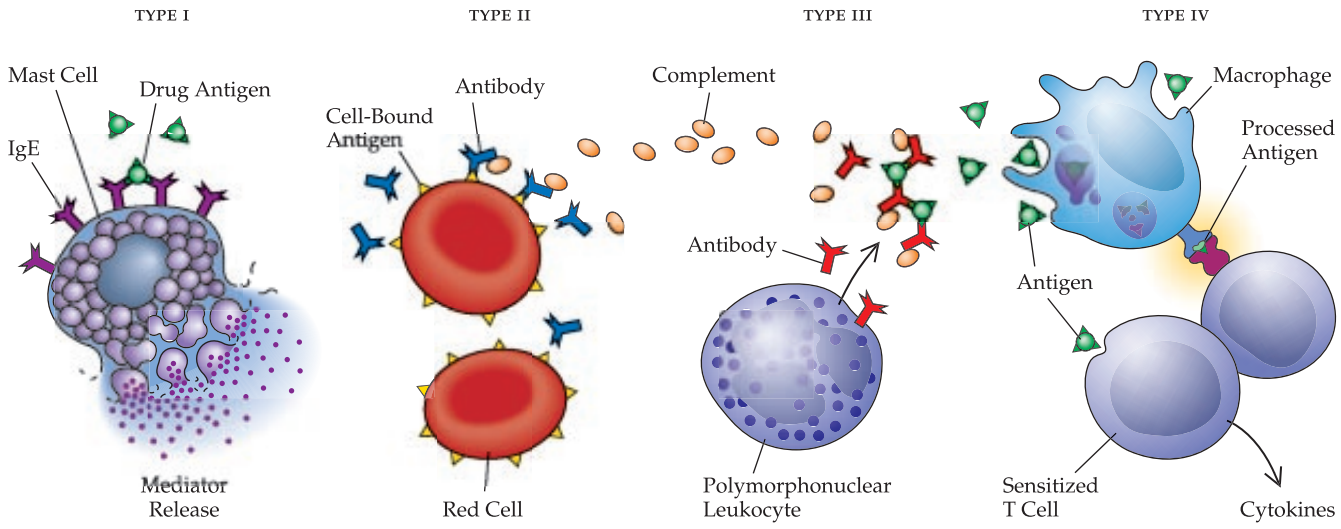

Figure 1 **The Gell and Coombs system defines four basic immunologic mechanisms for drug reactions.[25] Type I reactions (anaphylaxis) result from IgE antibodies binding to drug antigen and cross-linkage of adjacent IgE molecules, leading to mediator release. Type II (cytotoxic) reactions occur when IgG or IgM antibodies recognize drug antigen associated with cell membranes, causing complement activation. Type III (immune complex) reactions involve the formation of antigen-antibody complexes. Type IV (delayed hypersensitivity) reactions are mediated by sensitized lymphocytes.**

proteins (e.g., antisera, insulin). Reactions occur within seconds to minutes of exposure and range from full anaphylaxis to any component thereof, including pruritus, flushing, angioedema, urticaria, bronchospasm, laryngeal edema, rhinoconjunctivitis, hypotension, tachycardia, nausea, vomiting, diarrhea, and abdominal or uterine cramping. In contrast to anaphylaxis, syncope or vasovagal reactions are typically characterized by blanching rather than flushing and by bradycardia rather than tachycardia.

Type II (cytotoxicity) reactions result in cell destruction mediated by an interaction between IgG or IgM antibodies, complement, and a drug antigen associated with cell membranes. Clinical sequelae include immune hemolytic anemia, thrombocytopenia, and granulocytopenia. Heparin-induced thrombocytopenia is mediated by antibodies directed against antigen complexes of heparin and platelet factor 4 on the surface of platelets [*see 5:XIV Thrombotic Disorders*].

Type III (immune complex) reactions develop when a drug combines with antibodies to form immune complexes, the deposition of which causes tissue damage. Serum sickness is a type III reaction and may manifest as skin lesions (e.g., urticaria, angioedema, maculopapular or morbilliform rash, palpable purpura), arthralgias and arthritis, lymphadenopathy, fever, nephritis, and hepatitis. Serum sickness usually occurs after 1 to 4 weeks of drug use but may occur sooner in patients with previous exposure. Drug-induced lupus syndromes (e.g., from procainamide, hydralazine, or phenytoin) are also type II reactions. Patients rarely have renal involvement or anti–double-stranded DNA antibodies but usually have antihistone antibodies.

Type IV (delayed hypersensitivity) reactions are mediated by sensitized $CD4^+$ T cells. Allergic contact dermatitis is a classic example and typically develops 24 to 72 hours after topical exposure.

Diagnosis

To identify drug reactions, the physician needs to be familiar with general principles of drug reactions [*see Table 1*] and with the individual drugs the patient has taken. Diagnosis depends largely on the nature of the reaction and its timing in relation to drug use. For example, adverse immunologic reactions to drugs usually occur in the early weeks of drug exposure and become less common with continued drug administration. To confirm the clinical diagnosis, skin testing or drug challenges may be valuable in selected cases.

CLINICAL PRESENTATION

Dermatologic Reactions

Drug reactions involving the skin range from maculopapular and morbilliform rashes to urticaria, angioedema, erythema multiforme, erythema nodosum, bullous eruptions, and exfoliations. Drug eruptions usually occur within days of exposure (but may occur after drug cessation) and are symmetrical, truncal, and accompanied by pruritus and fever and occasionally eosinophilia. Palm and sole involvement suggests a viral exanthem rather than a drug reaction. In contrast to allergic contact dermatitis that is mediated by $CD4^+$ T cells, nonurticarial systemic drug rashes are more likely mediated by $CD8^+$ T cells.

Photosensitive drug rashes occur by two mechanisms: phototoxic or photoallergic. Phototoxic reactions are nonimmunologic, generally appear as sunburn 4 to 8 hours after light exposure, and often occur with the first exposure to the drug (e.g., tetracycline). Photoallergic reactions are typically eczematous rashes that occur after days or months of exposure (e.g., some sulfa reactions). Alteration of the drug by ultraviolet light enables conjugation of the drug to self-proteins and T cell–mediated immune responses. Neither type of photosensitive reaction is predictive of other types of adverse reactions to a drug.

Table 1 General Considerations in the Clinical Evaluation of Drug Reactions[4]

Identify drugs that have a history of causing problems in the patient; determine whether there are cross-reacting agents, and avoid them.
If the patient has a late reaction, such as a drug rash, take a careful history of all drugs used in the past month, because it is possible that the causative drug has been discontinued.
Drugs administered with impunity for prolonged periods (e.g., months to years) are rarely responsible for adverse immunologic reactions. Reactions are more likely to result from drugs introduced more recently.
Have a high index of suspicion for drug reactions whenever a patient experiences adverse clinical manifestations. Bear in mind that drug reactions can cause internal organ involvement (e.g., nephritis, hepatitis, isolated lymphadenopathy), often in the absence of eosinophilia.
If an immunologic drug reaction is suspected, stop all nonessential drugs and substitute non–cross-reactive drugs if possible.

Fever

Drug fever may occur by itself or be associated with other allergic manifestations, such as a rash. The fever stems from the release of pyrogens by phagocytic cells that have engulfed drug-IgG immune complexes or from cytokine release and other incompletely established processes associated with specific T cell activation. Drug fever usually occurs 7 to 10 days into a treatment course, with prompt defervescence within 48 hours of cessation of the responsible agent.

Systemic Manifestations

Drug reactions can result in systemic involvement, such as interstitial nephritis, nephrotic syndrome, hepatic reactions, myocarditis, and vasculitis. Lung involvement may present as part of a syndrome consisting of malaise, nonproductive cough, chest discomfort, and migratory infiltrates, with or without peripheral eosinophilia (Löffler syndrome). Long-term treatment with penicillin, sulfonamides, or phenytoin can result in generalized lymphadenopathy. Aseptic meningitis has been reported from nonsteroidal anti-inflammatory drugs (NSAIDs), radiocontrast media, and other agents.[3-5]

TESTING

Skin Testing

Drug reactions can be identified through immediate-type skin testing only when the process is IgE mediated. Non–IgE-mediated reactions, such as nonurticarial skin rashes, cannot be identified in this manner. Skin testing is reliable for protein agents and small-molecular-weight drugs whose allergenic metabolites have been identified and made available for skin testing (e.g., penicillin). Skin testing requires knowledgeable personnel and the use of appropriate concentrations (i.e., high

enough to provoke a reaction but low enough to avoid causing a systemic response).

In Vitro Testing

There are a limited number of radioallergosorbent tests (RASTs) available for detection of IgE antibodies against drugs, including β-lactam antibiotics and anesthetic agents. In vitro tests for drug allergy are generally less sensitive than skin tests but may be useful in certain cases in which skin testing is not possible (e.g., in patients with severe, generalized eczema or in those who must take medications that can suppress skin-test responses).[6]

Drug Challenges

When the probability of a true allergy is remote, a graded challenge can be used to confirm the clinical diagnosis of drug reaction. In graded challenges, the patient is given a test dose at a dose lower than would cause a serious reaction, followed by escalation of doses in large increments and observation between doses.

Reactions to Specific Drugs

PENICILLIN

Penicillin, a β-lactam antibiotic, is among the most common causes of immunologic drug reactions. Most deaths from penicillin reactions occur in patients with no history of penicillin allergy**.** Nonimmunologic rashes are frequently seen with ampicillin or amoxicillin in patients who have concomitant viral infections, chronic lymphocytic leukemia, or hyperuricemia and in patients taking allopurinol. These rashes are typically nonpruritic and are not associated with an increased risk for future intolerance of penicillin antibiotics.

Most immunologic reactions to penicillins are directed against β-lactam core determinants. Less than 5% of penicillin is metabolized to the minor determinants, which include benzyl penicillin G, penicilloates, and benzylpenicilloylamine. IgE antibodies to the minor determinants are usually responsible for severe immediate-type reactions to penicillin. The benzylpenicilloyl [BPO] moiety, the so-called major determinant, makes up 95% of penicillin metabolites but is less commonly responsible for severe immediate reactions.

Patients who have suffered IgE-mediated penicillin reactions tend to lose their sensitivity over time if penicillin is avoided. By 5 years after an immediate reaction, 50% of patients have negative skin tests. However, there is controversy about whether patients who have lost their sensitivity to penicillin may be more likely than others to be sensitized with subsequent penicillin exposure.[3,7,8] Skin testing with a major determinant preparation and penicillin G identifies at least 90% to 93% of patients at risk for immediate reaction to penicillin. The negative predictive value of penicillin skin testing is significantly increased by the addition of a minor determinant mixture, but that is not currently commercially available. Penicillin skin testing is usually reliable in identifying patients at risk for immediate reactions to the semisynthetic penicillins,[3,9] but reactions to unique semisynthetic side-chain determinants may occur in special-risk populations, such as cystic fibrosis patients.[10] Skin testing with the side-chain determinants is not commonly done.

Not everyone with a history of a reaction to penicillin should be skin tested, but it is important to skin-test patients with a history of anaphylaxis or urticaria associated with penicillin use before they are given penicillin again. Patients who have had maculopapular or morbilliform skin rashes from penicillin are not at a higher risk for immediate-type reactions, but skin testing may be considered because studies have demonstrated that patient histories can be unreliable. Penicillin should not be readministered to patients with a history of penicillin-induced Stevens-Johnson syndrome, toxic epidermal necrolysis (TEN), other exfoliative dermatitis, or bullous skin lesions; therefore, skin testing is not indicated in these cases. Patients with a family history of penicillin allergy but no personal history do not have an increased risk of allergy to penicillin and, therefore, do not require skin testing. Desensitization is not required in a patient with a history of an immediate reaction and a negative skin test, but a small test dose may be given as an additional precaution if the previous reaction was life threatening. If there is a compelling indication for a penicillin antibiotic (e.g., neurosyphilis), a rapid desensitization protocol should be used [*see Table 2*].[4,11-13]

Note: observe patient for approximately 15–40 min after each interval dose and for 30 min after final dose.

Cephalosporins and penicillin have similar bicyclic β-lactam structures and amide side chains [*see Figure 2*]. The degree of immunologic cross-reactivity between these β lactams is controversial, but patients with penicillin allergy are more likely than the general population to have a reaction to another β-lactam drug. Most experts agree that cephalosporins should be avoided in patients who have a history of an immediate-type reaction to penicillin. Immunologic reactions to cephalosporins are more

often related to side chains of the cephalosporin antibiotics than to β-lactam core determinants. Cephalosporin skin testing is experimental and has uncertain negative predictive value. There is a lower incidence of immediate-type reactions to third-generation cephalosporins than to the first- and second-generation compounds. Because of its 3-methylthiotetrazole side chain, cefoperazone can cause a nonimmunologic disulfiram-like reaction if taken after ingestion of alcohol. Carbapenems (imipenem) and carbacephems (loracarbef) contain bicyclic β-lactam rings that cause significant cross-reactivity with penicillin. Reactions to monobactams (aztreonam) are typically directed against side-chain determinants rather than the monocyclic β-lactam nucleus, but cross-reactivity occurs with ceftazidime, which shares an identical side chain with penicillin.[13-17]

SULFA

Drug exanthems from sulfonamide antibiotics are more common than immediate-type reactions, and there is significant cross-reactivity among sulfa compounds. Adverse effects from sulfa drugs occur in 2% to 10% of patients who do not have AIDS, whereas 50% of AIDS patients suffer ill effects.[3] The incidence of reactions may be related to the degree of immunodeficiency from HIV infection. The sulfapyridine moiety of sulfasalazine is responsible for most skin rashes from that agent. A 1-month graded challenge protocol is usually successful at inducing tolerance to sulfasalazine in patients who require this agent for treatment of inflammatory bowel disease.[18] Desensitization to sulfonamides may be considered to permit the use of these agents for *Pneumocystis carinii* pneumonia (PCP) prophylaxis in AIDS, toxoplasmosis, and other infections for which there are no good alternatives. A number of protocols have been published. Patients with acute PCP may require rapid desensitization protocols that permit therapeutic use of the medication within 6 to 8 hours[19]; those patients receiving a sulfonamide prophylactically can be desensitized with slowly increasing doses. Desensitization protocols should not be attempted in patients with a history of severe drug reactions, such as Stevens-Johnson syndrome or TEN.

VANCOMYCIN

Vancomycin infusions are commonly associated with the red man syndrome (hypotension, flushing, erythema, pruritus, urticaria, and pain or muscle spasms of the chest and back). The syndrome is caused by non–IgE-mediated histamine release that is more likely with rapid infusion rates (> 10 mg/min). Tolerance of readministration is promoted by reduction of the infusion rate and pretreatment with H_1 (but not H_2) antihistamines. Rarer IgE-mediated reactions to vancomycin can be identified by skin tests.[2-4]

ACE INHIBITORS

Nonimmunologic adverse effects of angiotensin-converting enzyme (ACE) inhibitors are thought to stem from an accumulation of bradykinin and other vasoactive peptides. The most frequently documented adverse reactions include cough (10% to 25%), rhinitis, and angioedema (0.1% to 0.2%). The onset of cough can occur from 1 day to up to 12 months after starting these drugs and may be associated with increased bronchial reactivity to methacholine. Cough usually resolves within several weeks after drug cessation but may persist for more than a month. In about 60% of cases, angioedema occurs within 2 weeks after patients start the drug, but it can occur after

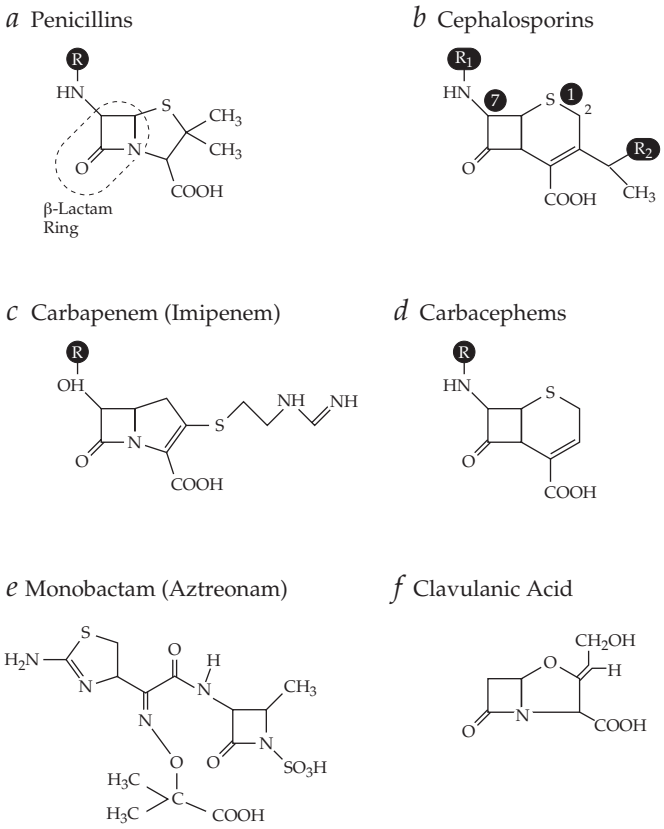

Figure 2 **Structure of β-lactam antibiotics. Substitutions at the R position of 6-aminopenicillanic acid create penicillin derivatives. Substitutions at positions 1, R1, R2, and C7 of 7-aminocephalosporanic acid create cephalosporin derivatives.**

months. Angioedema usually involves the face and oropharyngeal tissue. It can result in life-threatening upper airway obstruction. Visceral angioedema can cause abdominal pain. Cough and angioedema do not usually occur in the same patient. Skin testing is of no value. Intolerance to one ACE inhibitor usually predicts intolerance to all drugs of this class. Patients with idiopathic angioedema and urticaria are susceptible to more severe and frequent episodes when given ACE inhibitors. The angiotensin II receptor blockers are generally well tolerated in patients with idiopathic angioedema and urticaria or with ACE inhibitor–related angioedema.[2,4,20]

ASPIRIN AND NSAIDS

Aspirin and other NSAIDs may induce a variety of reactions, ranging from bronchospasm, rhinorrhea, urticaria, and angioedema to anaphylaxis. Aspirin-sensitive respiratory reactions are likely caused by derangement of arachidonic acid metabolism with increased leukotriene production. Mast cell activation may also occur. Patients with respiratory sensitivity to aspirin generally develop dose-dependent reactions to aspirin or structurally distinct NSAIDs that are significant inhibitors of cyclooxygenase-1 (COX-1) but often tolerate agents that have less effect on COX-1 (e.g., salsalate, acetaminophen, sodium or magnesium salicylate). Selective COX-2 inhibitors (e.g., celecoxib, rofecoxib) are well tolerated in these patients.[21] Patients may present with the so-called aspirin triad of concomitant asthma, nasal polyps, and aspirin sensitivity. Between 30% and 40% of patients with polyps and sinusitis and between 8% and 19% of

adults with asthma have positive bronchial responses to aspirin. Urticarial reactions from aspirin typically occur in a patient subset different from that in which respiratory reactions occur. Some patients with skin reactions to aspirin (often those with a history of idiopathic urticaria and angioedema) have cross-reactivity with NSAIDs, whereas other skin reactors and those who develop anaphylaxis have only specific sensitivity to aspirin or a particular NSAID. However, skin testing is not helpful. With appropriate precautions, oral desensitization with aspirin by experienced clinicians can be performed over several days. It is usually effective in patients with respiratory sensitivity but not in those with skin reactions.[4,5,22,23]

ANESTHETIC AGENTS

Adverse reactions to local anesthetic agents are rarely IgE mediated. More commonly, such reactions are toxic responses from inadvertent intravenous administration, overdose, rapid absorption, or anxiety. Symptoms often involve the central nervous system or the cardiovascular system and include hypotension, convulsions, and cardiorespiratory failure. Concurrent administration of epinephrine may be responsible for shakiness and tachycardia. Allergic contact dermatitis and some large local reactions do occur through delayed-type immunologic responses. Local anesthetics are either benzoid acid esters (type I [e.g., procaine, benzocaine]) or nonesters and amides (type II [e.g., lidocaine, bupivacaine, mepivacaine]). There is no cross-reactivity between the two classes, but type I agents cross-react with each other. Management of suspected local anesthetic allergy includes subcutaneous test dosing with the local anesthetic without epinephrine.

Histamine release has been implicated in some reactions from anesthesia-induction agents and muscle relaxants, but the responsible mechanisms for many reactions are not established. During anesthesia, generalized reactions may be caused by muscle relaxants (e.g., succinylcholine, alcuronium, pancuronium), induction agents (e.g., thiopental), opiates, or antibiotics. Narcotics stimulate mast cells directly without an IgE mechanism.

RADIOGRAPHIC CONTRAST MEDIA

Radiographic contrast media cause non–IgE-mediated anaphylactoid reactions that involve direct mast cell and perhaps complement activation; therefore, immediate-type skin testing and test dosing are not helpful. Shellfish allergy results from IgE-mediated reactions to shellfish proteins, and therefore, it is not predictive of risk for contrast reactions. A previous anaphylactoid reaction to contrast at any time in a patient's history is predictive of persistently increased risk for a repeat anaphylactoid reaction, even though the patient may have tolerated contrast without a reaction in the interim. Asthma and allergies are also associated with increased risk.[24]

The use of nonionic contrast media and medication pretreatment can reduce the risk of reaction. One commonly used pretreatment regimen consists of corticosteroids (prednisone, 50 mg, given 13 hours, 7 hours, and 1 hour before contrast administration), H_1 antihistamines (diphenhydramine, 50 mg orally, 1 hour before administration), and oral adrenergic agents (ephedrine, 25 mg, or albuterol, 4 mg, given orally, 1 hour before administration). H_2 receptor blockers are sometimes added. Despite an adequate pretreatment regimen, reactions can still occur. Corticosteroids administered only 1 to 2 hours before contrast do not reliably prevent reactions.

Management

DESENSITIZATION

If the probability of a drug allergy is high and drug administration is essential, one may consider desensitization, in which the drug is administered in increasing doses in small increments. Because of the risk of adverse reactions, only experienced physicians should perform desensitization. Once desensitization is achieved, the drug must be continued; otherwise, desensitization will be lost, and the patient will require repeat desensitization before readministration. Pretreatment with antihistamines and corticosteroids is not reliable for preventing IgE-mediated anaphylaxis but can be useful when an anaphylactoid reaction is of concern (as with radiographic contrast media). In extreme circumstances, when continued administration of a drug is essential but the patient is experiencing a reaction such as a late drug rash or interstitial nephritis, continued drug administration may be tolerated if corticosteroids and antihistamines are given to suppress the immunologic reaction. However, in such cases there is the risk of progression to an exfoliative skin rash, mucocutaneous disorders (e.g., Stevens-Johnson syndrome, TEN), nephritis, hepatitis, or serum sickness.

MANAGEMENT OF ACUTE REACTIONS

Treatment of acute adverse immunologic drug reactions includes stopping all nonessential suspect drugs and, if necessary, substituting new drugs that should not have cross-reactivity with any of the suspect drugs. Epinephrine, antihistamines, and corticosteroids are the mainstays of treatment of anaphylaxis, and other resuscitative measures may be required [*see 6:XIII Urticaria, Angioedema, and Anaphylaxis*]. Mild maculopapular rashes may respond to antihistamines alone, but progressing rashes or rashes associated with fever, nausea, or arthralgias should also be treated with systemic corticosteroids. For prolonged, severe reactions, several weeks of prednisone may be required.[2,3,13]

XV ALLERGIC REACTIONS TO HYMENOPTERA

David B. K. Golden, m.d., f.a.c.p.

Allergic reactions to insect venom primarily occur as a result of stings by insects of the order Hymenoptera. Allergic swelling can occur at the site of the insect sting, but only rarely does anaphylaxis result. Nonallergic reactions to insect venom have also been reported; these include nephropathy, central and peripheral neurologic syndromes, idiopathic thrombocytopenic purpura, and rhabdomyolysis. These are toxic reactions and are not IgE mediated. Allergic reactions to stings manifest themselves as either late-phase local inflammation (i.e., severe prolonged swelling) or systemic responses (e.g., anaphylaxis).

Epidemiology

Allergic reactions to Hymenoptera stings have been reported in persons of all ages. The reactions may be preceded by a number of uneventful stings. Systemic allergic reactions are reported in up to 1% of children and 3% of adults, although allergic antibodies to Hymenoptera venoms can be detected in 17% to 26% of adults.[1] The frequency of large local allergic reactions is uncertain but is estimated to be about 10% in adults. Fatal allergic reactions to insect stings may occur at any age but are most common in adults older than 45 years.[2] Half of those persons in whom a fatal reaction occurred had no previous history of allergy to insect stings; the other half had previous reactions but failed to take adequate preventive measures. In the United States, at least 40 deaths occur each year as the result of insect stings; other sting fatalities may go unrecognized. In many cases of unexplained sudden death, postmortem blood samples show the presence of both Hymenoptera venom–specific IgE antibodies and elevated serum tryptase levels, indicating the true cause of the fatal reactions.[3]

For 50 years, whole body extracts were used as standard treatment for immunotherapy; such use was based on a lack of knowledge of the natural history of anaphylaxis.[4] We now recognize that the risk of an anaphylactic reaction to a sting varies in accordance with the history of previous stings and is correlated with the results of venom skin testing or radioallergosorbent testing (RAST). The risk declines gradually with time [*see Table 1*]. In high-risk patients, the risk of reaction is 50% to 70%; other persons with a history of insect-sting allergy are at much lower risk. Most affected children have only cutaneous systemic reactions, with no respiratory or vascular symptoms, and have less than a 10% risk of a systemic reaction to a subsequent sting.[5] The risk is also less than 10% in adults or children who have experienced only large local reactions to stings. Furthermore, the allergy is self-limited in many cases. The risk of reaction falls from 50% initially to 33% after 3 to 5 years; the risk is 20% to 25% if more than 10 years have passed since the reaction.[6] However, in some individuals, the risk of anaphylaxis persists for decades, even with no intervening stings.

Etiology

Hymenoptera allergy is directed against the allergenic proteins in the venoms of the stinging insects. Three families of Hymenoptera are important causes of allergy. The bees (i.e., honeybees and bumblebees) and vespids (i.e., yellow jackets, hornets, and wasps) are the best known [*see Figures 1 and 2*]. Imported fire ants (*Solenopsis* species) are a rapidly increasing public health hazard in the Southeast and South Central United States, especially on the Gulf Coast [*see Figure 3*].[7] Honeybee stings are more common in agricultural areas. Yellow jackets are the most frequent culprits in the northern areas of North America and Europe, whereas paper wasps (*Polistes* species) are more commonly implicated along the Gulf Coast in the United States and the Mediterranean Coast in Europe.

Knowledge of the behavior of these insects can be helpful in evaluating the history of affected patients. Honeybees are relatively docile and rarely sting or swarm unless provoked. Stings usually occur as a result of garden exposures or from going barefoot outdoors. The barbed stinger of the honeybee remains in the skin, causing the death of the honeybee. Africanized honeybees (killer bees) are more aggressive and are now present in the southern United States.[8] Although an Africanized honeybee is no different from a domestic honeybee with regard to anatomy or venom, Africanized honeybees have a tendency to swarm with little provocation and to sting in large numbers. A large number of stings can cause massive envenomation; the resulting toxic reactions have been fatal to livestock and humans. Bumblebees sting infrequently, but a few cases of systemic reactions have been reported.

Yellow jackets usually nest underground or in the cracks of buildings or wooden ties or logs used in residential landscaping, whereas hornets generally build their nests in shrubs and trees. Paper wasps build an open nest with visible cells; nests are often found on the eaves or windowsills of a home or in the railings of decks or fences. Yellow jackets are scavengers; they are commonly found around food at picnics and in orchards, trash cans, and dumpsters. They are highly aggressive and will sting quite readily. Wasps are less aggressive but will sting readily when disturbed. The vespid stinger usually has finer barbs than the stinger of the bee and does not commonly remain in the skin.

Table 1 Risk of Systemic Reactions and Clinical Recommendations Based on Reaction to Previous Stings and Results of the Venom Skin Test or RAST

Reaction to Previous Sting	*Skin Test or RAST*	*Risk of Systemic Reaction*	*Clinical Recommendation*
None	Positive	10%–20%	Avoidance
Large local	Positive	5%–10%	Avoidance
Cutaneous systemic	Positive, child Positive, adult	1%–10% 10%–20%	Avoidance Venom immunotherapy
Anaphylaxis	Positive Negative	30%–70% 5%–10%	Venom immunotherapy Repeat skin test/RAST

RAST—radioallergosorbent testing

Figure 1 **The honeybee (*Apis mellifera*).**

Figure 2 **The European hornet (*Vespa crabro germana*) was introduced into the United States in the mid-19th century. In the United States, its habitat includes most of the eastern United States, Louisiana, and the Dakotas. Although it is a woodland species, its nests can be found in barns, attics, hollow walls, birdhouses, and abandoned beehives.**

Fire ants have stingers, and it is the sting rather than the bite that causes the allergic reaction. Fire ants are widespread in the southeastern United States; in many areas, stings are very frequent, with up to 50% of the population being stung each year. Fire ants build nests in the shape of large mounds; these nests are common in residential and coastal areas. In most cases of fire-ant stings, multiple ants each administer multiple stings, which cause minimal pain. The unique lesions form sterile pustules that can become infected if excoriated [*see Figure 4*].

The allergic sensitivity is directed against proteins in the venoms (but not in the saliva or bodies) of the stinging insects.[9] Honeybee venom contains unique allergens, whereas the vespid venoms cross-react extensively with one another and contain essentially the same allergens. The venom of *Polistes* wasps is less cross-reactive than that of the other vespids. Only 50% of patients who are allergic to yellow-jacket venom experience reactions to wasp venom. The allergenic proteins in fire-ant venom are unique.

Pathogenesis

The pathogenesis of Hymenoptera allergy is the same as that of other forms of anaphylaxis. An initial encounter with a sting in genetically susceptible individuals causes the production of IgE antibodies to the venom allergens. The IgE antibodies become affixed to tissue mast cells and circulating basophils, which thus become armed for response to a later encounter with the same allergen. A subsequent sting can cause cross-linking of these allergic antibodies, leading to the release of mediators (e.g., histamine, leukotrienes, and cytokines) that cause the clinical manifestations of the allergic reaction. There is an association between conditions involving abnormal mast cell number or function and insect-sting anaphylaxis. The allergic reactions to stings are more severe in patients with elevated baseline serum tryptase levels or mastocytosis, and there is a higher incidence of treatment failures and relapse after treatment in these patients.[10-12] Whole body extracts of fire ants are used for diagnostic testing and are effective for immunotherapy, whereas whole body extracts of the other Hymenoptera insects have proved not to contain venom allergens.

Diagnosis

CLINICAL MANIFESTATIONS

Allergic reactions to insect stings may cause local allergic inflammation or the full spectrum of manifestations of anaphylaxis. Large local reactions are late-phase allergic reactions. Progressive swelling begins 6 to 12 hours after the sting, reaching peak size in 24 to 48 hours and resolving in 5 to 10 days. Large local reactions are usually defined as being greater than 6 in. in diameter; they can be massive in size and cause considerable pain. On the extremities, inflammatory lymphangitic streaks occur toward the axillary or inguinal nodes; these streaks are mistaken for signs of infection. Systemic reactions most commonly cause cutaneous signs and symptoms, including generalized flushing, pruritus, urticaria, and angioedema. Other typical manifestations are respiratory (e.g., throat or chest tightness, dyspnea, wheezing) or circulatory (e.g., light-headedness or unconsciousness). Less common signs of anaphylaxis include gastrointesti-

Figure 3 **Red imported fire ant (*Solenopsis invicta*).**

Figure 4 **Appearance of a pustule resulting from the sting of a fire ant. This photograph was taken 24 hours after the patient was stung.**

nal or uterine cramps, cardiac arrhythmias (e.g., tachycardia or, occasionally, bradycardia), and coronary vasospasm.

In children, systemic reactions to stings usually cause only cutaneous symptoms (e.g., urticaria or angioedema). Respiratory symptoms are less common, and circulatory manifestations are infrequent. Systemic reactions usually follow a predictable and individual pattern in each patient, with worsening of the reaction occurring in less than 10% of cases.[13] Affected individuals commonly do not seek medical attention and usually fail to report having sting reactions unless they are asked.

The diagnosis of insect-sting allergy rests on a history of allergic reactivity, because venom-specific IgE antibodies can be detected in many normal individuals. The positive venom skin test provides confirmation of the allergic nature of the sting reaction and helps define allergenic specificity. The history is most important and should be reviewed in detail with respect to the nature, number, and timing of stings in the past; the time course of the reaction; and all associated symptoms and treatments. The family history, atopic history, and general medical history are also of interest. In addition, it is helpful to know of any medications the patient took before the reaction occurred, as well as any medications the patient is currently using.

PHYSICAL EXAMINATION

It is most important to measure the vital signs, including airflow, when there is dyspnea and to document cutaneous signs. Some patients have symptoms, such as dizziness and dyspnea, that do not correspond to the objective signs (e.g., blood pressure, peak expiratory flow rate) and may be the result of anxiety, panic, and hyperventilation. Any history suggestive of systemic allergic reaction must be taken seriously.

DIAGNOSTIC TESTS

The diagnosis of insect-venom allergy can be confirmed by skin tests or serologic tests using Hymenoptera venoms. Both methods are useful, and they are often complementary in the diagnostic evaluation of affected patients. Both methods require specific experience and training to prevent false interpretations. Diagnostic tests are not usually performed in the absence of a history of a systemic allergic reaction. This is because a positive test occurs in 20% to 30% of adults and is associated with a relatively low 17% chance of a systemic reaction to a future sting.[1]

Intradermal skin tests using serial dilutions of the five Hymenoptera venom protein extracts is the recommended procedure. In the case of fire-ant sensitivity, whole body extracts of imported fire ants give reasonable diagnostic sensitivity and specificity. For Hymenoptera venom testing, intradermal tests are performed with venom concentrations ranging from 0.001 to 1.0 μg/ml to find the minimal concentration that yields a positive result, as compared with a negative diluent control (e.g., human serum albumin saline) and a positive histamine control. Puncture tests with a venom concentration of 0.01 μg/ml may be used initially for patients with a history of very severe reactions.

The diagnosis of insect-sting allergy by detection of allergen-specific IgE antibodies in serum (typically by RAST) is a method of high potential but variable performance.[14] An elevation in the level of venom-specific IgE is certainly diagnostic; but the test is often qualitative and poorly standardized, and it yields negative results in 15% to 20% of patients whose skin-test results are positive.

In the majority of patients who have a definite history of insect-sting reactions, skin-test results are clearly positive; however, in many others, the results are clearly negative. Negative skin-test results in a patient with a history of insect-sting reactions may represent the loss of sensitivity, but it is important to test for venom-specific IgE antibodies in the serum (e.g., by use of RAST).[15] If necessary, the venom skin test may be repeated after several months. A few cases of sting anaphylaxis are non–IgE mediated and may be related to subclinical mastocytosis or simply toxic mast cell hyperreleasability.[12] It is important to note that the degree of sensitivity as detected by skin testing or RAST does not correlate reliably with the degree of sting reaction. The strongest sensitivity to skin tests often occurs in patients who have had only large local reactions, and some patients who have had near-fatal anaphylactic shock show only weak sensitivity on skin testing or RAST. Because of cross-reactivity, skin tests are positive to all three of the common vespid venoms (i.e., yellow jacket, yellow hornet, and white-faced hornet) in 95% of patients allergic to yellow-jacket venom. More than half of patients sensitive to yellow-jacket venom also have positive reactions to testing for sensitivity to *Polistes* wasp venom. It is possible to determine whether the patient has a specific or a cross-reactive sensitivity to wasp venom using a RAST-inhibition test in specialized laboratories.[16]

Differential Diagnosis

Although the diagnosis of insect-sting allergy is relatively straightforward, the history and diagnostic tests can be misleading in some cases. Local swelling may be the result of nonallergic inflammation, but infection is very uncommon and would likely occur many days after the sting. Local cutaneous signs should not be mistaken for systemic eruption. Symptoms of dyspnea, chest discomfort, and dizziness can be the result of hyperventilation associated with anxiety. Patients with asthma who receive a sting may have asthmatic symptoms that are difficult to distinguish from an allergic reaction. Approximately 1% of patients with a history of allergic reactions to insect stings have an underlying abnormality in the release of mediators by mast cells or basophils, as demonstrated by elevated baseline serum tryptase levels. Some of these patients have a form of mastocytosis.[10-12]

Treatment

ACUTE TREATMENT

The treatment of the acute systemic allergic reaction to insect stings is the same as that of other causes of anaphylaxis. The treatment of choice is epinephrine by intramuscular injection.[17,18] The recommended dose is 0.3 to 0.5 mg (0.3 to 0.5 ml of a solution of 1:1,000 weight in volume [w/v]) for adults and 0.01 mg/kg for children. Delay in the use of epinephrine has contributed to fatal reactions. Some persons in anaphylactic shock are resistant to epinephrine. Patients taking beta-blocker medications can also be resistant to the effects of epinephrine. In some cases, anaphylaxis is prolonged or recurrent (biphasic) for 6 to 24 hours and may require intensive medical care.[19] All patients with anaphylaxis should receive full emergency medical attention and remain under observation for 6 hours or longer. Corticosteroids have no role in the treatment of acute anaphylaxis; they are administered to prevent late-phase reactions, but there is no evidence that steroids prevent biphasic anaphylaxis.

Large local reactions may require a burst of corticosteroid, which is most effective if started within 2 hours of the sting. After an initial dose of 40 to 60 mg, the dose is tapered over 3 to 5 days.

PREVENTIVE TREATMENT

General Measures

Patients who are discharged from emergency care after suffering anaphylaxis must receive information on the risk of future reactions. They should also be advised to receive allergy consultation, and they should be given information about prevention. When outdoors, the affected person should avoid bushes and gardens, as well as food and drink that are most likely to attract insects. Drinks, especially in cans, bottles, and straws, can be an unsuspected source of a sting to the tongue or throat. Prescription of an epinephrine autoinjector (e.g., EpiPen and EpiPen Jr., Dey, Napa, California) should be considered in any patient who has experienced a systemic allergic reaction. Some patients may need to use epinephrine immediately after receiving a sting (until they can be immunized); however, most patients can wait for the signs of a developing reaction before using epinephrine. Delay in treatment is reasonable because the majority of persons with a history of mild to moderate systemic reactions do not react to a challenge sting. The age at which a patient should be prescribed an adult-strength autoinjector, rather than a pediatric autoinjector, is uncertain; use of the adult-strength injector may be considered when the child attains a weight of 25 kg.[20] All patients should understand that use of an epinephrine kit is not a substitute for emergency medical attention.

Venom Immunotherapy

Patient selection Current indications for venom immunotherapy are a history of previous systemic allergic reaction to a sting and a positive venom skin test.[21-23] The patients at highest risk are those with a recent history of anaphylaxis and positive skin-test results; in such patients, the risk of a systemic reaction to a subsequent sting is approximately 50%. Children and adults with a history of large local reactions are at low risk for a systemic reaction (i.e., < 10%),[24] as are children whose systemic reactions are limited to cutaneous signs and symptoms.[5] In these low-risk persons, venom immunotherapy is not required, but some patients will still request treatment for reasons related to fear of reaction or frequent exposure. Children with moderate or severe systemic reactions have a relatively high risk of recurrence even 10 to 20 years after allergic reaction to an insect sting.[25] There are some cases of progressively worsening reactions in adults, so all adults with systemic reactions are advised to undergo venom immunotherapy. There is no test that accurately predicts which patients will progress to more severe reactions and which will not.

Initial therapy Initial venom immunotherapy can be completed with a regimen of eight weekly injections or a traditional regimen lasting for 4 to 6 months.[21-23] Rush immunotherapy, typically administered over a period of 2 to 3 days, has been reported to be as safe and effective as the usual regimens.[26,27] The recommended maintenance dose is 100 μg of each of the venoms for which a positive result was seen on skin testing. Standard therapy is 85% to 98% effective in completely preventing systemic allergic reactions, but some patients require higher doses for full protection.[28] The same dose has been recommended for children 3 years of age and older, even though their immune response to venom immunotherapy is twice that of adults.

Adverse reactions Venom immunotherapy causes reactions no more frequently than inhalant allergen immunotherapy.[29] Systemic symptoms occur in 10% to 15% of patients during the initial weeks of treatment, regardless of the regimen used. Most reactions are mild, and fewer than half of the reactions require epinephrine. In unusual cases, there can be repeated problems with systemic reactions to injections. Large local reactions are common but are not predictive of systemic reactions to subsequent injections. All patients must achieve the full 100 μg dose to have optimal clinical protection.

Maintenance and monitoring After reaching the full dose, the same dose is repeated at 4-week intervals for at least 1 year. The dosing interval may then be increased to once every 6 to 8 weeks over several years of treatment. Therapeutic efficacy can be confirmed serologically, but use of only some assays for venom-specific IgG antibodies has correlated strongly with clinical protection.[30] Venom skin testing or RAST is repeated periodically—usually every 2 to 3 years—to determine whether there has been a significant decline in venom-specific IgE.[31] The results of skin testing generally remain unchanged during the first 2 to 3 years but show a significant decline after 4 to 6 years.[6] Fewer than 20% of patients have negative skin-test results after 5 years, but 50% to 60% have negative results after 7 to 10 years.[32]

Duration The package inserts for the commercial venom immunotherapy products available in the United States recommend indefinite immunotherapy. However, the published practice parameters reflect more recent experience and recommendations.[23,31] In most patients, skin-test results and RAST results remain positive after 5 to 10 years of treatment. Studies of several hundred adults and children show that even when skin tests remain positive, venom immunotherapy can usually be stopped after 5 years.[31] Observation of patients for 5 to 10 years after completing a 5- to 8-year course of venom treatment has shown a 5% to 10% risk of systemic symptoms after any sting but only a 2% risk of a reaction requiring epinephrine treatment.[33] Patients who have a higher frequency of relapse include those receiving honeybee-venom therapy, those with a history of very severe

pretreatment sting reactions, and those who have had a systemic reaction to a sting or an injection during the period of venom immunotherapy.[22] Several studies have shown that 5 years of therapy is superior to 3 years for suppression of the IgE response and for longer-lasting remission.[34,35] Some patients prefer to continue venom treatment for their continued sense of security. Children who have had a 3- to 5-year course of venom immunotherapy show persistent tolerance even 10 to 20 years after discontinuing treatment.[25]

David B. K. Golden, M.D., F.A.C.P., has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XVI FOOD ALLERGIES

A. Wesley Burks, m.d.

Definition

Food hypersensitivity (allergy) and food intolerance constitute the category of adverse reactions to food.[1,2] An adverse food reaction is a clinically abnormal response to an ingested food or food additive. Both food hypersensitivity and food intolerance have often been overdiagnosed, and both terms have been applied incorrectly to all adverse reactions to foods.

food intolerance

Food intolerance is a general term describing an abnormal physiologic response to an ingested food or food additive. Such reactions are apparently nonimmunologic in nature and have many possible causes, including toxic contaminants (e.g., histamine in scombroid fish poisoning or toxins secreted by *Salmonella*, *Shigella*, and *Campylobacter*), pharmacologic properties of the food (e.g., caffeine in coffee, tyramine in aged cheeses), characteristics of the host such as metabolic traits (e.g., lactase deficiency), and idiosyncratic responses.

food hypersensitivity

Food hypersensitivity is an immunologic reaction resulting from the ingestion of a food or food additive. This reaction can develop after ingestion of a small amount of the substance, and it is unrelated to any physiologic effect of the food or food additive. To most physicians, the term is synonymous with reactions that involve the immunoglobulin E (IgE) mechanism, of which anaphylaxis is the classic example. Although IgE-mediated (type I) hypersensitivity accounts for the majority of well-characterized allergic reactions to food, non–IgE-mediated immune mechanisms are believed to be responsible for a variety of hypersensitivity disorders. This chapter examines adverse food reactions that are IgE mediated, those that are non–IgE mediated, and those that have characteristics of both.

Epidemiology

The true incidence of adverse food reactions is still unknown. Up to 15% of the general population believe that they may be allergic to some food. However, the best available studies suggest that the actual prevalence of food allergy is 1.5% to 2% of the adult population.[3] The incidence of adverse food reactions in young children is estimated to be between 6% and 8%. Several well-controlled studies have shown that the vast majority of allergic reactions occur in the first year of life.

Pathophysiology

IgE-mediated reactions

A variety of hypersensitivity responses to an ingested food antigen may result from the lack of development of oral tolerance or a breakdown of oral tolerance in the gastrointestinal tract of a person who is genetically predisposed to such hypersensitivity. Either a failure to develop oral tolerance or a breakdown in oral tolerance results in excessive production of food-specific IgE antibodies. These food-specific antibodies bind high-affinity FcεI receptors on mast cells and basophils and low-affinity FcεII receptors on macrophages, monocytes, lymphocytes, eosinophils, and platelets.[2] After antigen-presenting cells process the food allergen and present the antigen to specific antibodies on mast cells or basophils, those cells release mediators such as histamine, prostaglandins, and leukotrienes [*see 6:X Allergic Response*]. These mediators promote vasodilation, smooth muscle contraction, and mucus secretion, resulting in the symptoms of immediate hypersensitivity. The activated mast cells also may release various cytokines that play a part in the IgE-mediated late-phase response. With repeated ingestion of a specific food allergen, mononuclear cells are stimulated to secrete histamine-releasing factors (HRF). The so-called spontaneous generation of HRF by activated mononuclear cells in vitro has been associated with increased cutaneous irritability in children with atopic dermatitis. A rise in plasma histamine levels has been associated with IgE-mediated allergic symptoms after blinded food challenges. In IgE-mediated GI reactions, endoscopic observation has revealed local vasodilation, edema, mucus secretion, and petechial hemorrhaging. Increased stool and serum levels of prostaglandin E_2 (PGE_2) and prostaglandin F_2 (PGF_2) have been seen after food challenges that cause diarrhea.

non–IgE-mediated reactions

Although a variety of non–IgE-mediated immune mechanisms for allergic reactions to food have been proposed, the scientific evidence supporting these mechanisms is limited. Type III (antigen-antibody complex–mediated) hypersensitivity reactions have been examined in several studies. Whereas IgE–food antigen complexes are seen more commonly in patients with food hypersensitivity, there is little support for disease mediated by food antigen–immune complexes. Type IV (cell-mediated) hypersensitivity has been suggested as the mechanism for several disorders in which the clinical symptoms do not appear until several hours after the ingestion of the suspected food. This type of immune response may contribute to some adverse food reactions (e.g., enterocolitis), but except in gluten-sensitive enteropathy, significant supporting evidence of a specific cell-mediated hypersensitivity disorder is lacking.

Diagnosis

IgE-mediated hypersensitivity

Gastrointestinal Reactions

Food-induced, IgE-mediated GI allergy may manifest as a variety of syndromes, including the oral allergy syndrome, immediate GI hypersensitivity, and a small subgroup of cases of allergic eosinophilic gastroenteritis.[4]

Oral allergy syndrome The oral allergy syndrome is considered a form of contact urticaria that is confined almost exclusively to the oropharynx and rarely involves other target organs [*see Table 1*]. The symptoms include rapid onset of pruritus and angioedema of the lips, tongue, palate, and throat. The symptoms generally resolve quite rapidly. This syndrome is most commonly associated with the ingestion of fresh fruits and vegetables. Interestingly, patients with allergic rhinitis as-

Table 1 Oral Allergy Syndrome[27]

Oral manifestations	Burning Swelling Itching Erythema Immediate onset of symptoms
Age of onset	Beyond infancy Typically younger than 5 yr
Proteins implicated	Heat-labile fresh fruit and vegetable allergens Pollen and latex cross-reactivity
Pathology	IgE antibodies
Treatment	Avoidance Cooking
Natural history	Unknown

sociated with certain airborne pollens (especially ragweed and birch pollens) are frequently afflicted with this syndrome. Patients with ragweed allergy may experience these symptoms after contact with certain melons (e.g., watermelons, cantaloupe, honeydew) and bananas. Patients with birch sensitivity often have symptoms after the ingestion of raw potatoes, carrots, celery, apples, and hazelnuts. The diagnosis of this syndrome is based on a suggestive history and positive prick skin tests with the implicated fresh fruits or vegetables, although the sensitivity of these tests may be limited in this disorder [*see* Prick Skin Tests, *below*].[5]

Immediate GI hypersensitivity Immediate GI hypersensitivity may accompany allergic manifestations in other target organs [*see Table 2*].[6,7] The GI symptoms vary but may include nausea, abdominal pain, abdominal cramping, vomiting, and diarrhea. In children with atopic dermatitis and food allergy, the frequent ingestion of a food allergen appears to induce partial desensitization of GI mast cells, resulting in less pronounced symptoms.

The diagnosis of immediate GI sensitivity is based on a suggestive clinical history, positive prick skin tests, resolution of symptoms after complete elimination of the suspected food allergen for up to 2 weeks, and positive results on oral food challenges. After patients have avoided a particular food for 10 to 14 days, it is not unusual for them to experience vomiting during a challenge, even though they were previously able to eat the food without vomiting.

Respiratory and Skin Reactions

Respiratory and ocular symptoms are common manifestations of IgE-mediated reactions to foods.[2,7] Symptoms may include periocular erythema, pruritus, and tearing; nasal congestion, pruritus, sneezing, and rhinorrhea; and coughing, voice changes, and wheezing. Isolated naso-ocular symptoms are an uncommon manifestation of food hypersensitivity reactions.

The skin is a frequent target organ in IgE-mediated food hypersensitivity reactions. The ingestion of food allergens can either trigger immediate cutaneous symptoms or aggravate chronic cutaneous symptoms. Acute urticaria and angioedema are probably the most common cutaneous manifestations of food hypersensitivity, generally appearing within minutes after ingestion of the food allergen. The foods that commonly cause these reactions in children include eggs, milk, peanuts, and tree nuts. In adults, this list includes fish, shellfish, tree nuts, and peanuts.

Atopic dermatitis is a chronic skin disorder that generally begins in early infancy and is characterized by typical distribution, extreme pruritus, and a chronically relapsing course; it is associated with asthma and allergic rhinitis [*see 2:IV Eczematous Disorders, Atopic Dermatitis, and Ichthyoses*].[8] Approximately one third of young children with atopic dermatitis have one or more food allergies. The immediate allergic reaction to foods in these patients is IgE mediated. However, their skin disease may be worsened by a mixed IgE-mediated and non–IgE-mediated reaction. Most young children with atopic dermatitis who have food allergy have reactions to milk, eggs, or peanuts.

MIXED IgE-MEDIATED AND NON–IgE-MEDIATED HYPERSENSITIVITY

Allergic Eosinophilic Gastroenteropathy

Allergic eosinophilic gastroenteropathy is a disorder characterized by infiltration of the gastric or intestinal walls with eosinophils; absence of vasculitis; and, frequently, peripheral blood eosinophilia [*see Table 3*].[4,9] Patients with this syndrome frequently have postprandial nausea and vomiting, abdominal pain, diarrhea, and, occasionally, steatorrhea; young infants experience failure to thrive, and adults have weight loss. There appears to be a subset of patients with allergic eosinophilic gastroenteritis who have symptoms secondary to food. These patients generally have the mucosal form of this disease, which is characterized by IgE-staining cells in jejunal tissue, elevated IgE in duodenal fluids, atopic disease, elevated serum IgE concentrations, positive prick skin tests to a variety of foods and inhalants, peripheral blood eosinophilia, iron deficiency anemia, and hypoalbuminemia.

The diagnosis of allergic eosinophilic gastroenteropathy is based on an appropriate history and a GI biopsy demonstrating a characteristic eosinophilic infiltration. Biopsies may need to be performed in multiple sites (up to eight) to effectively exclude eosinophilic gastroenteritis, because the eosinophilic infiltrates may be quite patchy. Patients with the mucosal form of the disease may have atopic symptoms, including food allergy, elevated serum IgE concentrations, and peripheral eosinophil-

Table 2 Immediate Gastrointestinal Hypersensitivity[27]

Manifestations	Nausea, abdominal pain and vomiting within 1–2 hr Diarrhea within 2–6 hr Frequently associated with atopic disease Food-specific IgE antibodies Radiographic: gastric hypotonia and pylorospasm
Age at onset	Infancy, childhood
Proteins implicated	Milk, eggs, peanuts, soy, cereal, fish
Pathology	IgE mediated
Treatment	Protein elimination
Natural history	80% of cases resolve after protein-elimination diet (except in the case of peanut and fish allergy)

Table 3 Allergic Eosinophilic Gastroenterocolitis[27]

Manifestations	Abdominal pain Anorexia Early satiety Failure to thrive Gastric outlet obstruction Gastric or colonic bleeding ±70% of cases atopic Elevated IgE ±Food-specific IgE 50% of cases with peripheral eosinophilia Radiographic Antral obstruction, gastroesophageal reflux, bowel wall edema
Age at onset	Birth to adolescence
Proteins implicated	Cow's milk, eggs, fish, soy, cereals Less than 50% of patients have skin-test specificity
Pathology	Marked eosinophilic infiltration of mucosa and submucosa in gastric antrum, esophagus, duodenum, and colon
Treatment	50% of patients respond to dietary elimination of documented allergen Excellent response to hydrolyzed protein formula in patients younger than 2 yr Excellent response to L-amino acid formula Responsive to steroids
Natural history	Disorder is typically prolonged

ia; they may also have positive skin tests or positive radioallergosorbent tests (RASTs). Other laboratory results consistent with this disease include findings of Charcot-Leyden crystals in the stool; anemia; and hypoalbuminemia. Such patients may also have abnormal results on D-xylose testing. An elimination diet for up to 12 weeks may be necessary before complete resolution of symptoms and normalization of intestinal histology.

NON–IgE-MEDIATED HYPERSENSITIVITY

Dietary Protein Enterocolitis

Enterocolitis from dietary protein (also known as protein intolerance) occurs most commonly in young infants between 1 week and 3 months of age [*see Table 4*]. The typical symptoms are isolated to the GI tract and consist of recurrent vomiting, diarrhea, or both. The symptoms can be severe enough to cause dehydration. Cow's milk and soy protein (particularly in infant formulas) are most often responsible for this syndrome, although egg sensitivity has been reported in older patients. The stools in affected children will often contain occult blood, polymorphonuclear neutrophils (PMNs), and eosinophils and are frequently positive for reducing substances (indicating malabsorbed sugars). Prick skin tests for the putative food protein are characteristically negative. Jejunal biopsies classically reveal flattened villi, edema, and increased numbers of lymphocytes, eosinophils, and mast cells. A food challenge with the responsible protein generally results in vomiting, diarrhea, or both within minutes to several hours; occasionally, patients experience shock.[4,10] It is not uncommon to find children who are sensitive to both cow's milk and soy protein. This sensitivity also tends to be lost by 18 to 24 months of age. Elimination of the offending allergen generally will result in improvement or resolution of the symptoms within 72 hours, although secondary disaccharidase deficiency may persist longer. Oral food challenges, which should be done in a medical setting because they can induce severe vomiting, diarrhea, dehydration, or hypotension, consist of administering 0.6 g/kg body weight of the suspected food allergen.

Dietary Protein Proctitis

Patients with dietary protein proctitis generally present in the first few months of life. This disorder is often secondary to cow's milk or soy protein hypersensitivity.[11] Most infants with this disorder do not appear ill and have normally formed stools; they generally come to medical attention because of blood (gross or occult) in their stools. GI lesions are confined to the small bowel. Grossly, the lesions range from patchy mucosal injection to severe friability with small aphthoid ulcerations and bleeding. Microscopically, they are characterized by mucosal edema with eosinophils in the epithelium and lumina propria. If lesions are severe, with crypt destruction, PMNs are also prominent.[12] It is believed that colitis induced by cow's milk or soy protein resolves by 6 months to 2 years after allergen avoidance; however, this belief is not strongly supported by well-controlled studies. Elimination of the offending food allergen leads to resolution of hematochezia within 72 hours, but the mucosal lesions may take up to 1 month to disappear.

Celiac Disease

Celiac disease is an extensive enteropathy leading to malabsorption. Total villous atrophy and an extensive cellular infiltrate are associated with sensitivity to gliadin, the alcohol-soluble portion of gluten found in wheat, oats, rye, and barley. The overall incidence of celiac disease is thought to be one in 4,000 population, but there is wide regional variation; for example, the incidence in Ireland has been reported to be as high as one in 500 population. There is apparently a genetic predisposition to this disease, given that approximately 90% of patients are HLA-B8 positive and nearly 80% have the HLA-DW3 antigen. Pa-

Table 4 Dietary Protein Enterocolitis[27]

Manifestations	Diarrhea with bleeding Anemia Emesis Abdominal distention Failure to thrive Hypotension Fecal leukocytes Normal IgE Food challenge: vomiting in 3–4 hr; diarrhea in 5–8 hr
Age at onset	1 day to 1 yr
Implicated proteins	Cow's milk, soy, rice, poultry, fish
Pathology	Patchy villous injury and colitis
Treatment	80% or more of patients respond to hydrolyzed casein formula; symptoms clear in 3–10 days Up to 20% of patients require L-amino acid formula or temporary intravenous therapy
Natural history	With treatment, 50% of cases resolve by 18 mo and 90% by 36 mo; in soy allergy, illness is often more persistent

tients often present with diarrhea or frank steatorrhea, abdominal distention and flatulence, and weight loss; occasionally, they have nausea and vomiting. Other extraintestinal symptoms and oral ulcers secondary to malabsorption are not common.

HISTORY AND PHYSICAL EXAMINATION

As with virtually all medical disorders, the diagnostic approach to a patient with a suspected adverse food reaction begins with the history and physical examination. Depending on the information derived from these initial steps, various laboratory studies may be helpful [*see Table 5*].[13-15]

In cases of suspected adverse food reactions, the value of the history depends largely on the patient's recollection of symptoms and on the examiner's ability to differentiate disorders provoked by food hypersensitivity from disorders with other etiologies. The history may be directly useful in diagnosing food allergy involving acute events (e.g., anaphylaxis after eating fish) but is not always reliable: in many series, less than 50% of reported allergic reactions to food could be substantiated by a double-blind, placebo-controlled food challenge (DBPCFC).[3,7] In chronic disorders such as atopic dermatitis, the history is typically an unreliable indicator of the offending allergen.

Several items of information are important in establishing that an allergic reaction to food occurred: (1) the type of food suspected to have provoked the reaction; (2) the quantity of the food ingested; (3) the length of time between ingestion and onset of symptoms; (4) the specific symptoms provoked; (5) whether similar symptoms developed on other occasions when the food was eaten; (6) whether other factors (e.g., exercise) were involved in the episode; and (7) the length of time since the last reaction.

Although any food may cause an allergic reaction, only a few foods account for 90% of such reactions. In children, these foods are eggs, milk, peanuts, soy, and wheat (and in Scandinavian countries, fish).

Diet Diary

A diet diary is often a useful adjunct to the medical history. Patients are asked to keep a chronologic record of all foods ingested over a specified period of time and to record any symptoms they experience during this period. The diary can be reviewed at a subsequent visit to determine whether there is a relationship between the foods ingested and the symptoms experienced. Uncommonly, this method will reveal an unrecognized association between a food and a patient's symptoms. Nevertheless, a diet diary is superior to the history in that it involves the collection of information on a prospective basis and is less dependent on the patient's or parent's memory.

Elimination Diet

Elimination diets are often used both in diagnosis and in management of adverse food reactions. If a certain food or foods are suspected of provoking the reaction, they are completely eliminated from the diet. The success of an elimination diet depends on several factors, including the correct identification of the allergen or allergens involved, the ability of the patient to maintain a diet completely free of all forms of the possible offending allergen, and the assumption that other factors will not provoke similar symptoms during the study period. The likelihood of all of these conditions being met is often slim. For example, in a young infant who is reacting to cow's milk formula, resolution of symptoms after substitution of soy formula or casein hydrolysate (e.g., Alimentum, Nutramigen) is highly suggestive of cow's milk allergy but also could reflect lactose intolerance. Avoidance of suspected food allergens before a blinded challenge is recommended so that reactions may be heightened. Elimination diets are rarely diagnostic of food allergy, particularly in chronic disorders such as atopic dermatitis or asthma.

Elimination diet
Prick skin testing
Radioallergosorbent tests
Open or single-blind challenge
Double-blind, placebo-controlled food challenge (optimal)

LABORATORY TESTS

Allergy Skin Tests

Prick skin tests Prick skin tests are highly reproducible[16] and are often utilized to screen patients with suspected IgE-mediated food allergies. The glycerinated food extracts (1:10 or 1:20 dilution)[7] and appropriate positive (histamine) and negative (saline) controls are applied by either the prick or puncture technique. A test that elicits a wheal (not including erythema) at least 3 mm greater than the negative control is considered positive; any smaller result is considered negative. Appropriate and good-quality food extracts must be utilized for results to be reliable.

A negative skin test confirms the absence of an IgE-mediated reaction (overall negative predictive accuracy is greater than 95%). However, skin testing with commercial reagents often fails to detect IgE-mediated sensitivity to certain fruits and vegetables (e.g., apples, oranges, bananas, pears, melons, potatoes, carrots, and celery), presumably because of the labile nature of the responsible allergens in these foods. In such cases, it may be necessary to use the so-called prick-by-prick method, in which the device used for introducing the allergen into the skin is first pricked into the food. In addition, false negative results are particularly common in very young children, possibly because of lower skin reactivity: children younger than 1 year may have IgE-mediated food allergy without a positive skin test, and children younger than 2 years may have smaller wheals.

A positive skin test to a food is not definitive; it merely indicates the possibility that the patient has symptomatic reactivity to that specific food (overall, the positive predictive accuracy is less than 50%). However, a positive skin test to a food that provokes a severe anaphylactic reaction when eaten by itself may be considered diagnostic. Atopy patch tests for food allergy have been developed, but there is as yet insufficient evidence to support their adoption in clinical practice.

Intradermal skin tests An intradermal skin test is more sensitive than a prick skin test but is much less specific than a DBPCFC.[17] In one study, no patient who had a negative prick skin test but a positive intradermal skin test to a specific food had a positive DBPCFC to that food.[17] In addition, intradermal skin testing is more likely to induce a systemic reaction than is

prick skin testing. For those reasons, intradermal skin tests have no role in the diagnosis of food allergy.

In Vitro Assays

RASTs and similar in vitro assays (including enzyme-linked immunosorbent assays [ELISAs]) are often used to screen for IgE-mediated food allergies. Although RASTs are generally considered slightly less sensitive than skin tests, one study comparing skin tests and Phadebas RAST (Pharmacia & Upjohn) with DBPCFCs found prick skin tests and Phadebas RAST to have similar sensitivity and specificity when a Phadebas score of 3 or greater was considered positive.[18] In this study, lowering the cutoff point for a positive result to a score of 2 brought a slight improvement in sensitivity at the expense of a significant decrease in specificity. In general, in vitro measurements of serum food-specific IgE performed in high-quality laboratories provide information similar to prick skin tests. The newest generation of in vitro studies for specific IgE includes the capsulated hydrolic carrier polymer–fluoroenzymeimmunoassay (RAST-FEIA). For patients with suspected food allergy, there are now accepted levels of food-specific IgE concentrations on CAP-FEIA testing that can predict a patient's being allergic to that food with greater than 95% certainty.[15] CAP-FEIA is best used for patients with allergic reactions to milk, eggs, and peanuts (and, possibly, wheat, soy, and fish).

Double-Blind Placebo-Controlled Food Challenge

The DBPCFC has been considered the gold standard for the diagnosis of food allergy.[4] This test has been used successfully by many investigators in both children and adults for the past several years to examine a wide variety of food-related complaints. The selection of foods to be tested in the oral challenge is based on the history or prick skin test (RAST) results.

A DBPCFC is the best means of controlling for the variability of chronic disorders (e.g., chronic urticaria, atopic dermatitis), any potential temporal effects, and acute exacerbations secondary to reducing or discontinuing medications. In particular, psychogenic factors and observer bias are eliminated. Rarely, a false negative DBPCFC may occur when the challenge material a patient receives is not of sufficient quantity to provoke the reaction or when the lyophilization of the food antigen has altered the relevant allergenic epitopes (as may occur with fish). Nevertheless, at present, the DBPCFC has proved to be the most accurate means of diagnosing food allergy.

PRACTICAL APPROACH TO DIAGNOSING FOOD ALLERGY

The diagnosis of food allergy remains a clinical exercise that utilizes a careful history, selective prick skin tests or RASTs (if an IgE-mediated disorder is suspected), appropriate exclusion diet, and blinded provocation. Other diagnostic tests that do not appear to be of significant value include assessment of food-specific IgG or IgG4 antibody levels, assessment of food antigen–antibody complexes, measures of lymphocyte activation (e.g., ^{3}H uptake, interleukin-2 production, presence of leukocyte inhibitory factor), and sublingual or intracutaneous provocation. Blinded challenges may not be necessary in suspected GI disorders, which often can be diagnosed on the basis of prechallenge and postchallenge laboratory values and biopsy results.

An exclusion diet that eliminates all foods suspected by history or prick skin testing (or, in IgE-mediated disorders, RAST) should be conducted for at least 1 to 2 weeks. Some patients with GI disorders may need to have the exclusion diet extended for up to 12 weeks after appropriate biopsies. If no improvement is noted after institution of the diet, food allergy is unlikely. In patients with some chronic diseases, such as atopic dermatitis or chronic asthma, other precipitating factors may make it difficult to discriminate the effects of the food allergen from other provocative factors.

Open or single-blind challenges in a clinic setting may be helpful to test for allergy to specific foods. Such challenges are less cumbersome and time-consuming than DBPCFCs. It is important that the clinician make an unequivocal diagnosis of food allergy; a presumptive diagnosis of food allergy based on a patient's history and prick skin tests or RAST results is no longer acceptable. There are exceptions to this, such as the patient who experiences severe anaphylaxis after the isolated ingestion of a specific food. Because of reliance on presumptive diagnosis, over one quarter of the United States population have altered their eating habits on the basis of misconceptions about food allergy.

Treatment

The only proven therapy for food allergy is the strict elimination of that food from the patient's diet. In infants, breast-feeding avoids contact with potentially allergenic foods if the mother avoids those foods. In infants with a family history of atopy, moreover, exclusive breast-feeding for at least the first 4 months of life appears to lessen the likelihood of atopic dermatitis.[19] Elimination diets should be supervised because they may lead to malnutrition or eating disorders, especially if they involve the elimination of a large number of foods or are utilized for extended periods of time. Studies have shown that symptomatic food sensitivity generally is lost over time, except for sensitivity to peanuts, tree nuts, and seafood.

Symptomatic food sensitivity is usually very specific; patients rarely react to more than one member of a botanical family or animal species. Consequently, clinicians should confirm that patients are not unnecessarily limiting their diet for fear of allergic reactions. Risk factors for more severe anaphylactic reactions include the following: (1) a history of a previous anaphylactic reaction; (2) a history of asthma, especially if poorly controlled; (3) allergy to peanuts, nuts, fish, or shellfish; (4) current treatment with beta blockers or angiotensin-converting enzyme inhibitors; and, possibly (5) female sex.

PHARMACOLOGIC THERAPY

Several medications have been used in an attempt to protect patients with food hypersensitivity, including oral cromolyn, H_1 and H_2 antihistamines, ketotifen, corticosteroids, and prostaglandin synthetase inhibitors. Some of these medications may modify food allergy symptoms, but overall they have minimal efficacy or unacceptable side effects.

Epinephrine

The importance of prompt administration of epinephrine when symptoms of systemic reactions to foods develop cannot be overemphasized [*see 6:XIII Urticaria, Angioedema, and Anaphylaxis*]. Patients with a history of anaphylaxis should always carry an epinephrine autoinjector (Epi-Pen [0.3 mg] or Epi-Pen, Jr. [0.15 mg]). For anaphylaxis, epinephrine is given in a dose of 0.01 mg/kg. The route of administration can be intramuscular or subcutaneous, but most recent studies suggest that intramuscular administration is better.

IMMUNOTHERAPY

Blinded, placebo-controlled studies of rush immunotherapy for the treatment of peanut hypersensitivity demonstrated efficacy in a small number of patients.[20] The adverse reaction rates were significant, and such reactions preclude general clinical application at this time. Except for patients who are at risk of life-threatening reactions to minuscule amounts of peanut, there is no use for immunotherapy in food allergies. Newer types of immunotherapy for preventing food-induced anaphylaxis that are being developed include the following: (1) humanized anti-IgE monoclonal antibody therapy, (2) plasmid-DNA immunotherapy, (3) peptide fragments (so-called overlapping peptides), (4) cytokine-modulated immunotherapy, (5) immunostimulatory sequence-modulated immunotherapy, (6) bacterial-encapsulated allergen immunotherapy, and (7) recombinant protein immunotherapy.[21] A recent study with anti-IgE in peanut-allergic patients[22] demonstrated that this medication may eventually be helpful for preventive treatment of food-induced anaphylaxis.

PATIENT EDUCATION

Patient education and support are essential for patients with food allergy. In particular, adults and older children who are prone to anaphylaxis, as well as parents of pediatric patients, must be informed in a direct but sympathetic way that these reactions are potentially fatal.

When eating away from home, food-sensitive persons should feel comfortable requesting information about the contents of prepared foods. For school-aged children, the American Academy of Pediatrics Committee of School Health has recommended that schools be equipped to treat anaphylaxis in allergic students. Children older than 7 years can usually be taught to inject themselves with epinephrine. The physician must be willing to explain these issues to school personnel and, with the parents, help instruct these personnel in how to deal with them. In the home, the family should eliminate the incriminated allergen or, if this is not practical, place warning stickers on foods with the offending antigens. A variety of groups can help provide patients with support, advocacy, and education about food allergy [*see Table 6*].

Prognosis

Young children who are diagnosed with anaphylaxis to foods such as milk, eggs, wheat, or soybeans often outgrow this clinical sensitivity after several years.[9,23,24] Children who develop food sensitivity after 3 years of age are less likely to lose their food reactions over a period of several years. Patients who have very mild reactions (i.e., skin symptoms only) to peanuts early in life (i.e., during the first 12 to 24 months) may outgrow their symptoms.[25,26] Allergies to foods such as tree nuts, fish, and seafood are generally not outgrown regardless of the age at which they develop. These persons appear likely to retain their allergic sensitivity for a lifetime. Consequently, new strategies are being evaluated to desensitize patients to these foods.

The author owns stock, stock options, and/or bonds in SEER Inc.

I INFECTIONS DUE TO GRAM-POSITIVE COCCI

Dennis L. Stevens, ph.d., m.d., f.a.c.p.

Pneumococci

Pneumococci are gram-positive, lancet-shaped diplococci that may also grow in short chains. When cultured on blood agar plates, they form small, colorless mucoid colonies with characteristic central depressions. The colonies are surrounded by greenish discoloration of the blood agar, termed α-hemolysis. Laboratories have traditionally identified pneumococci on the basis of sensitivity to surface-active agents such as bile or optochin; rapid speciation can now be accomplished with a latex agglutination test or a DNA probe.

Although there is only one species of *Streptococcus pneumoniae,* there are at least 84 distinct serotypes, which are differentiated by the composition of the polysaccharide polymer that forms their outer capsule. Each capsular type is chemically and antigenically unique. The pneumococcal polysaccharide capsule is crucial to virulence. The capsule allows the bacteria to resist phagocytosis by leukocytes unless the organisms have been opsonized by antibody or serum complement components. Antibodies to capsular polysaccharide are essential for recovery from untreated pneumococcal pneumonia. Although such antibodies provide long-lasting immunity, the immunity is strictly type specific. Certain pneumococcal serotypes, such as the heavily encapsulated type 3 pneumococcus, are particularly virulent. In fact, only 23 serotypes account for about 80% of bacteremic pneumococcal infections in the United States; capsular polysaccharides from these 23 serotypes are incorporated into the polyvalent pneumococcal vaccine that has been available since 1983.

Although the polysaccharide capsule is the critical factor in determining the virulence of pneumococci, several proteins also contribute to the pathogenesis of pneumococcal infections. Surface protein A, neuraminidase, pneumolysin, and IgA protease appear to be the most important of these proteins.[1]

epidemiology of pneumococcal infections

The nasopharynx is the natural habitat of the pneumococcus; humans are the only known hosts. The nasopharyngeal carrier rate varies widely, from a low of 5% to 10% to a high of up to 60% in closed populations during the winter.[2] Pneumococci are fastidious, nonsporulating bacteria. Because they are rapidly killed by drying or by extremes in temperature, person-to-person spread by droplets requires close contact.

The pneumococcus remains the most important cause of bacterial pneumonia; it may account for as many as 500,000 cases each year in the United States. Like other respiratory tract infections, pneumococcal pneumonia is more common in winter. Cigarette smoking is the strongest independent risk factor for invasive pneumococcal disease in immunocompetent, nonelderly adults.[3] Extremes of age and chronic disease or immunosuppression are also risk factors [*see Table 1*].[4] Diseases that increase risk include cirrhosis, sickle cell anemia, multiple myeloma, chronic lung disease, and cancer. Organ transplantation recipients are also highly susceptible.

The pneumococcus accounts for up to 40% of community-acquired pneumonias, causing or contributing to 40,000 deaths annually. The overall case-fatality rate of this pneumonia is 5% to 12%[5]; patients who are very young, elderly, alcoholic, leukopenic, infected with HIV, or infected with certain virulent pneumococcus serotypes (notably, type 3) are at the highest risk. Pneumococcal bacteremia develops in about 50,000 Americans annually, with a case-fatality rate of 20%—a rate that has not changed over the past 40 years.[6] Pneumococcal otitis media is one of the most common childhood illnesses; the estimated incidence in the United States is seven million cases a year. Pneumococci cause about 3,000 cases of meningitis each year, with a case-fatality rate of about 21%.[7]

Epidemics of pneumococcal disease were common in the preantibiotic era, but sporadic cases are now the rule. Outbreaks have occurred, however, in shelters for the homeless, in jails, and in child care centers. Pneumococcal infection is typically community acquired, but it can occur nosocomially, particularly in chronically ill immunosuppressed patients; because of underlying diseases, the case-fatality rate of nosocomial pneumococcal bacteremia is 40%.[8] The incidence of pneumococcal bacteremia is increased about 40-fold in patients with AIDS.

pathogenesis of pneumococcal infections

Pneumococci produce IgA protease, which cleaves the secretory immunoglobulin IgA1. IgA protease may be partly responsible for the high carrier rate and the respiratory tract pathogenicity of these bacteria. The organisms do not provoke an inflammatory response or cause clinical illness in the nasopharynx. Host defense mechanisms prevent penetration into more vulnerable areas, such as the paranasal sinuses, the middle ear, and pulmonary alveoli. Examples of these defenses include the cough, gag, and sneeze reflexes; the viscous mucus that lines the respiratory epithelium and traps bacteria; and ciliary action, which expels trapped particles. Pneumococcal infection often follows influenza[9] or other viral infections of the upper respiratory tract, which impair host defenses by increasing the volume and decreasing the viscosity of secretions. Other factors that predispose to pneumococcal infection include dementia, seizure disorders, alcoholism, stupor, and other conditions that increase

Table 1 Incidence of Pneumococcal Disease According to Age and Underlying Disease

Risk Factor	*Cases of Pneumococcal Disease per 100,000 Population*
Age	
< 1 yr	21
1 yr	51
> 65 yr	45
Chronic medical conditions	176–483
Severe immunosuppression	562–2,031

the likelihood that oropharyngeal contents will be aspirated into the lungs. Air pollution, cigarette smoking, heart failure, chronic obstructive pulmonary disease (COPD), and HIV infection increase the risk of pneumococcal infection, but diabetes does not.

Pneumococcal pneumonia begins with aspiration of small quantities of oropharyngeal secretions containing pneumococci. Normally, alveolar macrophages ingest and kill such bacteria, but in the absence of type-specific immunity, strains of pneumococci are protected from ingestion. The presence of pneumococci in the alveoli provokes a vigorous inflammatory response. The earliest manifestations are vasodilatation, increased vascular permeability, and exudation of edema fluid—the classic pathologic stage of congestion. Pneumococci can survive and even proliferate in the edema fluid. The organisms appear to float to adjacent alveoli, producing lobar consolidation. Within hours to days, polymorphonuclear leukocytes arrive and progressively pack the alveoli to produce the traditional stages of red and gray hepatization. However, only a minority of the pneumococci are phagocytosed and killed by the leukocytes in the first days of infection. Capsular polysaccharide antigen is often present in the serum and urine during these early stages.

After 5 to 7 days, type-specific anticapsular antibody appears. This results in a more efficient and enhanced opsonization that involves anticapsular antibody and the classical complement pathway. As pneumococci are ingested and killed by the polymorphonuclear leukocytes, the patient experiences a clinical crisis, marked by an abrupt fall in temperature and an increase in well-being; resolution commences. Because pneumococci only rarely produce significant tissue necrosis, healing is usually complete, and residual fibrosis is minimal.

CLINICAL PNEUMOCOCCAL INFECTIONS

Pneumonia

Clinical presentation Sir William Osler's classic description of pneumococcal pneumonia was recorded in 1892,[10] only 10 years after the discovery of the pneumococcus, but it remains lucid and accurate today:

> Abruptly, or preceded by a day or two of indisposition, the patient has a severe chill, lasting from ten to thirty minutes. In no acute disease is an initial chill so constant or so severe. The fever rises quickly. There is pain in the side, often of an agonizing character. A short, dry painful cough soon develops and the respirations are increased in frequency. When seen on the second or third day the patient presents an appearance which may be quite pathognomonic. He lies flat in bed, often on the affected side; the face is flushed, particularly the cheeks; the breathing is hurried; the alae nasi dilate with every inspiration; the eyes are bright, the expression is anxious, and there is a frequent short cough which makes the patient wince and hold his side. The expectoration is blood-tinged and extremely tenacious. The temperature rises rapidly to 104° or 105°. The pulse is full and bounding and the pulse-respiration ratio much disturbed. Examination of the lung shows the physical signs of consolidation—blowing breathing and fine rales. After persisting for from seven to ten days the crisis occurs, and with a fall in the temperature the patient passes from a condition of extreme distress and anxiety to one of comparative comfort.
>
> Pneumonic sputum is viscid, tenacious, and blood-tinged. The gummous viscidity, together with the red blood–corpuscles in various stages of alteration, give pathognomonic characters to the sputa, unknown in any other disease. The rusty tinge becomes more marked as the disease progresses, and so tenacious is the expectoration that it has to be wiped from the lips of the patient, and a spitcup, half full, may be inverted without spilling. Microscopically, the sputum contains red blood–corpuscles in all stages of degeneration, alveolar epithelium, diplococci and other micro-organisms, cell-moulds of the alveoli, and, in some cases, small fibrinous casts of the bronchioles. The latter are sometimes plainly visible to the naked eye.

It should be emphasized, however, that not all patients with pneumococcal pneumonia present with a viral upper respiratory tract infection that is followed by the abrupt onset of fever, chills, pleurisy, dyspnea, and cough productive of purulent or blood-tinged sputum. If the patient has used antipyretics, fever can be modest or absent. The initial rigor may also be absent, but patients may occasionally have recurrent chills. In elderly or debilitated patients, confusion or stupor may be the presenting feature, far overshadowing pulmonary symptoms. In contrast, patients with chronic pulmonary disease may have rapidly progressive respiratory failure, which is disproportionately more severe than fever, sputum production, or other manifestations of infection. In rare cases, asplenic patients present with shock and hemorrhagic skin lesions that reflect disseminated intravascular coagulation. Because modest hyperbilirubinemia is common in pneumococcal pneumonia, right lower lobe pneumonia may masquerade as acute cholecystitis because of fever, jaundice, and right upper quadrant discomfort.

Laboratory tests The key to the diagnosis of pneumococcal pneumonia is the Gram stain of a sputum smear, which typically reveals many polymorphonuclear leukocytes and abundant lancet-shaped gram-positive diplococci. If the patient cannot spontaneously produce an adequate sputum specimen, chest physiotherapy or nasotracheal suctioning should be considered. Sputum specimens should be promptly cultured on blood agar plates, preferably in 5% CO_2 incubators. Because pneumococci are fastidious and fragile, the sputum culture may be negative in patients with clearly positive Gram stains. It is important to obtain blood cultures in all patients with suspected pneumococcal pneumonia. In 25% to 30% of these patients, the blood culture will be positive—a finding that confirms the diagnosis even if sputum cultures are negative. An immunochromatographic test can be used to detect pneumococcal polysaccharide in the urine of patients with pneumonia, but pneumococcal nasopharyngeal colonization can produce false positive results.[11]

Imaging tests The classic physical and radiographic findings of lobar consolidation may be absent in patients with pneumococcal pneumonia. In fact, a bronchopneumonic pattern is radiographically more common than lobar consolidation. Dehydration may minimize pulmonary findings, and underlying chronic lung disease may predispose to patchy areas of pulmonary infiltration. Pleural effusions are relatively common and can occasionally obscure the underlying pulmonary parenchymal involvement.

Differential diagnosis Other bacterial and nonbacterial pneumonias must be considered in the differential diagnosis of pneumococcal pneumonia [*see 7:XX Pneumonia and Other Pulmonary Infections*]. Less commonly, pulmonary edema, pulmonary emboli, atelectasis, or lung tumors are mistaken for pneumonia.

Complications and prognostic indicators The complications associated with pneumococcal pneumonia have diminished

markedly in the antibiotic era. Intrathoracic complications include pleurisy with sterile pleural effusion (common) and empyema (uncommon). Lung abscess is rare; if abscess or empyema occurs, it is likely to be caused by the heavily encapsulated type 3 pneumococcus or by a concomitant anaerobic infection. Purulent pericarditis is even rarer than abscess or empyema. Radiographic abnormalities often resolve slowly. About one third of patients have persistent consolidation at 1 month; although consolidation should resolve in all patients by 8 to 10 weeks, volume loss, pleural disease, and interstitial changes can persist for up to 4 months.

Bacteremia is by far the most common extrathoracic complication. Approximately 90% of patients with pneumococcal bacteremia have pneumonia, but patients occasionally present with pneumococcal bacteremias without an identifiable septic focus. Recurrent pneumococcal bacteremia may develop in patients with underlying diseases. Bacteremia is an adverse prognostic sign. The reported fatality rate is 11% to 36%, but it is probably higher in the elderly and in patients with severe underlying diseases. Metastatic infections such as meningitis, septic arthritis, peritonitis, and endocarditis are relatively uncommon; they appear to be more common and to occur at younger ages in African Americans than in whites.[12]

Several factors are associated with worse outcomes in pneumococcal pneumonia [*see Table 2*]. Interestingly, a lack of febrile response and a normal or low white blood cell count are readily measurable factors that are associated with worse outcome. Thus, although white blood cell counts of 25,000 to 30,000 with a left shift may be alarming, they indicate a favorable host response to infection.[13]

Table 2 Factors Associated with Adverse Outcomes in Pneumococcal Pneumonia

Infection with type 3 pneumococci
Bacteremia
Hypothermia
Neutropenia
Multilobe infection
Extrapulmonary infection (meningitis, empyema)
Hypotension

Pneumococcal Infections in Persons Infected with HIV

The pneumococcus is the leading cause of invasive bacterial respiratory tract infections in HIV-positive persons. The clinical features, causative serotypes, antimicrobial resistance patterns, and mortalities of pneumococcal infection in HIV-positive patients are similar to those in HIV-negative patients. Severe infections, unusual extrapulmonary manifestations, and late relapses are more common in these patients, however. Pneumococcal vaccine should be administered as soon as possible after the diagnosis of HIV infection; despite the decreased efficacy of vaccine in patients with advanced AIDS, vaccination is a cost-effective preventive intervention at all stages of HIV infection.[14]

Other Pneumococcal Infections

Upper respiratory tract infections Pneumococci spread from the nasopharynx to the upper respiratory tract to produce acute otitis media, especially in children. Acute mastoiditis, once a frequent sequela of acute otitis media, is now unusual. Pneumococci are a cause of acute purulent sinusitis in all age groups [*see 7:XIX Bacterial Infections of the Upper Respiratory Tract*].

Meningitis Pneumococci can reach the central nervous system either by bacteremic spread from a pulmonary focus or by direct extension from otitis or sinusitis. Patients with skull fractures and cerebrospinal fluid rhinorrhea or otorrhea are particularly prone to recurrent attacks of pneumococcal meningitis [*see 7:XXXVI Bacterial Infections of the Central Nervous System*].

Septic arthritis and osteomyelitis Pneumococci are a relatively common cause of acute septic arthritis, which results from bacteremic seeding; prosthetic joints may be involved [*see 7:XV Septic Arthritis*]. Pneumococcal osteomyelitis is uncommon.

Cardiac infections Antibiotics have greatly reduced the incidence of pneumococcal pericarditis, which can result from direct extension of pneumonia or empyema or from hematogenous seeding. Pneumococcal endocarditis has also become uncommon in the antibiotic era.[15]

Postsplenectomy infections Overwhelming postsplenectomy pneumococcal infection is an uncommon but important syndrome. In addition to patients who have undergone splenectomy, other patients at risk include those with sickle cell disease or other hemoglobinopathies that produce functional asplenia, as well as those with congenital asplenia. The syndrome is often marked by acute onset of fever, hemorrhagic skin lesions suggestive of disseminated intravascular coagulation or purpura fulminans, and shock. Hypoglycemia may be present. If therapy is not administered, death often occurs in less than 24 hours. Even when patients receive penicillin and cardiovascular support, mortality exceeds 50%. A similar syndrome can occur in healthy adults but is rare.[16]

Other infections Primary pneumococcal peritonitis can occur in patients who have cirrhosis, nephrotic syndrome, systemic lupus erythematosus, or other host defects [*see 7:XXI Peritonitis and Intra-Abdominal Abscesses*]. In rare cases, pneumococci can infect the liver, the gallbladder, or pelvic organs; soft tissue infections and cellulitis caused by *S. pneumoniae* are also unusual.

TREATMENT OF PNEUMOCOCCAL INFECTIONS

For many years, all isolates of *S. pneumoniae* were penicillin sensitive; until 1965, most isolates in the United States were sensitive to less than 0.04 μg/ml penicillin. Subsequently, resistance to penicillin has become progressively more prevalent. Although pneumococci do not display plasmid-mediated penicillinase production, they can develop chromosomal mutations that confer resistance to penicillin by altering the affinity of the penicillin-binding proteins in their cell walls. Gradual remodeling of three or four of the penicillin-binding proteins in parallel produces a stepwise increase in the level of resistance. The DNA sequences responsible for resistance probably originated in other streptococcal species and were transferred to pneumococci by heterologous recombination.[16]

Pneumococci for which the minimum inhibitory concentration (MIC) of penicillin is less than 0.1 μg/ml are considered penicillin sensitive; those in which the MIC of penicillin is 0.1 to 1.0 μg/ml are considered intermediately resistant; and those for which the MIC is greater than 1.0 μg/ml are considered resistant. About 24% of pneumococcal organisms isolated in the

United States are penicillin-nonsusceptible *S. pneumoniae* (PNSP), but in some areas, more than one third of *S. pneumoniae* isolates are resistant to penicillin.[17] The prevalence of PNSP increases in patients who have been using antibiotics; it is highest in children younger than 6 years and in adults older than 65 years. Resistant strains can be spread from person to person, especially in closed population groups, such as those in day care centers, jails, and nursing homes. Infection with PNSP is associated with an increased likelihood of an adverse outcome.[18]

Pneumococci that are resistant to penicillin are often resistant to other antimicrobial drugs.[17] First- and second-generation cephalosporins are generally ineffective against these organisms, but third-generation cephalosporins (particularly ceftriaxone and cefotaxime) and carbapenems are usually active. Erythromycin and the other macrolides are generally ineffective, as are clindamycin and trimethoprim-sulfamethoxazole (TMP-SMX); chloramphenicol has variable efficacy. Rifampin and vancomycin are active against virtually all isolates, but vancomycin tolerance has been identified and may become a concern in the future.[19] Whereas many pneumococci have become resistant to the older fluoroquinolones, such as ciprofloxacin,[20] newer agents in this class, such as levofloxacin, sparfloxacin, gatifloxacin, and moxifloxacin, are generally active against penicillin-resistant pneumococci. Levofloxacin resistance has been documented, however, especially in elderly nursing home patients, in patients with COPD, and in patients who had prior exposure to fluoroquinolones.[20] Linezolid[21] is active against all pneumococci, as are ketolides, the still-investigational glycylcyclines, and daptomycin. Because of the increasing problem of PNSP, organisms isolated from clinical sources should be screened for penicillin resistance with a 1 μg oxacillin disk. Isolates with oxacillin inhibition zones of less than 19 mm should be studied further to determine the MICs of penicillin and other antimicrobial agents that are likely to be used in treatment.

Guidelines for treatment of patients with PNSP are being formulated.[22] Pneumonia caused by PNSP strains can still be treated with penicillin G, although dosages must be in the range of 10 to 20 million units a day for average-size adults [*see Table 3*]. Ceftriaxone and cefotaxime are generally effective, but treatment failures in patients with meningitis have been reported. Until the results of susceptibility testing are available, it may be advisable to add vancomycin to the regimen of cefotaxime or ceftriaxone for patients with life-threatening pneumococcal infections such as meningitis. Vancomycin is an effective alternative for patients in whom treatment fails and for those who cannot tolerate cephalosporins; however, because of the limited CSF penetration of I.V. vancomycin in patients with pneumococcal meningitis, concurrent therapy with intrathecal vancomycin or I.V. rifampin may be advisable. The role of imipenem or meropenem in treating patients with PNSP is being explored. The newer fluoroquinolones (levofloxacin, sparfloxacin, gatifloxacin, and moxifloxacin) may be useful in adults, though none have indications in children. Linezolid has been approved for the treatment of pneumonia caused by PNSP, though no studies have been completed in patients with meningitis. To limit the spread of PNSP, physicians should avoid the inappropriate use of antibiotics and encourage the appropriate use of the pneumococcal vaccine.

Penicillin remains the drug of choice for susceptible pneumococci; cephalosporins are also active against such organisms but must be used with caution in patients allergic to penicillin. Other drugs that can be used to treat susceptible pneumococci include erythromycin and the new macrolides, ketolides, vancomycin, and the newer fluoroquinolones. Clindamycin has been a useful drug for treating a variety of pneumococcal infections, though inducible clindamycin resistance has been recently reported. TMP-SMX is a particularly good choice for patients with sinusitis or otitis; chloramphenicol may be useful for treating meningitis caused by susceptible pneumococci in patients who cannot tolerate penicillin, third-generation cephalosporins, or meropenem. Patients with pneumococcal pneumonia can be switched from intravenous to oral antibiotics once they are clinically stable, even if bacteremia was present.[23]

Table 3 Antibiotic Treatment for Penicillin-Resistant *S. pneumoniae*

Drug	*Dosage*	*Comments*
Penicillin G	10–20 million units/day	Despite resistance, high-dose penicillin is effective for pneumonia
Cephalosporins		Relative efficacy high, but cephalosporin resistance occurs*
Ceftriaxone	1 g I.V. q.d.	
Cefotaxime	3 g I.V. q. 6 hr	
Chloramphenicol	1 g I.V. q. 6 hr	Variable efficacy; used sparingly because of toxicity
Rifampin*	600 mg I.V. q. 24 hr	Used as part of combination therapy for meningitis only
Vancomycin	1 g I.V. q. 12 hr	Intermediate efficacy; not justified for pneumonia but can be considered for meningitis*
Fluoroquinolones		High efficacy for pneumonia; resistance to fluoroquinolones has been described
Levofloxacin	500 mg I.V. q.d.	
Gatifloxacin	400 mg I.V. q.d.	
Moxifloxacin	400 mg I.V. q.d.	
Linezolid	600 mg I.V. q. 12 hr	High efficacy for pneumonia; not studied for meningitis
Telithromycin	800 mg p.o., q.d.	High efficacy; macrolide-resistant pneumococci are susceptible to telithromycin and other ketolides
Meropenem	1 g I.V. q. 8 hr	Could be used for cephalosporin-resistant pneumococci, but its effectiveness has not been studied systematically

*Triple-drug therapy with vancomycin, rifampin, and either ceftriaxone or cefotaxime may be necessary for pneumococcal meningitis if the minimum inhibitory concentration of either cephalosporin is > 4 mg/ml. Despite this resistance, vancomycin and cefotaxime demonstrate synergy.

PREVENTION OF PNEUMOCOCCAL INFECTIONS

A vaccine containing 50 μg of purified capsular polysaccharide from 14 pneumococcal types was approved by the Food and Drug Administration in 1977, and an expanded vaccine containing 25 μg of polysaccharide from 23 pneumococcal types was released in 1983. These 23 types account for the great majority of serious pneumococcal infections in the United States, including 88% of invasive infections with penicillin-resistant strains.[17] Because polysaccharide vaccines are not effective in children younger than 2 years, a protein-polysaccharide conjugate vaccine containing approximately 2 μg of polysaccharides from the seven most important strains conjugated to diphtheria toxoid was introduced for pediatric use in 2000.[24]

The 23-valent pneumococcal vaccination produces serum antibody titers that are protective in healthy adults; although most elderly people mount an adequate serologic response, some produce low antibody titers or functionally deficient antibodies. Patients with Hodgkin disease respond better to vaccination before staging laparotomy and splenectomy; chemotherapy markedly impairs the response to vaccination and accelerates the decline in antibody titers. Dialysis and transplant patients may respond to vaccination suboptimally,[25] as do many patients with myeloma, lymphoma, leukemia, AIDS, and low serum vitamin B_{12} levels.

The pneumococcal vaccine is safe.[26] Mild erythema and pain at the injection site may occur in up to one third of vaccine recipients, but fever, severe local reactions, and other serious side effects occur in fewer than 1%. Despite its immunogenicity and safety, the pneumococcal vaccine remains controversial because its efficacy has been difficult to demonstrate in certain population groups. In general, the evidence for efficacy has been stronger for the prevention of invasive pneumococcal disease than for nonbacteremic pneumonias[27]; the evidence is also stronger for the protection of low-risk persons than for the protection of elderly or debilitated patients.

Perhaps as a result of conflicting data, pneumococcal vaccine has not been well accepted, and only 35% of vaccine candidates have been immunized. Given the expense of large-scale field trials, the controversy is unlikely to be resolved in the near future, and recommendations for vaccine use must be formulated from the current information. Because of its safety and modest cost, the pneumococcal vaccine is cost-effective, even in the elderly.[28] The vaccine is recommended for healthy adults older than 65 years and for patients with chronic cardiopulmonary disease, functional or anatomic asplenia (including sickle cell disease), Hodgkin disease, multiple myeloma, cirrhosis, alcoholism, renal failure, CSF leaks, immunosuppression, or HIV infection. Members of certain vulnerable population groups, such as Native Americans, are also candidates for the vaccine. When possible, the vaccine should be administered 2 weeks before elective splenectomy or chemotherapy [*see CE:V Adult Preventive Health Care*].

The pediatric conjugate vaccine is safe and effective[29] and has reduced by 60% the rate of invasive infection caused by vaccine and vaccine-related serotypes in children younger than 5 years. Currently, it is recommended for all infants, as well as for children up to 60 months of age who are at increased risk for pneumococcal infection; vulnerable children older than 5 years should continue to receive the adult 23-valent vaccine.[22]

Although antibody titers wane,[30] routine revaccination is not recommended. Apart from local reactions, however, revaccination after 5 or more years is safe[31] and should be considered for adults who are at the highest risk for pneumococcal infection. The safety of the pneumococcal vaccine during pregnancy has not been evaluated; women who are at high risk for pneumococcal infection should be vaccinated before they become pregnant. The pneumococcal and influenza vaccines may be administered simultaneously at different sites when both are indicated.

Because of vaccine failures, additional strategies have been devised to protect vulnerable patients from pneumococcal infection. Long-term prophylaxis with orally administered low-dose penicillin protects children with sickle cell anemia from acquiring pneumococcal septicemia. It has also been recommended for young children with anatomic or functional asplenia. For asplenic adults, many physicians prefer vaccination with pneumococcal, meningococcal, and *Haemophilus influenzae* type b vaccines; these vaccines can be administered simultaneously. Vulnerable patients should be instructed to seek medical care at the first sign of infection and should be provided with ampicillin for self-administration if medical attention is not immediately available.

Additional work to enhance the efficacy of pneumococcal vaccines is needed. The development of a conjugated polysaccharide-protein vaccine for adults is particularly promising.

Streptococci

The streptococci, a large and diverse group of organisms widely distributed in nature, are part of the normal human flora. They vary in their pathogenic potential from many harmless species to a few very significant pathogens, such as *S. pneumoniae* and *S. pyogenes*.

Streptococci are gram-positive, round to ovoid cocci that can appear in pairs but more characteristically grow in chains of varying length. They are fastidious organisms requiring many nutrients. Although most are facultative anaerobes, some are obligate anaerobes. All species are nonmotile and nonsporulating and lack the enzyme catalase.

When grown on blood agar plates, most streptococci form small (1 to 2 mm), round, nonpigmented colonies. Streptococci are often characterized by changes in the appearance of the blood agar surrounding their colonies. Three types of reaction may occur: α-, β-, and γ-hemolysis. In α-hemolysis, green discoloration results from reduction of red blood cell hemoglobin and not from true hemolysis. In β-hemolysis, lysis of the red blood cells produces clearing of the blood agar. In the γ reaction, there is no change in the agar. Hemolysis alone, however, cannot be used for classification, because biologically dissimilar species can cause identical hemolytic reactions.

A far superior classification is the serologic system. In 1933, Rebecca Lancefield demonstrated that an antigenic carbohydrate could be extracted from the cell wall of streptococci. On the basis of chemical composition and immunologic reactivity of this carbohydrate, hemolytic streptococci can be divided into 18 groups (A through H and K through T). The species within each group tend to be biologically similar and to have a similar human pathogenic potential [*see Table 4*]. There are also separately classified nongroupable and anaerobic streptococci.

GROUP A STREPTOCOCCI

The group A streptococcus, *S. pyogenes*, ranks as one of the most important human pathogens. This organism can be recognized in the laboratory by the generous zone of β-hemolysis produced by most isolates. Up to 4% of group A streptococci, however, may be nonhemolytic while still retaining their full pathogenic potential. Because many other streptococci can produce β-hemolysis, a confirmatory test is necessary to identify β-hemolytic

streptococci as group A. The traditional screening test is the bacitracin test; almost all group A streptococci are inhibited by very low concentrations of bacitracin. Definitive speciation of group A streptococci can now be accomplished rapidly through identification of the group A carbohydrate by immunologic techniques.

The group A streptococcus is structurally complex. The capsule consists of hyaluronic acid, which is similar to the hyaluronic acid of human connective tissue and is therefore nonantigenic. The cell wall is composed of group-specific carbohydrates, structural proteins, and mucopeptide. The group-specific carbohydrate is responsible for the Lancefield serologic grouping; in group A streptococci, this carbohydrate is a polymer of rhamnose and *N*-acetyl glucosamine. Three structural proteins are part of the cell wall. The most important is the M protein, which is a crucial marker of virulence because it impedes phagocytosis by polymorphonuclear leukocytes. Anti-M antibodies are protective because they opsonize the bacteria, thus promoting phagocytosis and killing. Among group A streptococci, there are more than 120 antigenically distinct M proteins and hence more than 120 M types. M typing of strains is useful for epidemiologic purposes. Clearly, a polyvalent M protein vaccine containing the most common M types would be necessary to provide protection in communities.

The third component of the group A cell wall is a mucopeptide composed of repeating units of *N*-acetyl glucosamine and *N*-acetyl muramic acid. This element can produce carditis in laboratory rabbits, but its role in human rheumatic fever is unknown. C5 peptidase is a cell-associated protein that cleaves the C5 component of complement, rendering it inactive. Streptolysin S is a cell-associated hemolysin that lyses red blood cells on contact. The final structural element is the lipid-protein protoplast membrane. This membrane has certain antigens that cross-react with antigens in human cardiac muscle. The importance of this phenomenon in the pathogenesis of rheumatic fever is uncertain.

Epidemiology of Group A Streptococcal Infections

The natural reservoirs of group A streptococci are the human pharynx and skin. Group A streptococci are transmitted by

Table 4 Medically Important Streptococci and Enterococci

Streptococcus *Group*	*Representative Species*	*Hemolysis*	*Characteristics*	*Human Habitat*	*Human Diseases*
A	*S. pyogenes*	β (rarely γ)	Bacitracin sensitive; produces many extracellular enzymes and toxins	Nasopharynx Skin Rectum	Many diseases (*S. pyogenes* is the major human pathogen)
B	*S. agalactiae*	β (α, γ)	May be bacitracin sensitive; hydrolyzes sodium hippurate	Nasopharynx Genitourinary tract	Neonatal sepsis and meningitis Puerperal infections Urinary tract infections Endocarditis
C	*S. equi*	β (α, γ)	May be bacitracin sensitive; produces extracellular enzymes similar to those made by group A	Nasopharynx Genitourinary tract GI tract Skin	Skin and wound infections Bacteremias Endocarditis Pharyngitis
G	*S. canis*	β (α, γ)	Similar to group C	Similar to group C	Similar to group C
D	*S. bovis* *S. equinus*	β, γ (α)	Heat resistant; bile resistant; NaCl sensitive; penicillin sensitive	GI tract Genitourinary tract	Urinary tract infections Bacteremia Endocarditis
F	*S. anginosus*	β (α, γ)	Tiny colonies on blood agar; growth enhanced by 10% CO_2	Oropharynx GI tract Genitourinary tract	Sinusitis Meningitis Brain abscess Pneumonia Endocarditis
H	*S. sanguis*	α (β, γ)	Bile resistant	Oropharynx GI tract	
K	*S. salivarius*	γ (α)	Can grow at 45° C	Oropharynx	
Nongroupable	Viridans streptococci, including *S. mitis*, *S. mutans*, and others	α	No group-specific carbohydrate antigen yet recognized	Oropharynx	Endocarditis
Anaerobic streptococci	Many, including the peptostreptococci	γ (β, α)	Obligate anaerobes; tiny colonies on blood agar; no group-specific carbohydrate	Oropharynx GI tract Genitourinary tract	Sinusitis Pneumonia Lung abscess Empyema Brain abscess Soft tissue infections Bone and joint infections
Enterococci	*Enterococcus faecalis* *E. faecium*	β, γ (α)	Heat resistant; bile resistant; 6.5% NaCl resistant; penicillin resistant	GI tract Genitourinary tract	Endocarditis Peritonitis Urinary tract infections Wound infections

droplets, either from asymptomatic nasopharyngeal carriers or from persons with symptomatic pharyngitis.[32] Both the carrier rate and the incidence of pharyngitis are highest in late winter and early spring, in temperate climates, and in school-aged children. The epidemiology of streptococcal pyoderma is quite different. It is most common in young children and has its peak in late summer and early fall. Group A streptococci can colonize normal skin and spread from person to person by direct contact. Nosocomial transmission can occur, resulting most often in postoperative wound infections or postpartum sepsis. On occasion, streptococcal infections can occur in epidemic fashion as a result of contaminated foods.

Several different M types of group A streptococci may be present in a community over the course of a year; thus, individuals (predominantly children from 5 to 10 years of age) may have three to four episodes of pharyngitis per year. In contrast, although 5% of adults may carry group A streptococci in their throats, symptomatic infection is uncommon, perhaps because of the acquistion of type-specific immunity from frequent pharyngeal infections earlier in life. The epidemiology of specific streptococcal infections varies widely, both geographically and temporally. Currently, scarlet fever and rheumatic fever are uncommon in the Western world, where they were very common as late as the 1940s. Interestingly, in northern climates, streptococcal pharyngitis has not decreased in prevalence over the past 100 years, even in developed countries. Around 1980, there was a dramatic increase in the incidence of severe invasive group A streptococcal infections such as necrotizing fasciitis, bacteremia, and the streptococcal toxic-shock syndrome (TSS); this higher incidence has persisted to the present time.[33]

Pathogenesis of Group A Streptococcal Infections

The ability of streptococci to adhere to mucosal and epidermal surfaces is important for the first step of pathogenesis, colonization. In the throat, colonization appears to be related to the elaboration of fibronectin-binding proteins (protein F). On the skin, group A streptococci adhere to CD44 on the surface of keratinocytes, largely through the bacteria's hyaluronic acid capsule. Adherence through these ligand pairs is sufficient to cause pharyngitis and impetigo, respectively. Although invasion of cell lines of mucosal and keratinocyte origin can occur in vitro, the role of cellular invasion in the pathogenesis of pharyngitis, impetigo, cellulitis, and erysipelas is unclear, because cellular and tissue destruction are either uncommon or are not sufficient to be clinically recognized. Still, an intracellular location could in part explain prolonged carriage and, in some cases, the failure of penicillin to eradicate infection. In necrotizing fasciitis, pneumonia, myositis, and other infections associated with bacteremia, direct invasion probably occurs. The organisms elaborate enzymes such as streptolysin O and S and nicotinamide adenine dinucleotide glycohydrolase (NADase), which can account for their characteristic ability to produce inflammation and tissue damage and to spread rapidly in tissues. Streptokinase catalyzes the conversion of plasminogen to plasmin and thus promotes fibrinolysis. Four distinct streptococcal deoxyribonuclease (DNase) enzymes have been identified; most streptococcal strains produce DNase B. Group A streptococci also produce hyaluronidase, which is known as spreading factor because of its ability to digest the hyaluronic acid of connective tissue. Except for streptolysin S, these enzymes are all antigenic. Although antibodies directed against these enzymes do not protect the patient against recurrent streptococcal infections, the tests for such antibodies can be used to obtain accurate serodiagnosis.

The second most common way in which group A streptococci cause disease is by elaboration of exotoxins, which are responsible for scarlet fever and streptococcal TSS. Three antigenically distinct pyrogenic exotoxins (formerly called erythrogenic toxins)—types A, B, and C—have been recognized for several decades, yet in the past 3 years, 12 additional pyrogenic exotoxins have been discovered. Elaboration of type A and type C pyrogenic exotoxin depends on lysogeny of the streptococci by a bacteriophage; on occasion, certain group C or group G streptococci or even staphylococci can produce a pyrogenic toxin. From the site of the streptococcal infection, which is usually in the pharynx, the toxin enters the circulation, producing the characteristic rash of scarlet fever through an unknown mechanism. In addition, these toxins function as superantigens that simultaneously attach to the major histocompatibility complex of antigen-presenting cells and to V beta regions of the T cell receptor, resulting in generation of inflammatory cytokines (tumor necrosis factor–α [TNF-α], interleukin-1 [IL-1], and IL-6), as well as the lymphokines TNF-β, gamma interferon, and IL-2. These cytokines play important roles in the pathogenesis of shock and organ failure. Antibodies to the toxins prevent development of a rash but do not protect against the underlying infection.

Finally, an immune response to antecedent infection with group A streptococci can produce nonsuppurative syndromes. Acute rheumatic fever (ARF) and acute glomerulonephritis begin 1 to 3 weeks after a group A streptococcal infection, usually when the infection is no longer active. Despite their common origins as poststreptococcal disorders, ARF and acute glomerulonephritis differ significantly in their epidemiologic and pathogenetic features.

Acute Group A Streptococcal Diseases

Upper respiratory tract infection Group A streptococci are the most important cause of bacterial pharyngitis and tonsillitis.[34] They also cause sinusitis, otitis, mastoiditis, cervical lymphadenitis, peritonsillar abscesses, and retropharyngeal abscesses. Rarely, streptococcal pharyngitis has been associated with streptococcal TSS [*see 7:XIX Bacterial Infections of the Upper Respiratory Tract*].

Pneumonia Streptococcal pneumonia is uncommon, accounting for less than 5% of all bacterial pneumonias. Although it is seen most frequently as a sequela of influenza, it can occur as a primary infection and may even produce epidemics in closed groups. Streptococcal pneumonia presents acutely as fever, chills, and productive cough. Its distinguishing features are pleuritic chest pain and rapidly progressive empyemas, both of which occur in approximately 60% of patients.

Lymphadenitis and lymphangitis Group A streptococci are frequently responsible for suppurative lymphadenitis, particularly in patients with streptococcal infections of the respiratory tract or skin. In patients with a variety of soft tissue infections, red streaks that extend proximally are suggestive of group A streptococcal infection and are harbingers of lymphadenitis and subsequent bacteremia.

Wound infections Group A streptococcal wound infections are characterized by early onset, often within 24 hours after surgery or injury. Patients present acutely with fever and sys-

temic toxicity. Frequently, the infected wound appears relatively benign. A modest amount of thin serosanguineous fluid is often present in the wound. Gram stain of a smear of the fluid reveals gram-positive cocci in chains but a relative absence of acute inflammatory cells. If the infection is caused by strains of group A streptococci that produce pyrogenic exotoxins, a diffuse generalized erythema may develop (surgical scarlet fever).

Bone and joint infections Group A streptococci are relatively common causes of infections of bones and joints, usually from bacteremic seeding.

Postpartum infections The incidence of puerperal fever (childbed fever) diminished markedly from the 1850s, when it was common, to the 1990s, but it has increased in frequency over the past decade. The onset is abrupt, most often within 24 to 48 hours after delivery. Fever, chills, systemic toxicity, abdominal or pelvic pain, and a serosanguineous and odorless vaginal discharge are common; without treatment, endometritis may rapidly progress to pelvic peritonitis and bacteremia. These infections have also been associated with streptococcal TSS. Group A streptococci are the classic cause of puerperal fever, but other organisms, including group B streptococci and other streptococci and gram-negative bacilli, can cause infections with similar clinical features.

Bacteremia The incidence of group A streptococcal bacteremia appears to be rising. It often develops from a primary infection of skin, soft tissue, or a wound.[35] The respiratory tract is the second most common source, but bacteremia after uncomplicated streptococcal pharyngitis is uncommon. In 18% of cases, no primary focus of infection can be identified. About 80% of patients have underlying problems, ranging from diabetes or malignancies to drug abuse. Osteomyelitis, septic arthritis, meningitis, and endocarditis[36] are among the potential complications; overall mortality is 15%. Bacteremia is present in 60% of patients with necrotizing fasciitis and streptococcal TSS. Although meningitis can result from group A streptococcal bacteremia, this rare infection is more often a sequela of neurosurgical conditions.[37]

Skin and soft tissue infections Group A streptococci are important causes of cutaneous infections, which can range from very superficial infections of the epidermis (e.g., impetigo) to deeper subcutaneous infections with systemic symptoms (e.g., erysipelas or cellulitis)[38] to life-threatening processes (e.g., necrotizing fasciitis and gangrenous myositis) that require surgery and antibiotic therapy[39] [*see 2:VII Fungal, Bacterial, and Viral Infections of the Skin*].

Necrotizing fasciitis The widespread publicity that has been given to necrotizing fasciitis (previously known as streptococcal gangrene) has fueled popular concern about invasive group A streptococcal infections. An estimated 10,000 to 15,000 cases of invasive group A streptococcal infections occur each year in the United States; of these, necrotizing fasciitis occurs in 5% to 10%, with a case-fatality rate of about 30%. Most group A streptococci that cause invasive disease produce pyrogenic (formerly erythrogenic) toxin, but the genetic heterogenicity of causative strains does not support a clonal basis for the resurgence of invasive streptococcal infections.

Group A streptococcal necrotizing fasciitis is usually community acquired and sporadic in nature.[39] It occurs in all age groups. Many patients have predisposing conditions, which may include chickenpox, trauma, diabetes, or alcoholism.[40,41] In roughly 50% of patients, necrotizing fasciitis begins at the site of cutaneous penetrating trauma such as burns, insect bites, sliver injuries, abrasions, chickenpox vesicles, or surgical incisions. In the remaining cases, necrotizing fasciitis begins at the site of nonpenetrating deep trauma such as hematoma, ankle sprain, tendon rupture, or muscle tear. Most likely, group A streptococci translocate from the pharynx to the site of injury via the bloodstream. Because this type of infection begins deep within fascia and muscle, cutaneous changes are initially less prominent than pain, swelling, and systemic toxicity. Without aggressive therapy, however, the necrosis spreads to the skin and deep tissues. Computed tomography or magnetic resonance imaging can help define the depth and extent of infection, but in patients with preexisting trauma, infection may be difficult to distinguish from trauma alone. In addition to antibiotics and meticulous metabolic and circulatory support, prompt and aggressive surgical debridement is required; amputation may be necessary. Bacteremia and toxic streptococcal syndrome often complicate necrotizing fasciitis and are adverse prognostic features.

Diseases Caused by Toxin Production

Streptococcal toxic-shock syndrome Since the first description of streptococcal TSS in 1987, the incidence of this disorder has remained relatively constant.[42] Like staphylococcal TSS [*see* Staphylococci, *below*], streptococcal TSS appears to be mediated by a toxin, which in the case of the streptococcal form is probably a pyrogenic exotoxin. Like the staphylococcal toxin, the streptococcal toxin enters the circulation and functions as a superantigen, stimulating the release of host proteins that appear to mediate the shock syndrome.

The primary focus of infection is most often a soft tissue infection; respiratory infections are the next most common focus. Hypotension occurs in all patients and is often severe. Clinical features can include a generalized erythematous rash (10% of cases) that may undergo desquamation; acute respiratory distress syndrome (60% of cases); renal failure (80% of cases); and soft tissue necrosis, such as necrotizing fasciitis or myositis. Laboratory evidence of multiorgan involvement typically can be found and characteristically includes evidence of renal impairment, hepatic abnormalities, and disseminated intravascular coagulation, though clinical evidence of coagulopathy is rarely present.[43]

Management issues are complex and are reviewed in detail elsewhere,[43] but aggressive fluid replacement is crucial; with it, hypotension resolves in 50% of patients. Patients with refractory hypotension may require replacement of albumin and correction of hypocalcemia. Brisk hemolysis can occur, particularly in the 60% of patients who have bacteremia, and may necessitate transfusion. Surgical consultation and aggressive surgical debridement of devitalized tissue are also crucial. Dialysis is necessary in patients who experience renal failure; ventilatory support is necessary in acute respiratory distress syndrome. Mortality in most streptococcal TSS series ranges from 30% to 70%. Intravenous immunoglobulin looked promising in initial case reports and in one observational study, but a subsequent double-blind study in Scandinavia did not demonstrate significant reduction in mortality or attenuation of necrotizing fasciitis, though the trial was cut short because of low enrollment.[44] Earlier diagnosis, aggressive fluid resuscitation, and appropriate antibiotics may be responsible for the somewhat lower mortalities reported in more recent series.[43]

Scarlet fever The incidence of scarlet fever has declined sharply in the antibiotic era. The initial symptoms are fever and sore throat. Within 1 to 5 days, the characteristic fine, red, sandpaperlike eruption appears, often beginning on the chest and rapidly spreading to other parts of the body. Although the tongue and buccal mucosa are classically involved, the perioral area may be spared, thus accounting for the typical circumoral pallor. The rash is caused by hyperemia and capillary damage produced by pyrogenic toxin. In areas of trauma, such as the antecubital fossae, punctate hemorrhages (Pastia sign) may occur. Nausea and vomiting may be present, and fever and prostration may be severe. Desquamation of skin and mucous membranes is prominent during healing; one characteristic feature is the strawberry tongue. Therapy is the same as that for the underlying streptococcal infection.

Delayed Diseases Caused by the Host Immune Response

Group A streptococci can produce disease by a mechanism that is rarely a feature of other infections—a host immune response that subsequently produces tissue damage. ARF and acute glomerulonephritis are the major syndromes produced in this fashion; both are characterized by a latent period between the streptococcal infection and its inflammatory consequences. Erythema nodosum is a third poststreptococcal syndrome, but it is less specific and less serious than ARF and acute glomerulonephritis.

Acute rheumatic fever ARF is strictly a sequela of streptococcal pharyngitis. Although many strains of group A streptococci can provoke ARF, the syndrome most often follows pharyngeal infection by certain M protein types (especially M5, M18, and M3), which are heavily encapsulated, mucoid organisms. In about half the cases, the antecedent pharyngitis is clinically silent, but all patients with ARF have serologic evidence of a recent group A streptococcal infection. The risk of ARF after untreated streptococcal pharyngitis is less than 3%; the latent period between the pharyngitis and the onset of ARF averages 18 days.

Although common in developing nations, ARF is now quite uncommon in industrialized nations. However, the occurrence of several outbreaks in the United States in the 1980s demonstrates that ARF can still be an important problem in affluent societies. The disease occurs most often in children from 5 to 15 years of age; adults may present with atypical features, including synovitis without carditis.

Despite intensive study, the pathogenesis of ARF is unclear. The most widely held theory proposes that a genetically susceptible host develops an autoimmune response to epitopes in the organism that are cross-reactive with epitopes in tissues of the heart, joints, skin, or CNS.[45] Alternatively, streptococcal toxins or immune complexes may create alterations in tissue antigens that in turn provoke an autoimmune response that damages host tissues.

There are five major clinical manifestations of ARF: carditis, polyarthritis, chorea, subcutaneous nodules, and erythema marginatum. Carditis develops in about 60% of patients; it involves the endocardium, myocardium, and pericardium. The typical manifestations of rheumatic carditis are sinus tachycardia (sometimes with first-degree heart block), mitral regurgitation, a pericardial friction rub, and cardiomegaly; congestive heart failure indicates severe carditis. Although most cases of carditis resolve within 3 months, patients with moderate to severe carditis or recurrent ARF are at risk for the late manifestation of mitral valve or aortic valve scarring [*see 1:XI Valvular Heart Disease*]. Polyarthritis develops in about 70% of patients with ARF. It is characteristically a migratory arthritis involving the large joints of the extremities; it resolves without sequelae in days to weeks.[46] On rare occasions, adults may develop a persistent arthropathy of the hands and feet. Chorea, subcutaneous nodules, and erythema marginatum are all self-limited; each occurs in fewer than 10% of children with ARF and only very rarely in adults.

Table 5 Revised Jones Criteria for the Diagnosis of Acute Rheumatic Fever[47]

Major manifestations	Carditis Polyarthritis Chorea Erythema marginatum Subcutaneous nodules
Minor manifestations	Clinical Previous rheumatic fever or rheumatic heart disease Arthralgia Fever Laboratory Elevated acute-phase reactants Erythrocyte sedimentation rate C-reactive protein level Prolonged PR interval
Supporting evidence of streptococcal infection	Increased titer of antistreptococcal antibodies (e.g., anti–streptolysin O) Positive throat culture for group A *Streptococcus*

Note: The presence of two major manifestations or of one major and two minor manifestations indicates a high probability of acute rheumatic fever, if there is supporting evidence of group A streptococcal infection.

The minor manifestations of ARF are fever, arthralgias, and inflammation. The inflammation in such cases is evidenced by elevated erythrocyte sedimentation rates and C-reactive protein levels.

The diagnosis of ARF is made on the basis of clinical features. The classic Jones criteria include the presence of either two major manifestations or one major and two minor manifestations, as well as laboratory evidence of a recent streptococcal infection (e.g., a positive throat culture or rising antistreptococcal antibody levels) [*see Table 5*].[47]

Treatment of ARF focuses on eradication of streptococcal pharyngitis and reduction of inflammation [*see Table 6*]. Most clinicians recommend a course of penicillin or, as an alternative, other antistreptococcal antibiotics, even if the throat culture is negative at the time ARF is diagnosed. Anti-inflammatory therapy includes aspirin and bed rest until inflammatory symptoms resolve; corticosteroids may have a role for patients with severe carditis.

ARF can be prevented by adequate treatment of streptococcal pharyngitis, even if antibiotics are delayed for up to 9 days after the onset of pharyngitis. Patients with a history of ARF are particularly vulnerable to recurrent attacks. Consequently, they should receive continuous prophylaxis for at least 5 years with daily oral penicillin (250 mg twice a day) or monthly injections of 1.2 million units of benzathine penicillin G. Oral sulfadiazine or erythromycin may be administered to patients allergic to penicillin. Prophylaxis can be discontinued when young patients who are at low risk for recurrence reach adulthood or when small children are no longer in the household.

Table 6 Drug Treatment for Acute Rheumatic Fever[93]

Drug	*Dosage*	*Comments*
Penicillin	Acute treatment: Benzathine penicillin G, 1.2 million units I.M. Penicillin V,* 500 mg p.o., b.i.d.–t.i.d. Prophylaxis: Penicillin VK, 250 mg p.o., b.i.d. Benzathine penicillin G, 1.2 million units I.M. q. 4 wk	Acute treatment is given for patients with acute rheumatic fever who have a positive throat culture for group A *Streptococcus;* benzathine penicillin can be given if compliance is uncertain; prophylaxis for patients with history of acute rheumatic fever is begun immediately after the acute episode and continued until the patient reaches young adulthood
Sulfadiazine	1 g p.o., q.d	For prophylaxis in patients allergic to penicillin
Erythromycin	Acute treatment: erythromycin ethylsuccinate, 250 mg q.i.d. Prophylaxis: 250 mg p.o., b.i.d.	Acute treatment or prophylaxis for patients allergic to penicillin
Aspirin	90–100 mg/kg/day for 2 wk, then 60–70 mg/kg/day for 6 wk	Anti-inflammatory agents do not alter the development of chronic heart disease but reduce symptoms; blood salicylate levels of 20 mg/100 ml are desirable
Prednisone	40–60 mg q.d. for 2 wk, then taper off over 3 wk	Prednisone or a nonsteroidal anti-inflammatory drug can be used when symptoms are not controlled with aspirin alone

*Phenoxymethyl penicillin.

Acute glomerulonephritis Acute poststreptococcal glomerulonephritis appears to result from the deposition of circulating antigen-antibody complexes and complement in renal glomeruli [*see 10:V Glomerular Diseases*]. Only group A streptococci of certain M protein types can produce glomerulonephritis; it is unknown why only approximately 15 of the more than 80 M types are nephritogenic. Acute glomerulonephritis can follow either streptococcal pharyngitis or pyoderma but is more common after skin infections.

The incidence of acute glomerulonephritis after infection with nephritogenic streptococci varies but may reach 10% to 15% in certain epidemic situations. The prognosis is generally good, especially in children, and recurrences are uncommon; therefore, penicillin prophylaxis is not indicated. In fact, it is not certain that penicillin therapy for streptococcal pharyngitis or pyoderma affects the incidence of subsequent acute glomerulonephritis.

Erythema nodosum The painful pretibial nodules of erythema nodosum can develop after streptococcal infections of the skin, pharynx, or other sites. However, this nonsuppurative sequela may be associated with other infectious processes, such as tuberculosis or systemic mycoses, and with noninfectious processes, such as inflammatory bowel disease or hypersensitivity reactions.

Diagnosis of Group A Streptococcal Infections

The diagnosis of group A streptococcal infections depends on recognizing the clinical syndromes and culturing the bacterium from appropriate specimens. Streptococcal pharyngitis can be diagnosed rapidly by detecting streptococcal antigens on throat swab specimens, but results are dependent on the type of rapid test and the expertise of the laboratory technician [*see 7:XIX Bacterial Infections of the Upper Respiratory Tract*]. Rapid tests have incomplete sensitivity, so if a rapid test is negative, a throat culture should be obtained. Serologic tests may be extremely useful, albeit retrospectively, in documenting recent streptococcal infection. Many of the enzymes and toxins produced by group A streptococci are antigenic, and a variety of antibody tests are available. The most widely used is the anti–streptolysin O titer, which is elevated after most respiratory tract infections; anti-DNase B titers are also elevated after most group A streptococcal infections [*see Table 7*].

Treatment of Group A Streptococcal Infections

Despite the widespread use of penicillin, group A streptococci continue to be uniformly sensitive to this agent, which remains the drug of choice. The dose schedule and duration vary enormously. The standard therapy for pharyngitis is 10 days of low-dose oral penicillin (or a single I.M. dose of benzathine penicillin G), but a large trial suggested that 5 days of therapy with various

Table 7 Laboratory Tests for Streptococcal Pharyngitis[94]

Test	*Sensitivity (%)*	*Specificity (%)*	*Comments*
Rapid tests	70–90	95	Results are operator dependent; only qualified personnel should perform the test
Anti-streptolysin O titer	80	90	Elevation may also occur after infection with group C or G streptococci; a single titer > 200 Todd units/ml is significant; a rise in titer of > 2 dilutions between acute and convalescent sera is significant; responses are good after throat infections and poor after skin infections
Anti-DNase B titers	80	95	Consistent titer rises after throat or skin infection
Anti-hyaluronidase titers	80	95	Consistent titer rises after throat or skin infection

DNase—deoxyribonuclease

β-lactams or macrolides may be as effective.[48] Similarly, although oral penicillin is usually administered four times a day, a meta-analysis found that twice-daily dosing is as effective for children.[49] In contrast, more invasive streptococcal infections require much more intensive treatment, such as prolonged high-dose I.V. therapy for osteomyelitis or endocarditis. In patients who are allergic to penicillins, cephalosporins are effective but must be used with caution because of the risk of allergic cross-reactivity. Erythromycin, vancomycin, and clindamycin are generally excellent alternatives, although occasionally, clinical isolates are resistant to these agents. Erythromycin-resistant strains have become prevalent, especially in Japan and Finland and, more recently, in the eastern United States. Reducing the use of macrolide antibiotics can control this problem. Many strains of group A streptococci are now resistant to tetracyclines and TMP-SMX. The newer fluoroquinolones levofloxacin, sparfloxacin, gatifloxacin, and moxifloxacin are active against group A streptococci, but these agents are not indicated in children. In patients with necrotizing fasciitis and streptococcal TSS, clindamycin's ability to suppress streptococcal toxins may make it preferable to penicillin.

INFECTIONS CAUSED BY NON–GROUP A STREPTOCOCCI

Streptococci belonging to all the Lancefield groups can cause disease ranging in severity from urinary tract infections to meningitis, bacteremia, and endocarditis [*see Table 4*]. None of the non–group A organisms, however, have been implicated in rheumatic fever.

Groups C and G Streptococci

Groups C and G streptococci have many similarities to group A streptococci, although they are much less commonly implicated as pathogens. Most strains of groups C and G are β-hemolytic, and some are bacitracin sensitive. Bacteria in both groups can produce many of the same enzymes and toxins produced by group A streptococci, including streptolysin O, streptokinase, NADase, DNase, hyaluronidase, and pyrogenic toxin. The group-specific carbohydrate of group C is similar to that of group A, and groups A, C, and G all have cross-reacting cell membrane antigens.

First recognized as animal pathogens, groups C and G streptococci may be part of the resident flora of the pharynx, skin, genitourinary tract, and gastrointestinal tract.[50] Group C streptococci can cause pharyngitis in adults. Groups C and G streptococci can cause skin and wound infections, puerperal sepsis, bacteremia, endocarditis, pericarditis, septic arthritis, meningitis, scarlatiniform eruptions, myositis, and TSS.[51] In rare instances, groups C and G streptococci cause poststreptococcal glomerulonephritis. Groups C and G streptococci are sensitive to penicillin, which is the drug of choice, and to erythromycin, vancomycin, and other antibiotics.

Group B Streptococci

Group B streptococci are important human pathogens.[52] Most group B streptococci are β-hemolytic; up to 20% are sensitive to low-dose bacitracin. They can be presumptively separated from group A streptococci on the basis of their ability to hydrolyze sodium hippurate, but definitive identification depends on immunologic identification of the group B carbohydrate.

Group B streptococcal infections are the leading cause of bacterial disease and death in newborns; maternal infections can also occur in the peripartum period.[52] The organisms reside in the vagina and infect neonates during passage through the birth canal; premature labor, prolonged membrane rupture, and intrapartum fever are risk factors for neonatal infection. The intrapartum administration of antibiotics to women at high risk can prevent neonatal infection; screening during the third trimester of pregnancy and treatment with penicillin have substantially reduced the incidence of perinatal and peripartum group B streptococcal infections.[53]

Group B streptococci can cause a broad range of infections in nonpregnant adults. Persons of any age can be affected, but elderly patients are most vulnerable.[54] Other risk factors include genitourinary disorders, diabetes, cancer, HIV infection, and peripheral vascular disease. In addition to bacteremia, infections caused by group B streptococci include urinary tract infections, septic arthritis, endocarditis, meningitis, pulmonary infections, and infections of the skin, soft tissue, and wounds. Necrotizing fasciitis and streptococcal TSS[55] have also been reported.

Although group B streptococci are sensitive to clinically achievable levels of penicillin, the MICs are somewhat higher than those for group A streptococci. The great majority of group B streptococci are sensitive to ampicillin, cephalosporins, vancomycin, erythromycin, and clindamycin but are resistant to tetracycline.

Group D Streptococci

Group D streptococci (*S. bovis* and *S. equinus*) can be identified in the laboratory by their ability to resist heat and bile but not 6.5% NaCl broth. Both species reside in the human GI and genitourinary tracts. *S. equinus* rarely causes human disease, but *S. bovis* is a relatively common cause of endocarditis, which may be more severe than the subacute bacterial endocarditis caused by viridans streptococci.[56] *S. bovis* bacteremia is significantly linked to carcinoma of the colon; therefore, the GI tract of any patient with this infection should be aggressively evaluated. *S. bovis* is sensitive to penicillin and other antibiotics and responds well to therapy with penicillin alone.

Nongroupable Streptococci

Up to 30% of streptococcal isolates are not groupable under the currently available Lancefield antisera classification. These organisms are capable of producing a great variety of pyogenic infections, among which subacute bacterial endocarditis stands out as the most important. Nongroupable streptococci can also cause bacteremia and pneumonia, especially in immunosuppressed patients[57]; meningitis is rare.[58] Members of the *S. milleri* group have a propensity to produce abscesses, particularly in the brain or liver.[59] Classically, subacute endocarditis is caused by viridans streptococci—nongroupable, α-hemolytic bacteria that are part of the normal flora of the oropharynx [*see 7:XVIII Infective Endocarditis*]. Many species of viridans streptococci can cause endocarditis; *S. sanguis*, *S. mutans*, *S. mitis*, and members of the *S. milleri* group are commonly responsible. Infections caused by members of the *S. milleri* group may be more destructive than those caused by the other species. About 10% of viridans streptococci are nutritionally variant, requiring supplementary pyridoxal to grow on agar plates. Up to one third of these organisms require serum penicillin levels of greater than 0.1 μg/ml to inhibit growth. Although this level is higher than the levels that kill most other streptococci, this concentration can be easily achieved clinically. Synergistic penicillin-aminoglycoside therapy has been recommended for endocarditis caused by these organisms. Penicillin-tolerant and penicillin-resistant strains of viridans streptococci have been

increasingly recognized; vancomycin or penicillin-aminoglycoside therapy has been recommended for endocarditis caused by penicillin-resistant streptococci.

Anaerobic Streptococci

Various anaerobic and microaerophilic streptococci reside in the oropharynx, the GI tract, and the genitourinary tract. These organisms cause a great variety of infections, including aspiration pneumonia, lung abscess, empyema, sinusitis, brain abscess, bone and joint infections, and skin and wound infections. Anaerobic streptococci often participate in these processes, along with other anaerobic or aerobic bacteria. Foul-smelling pus is characteristic of these infections, and gas may be present in soft tissues. The anaerobic streptococci are penicillin sensitive.

Enterococci

Although they were long considered to be streptococci, the enterococci have been reclassified into their own genus, *Enterococcus*. Of the infections caused by enterococci, 80% to 85% are caused by *E. faecalis;* most of the others are caused by *E. faecium,* but *E. durans, E. avium,* and other species can also cause disease in humans. Morphologically indistinguishable from streptococci and immunologically similar to members of group D streptococci, the enterococci are metabolically unique in their ability to resist heat, bile, and 6.5% NaCl broth. Unlike streptococci, enterococci are uniformly penicillin resistant. Both major enterococcal species reside in the GI and genitourinary tracts, and both can cause urinary, abdominal, and disseminated infections, including endocarditis on preexisting valvular lesions.

PATHOGENESIS OF ENTEROCOCCAL INFECTIONS

The primary reason enterococci have emerged as major human pathogens is that these organisms are resistant to many antibiotics. Enterococci are intrinsically resistant to penicillin because they have unique penicillin-binding proteins that permit cell wall synthesis to proceed even in the presence of β-lactam antibiotics. In addition, enterococci that produce β-lactamase have been recognized; although these strains are still relatively uncommon, they may pose problems in the future. Enterococci can also demonstrate low-level resistance to aminoglycosides, but synergistic therapy with a penicillin and an aminoglycoside has been successful against most species. However, high-level resistance to the aminoglycosides streptomycin and gentamicin has emerged during the past 20 years. More recently, vancomycin-resistant enterococci (VRE) have been recognized as nosocomial pathogens.[60] VRE colonization of the GI tract and skin often precedes overt infections. Colonization and infection are usually hospital-acquired; they are most common in patients who have prolonged hospitalizations or serious underlying diseases or who have undergone previous therapy with multiple antibiotics. Antibiotics that are active against anaerobes are particularly likely to promote intestinal colonization.[61] VRE are often carried by medical personnel and can spread from patient to patient. Because they often occur in very ill patients and are so difficult to treat, VRE infections pose a major threat. The mortality associated with VRE bacteremia approaches 45%.[59]

CLINICAL ENTEROCOCCAL INFECTIONS

Enterococci, alone or with other enteric organisms, are relatively common causes of urinary tract infections, wound infections, and peritonitis and intra-abdominal abscesses. Enterococci have become an increasingly prominent cause of bacteremia,[62] which usually originates from a focus in the urinary tract or abdomen; the incidence of nosocomial bacteremias caused by these organisms is also increasing, particularly in patients who have received cephalosporins or other broad-spectrum antibiotics. Enterococcal endocarditis may affect normal, diseased, or prosthetic valves and may pursue an acute destructive course. Enterococcal meningitis is much less common but may be very difficult to treat. Enterococcal infections are most common in persons with underlying genitourinary or GI disease, in the elderly, and in debilitated persons. Enterococci have become an important cause of disease in hospitalized patients; they are now the second most common nosocomial pathogen in the United States, occurring less commonly than *Escherichia coli* but more commonly than *Pseudomonas aeruginosa* and *Staphylococcus aureus*.

TREATMENT OF ENTEROCOCCAL INFECTIONS

Changing resistance patterns will necessitate changes in antibiotic therapy for patients with enterococcal infections [*see Table 8*]. Traditionally, ampicillin has been the drug of choice for enterococcal urinary tract infections, largely because of the high concentrations of drug excreted in the urine. In penicillin-allergic patients, nitrofurantoin, a fluoroquinolone, or TMP-SMX may be effective for the treatment of simple urinary tract infections; however, because in vitro susceptibility testing of enterococci is often misleading and because resistance to these agents may rapidly emerge, patients should be continually evaluated through assessment of their clinical response and by use of follow-up cultures.

Deep tissue and bloodstream infections have traditionally been treated with ampicillin and gentamicin, with vancomycin, or with vancomycin and gentamicin. Although these agents are still appropriate for most enterococcal infections, all clinically significant isolates should be subjected to testing for β-lactamase production, high-level aminoglycoside resistance, and vancomycin resistance to determine whether an alternative therapy is necessary. Infections caused by enterococci that produce β-lactamase can be treated with an antimicrobial agent that combines a penicillin with a β-lactamase inhibitor. Infections caused by strains that are highly resistant to aminoglycosides can be treated with vancomycin. Infections caused by vancomycin-resistant strains are the most difficult to treat; linezolid has been particularly helpful, and quinupristin-dalfopristin is also effective.[63] Doxycycline, chloramphenicol, and, for urinary tract infections, nitrofurantoin have also been used. In all cases, removal of infected indwelling catheters and foreign bodies and drainage of septic foci are essential. It is also essential to limit the spread of VRE by intensive surveillance, infection-control measures,[64] and prudent use of vancomycin and other antibiotics.

Staphylococci

Staphylococci are nonsporulating, nonmotile gram-positive cocci that have an average diameter of 1 μm. Microscopically, staphylococci tend to be larger and rounder than streptococci. Because cell division occurs on three planes, these organisms are typically found in grapelike clusters and tetrads, as well as in pairs and sometimes in short chains. When grown on blood agar, staphylococci form small (1 to 2 mm), smooth, round colonies that are often pigmented and may be surrounded by a zone of β-hemolysis.

Table 8 Antibiotic Treatment for Enterococcal Infections[95]

Drug	*Dose*	*Comments*
Ampicillin + gentamicin	Ampicillin: 2 g I.V. q. 4 hr Gentamicin: 1 mg/kg I.V. q. 8 hr	Indicated in patients with endocarditis or meningitis*
Vancomycin + gentamicin	Vancomycin: 1 g I.V. q. 12 hr Gentamicin: 1 mg/kg I.V. q. 8 hr	For penicillin-allergic patients*
Ampicillin-sulbactam	2 g I.V. q. 4 hr	For infections caused by enterococci that produce β-lactamase; these appear to be rare
Vancomycin	1 g I.V. q. 12 hr	For infection caused by strains resistant to aminoglycosides
Linezolid	600 mg q. 12 hr I.V. or p.o.	For infection caused by vancomycin-resistant strains
Quinupristin-dalfopristin	7.5 mg/kg I.V. q. 8 hr	For infection caused by vancomycin-resistant strains; not effective against *E. faecalis*
Doxycycline	100–200 mg I.V. or p.o. q. 12 hr	For infection caused by vancomycin-resistant strains; experience very limited
Chloramphenicol	500 mg I.V. or p.o. q. 6 hr	For infection caused by strains resistant to vancomycin, aminoglycosides, and penicillin
Nitrofurantoin	100 mg p.o. q. 12 hr	For urinary tract infections caused by vancomycin-resistant strains

*If high-level resistance to gentamicin (500–2,000 μl) is detected, perform susceptibility testing to streptomycin; substitute streptomycin if sensitive.

Staphylococci are very hardy organisms and can withstand much more physical and chemical stress than pneumococci and streptococci. For example, staphylococci resist drying, withstand 10% NaCl broth, and will survive and even replicate at temperatures between 10° and 45° C. Because staphylococci are facultative anaerobes, they will grow in the presence or absence of oxygen. Staphylococci are catalase positive.

Of the species of staphylococci, *S. aureus* is by far the most important human pathogen. *S. aureus* can be tentatively identified in the laboratory on the basis of its production of a golden-yellow pigment, which may not be apparent until after 24 hours of growth. Because some strains are nonpigmented, definitive identification of *S. aureus* depends on its ability to produce the enzyme coagulase and to ferment mannitol. The most important coagulase-negative organism is *S. epidermidis,* which is universally present as part of the normal skin flora but can produce disease in certain circumstances, such as infection of an indwelling prosthesis. Another important coagulase-negative species is *S. saprophyticus,* which causes urinary tract infections.

STAPHYLOCOCCUS AUREUS

The cellular structure of *S. aureus* is complex.[65] Most strains have polysaccharide microcapsules.

The cell wall of *S. aureus* is structurally similar to that of group A streptococci: both have a carbohydrate antigen, a protein component, and a mucopeptide. The carbohydrate antigen is a teichoic acid, which in *S. aureus* is a polymer of *N*-acetylglucosamine and polyribitol phosphate. Antibodies to teichoic acid can be detected in normal human serum, and elevated antibody titers are present in patients with deep-seated staphylococcal infections. Teichoic acid has no established role in virulence, and antibodies to this carbohydrate are not protective. The protein component of the cell wall includes protein A, which reacts with IgG of normal human serum. Protein A interacts with the Fc component rather than the Fab component of IgG and hence is not a true antigen. Protein A may be antiphagocytic, but its role in virulence has not been clearly established. The cell wall mucopeptide of staphylococci is structurally similar to the mucopeptide of other gram-positive bacteria.

Epidemiology of Staphylococcal Infections

S. aureus is an extremely widespread organism; it can be cultured from environmental surfaces, clothing, bedding, and the air, although transmission of staphylococci by airborne droplets or fomites does not appear to be a major route of infection. Humans—either asymptomatic carriers or persons with staphylococcal lesions—are the reservoir of infection. Nasal carriage is common; rates of nasal carriage range from 15% to more than 50% and are increased in hospitalized patients, dialysis patients, intravenous drug users, and insulin-injecting diabetic patients. Other relatively common sites of colonization include the rectum, the perineum, and the pharynx. *S. aureus* can often be cultured from normal skin, but skin colonization is probably brief, with repeated repopulation occurring from the nose. It is unclear why some persons are prolonged carriers, others are transient carriers, and others resist colonization and why some persons carry many organisms, whereas others have low colony counts. Person-to-person transmission is more likely from nasal carriers of large numbers of organisms and from persons with active staphylococcal infections of the skin or respiratory tract. Nasal carriage increases the risk of bacteremia and of skin and wound infections, including recurrent furunculosis[66]; upper respiratory tract viral infections appear to increase bacterial shedding by *S. aureus* nasal carriers. Periodic application of mupirocin ointment in nasal carriers reduces the rate of carriage and lowers the risk of skin infections.

Minor staphylococcal infections are extremely common. It is the rare person who has not at some time experienced a staphylococcal furuncle (boil), paronychia, or hordeolum (sty). Serious staphylococcal infections generally require a predisposing insult to host defenses. Most often, this takes the form of skin disease, trauma, or a viral infection of the respiratory tract, especially influenza or measles. Other predisposing factors include foreign bodies, liver disease, neoplasia, diabetes, renal failure, defects in leukocyte or immunoglobulin function, narcotics addiction, and broad-spectrum antibiotic therapy.

Unlike the incidence of infections from other gram-positive cocci, the incidence of serious staphylococcal infection increased sharply after the introduction of antibiotics. Much of this increase can be attributed to the development of antibiotic resis-

tance. When penicillin was first introduced, fewer than 10% of staphylococci were penicillin resistant; this percentage has increased steadily and now includes the great majority of staphylococci. During the late 1950s, staphylococcal infection reached epidemic proportions, and hospital-acquired infections were a particularly grave problem. With the introduction of methicillin in 1959 and other penicillinase-resistant antibiotics in the 1960s, the incidence of nosocomial staphylococcal infection temporarily declined. Unfortunately, however, methicillin-resistant staphylococci have slowly but progressively emerged as major nosocomial pathogens in many parts of the world. In addition, in recent years, community-acquired methicillin-resistant *S. aureus* (MRSA) infections have increased in prevalence in many regions of the United States, Japan, and Southeast Asia. Vancomycin-intermediate and vancomycin-resistant strains have appeared in both Japan and the United States.[67]

Pathogenesis of Staphylococcal Infections

The earliest tissue response in staphylococcal infection is acute inflammation with a vigorous exudation of polymorphonuclear leukocytes. Vascular thrombosis and tissue necrosis quickly lead to abscess formation. As a result of the development of a fibrin meshwork and, later, fibroblast proliferation, these abscesses become walled-off zones of loculated infection and tissue destruction, with dying leukocytes and viable bacteria at the center. Fibrosis and scarring are often prominent in healing.

Most strains of *S. aureus* produce a variety of extracellular products, including both enzymes and toxins, that may account for the tendency to produce burrowing, destructive, localized infections. The enzyme coagulase causes plasma to clot, thus promoting the fibrin meshwork that contributes to abscess formation. Staphylococci can also produce lipase, protease, hyaluronidase, and DNase, which can add to tissue damage. Another important enzyme is penicillinase. Because penicillinase has no role in pathogenicity, staphylococci that produce penicillinase are no more virulent than non–penicillinase-producing strains. Nevertheless, this enzyme is clinically and epidemiologically important because it hydrolyzes the β-lactam ring of penicillin, thereby inactivating the molecule. The production of penicillinase is controlled by plasmids, or episomes, which are extrachromosomal DNA molecules that replicate during cell division. Unlike the R factors of gram-negative bacilli, however, the plasmids responsible for penicillinase production do not usually mediate resistance to multiple antibiotics.

Of even greater interest are the nonenzymatic toxins produced by *S. aureus*. α-Toxin is a cytotoxin that produces pores in cell membranes, thereby altering their permeability and resulting in cell damage or death. α-Toxin damages red and white blood cells and activates platelets. Injection of α-toxin into animals can produce dermal necrosis and contraction of vascular smooth muscle, leading to tissue ischemia. Another potential virulence factor is leukocidin, which consists of two leukotoxic proteins that are capable of disrupting lysosomal membranes. Occasionally, strains of staphylococci produce exfoliatin, which causes the epidermolysis characteristic of staphylococcal scalded skin syndrome (SSSS). Some strains of staphylococci can also produce one of four antigenically distinct enterotoxins that cause the vomiting and diarrhea characteristic of staphylococcal food poisoning. In rare instances, staphylococci produce an erythrogenic toxin that causes scarlet fever. Finally, a staphylococcal exotoxin, toxic-shock syndrome toxin–1 (TSST-1), appears to be responsible for menstrually related staphylococcal TSS. Interestingly, staphylococcal TSS associated with nasal packing and other surgical wound infections is mediated by one of the enterotoxins, most commonly enterotoxin-B.

Host resistance and immunity to staphylococci are poorly understood. The importance of the granulocyte is supported by the susceptibility to staphylococcal infections seen in patients with neutropenia or various disorders of neutrophil function, such as chronic granulomatous disease, Chédiak-Higashi syndrome, and various disorders of chemotaxis, such as the lazy leukocyte syndrome. The most important factors predisposing to staphylococcal infections are not immunologic defects but mechanical defects. Minute skin abrasions, for example, probably provide the portal of entry in staphylococcal skin infections and in many cases of staphylococcal bacteremia. I.V. drug abuse accounts for many cases of staphylococcal bacteremia and endocarditis. Indwelling venous catheters are particularly important in nosocomial infections; plastic catheters become coated with fibrinogen and fibrin, which interact with adhesins on the bacterial cell surface and bind staphylococci to the catheter.

Clinical Staphylococcal Infections

Skin and soft tissue infections The most frequent manifestations of staphylococcal disease are skin and soft tissue infections. These range from processes that can cause great discomfort but are rarely hazardous, such as impetigo, folliculitis, furuncles, carbuncles, and paronychia, to much more serious deep tissue infections, such as cellulitis and wound sepsis [*see 2:VII Fungal, Bacterial, and Viral Infections of the Skin*].

Staphylococcal skin infections are epidemiologically significant in the transmission of serious staphylococcal disease. Even localized infections can give rise to bacteremia and endocarditis, and furuncles of the nose and face may occasionally produce CNS infection such as cavernous vein thrombophlebitis by spreading along venous channels that lack valves.

Bone and joint infections Staphylococci are among the principal causes of septic arthritis and osteomyelitis of the long bones and of vertebral bodies and disk spaces [*see 7:XV Septic Arthritis and 7:XVI Osteomyelitis*]. These infections may result from hematogenous seeding of proximal and distal long bones and joint spaces or contiguous spread of infection; infections of orthopedic prostheses are particularly serious.[68] In addition to causing acute osteomyelitis, staphylococci have a propensity for causing chronic bone infections, usually of the metaphysis of long bones, in which active localized infection can persist for many decades without undergoing dissemination. *S. aureus* is also the leading cause of septic bursitis.

Respiratory tract infections Although staphylococci reside in the nasopharynx, they do not cause pharyngitis; they are rarely involved in acute otitis, sinusitis, or mastoiditis, but they can participate in chronic infections of these regions [*see 7:XIX Bacterial Infections of the Upper Respiratory Tract*].

S. aureus accounts for fewer than 10% of all cases of bacterial pneumonia, but it is nevertheless an important pathogen of the lower respiratory tract. Staphylococcal pneumonia can occur either by spread from the upper airways or by hematogenous seeding. Except in infants, airborne staphylococcal pneumonia is rare as a primary infection. It usually occurs after viral respiratory tract infections, especially influenza. Thus, clinical illness often follows a biphasic course: viral symptoms lasting 4 or 5 days precede an abrupt deterioration as staphylococcal pneumonia pro-

gresses. Staphylococcal pneumonia also occurs as a nosocomial infection, particularly in patients on ventilators and in elderly, debilitated patients[69]; in such patients, mortality is 32%. *S. aureus* can cause pneumonia in HIV-infected persons; these infections are often community acquired and have a mortality of 38%, even with appropriate antibiotic therapy.

Patients with staphylococcal pneumonia are acutely ill; purulent sputum production is the rule, and polymorphonuclear leukocytes and staphylococci can be identified on Gram stain of the sputum. Radiographs show a characteristic patchy bronchopneumonic pattern, often with multiple areas of consolidation. Because these organisms tend to produce tissue necrosis, cavitation is relatively common, and lung abscesses and empyemas may develop; fibrosis and scarring often occur during healing. Hematogenous staphylococcal pneumonia is a complication of staphylococcal bacteremia, especially when endocarditis of the tricuspid valve leads to septic embolization. Sputum production tends to occur later and is less prominent than in airborne pneumonias. Typical radiographic features include multiple small areas of infiltration, which, although sometimes evanescent, often progress to cavitation. Staphylococcal pneumonia is a life-threatening disease requiring high-dose parenteral antibiotic therapy, often for 2 to 4 weeks. Patients with abscess formation and empyema generally require therapy for 3 to 4 weeks; empyemas must be drained.

Bloodstream infections Most patients with *S. aureus* bacteremia are acutely ill; more than 50% have temperatures in excess of 40° C (104° F), and most experience chills and exhibit systemic toxicity. Serious underlying diseases are present in 75% to 85% of patients. The overall mortality is about 23%.[70] Up to 80% of patients with staphylococcal bacteremia acquire the infection in the hospital, often from infected I.V. catheters, skin and wound infections, or pulmonary tract infections.[71] I.V. drug abuse is responsible for more than 50% of the community-acquired cases. Patients with community-acquired bacteremias are more likely to have endocarditis and secondary metastatic infections than patients with nosocomial infections, who are more likely to have an evident portal of entry and severe underlying diseases. Bacteremic seeding can lead to secondary staphylococcal infection of the lungs, bones and joints, and the genitourinary tract. Evidence of CNS involvement suggests endocarditis and is an adverse prognostic sign.

Patients with staphylococcal bacteremia have generally been treated with parenteral antibiotics for 4 to 6 weeks. This recommendation was made on the basis of the results of a study conducted from 1940 to 1954 in which endocarditis developed in 64% of 55 patients with staphylococcal bacteremia.[72] Subsequent investigations suggested that patients with a removable or treatable primary focus of infection (most often, infected I.V. devices) who have no clinical evidence of endocarditis can be treated safely with only 10 to 21 days of I.V. antibiotics.[73] Other studies, however, reported development of endocarditis in 22% to 38% of patients with a primary focus of bacteremia. Therefore, the possibility of endocarditis should not be ignored, even if a primary focus is present. Moreover, major complications, including shock, acute respiratory distress syndrome, and metastatic infection, can occur even in the absence of endocarditis.

Controlled trials are necessary to determine the safety and efficacy of short-term therapy for staphylococcal bacteremia. It may therefore be prudent to treat patients with staphylococcal bacteremia as though they have endocarditis, unless all of the following features are present: clear evidence of only a transient bacteremia; a removable primary focus of infection; a benign clinical course; an absence of echocardiographically demonstrable valvular abnormalities and metastatic infection; and intact host defenses. Negative titers of teichoic acid antibodies would bolster the decision to shorten the I.V. antibiotic therapy, which should, in any case, be continued for at least 10 to 15 days. A regimen of I.V. antibiotics followed by oral antibiotic therapy has been suggested, but more studies are needed before this regimen can be widely recommended. Clearly, the physician must individualize therapy by balancing the morbidity and expense of 4 to 6 weeks of antibiotic therapy against the risks of undertreating endocarditis, which is a life-threatening infection.[74] Transesophageal echocardiography can establish a diagnosis of *S. aureus* endocarditis[75] [*see 7:XVIII Infective Endocarditis*].

Because of the high mortality associated with staphylococcal bacteremia and endocarditis, combination therapies utilizing nafcillin or vancomycin with gentamicin or rifampin are being studied. Thus far, combination therapy appears to reduce the duration of bacteremia, but it does not change the long-term mortality. Combination treatment may also be useful in patients who fail to respond to conventional single-drug treatment. I.V. drug abusers with uncomplicated right-sided endocarditis may respond well to abbreviated therapy.

Because of the propensity of staphylococci to form abscesses, it is particularly important to evaluate bacteremic patients for a loculated infection that may require surgical drainage. Management of staphylococcal bacteremia in patients with Hickman catheters almost always requires catheter removal in addition to antibiotic therapy. Staphylococcal endocarditis appears to be increasing in frequency; its clinical features and therapy are reviewed elsewhere[76] [*see 7:XVIII Infective Endocarditis*].

CNS infection Staphylococcal infections of the CNS present most often as aseptic meningitis in patients with staphylococcal bacteremia, and especially those with endocarditis; the CSF typically reveals modest pleocytosis, and cultures and Gram stains are negative. *S. aureus* is an uncommon cause of purulent meningitis. Direct extension of infection from traumatic or neurosurgical wounds or from osteomyelitis of the mastoids or other cranial bones is a more frequent cause of staphylococcal meningitis than hematogenous seeding. Nafcillin has been shown to penetrate the CSF and should be administered in dosages of approximately 2 g I.V. every 4 hours for the average-sized adult with normal renal function. When nafcillin cannot be used because the infecting organisms are methicillin-resistant[77] or because the patient is allergic to penicillin, therapy must be individualized. Options such as high-dose I.V. vancomycin and rifampin should be considered. In patients who do not respond favorably, there may be a role for intrathecal vancomycin or bacitracin; or for I.V. TMP-SMX, erythromycin, or chloramphenicol.

Another uncommon infection of the CNS in which *S. aureus* is a major pathogen is spinal epidural abscess. Patients with this disease often have underlying vertebral osteomyelitis. These patients present with fever and back pain; radicular pain, weakness, and paralysis evolve as cord compression occurs. Immediate surgical decompression is mandatory.

GI tract infections Staphylococci can also affect the GI tract. Staphylococcal food poisoning occurs when food handlers who have contaminated superficial wounds or who are shedding in-

fected nasal droplets inoculate foods with enterotoxin-producing strains of *S. aureus*. If the contaminated food is not refrigerated, the organisms produce enterotoxin within 4 to 6 hours. The symptoms begin abruptly within 1 to 6 hours after the ingestion of preformed enterotoxin. They consist of salivation, nausea, vomiting, abdominal pain, diarrhea, and prostration. Nausea and vomiting are the most prominent features, because of the enterotoxin's ability to affect the vomiting center of the brain. The symptoms usually subside within 24 hours; there is no specific therapy other than fluid and electrolyte repletion, although I.V. hydration may be necessary in cases of severe disease. In the 1950s and 1960s, GI superinfection or enterocolitis occurred in patients receiving tetracycline or chloramphenicol treatment. Recently, similar cases have occurred, caused by methicillin-resistant strains.

Genitourinary infections *S. aureus* can occasionally produce genitourinary infections. From 7% to 27% of patients with staphylococcal bacteremia have positive urine cultures. Most of these patients have no gross renal infection, but in some, hematogenous pyelonephritis, renal cortical abscesses, renal carbuncles, perinephric abscesses, or prostatic abscesses may develop. These processes should be considered in all patients with positive urine cultures and in patients with staphylococcal bacteremia and persistent fever, flank pain, or abnormal urine sediments. I.V. pyelography, nephrotomography, renal ultrasonography, and CT may be diagnostically helpful. Prostatic abscesses may require repeated rectal examination or ultrasound for diagnosis. *S. aureus*, either alone or with other genitourinary pathogens, can also cause nosocomial urinary tract infections in patients with indwelling urethral catheters.

Other staphylococcal infections *S. aureus* can produce infection of sebaceous glands of the eyelid (sty), purulent conjunctivitis, and orbital cellulitis. It can cause parotitis, which occurs most often in patients who are elderly, debilitated, and dehydrated. Decades ago, parotitis was most common in patients with renal failure, whereas today, it is most common in patients with Sjögren syndrome. Mastitis is most frequent in nursing mothers in the early postpartum period but may occur in neonates or in nonlactating women. Infection of muscle is rare in temperate climates but common in the tropics. Tropical pyomyositis presents as fever and multiple muscle abscesses. The diagnosis should be suspected in recent immigrants from tropical areas but should also be considered in patients who have not traveled and in patients with AIDS. CT may be helpful in detecting muscle abscesses. Purulent pericarditis can result either from direct extension of a pneumonia or empyema or from hematogenous seeding. Staphylococcal bacteremia can produce metastatic abscesses of any organ, including the liver and spleen. Patients who have metastatic abscesses may have persistent fever; in such patients, diagnosis may be difficult if localizing symptoms are absent. *S. aureus* can cause peritonitis in patients on continuous ambulatory peritoneal dialysis.

Treatment of Staphylococcal Infections

It is extremely important to establish a microbiologic diagnosis in staphylococcal infections and to utilize cultures and sensitivities to direct therapy. Choice of empirical antibiotics and of the route of administration depend on the seriousness of the infection, the trends in staphylococcal resistance patterns in the specific geographical area, and the risk factors for methicillin resistance in a given patient.

In addition to paronychia and sties, minor staphylococcal infections of the skin, such as folliculitis and furunculosis, generally respond well to the topical application of warm soaks. Larger focal infections such as carbuncles may have to be incised and drained. Antibiotics should be added when fever or systemic symptoms are present, when lesions are large or numerous, when lesions fail to respond to local therapy, when patients have underlying medical problems such as valvular heart disease or a cardiac prosthesis, or when the nose or face is involved. Cloxacillin or dicloxacillin in an oral dosage of 250 to 500 mg every 6 hours is generally sufficient. Cephalexin, erythromycin, or the newer macrolides are excellent alternatives, as is clindamycin in an oral dosage of 150 to 300 mg every 6 hours [*see Table 9*].

For serious staphylococcal infections, such as cellulitis, deep wound sepsis, pneumonia, septic arthritis, osteomyelitis, bacteremia, endocarditis, or meningitis, parenteral antibiotics are mandatory. Oxacillin or nafcillin in a dosage of 1 g every 4 hours may suffice for cellulitis or pneumonia [*see 7:XIV Chemotherapy of Infection*], but a dosage of 2 g every 4 hours should be used for osteomyelitis, endocarditis, or CNS infections in the average-sized adult with normal renal function. Parenteral cephalosporins such as cephalothin and cefuroxime are excellent alternatives unless CNS infection is present. For patients who are allergic to penicillin, erythromycin and clindamycin have produced good results in the treatment of cellulitis, pneumonia, and osteomyelitis; vancomycin is preferred for the treatment of endocarditis in these patients because it is a bactericidal antibiotic.

Although only about 10% of all *S. aureus* strains are penicillin sensitive, penicillin G remains the drug of choice for sensitive organisms. Care must be taken in sensitivity testing, however, because penicillinase is an inducible enzyme. It is best to reserve penicillin G for staphylococci that are shown to be penicillinase negative or for staphylococci that have extremely large zones of inhibition by penicillin on Kirby-Bauer sensitivity testing. Methicillin resistance may be overlooked occasionally on routine sensitivity testing because it is more readily expressed at lower temperatures (30° C), at higher salt concentrations, or after 48 hours of incubation.

Synergism between penicillins and aminoglycosides against *S. aureus* has been demonstrated in vitro and in experimental staphylococcal infections. However, a clinical benefit of combination therapy for *S. aureus* endocarditis has not yet been demonstrated. Most staphylococci are extremely sensitive to rifampin, which may be combined with other antistaphylococcal drugs in certain difficult clinical situations. However, staphylococci rapidly develop resistance to rifampin when the drug is used alone, and resistance may even arise during combination therapy. The utility of ciprofloxacin is limited by the emergence of resistance. Only time will tell if the newer fluoroquinolones, such as levofloxacin and sparfloxacin, will be more successful; combinations of rifampin and a fluoroquinolone are being investigated.

MRSA Since its first appearance in 1970, MRSA has been a growing problem. These organisms produce a cell-wall penicillin-binding protein with a low affinity for β-lactam antibiotics. Initially, MRSA was a nosocomial pathogen in university hospitals. Although hospitals are still the most common setting, these organisms have also become important problems in long-term care facilities and are increasingly being acquired in the community.[78] MRSA has proved to be difficult to control; infected patients should be subjected to strict barrier precautions.[79] Both pa-

Table 9 Antibiotic Treatment for Staphylococcal Infections

Route	*Drug*	*Dosage*	*Comments*
Oral	Cloxacillin or dicloxacillin	250–500 mg q. 6 hr	Excellent efficacy
	Erythromycin	250 mg q. 6 hr	Alternative for penicillin-allergic patients with cellulitis, pneumonia, or osteomyelitis
	Clindamycin	150–300 mg q. 6 hr	Alternative for penicillin-allergic patients with cellulitis, pneumonia, or osteomyelitis
	Rifampin *plus* ciprofloxacin	600 mg q.d. 250 mg b.i.d.	May be useful in right-sided endocarditis; utilized because of noncompliance in I.V. drug abusers
Oral or intravenous	Linezolid	600 mg q. 12 hr	For MRSA; may be more suitable than other anti-MRSA agents for staphylococcal TSS; for vancomycin-resistant infection
Intravenous	Vancomycin	1 g q. 12 hr	Alternative for penicillin-allergic patients with endocarditis and for MRSA
	Oxacillin or nafcillin	For cellulitis or pneumonia: 1 g q. 4 hr For osteomyelitis, endocarditis, CNS infections: 2 g q. 4 hr	Favored choice for non-MRSA strains
	Cephalosporins Cephalothin Cefuroxime	 2 g I.V. q. 6 hr 1,500 mg I.V. q. 8 hr	Alternative agent unless CNS infection is present
	Penicillin G	2–4 million units q. 4–6 hr	First choice for sensitive organisms
	Daptomycin	4 mg/kg/day	For MRSA, except in endocarditis; for vancomycin-resistant infection; dose-related myopathy
	Quinupristin-dalfopristin	7.5 mg/kg q. 8 hr	For MRSA; can cause phlebitis and myopathy; requires central line placement

CNS—central nervous system MRSA—methicillin-resistant *Staphylococcus aureus* TSS—toxic-shock syndrome

tients and hospital personnel may become asymptomatic carriers. The carrier state is typically prolonged, often exceeding 3 years; antibiotics are usually ineffective. Topical mupirocin ointment can reduce the MRSA carrier rate,[80] but because recolonization is common, mupirocin is not recommended for extended use in long-term care facilities.

The virulence and clinical manifestations of MRSA are no different from those of methicillin-susceptible *S. aureus*[81]; compared to methicillin-sensitive strains, however, a higher percentage of MRSA strains possess the toxins TSST-1, enterotoxins, and the Panton-Valentine leukocidin. MRSA strains are also resistant to all β-lactam antibiotics, erythromycin, and chloramphenicol; even if the organisms appear to be sensitive to cephalosporins in disk diffusion testing, one should not rely on these agents. In the past, vancomycin has been the only alternative for treating MRSA. Interestingly, vancomycin is less effective than nafcillin for strains sensitive to both agents. Linezolid, daptomycin, teicoplanin, and quinupristin-dalfopristin are newer antibiotics with activity against MRSA. Daptomycin is approved for skin and soft tissue infection, but because it is rapidly bactericidal, it needs to be studied as a treatment for endocarditis caused by MRSA. Linezolid has been approved for skin and soft tissue infections, as well as for pneumonia caused by MRSA; evidence is accumulating that, like clindamycin, it is a potent suppressor of staphylococcal toxin production. Because of this characteristic, it may be a more suitable agent to use in patients with staphylococcal TSS. Quinupristin-dalfopristin often causes phlebitis and myopathy. Thus, its use requires placement of a central line.

Vancomycin resistance With the increased use of vancomycin, strains of *S. aureus* with reduced susceptibility to vancomycin have begun to appear.[67] Although these organisms are still very uncommon in the United States, vigorous control measures are required to prevent them from joining VRE as major nosocomial pathogens.[82] Daptomycin and linezolid have excellent activity against vancomycin-intermediate and vancomycin-resistant *Staphylococcus.*

Adjunctive measures In addition to vigorous antibiotic therapy, other measures are often necessary to treat staphylococcal infections. In particular, it is important to remove indwelling venous catheters or other foreign bodies that may be a portal of entry for staphylococcal bacteremia or a nidus for persistent infection. Patients must be evaluated for the presence of staphylococcal abscesses, which often must be drained. Finally, endocarditis and metastatic infection are a concern in all patients with staphylococcal bacteremia.

Prevention Epidemiologic control of staphylococcal infection requires ongoing surveillance and the reporting of infections. Contact precautions should be followed in the management of patients with active infections of the skin or wounds. Respiratory precautions may be useful in the management of patients with staphylococcal pneumonia, although droplet spread is much less important than transmission by direct contact. The treatment of nasal or rectal carriers can be frustrating, particularly if the carriers are hospital personnel or persons suffering from recurrent furunculosis. Topical treatment with germicidal soaps,

povidone-iodine, or antibiotic ointments has been advocated, but long-term results have been disappointing. Orally administered antibiotics, including rifampin, TMP-SMX, and ciprofloxacin, have also failed to live up to initially promising findings. Bacterial interference, which attempts to replace epidemiologically virulent strains of staphylococci with strains that have been deliberately colonized and are less virulent, has generally been abandoned, in part because infection has been caused by these supposedly less virulent strains.

Attempts to develop staphylococcal vaccines are continuing.[83] In a clinical trial in dialysis patients, vaccination with a staphylococcal surface carbohydrate conjugated to *Pseudomonas* exotoxin A significantly reduced the incidence of bacteremia, though protective antibodies lasted only 8 months.[84]

Intranasal therapy with mupirocin ointment may help control the staphylococcal carrier state. A naturally occurring antibiotic produced by *P. fluorescens,* mupirocin inhibits *S. aureus* (including penicillin- and methicillin-resistant strains) and other aerobic gram-positive cocci by binding reversibly to bacterial isoleucyl transfer RNA synthetase; no cross-resistance has been observed between mupirocin and other antibiotics. A placebo-controlled trial of mupirocin in 34 patients who were *S. aureus* carriers found that a monthly course of nasal mupirocin reduced the incidence of nasal colonization and skin infections for at least 1 year. Mupirocin was administered intranasally twice daily for 5 days; side effects were minimal.[85] Additional studies have confirmed the benefits of mupirocin. However, because resistance to mupirocin and recolonization after therapy can occur, routine use of mupirocin should be avoided.[80] The FDA has approved mupirocin for the topical treatment of impetigo.

Staphylococcal Toxic-Shock Syndrome

Staphylococcal TSS was first reported in 1978; by 1990, more than 3,300 cases had been reported in the United States, 90% of which occurred during menstruation in women who were using tampons. The incidence of staphylococcal TSS declined precipitously after superabsorbent tampons were withdrawn from the market. Currently, fewer than 100 cases occur each year, and nonmenstrual cases occur more often than those associated with menstruation. Most cases are now nosocomially acquired, often as a result of postoperative staphylococcal wound infections, particularly those associated with nasal packing after rhinoplasty. Staphylococcal TSS caused by toxin-producing strains of MRSA has been reported from the United States and Japan.

TSS is a multisystem disease with diverse clinical manifestations [*see Table 10*]. Leukocytosis and thrombocytopenia (< 100,000 platelets/mm^3) are common findings. Urinalysis may show mild pyuria and, occasionally, microscopic hematuria. Blood urea nitrogen and creatinine levels are elevated in more than 50% of patients. Serum bilirubin and hepatic enzyme levels are elevated in about half of patients. Serum creatine kinase levels are high in more than one third of patients, and myoglobinuria has developed in some patients. Elevated serum amylase levels are also found, but such elevations may be related to azotemia rather than to clinically evident pancreatitis. Unexplained marked hypocalcemia is often observed. The drop in serum calcium level is out of proportion to the degree of hypoalbuminuria noted in some patients and may be caused by elevated serum calcitonin levels. Blood cultures show no growth in almost all cases. Group A streptococci can produce a severe form of TSS that resembles staphylococcal TSS; in streptococcal TSS, however, bacteremia is common, necrotizing fasciitis may be present, and mortality is much higher (30% to 70%) [*see* Streptococcal Toxic-Shock Syndrome, *above*].

Treatment The management of staphylococcal TSS calls for immediate correction of hypotension and shock with vigorous fluid replacement, attention to the site of *S. aureus* colonization or infection (e.g., removal of tampon and drainage of any abscess), and systemic antimicrobial therapy with an antistaphylococcal agent. Albumin replacement may be needed to counter capillary leak; in addition, correction of hypocalcemia, use of renal dialysis, and ventilator support may be necessary. Because of the emergence of staphylococcal TSS caused by MRSA, empirical antibiotic therapy should be with vancomycin, daptomycin, or linezolid [*see Table 11*]. Protein synthesis inhibitors such as clindamycin and linezolid have been shown to suppress TSST-1 production, so linezolid is a reasonable choice. In contrast, cell-wall–active agents cause release of TSST-1. A retrospective analysis of 45 patients suggested that glucocorticoids may assist in recovery,[86] but more data are needed before glucocorticoids can be recommended for all patients with staphylococcal TSS. Most patients recover in 1 to 2 weeks; mortality is about 5%.

Table 10 Clinical Manifestations of Staphylococcal Toxic-Shock Syndrome

High fever
Scarlatiniform eruption
Hypotension and shock
Desquamation, particularly of palms and soles, during convalescence
MANIFESTATIONS OF SPECIFIC ORGAN INVOLVEMENT
Mucous membranes: hyperemia of conjunctivae, pharynx, and vagina
Gastrointestinal tract: vomiting and diarrhea at onset
Muscle: severe myalgias (elevated serum creatine kinase level; rhabdomyolysis in some patients)
Central nervous system: toxic encephalopathy (disorientation, delirium, or obtundation in absence of high fever or shock)
Kidney: azotemia; pyuria in absence of demonstrable urinary tract infection
Liver: elevations of serum bilirubin and aspartate aminotransferase
Blood: thrombocytopenia

COAGULASE-NEGATIVE STAPHYLOCOCCI

S. epidermidis and other coagulase-negative staphylococcal species are organisms of low pathogenic potential that are universally present as part of the normal skin flora. Because of their ubiquity, coagulase-negative staphylococci are frequently isolated from clinical specimens, including blood cultures. Most often, they are skin contaminants rather than true pathogens; unfortunately, neither clonal variability[87] nor molecular typing[88] can reliably distinguish between contaminants and pathogens. In certain circumstances, however, these organisms can cause significant disease. In the great majority of cases, coagulase-negative staphylococci are opportunistic pathogens, producing infection only in patients with significant underlying medical problems.[89] They most often produce infections in patients with indwelling I.V. catheters or implanted prosthetic devices. Many strains produce an exopolysaccharide that functions as a capsule.[90] This slime layer is an adhesive that binds the organism to implanted

Table 11 Antibiotic Treatment for Staphylococcal Toxic-Shock Syndrome*

Drug	*Dosage*	*Comments*
Vancomycin	1 g I.V. q. 12 hr	Consider if patient has risk factors for MRSA
Daptomycin	4 mg/kg/day	Rapidly bactericidal
Linezolid	600 mg I.V. q. 12 hr	Suppresses toxin synthesis; has good activity against MRSA
Clindamycin	600–800 mg I.V. q. 8 hr	Suppresses toxin synthesis; inducible clindamycin resistance has been described in community-acquired MRSA
Nafcillin	2 g I.V. q. 4 hr	For non-MRSA infection

*No comprehensive studies of antibiotic treatment in staphylococcal toxic shock syndrome have been done. In general, clindamycin and linezolid are favored, because of their ability to suppress toxin synthesis; conversely, cell-wall–active agents cause release of toxin.

devices; it also inhibits the action of antibiotics, further contributing to pathogenicity.

Coagulase-negative staphylococci are now the leading cause of nosocomial bacteremia, which most often results from the use of I.V. catheters, especially centrally placed catheters. Patients with this infection may have signs of phlebitis at the needle or catheter site and may present with persistent low-grade fevers or high-spiking temperature elevations. The I.V. needle or catheter should be removed and a course of parenteral antibiotics administered. Metastatic infection is uncommon but can be serious. These organisms can also be an important cause of bacteremia in immunosuppressed patients. The mortality in patients with coagulase-negative staphylococcal bacteremia approaches 40%, in part because these patients have such serious underlying diseases; mortality attributable to the infection itself is about 13%.

An even more serious problem occurs when *S. epidermidis* or other coagulase-negative staphylococci infect indwelling ventriculoatrial shunts. Patients with this condition may present with bacteremia, meningitis, or both. In addition to high-dose antibiotic therapy, management must often include shunt removal or revision. Vascular grafts and joint prostheses may also become infected. These infections are generally indolent and are more likely to produce pain and joint dysfunction than fever and local inflammatory signs. Diagnosis may be difficult because coagulase-negative staphylococci can be recovered from joint aspirates, either as pathogens or contaminants. These organisms can sometimes cause indolent wound infections or osteomyelitis. Here, too, diagnosis may be difficult, but visualization of the staphylococci on Gram stain, their consistent isolation on culture, and the absence of other pathogens should suggest their etiologic role.

The most serious therapeutic problem caused by coagulase-negative staphylococci is prosthetic valve endocarditis. The disease typically has a subacute course, but eradication of the organisms is often very difficult because of antibiotic resistance. Medical therapy with high-dose antibiotics should be attempted, but valve replacement is necessary if infection persists or if significant valve dysfunction occurs. Mortality is high, approaching 50% with or without surgical therapy. Coagulase-negative staphylococci may also cause endocarditis on native valves.[89]

Antibiotic therapy for deep-seated coagulase-negative staphylococcal infections is difficult. Fifty percent of strains are resistant to methicillin and other semisynthetic penicillins. Whereas most strains appear to be sensitive to cephalosporins on disk diffusion testing, these results correlate poorly with actual bactericidal activity. Vancomycin, gentamicin, and rifampin are bactericidal against most coagulase-negative staphylococci. Vancomycin or rifampin resistance is rare but may emerge during therapy. Vancomycin is generally the drug of choice, but for serious infections, the addition of rifampin or gentamicin should be strongly considered. Linezolid and quinupristin-dalfopristin have good activity against methicillin-resistant coagulase-negative staphylococci, and clinical trials have proved their efficacy in vivo.[91] Although these agents are good alternatives, additional studies are clearly needed.

S. saprophyticus is a coagulase-negative member of the normal skin flora that can be distinguished from *S. epidermidis* by its resistance to the antibiotic novobiocin. Previously dismissed as a nonpathogen, *S. saprophyticus* is now clearly recognized to be an important cause of urinary tract infections. *S. saprophyticus* is second only to *E. coli* as a cause of cystitis in sexually active young women, accounting for 10% to 15% of such cases.[92] *S. saprophyticus* is much less likely to produce infections in men; however, *S. saprophyticus* commonly infects elderly men who have undergone urinary tract instrumentation. The clinical features of *S. saprophyticus* infections resemble those of other urinary tract infections; bacteremia and systemic toxicity are rare, even when upper urinary tract infection occurs. *S. saprophyticus* is sensitive to most antimicrobial agents that are used to treat urinary tract infections.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

II TUBERCULOSIS

Michael K. Leonard, Jr., m.d.
Henry M. Blumberg, m.d., f.a.c.p.

Tuberculosis is a bacterial disease caused by *Mycobacterium tuberculosis,* a relatively slow-growing, aerobic, acid-fast bacillus. Classically, tuberculosis is a pulmonary disease, but disseminated and extrapulmonary manifestations may also occur, especially in immunocompromised persons. Tuberculosis is transmitted person to person and is usually contracted by inhalation of *M. tuberculosis* droplet nuclei generated by an infectious person.

After *M. tuberculosis* enters the body, the host's cell-mediated immunity may contain the organism but not eradicate all the bacilli, resulting in latent *M. tuberculosis* infection (LTBI). *M. tuberculosis* can remain dormant and persist (e.g., within macrophages); persons with dormant *M. tuberculosis* are at risk for reactivation and development of active tuberculosis. Treatment of LTBI can markedly reduce the risk of progression to active disease.[1,2]

If host defenses are unable to contain the infection, the bacillary load increases markedly and LTBI progresses to active tuberculosis. Persons with tuberculosis (also called tuberculosis disease or active tuberculosis) generally are symptomatic and may be infectious if they have pulmonary or laryngeal disease. Active tuberculosis is a life-threatening condition that requires treatment with a multidrug regimen for a minimum of 6 months.[3]

Epidemiology

Tuberculosis has emerged as an enormous global public health epidemic. Worldwide, it is the second leading infectious cause of death, after HIV infection.[4] The World Health Organization (WHO) has estimated that every year, about 9 million persons develop active tuberculosis, and more than 2 million persons die from the disease.[5] Most of these deaths occur in resource-poor countries, where about 95% of the cases are found. Most cases of tuberculosis (5 to 6 million a year) occur in persons 15 to 49 years of age. Sub-Saharan Africa has the highest incidence (≥ 300 per 100,000 population annually), in part because of high rates of HIV coinfection [*see Figure 1*].[4] For example, rates of HIV coinfection in patients with tuberculosis reportedly exceed 60% in Botswana, South Africa, Zambia, and Zimbabwe. The most populous countries of Asia have the largest numbers of cases: India, China, Indonesia, Bangladesh, and Pakistan together account for more than half the global burden, and 80% of new cases occur in 22 high-burden countries. In general, tuberculosis is declining in western and central Europe, North and South America, and the Middle East. By contrast, there have been striking increases in countries of the former Soviet Union and in sub-Saharan Africa, because of the HIV epidemic.[4,5] It has been estimated that about two billion persons, or one third of the world's population, are infected with *M. tuberculosis* and thus are at risk for progression to active disease. There are major concerns that without increased attention to the disease and the development of new tools for treatment and control (e.g., an effective vaccine; new therapeutic agents and shorter treatment regimens; and improved diagnostics, including those for LTBI), the global tuberculosis epidemic will continue to worsen.

In the United States and western Europe, tuberculosis was a leading cause of death until early in the 20th century. The incidence of tuberculosis in the United States began to decline with improved living conditions and public health measures, even before the availability of effective chemotherapy. After the introduction of effective therapy in the mid-20th century, the incidence of tuberculosis decreased even further. Between 1985 and 1992, however, the United States experienced a resurgence of tuberculosis because of underfunding of tuberculosis control efforts, the decline of the public health infrastructure, and the emergence of the HIV epidemic. With increased attention and funding, the number of tuberculosis cases in the United States declined from a peak of 26,673 in 1992 to 14,511 in 2004 (a decline in rate from 10.5 to 4.9 cases per 100,000 population) [*see Figure 2*].[6] The implementation of directly observed therapy (DOT) and improved infection control activities in hospitals and other institutional settings have contributed greatly to this decline.[6]

Most tuberculosis cases in the United States now occur in foreign-born persons and in nonwhites.[6] In 2004, tuberculosis case rates in African Americans born in the United States were more than eightfold higher than those in native whites. In the United States, rates are also much higher in Hispanics and Asians (especially foreign born) than in whites. The 2004 tuberculosis rate in foreign-born persons (22.5 cases per 100,000 population) was 8.7 times greater than that in United States–born persons (2.6 cases per 100,000 population).[6] In 2003, the top five countries of birth of foreign-born patients with tuberculosis were Mexico (25.6%), the Philippines (11.6%), Vietnam (8.4%), India (7.7%), and China (4.8%). Molecular typing studies have suggested that in foreign-born persons in the United States, most tuberculosis cases result from the reactivation of LTBI, whereas in persons born in the United States, many cases (perhaps a third or more) result from recent transmission.[7,8] Foreign-born persons may also be more likely to experience extrapulmonary tuberculosis.

Tuberculosis is not evenly distributed within the population. The disease is much more common in the economically disadvantaged, including the homeless and indigent inner-city residents.[9] Tuberculosis is 200 times more likely to occur in HIV-positive persons than in HIV-negative persons.[10] Persons with HIV coinfection are more likely to have extrapulmonary or disseminated tuberculosis, frequently along with pulmonary disease.

Other population groups that are at increased risk or that have a disproportionately high incidence of disease include immigrants (this is especially true during the first 5 years of arriving in the United States); substance abusers, including injection drug users and alcohol abusers; homeless persons; residents in certain institutional settings, such as correctional facilities and long-term care facilities; persons who are taking immunosuppressive drugs; and persons who have certain malignancies, diabetes mellitus, renal failure, or other debilitating conditions.[1,11] Travelers to countries where tuberculosis is endemic are likely to be at somewhat increased risk for developing tuberculosis.[12]

During 2004, drug resistance in initial isolates of *M. tuberculosis* from persons with no previous history of treatment of tuberculosis was more common in foreign-born patients than in United States–born patients. Such isolates included strains of *M. tuberculosis* resistant to at least isoniazid and rifampin (multidrug-resistant tuberculosis [MDR-TB]). The rate of MDR-TB was higher in foreign-born than in United States–born persons (1.4% versus 0.6%), reflecting likely exposure to tuberculosis in countries where rates

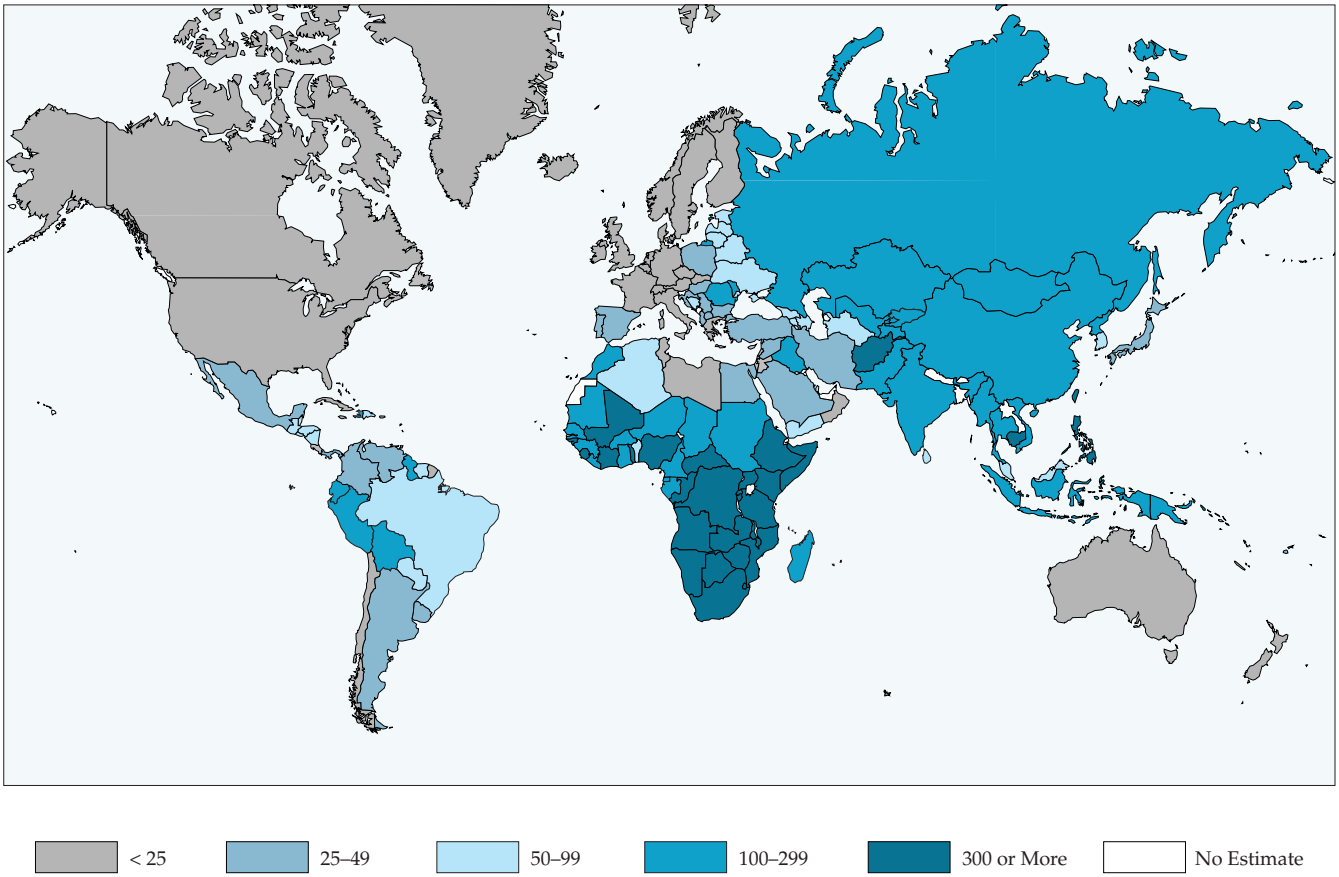

Figure 1 **Incidence of global tuberculosis as estimated by the World Health Organization, 2002.[1]**

of MDR-TB are higher than in the United States. Rates of MDR-TB in the United States have decreased since the early 1990s.[6] The decrease occurred in large part because of the dramatic reduction of MDR-tuberculosis cases in New York City: in the early 1990s, MDR-TB accounted for nearly a fifth of all tuberculosis cases in New York City.[13,14] A key element of this decrease has been enhanced tuberculosis control through an improved public health structure and greater attention to treatment of tuberculosis, including greater use of DOT.

Etiology and Genetics

Tuberculosis is spread person to person via airborne droplet nuclei. These particles, which are 1 to 5 μm in diameter and contain *M. tuberculosis,* are generated by persons with pulmonary or laryngeal tuberculosis when they cough, sneeze, speak, or sing. Most secondary cases of tuberculosis occur in household members or other close contacts of the index case. Prolonged exposure to the index case increases the risk of becoming infected, although on occasion, transmission can occur after brief exposures. Infectivity is greatest in patients whose sputum smear is AFB positive; this group may include those with cavitary disease or tuberculosis of the larynx. Coughing further enhances shedding. Persons with tuberculosis who are AFB smear–negative (and culture positive) are thought to be less infectious than AFB smear–positive patients but may still transmit tuberculosis.[15]

Some patients may have an increased susceptibility to tuberculosis that is genetically determined. For example, concordance for tuberculosis is significantly higher in monozygous twins (65% to 85%) than in dizygous twins (25% to 35%).[16] African Americans and Native Americans may be more susceptible than whites to *M. tuberculosis* infection.[17] Other studies have suggested that patients carrying mutations in the receptors for interferon gamma (IFN-γ) and interleukin-12 (IL-12) are at increased risk for severe atypical mycobacterial and disseminated bacillus Calmette-Guérin (BCG) infections.[18] Several associations have also been made with variants of genes thought to be important in the pathogenesis of tuberculosis, including *NRAMP1* and genes that code for the vitamin D receptor (*VDR*), IL-10, tumor necrosis factor–α (TNF-α), and IL-1. Four polymorphic-derived deletions or point mutations of the *NRAMP1* gene have been associated with increased susceptibility to tuberculosis in Gambia and in other populations in Japan, Guinea, and Korea.[18] Associations between genetic polymorphisms and tuberculosis susceptibility differ according to ethnic origin,[19] but the extent to which genetic polymorphisms contribute to the global burden of disease has not been fully elucidated, in part because of the great difficulty of separating lifelong environmental influences from genetic predisposition.[4]

Pathogenesis

The pathogenesis of tuberculosis is unique among infectious diseases because of the highly variable but sometimes long latency period between infection and clinical illness. Although a single tubercle bacillus theoretically can cause infection, it must first bypass the upper airway defense mechanisms and lodge in the distal pulmonary alveoli. Infectious droplet nuclei are inhaled

and lodge in the alveoli in the distal airways, whereas larger particles are usually trapped in the upper respiratory tract. *M. tuberculosis* is taken up by alveolar macrophages, and this can result in infection with the organism. After exposure to someone with infectious tuberculosis, the exposed person experiences one of four potential outcomes [*see Figure 3*]: (1) no infection (as measured by a negative tuberculin skin test); (2) infection, with rapid progression to active disease (primary tuberculosis); (3) LTBI, in which immune mechanisms prevent the progression to active disease; and (4) LTBI followed by subsequent reactivation and development of active tuberculosis months to years later.[20,21]

The immune response mounted against *M. tuberculosis* is multifaceted and complex. Effective innate immune responses to *M. tuberculosis* are clearly important, given that a significant proportion of persons exposed to *M. tuberculosis* do not become infected after exposure. For example, contact investigations have shown that at most only 30% to 50% of persons with heavy exposure to someone with tuberculosis will become infected, as demonstrated by conversion on tuberculin skin testing. If infection does occur, *M. tuberculosis* multiplies within alveolar macrophages and subsequently disseminates through blood and lymphatic pathways to areas of high oxygen tension. Hence, the lung apices are a common repository. Other frequently infected areas include the renal cortex, the vertebral column, and the metaphyseal ends of long bones. After 6 to 8 weeks, an adaptive cell-mediated immunity is well established, and results of tuberculin skin testing become positive.

M. tuberculosis is an obligate aerobe. Consequently, it grows most successfully in those human tissues having the highest oxygen tension, such as the lung apices. It is a slow-growing organism, with a generation time estimated to be 12 to 18 hours. As a result, tuberculous lesions in humans typically evolve from a subacute to a long-term stage, and laboratory isolation of the organism usually requires weeks rather than a day or two, as is the case for most bacteria.

The cell walls of *Mycobacterium* species have a high lipid content because of the presence of mycolic acids. Therefore, mycobacteria are impermeable to, and undetectable with, the usual bacteriologic stains, such as Gram stain. Mycobacteria, including *M. tuberculosis,* are acid-fast bacilli (AFB); the lipoid capsule of the acid-fast organism takes up carbol-fuchsin and resists decolorization with a dilute acid rinse. Finally, although tubercle bacilli require special enriched media to grow in the laboratory, these organisms are resistant in vivo to physical stress.

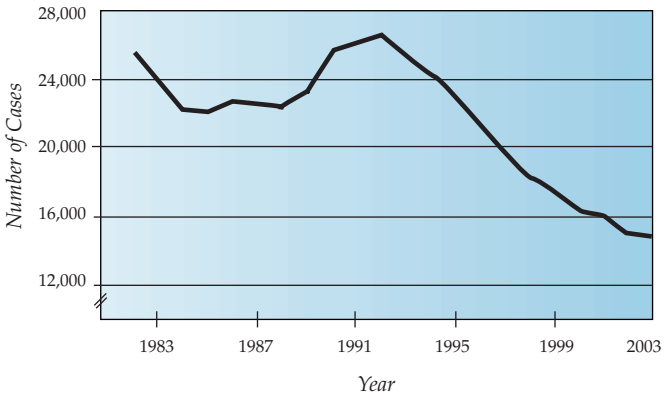

Figure 2 **Number of tuberculosis cases reported in the United States, 1982–2003.[4]**

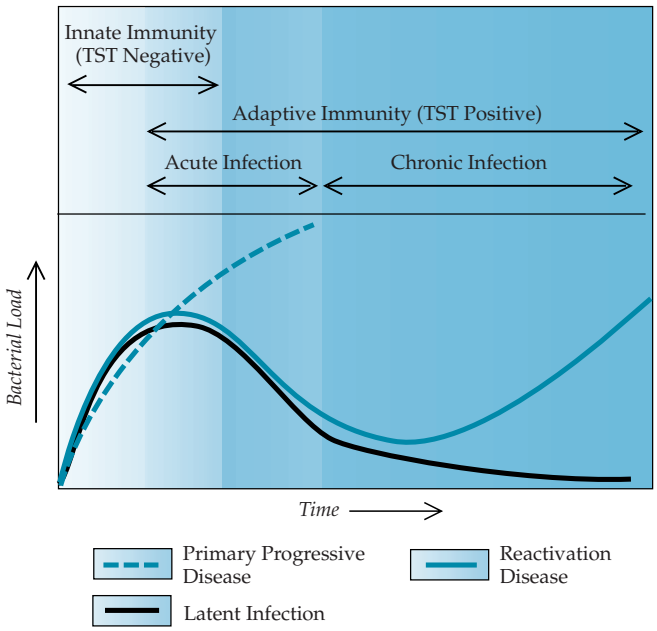

Figure 3 **Natural history of *Mycobacteria tuberculosis* infection.[96] The innate immune system provides the first line of defense against *M. tuberculosis,* and often prevents infection. Results of tuberculin skin testing (TST) are negative at this stage. Subsequent control of tuberculosis is provided by the adaptive immune system; this results in positive TST results. In 90% of cases, host defenses kill the great majority of organisms, but some *M. tuberculosis* bacilli persist within macrophages, resulting in latent infection. Reactivation of disease occurs in 5% to 10% of patients, sometimes years later. Less than 5% of patients experience primary progressive disease.**

A wide range of immune components are involved in an effective response against *M. tuberculosis.* These components include T cells ($CD4^+$ and $CD8^+$, which are activated in response to *M. tuberculosis* infection), cytokines (including IFN-γ, IL-12, TNF-α, and IL-6), and macrophages.[21] The macrophage is felt to play a key role in the control of *M. tuberculosis* infection; the organism can multiply within resting macrophages, but it can be inhibited or killed when the macrophage is activated.[21]

Cytokines produced by T cells contribute to the immune response in a multitude of ways, such as by activating macrophages, the host cell in which *M. tuberculosis* primarily resides. $CD4^+$ and $CD8^+$ T cells can also be cytotoxic for infected cells. $CD4^+$ T cells play a key role in the immune response, as demonstrated by a marked increase in susceptibility to tuberculosis in HIV-infected persons whose $CD4^+$ T cells are depleted. The predominance of T helper type 1 (Th1) cell response is associated with protection and control of tuberculosis infection, whereas Th2 responses predominate in patients who are unable to contain the infection and who develop active disease. Th1 responses are markedly impaired in HIV-infected persons, especially those with low $CD4^+$ T cell counts and advanced disease. IL-12 is an important cytokine in controlling *M. tuberculosis.* It is produced by activated macrophages and drives development of a Th1 response, which stimulates $CD4^+$ T cells to release IFN-γ. IFN-γ alone is insufficient to control *M. tuberculosis.* IFN-γ is, however, a crucial element in the control of tuberculosis, and it also stimulates the macrophage to release TNF-α, which is important in granuloma formation and control of the extent of infection. The importance of TNF-α has been demonstrated by the marked in-

crease in risk of progression to active tuberculosis, including extrapulmonary and disseminated disease, in patients with LTBI who were treated with the anti-TNF monoclonal antibody infliximab for rheumatologic and immunologic diseases.[22]

After exposure to and infection with *M. tuberculosis,* most persons develop LTBI [*see Figure 3*]. This chronic infection stimulates formation of granulomas in the lungs or other tissues; these granulomas consist of lymphocytes ($CD4^+$ and $CD8^+$ T cells, as well as B cells) that surround macrophages, some of which contain *M. tuberculosis,* as well as other cells such as fibroblasts. The development of a granuloma serves to limit the spread of the infection by walling off the organisms from the rest of the lung or other organ tissue. After the development of cell-mediated immunity, host defenses are able to respond to *M. tuberculosis;* the great majority of the organisms are killed, and the mycobacterial load is greatly reduced [*see Figure 3*]. However, host defenses are not able to entirely eradicate all organisms; some *M. tuberculosis* persist within macrophages, and thus the possibility remains for reactivation of disease. The mechanism of resistance by *M. tuberculosis,* persistence in macrophages over many years, and reactivation is poorly understood.

As a result of host defenses, most patients experience complete healing of these initial tuberculous lesions. In patients whose primary lesions heal, the chest radiograph may be normal or it may show focal calcifications. The primary lower lobe lesion and its draining node may be recognized radiographically as the Ghon complex; apical calcifications (Simon foci) may be present. Although inactive, these lesions contain small numbers of dormant but viable tubercle bacilli, and breakdown of the lesions can lead to reactivation of infection.

In about 5% to 10% of immunocompetent persons infected with *M. tuberculosis,* LTBI progresses to active disease.[23] The risk of reactivation is greatest within the first 2 years of the initial infection, but there is a subsequent lifetime risk of up to 5% for reactivation, which can occur many decades after initial infection.[24] Immune compromise increases the risk of progression to active disease. HIV infection is the greatest single risk factor for progression to active disease in adults. Progression from LTBI to active disease takes place at a rate of 10% a year in HIV-infected persons[2]; those with low $CD4^+$ T cell counts may be incapable of controlling infection and may develop active disease rapidly after exposure and infection. Other medical conditions that predispose to the development of active disease include diabetes mellitus, renal failure, certain malignancies, cancer chemotherapy, therapy with corticosteroids or other immunosuppressive drugs (including TNF-α inhibitors such as infliximab, etanercept, and adalimumab), transplantation, and malnutrition. Tuberculosis may also develop in patients without these underlying risk factors, however, for reasons that are not well understood. In some patients, including those who are infected with HIV and those living in regions where tuberculosis is hyperendemic, exogenous reinfection can occur.[25] In the United States, however, molecular epidemiologic investigations indicate that most recurrences result from relapse of disease rather than reinfection with a different strain of *M. tuberculosis*.[26]

Forms of Tuberculosis

PULMONARY TUBERCULOSIS

In the United States, about 80% of tuberculosis cases are pulmonary disease.[27] Pulmonary tuberculosis can be divided into primary tuberculosis (i.e., developing soon after infection) and secondary tuberculosis (i.e., developing after a variable period of LTBI). Secondary disease is also known as postprimary or reactivation tuberculosis.

Primary Disease

Primary tuberculosis is frequently localized to the middle and lower lung zones and is accompanied by hilar or paratracheal lymphadenopathy. In some cases, the lesion heals spontaneously and may later be evident on chest x-ray as a small calcified nodule (Ghon lesion). Primary disease was once most common in young children, but it has been seen with increasing frequency in adults who are debilitated or immunosuppressed, especially from HIV infection. Primary tuberculosis typically manifests as one of four broad syndromes: a syndrome resembling atypical pneumonia; tuberculous pleuritis with pleural effusion; direct progression to upper lobe disease; and progression to extrapulmonary disease. Uncommon manifestations of primary tuberculosis include erythema nodosum and other hypersensitivity reactions, such as reactive arthritis (Poncet disease).

The most common form of primary tuberculosis is a syndrome that is similar to atypical pneumonia, with fever and nonproductive cough. The chest radiograph may show unilateral, lower lobe, patchy parenchymal infiltrates; paratracheal or hilar adenopathy; or both. Although patients with this form of tuberculosis should receive full antituberculous chemotherapy, the symptoms may resolve even without therapy. Resolution without therapy would not be expected in most immunocompromised persons, however.

Tuberculous pleuritis with pleural effusion results from penetration of bacilli into the pleural space from an adjacent subpleural focus. This can occur early in the course of infection and may represent a hypersensitivity response to only a few organisms in the pleural space.[28] In immunocompetent patients, this form of tuberculous pleuritis may go unnoticed, and the process may resolve spontaneously. Other patients, however, including both immunocompetent and immunosuppressed persons, may have an acute illness with high fever, cough, and pleuritic chest pain; if the effusion is large, dyspnea may also occur. Chest radiography often reveals unilateral pleural effusion, generally without identifiable parenchymal lesions. The tuberculin skin test is strongly positive in the majority of immunocompetent persons with tuberculous pleurisy, but it is positive in only about 40% of HIV-infected patients who have the syndrome.

Direct progression of primary tuberculosis to upper lobe disease is relatively rare. Progression of primary infection to extrapulmonary tuberculosis (also known as progressive primary tuberculosis) was once most common in young children, who presented with cervical adenitis, miliary tuberculosis, or tuberculous meningitis; currently, it is most often observed in persons with HIV infection.

Secondary Disease

Reactivation pulmonary disease is the most common clinical form of tuberculosis. Classic symptoms include cough, fever, and sweats. Symptoms usually begin insidiously and progress over a period of several weeks or even months before diagnosis. Cough may be nonproductive, or it may gradually become productive. Dyspnea is relatively uncommon in the absence of underlying chronic lung disease. Systemic symptoms, which are often prominent, include fever, anorexia, weight loss, night sweats, and malaise. Fever is reported in 37% to 80% of patients with tuber-

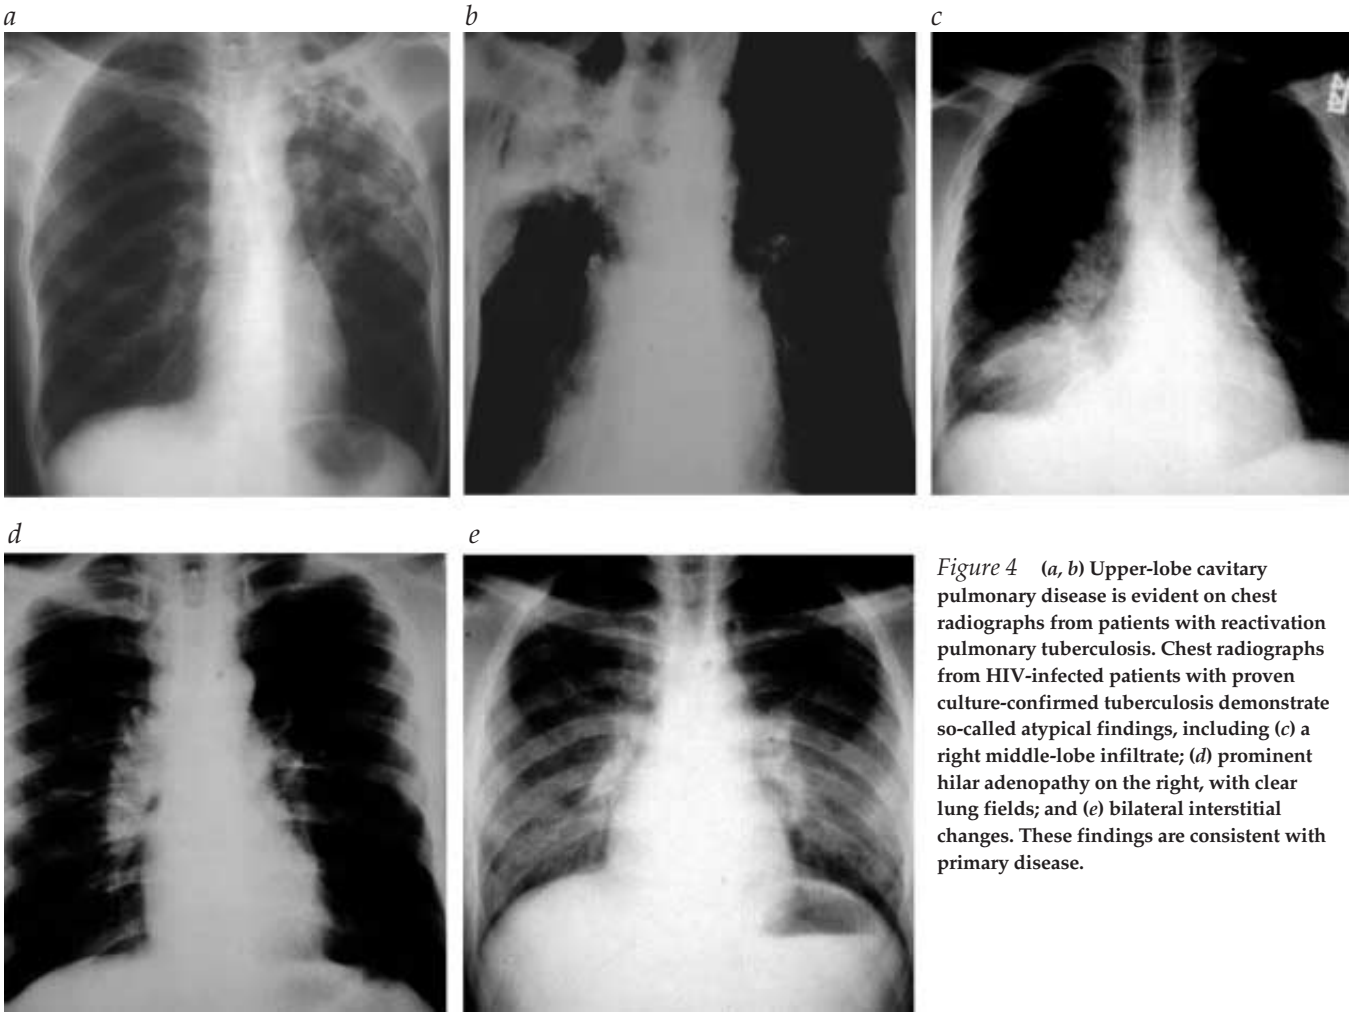

Figure 4 **(*a*, *b*) Upper-lobe cavitary pulmonary disease is evident on chest radiographs from patients with reactivation pulmonary tuberculosis. Chest radiographs from HIV-infected patients with proven culture-confirmed tuberculosis demonstrate so-called atypical findings, including (*c*) a right middle-lobe infiltrate; (*d*) prominent hilar adenopathy on the right, with clear lung fields; and (*e*) bilateral interstitial changes. These findings are consistent with primary disease.**

culosis[28]; low-grade fevers are typical, but some patients have high temperatures and even chills. However, in some patients with pulmonary tuberculosis, these classic symptoms may be absent, making diagnosis more difficult.[29] In addition, in patients with advanced disease who present with respiratory failure, tuberculosis may not be considered in the differential diagnosis, and as a result, the diagnosis of pulmonary tuberculosis may be delayed.

Hemoptysis from endobronchial erosion may occur in tuberculosis; it is usually minor but denotes advanced disease. Massive hemoptysis resulting from the erosion of a pulmonary artery by an advancing cavity (Rasmussen aneurysm) is a terminal event that was occasionally seen in the prechemotherapy era but is currently rare. Hemoptysis may also occur in patients with inactive disease (e.g., after completion of therapy) who develop *Aspergillus* superinfection of a residual cavity (aspergilloma).

Physical Examination Findings

Physical examination is typically of limited usefulness in differentiating tuberculosis from other pulmonary infections. Some patients with tuberculosis have no abnormalities that are detectable by chest examination, whereas others have rales in the involved areas. Coarse rhonchi may evolve as secretions increase. Bronchial breath sounds may be present in areas of consolidation.

Imaging Studies

A chest radiograph is an important tool in the diagnosis of pulmonary tuberculosis. Typical features include unilateral or bilateral infiltration; cavitation is common in patients with reactivation disease [*see Figure 4*]. The most frequent sites of involvement in reactivation disease are, in decreasing order, the apical and posterior segments of the right upper lobe, the apical-posterior segment of the left upper lobe, and the superior segments of the lower lobes. Lower-zone disease is seen at presentation in fewer than 15% of HIV-seronegative adults; it is much more common in HIV-infected persons (e.g., as part of primary disease) and is somewhat more common in patients with diabetes mellitus and in patients with prominent peribronchial and endobronchial involvement. Chest radiographs appear normal in about 10% of persons with tuberculosis and HIV coinfection,[30] whereas normal chest radiographs are extremely rare in HIV-seronegative persons with tuberculosis.

Computed tomography is more sensitive than chest radiography. CT scans may show nodular or branching linear centrilobular lesions in very early disease and in patients with tuberculosis and an apparently normal chest radiograph.

EXTRAPULMONARY TUBERCULOSIS

Tuberculosis may affect any organ system. Extrapulmonary tuberculosis results from hematogenous dissemination of tuber-

cle bacilli with incomplete immunologic control of the disease, either during primary infection or as a result of reactivation from a site of latent infection.

In order of frequency, extrapulmonary tuberculosis involves the lymph nodes, the pleura, the genitourinary tract, bone and joints, the meninges, and the peritoneum. Extrapulmonary tuberculosis, including miliary (disseminated) disease, is being seen more frequently because of its increased prevalence in HIV-infected persons. It is not unusual for HIV-infected patients with tuberculosis to have concomitant pulmonary and extrapulmonary disease. Very young children, immunocompromised patients, and perhaps patients born in foreign countries are also at increased risk for extrapulmonary disease, as are patients with LTBI who have been treated with TNF-α inhibitors such as infliximab, etanercept, and adalimumab.[22]

Tuberculous Lymphadenitis

Tuberculosis of the lymph nodes is the most common form of extrapulmonary tuberculosis, accounting for up to 40% of extrapulmonary cases. It is frequently encountered in HIV-infected persons. Tuberculous lymphadenitis is also seen in young children; women, especially nonwhites, also appear to be at increased risk. The cervical nodes (posterior and anterior) and supraclavicular lymph nodes are most commonly affected. In addition, mediastinal lymphadenitis may appear with early or primary disease, because these nodes drain the lung. HIV-seronegative patients are often afebrile and present with slowly enlarging, painless mass lesions. Patients with HIV infection or AIDS may be febrile. The diagnosis can be established by fine-needle aspiration or lymph node biopsy. Therapeutic lymph node excision is not indicated except in unusual circumstances. For large lymph nodes that are fluctuant and that appear to be about to drain spontaneously, aspiration or incision and drainage appear to be beneficial, although this approach has not been examined systematically.[3]

Pleural Tuberculosis

Pleural tuberculosis generally results from primary progressive *M. tuberculosis* infection; less commonly, it may occur as part of the reactivation of LTBI. As noted, pleural disease typically occurs when a few organisms from the lungs gain access to the pleural space and, in the presence of cell-mediated immunity, cause a hypersensitivity response. Physical findings are those of a pleural effusion: dullness to percussion and absence of breath sounds. A chest radiograph usually demonstrates a unilateral pleural effusion. Thoracentesis is required for diagnosis; findings include an exudative effusion with a protein concentration that is greater than 50% of the serum level, a normal to low glucose level, and the presence of white blood cells, most of which are lymphocytes and mononuclear cells rather than neutrophils. A pleural biopsy can greatly increase the likelihood of obtaining a positive culture (increasing the yield to greater than 80%) compared with pleural fluid culture alone.

Tuberculous empyema has become much less common than it was in the prechemotherapy era. It results from the rupture of a lung cavity into the pleural space or from a bronchopleural fistula. The rupture of a cavity results in the discharge of a large number of organisms into the pleural space; in addition, parenchymal disease is often present on chest radiograph, and a pyopneumothorax with an air-fluid level may also be visible. The effusion is purulent and thick and contains large numbers of white blood cells, predominantly lymphocytes. Treatment consists of drainage (often requiring a surgical procedure) and antituberculous chemotherapy. Surgery, when needed, should be undertaken by experienced thoracic surgeons.[3]

Genitourinary Tuberculosis

Genitourinary tuberculosis accounts for about 15% of extrapulmonary tuberculosis cases and may involve any part of the genitourinary tract. It usually results from hematogenous seeding after primary infection. Historically, it has occurred years after primary infection. Local symptoms predominate: dysuria, hematuria, and frequent urination are common, and flank pain may also be noted.[28] Renal tuberculosis often has an insidious onset and subtle symptoms; consequently, advanced destruction of the kidneys may have taken place by the time the diagnosis is established. The urine sediment is abnormal in about 90% of patients with renal tuberculosis; urinary findings include pyuria, hematuria, or both. Imaging studies may reveal structural abnormalities; calcification, cavitation, and ureteral strictures and fibrosis suggest tuberculosis, whereas calyceal dilatation, cortical scarring, and papillary necrosis are nonspecific. A CT scan is as useful as an intravenous pyelogram for visualizing advanced urinary tract tuberculosis; ultrasonographic studies are less accurate. The finding of so-called sterile pyuria (i.e., acidic urine that contains white blood cells but in which no bacterial organisms are isolated on routine urine culture) should prompt culture of the urine for mycobacteria. AFB smears should be performed on urine, although the yield is low compared with that of AFB urine culture; nucleic acid amplification (NAA) testing (see below) of urine may provide a more rapid diagnosis than AFB culture but is not a substitute for a culture.[31]

Genital tuberculosis is more common in women than men. In women, genital involvement may occur without renal tuberculosis; pelvic pain, menstrual irregularities, and infertility are possible presenting complaints. Occasionally, ovarian masses from tuberculosis may be mistaken for ovarian tumors. The differential diagnosis may also include pelvic inflammatory disease. The physical examination may be normal or may reveal an adnexal mass. Endometrial curettage, cervical biopsy, and laparoscopic exploration are all useful as diagnostic procedures. Surgery is often needed for diagnosis of tubo-ovarian abscesses or pelvic peritonitis.

Male genital tuberculosis can result from hematogenous seeding or can spread from infected urine after reactivation in the upper urinary tract. About 50% of male patients with genital tuberculosis also have renal tuberculosis; this is a higher proportion than is found in women with genital tuberculosis. Male patients may present with slowly enlarging mass lesions of the epididymis, prostate, or seminal vesicles. Genital tuberculosis in both men and women responds well to chemotherapy.

Musculoskeletal Tuberculosis

Tuberculosis can affect any bone or joint, but involvement of the spine (Pott disease) is the most common type of skeletal tuberculous disease, accounting for up to 50% of cases.[32] The thoracic spine is the most common site of spinal tuberculosis. Upper thoracic vertebral body involvement is more common in children, whereas lower thoracic and upper lumbar disease is more common in adults. Often, two or more vertebral bodies are involved; vertebral body involvement can lead to disease of an adjacent intervertebral disk and paraspinous abscesses. With advanced disease, collapse of vertebral bodies may result in kyphosis (gibbus) or even paraplegia.[33]

Figure 5 **(*a*) Plain film and (*b*) MRI from a patient with skeletal tuberculosis (Pott disease) demonstrate radiographic findings of vertebral tuberculosis: anterior disk destruction and collapse, loss of vertebral body height, and disk-space narrowing. Extensive anterior vertebral body destruction can lead to anterior angulation of the spine, producing the characteristic gibbus deformity seen on the MRI. (*c*) CT scan from a different patient with vertebral osteomyelitis shows a psoas abscess, which is not uncommonly associated with vertebral tuberculosis.**

The usual presenting symptom of skeletal tuberculosis is pain. Patients with joint involvement can have swelling of the joint and limitation of motion. Tuberculous joint involvement can sometimes become apparent after trauma to the joint. Because of the subtle nature of the symptoms, especially initially, diagnosis of skeletal and joint disease can be delayed for long periods.

Radiographically, tuberculosis of bones appears as an array of destructive osteolytic lesions with relatively little reactive bone formation. CT and MRI are useful imaging tests [*see Figure 5*]. Definitive diagnosis requires biopsy and culture of affected bone or, in patients with joint involvement, arthrocentesis with culture of synovial fluid. Tuberculous arthritis is characteristically a chronic, slowly progressive, destructive monoarticular process. The synovial fluid has a high protein level, a low glucose level, and a poor mucin clot. The white blood cell count is variable but is typically in the range of 10,000 to 20,000/μl; neutrophils often predominate. AFB smears are rarely positive because of the paucibacillary nature of this form of tuberculosis, but culture and biopsies of the synovium are helpful.

Tuberculous rheumatism (Poncet disease) is a rare form of acute polyarthritis that results from a hypersensitivity reaction rather than direct synovial infection. Prosthetic joint tuberculosis and tubercular tenosynovitis are uncommon. For skeletal tuberculosis, tumor is the major consideration in the differential diagnosis, and fungal and pyogenic infections are additional considerations.

Randomized trials in patients with spinal tuberculosis demonstrated no additional benefit of surgical debridement or radical operation (i.e., resection of the spinal focus and bone grafting) in combination with chemotherapy compared with chemotherapy alone.[34] Myelopathy with or without functional impairment most often responds to chemotherapy. However, in some circumstances, surgery appears to be beneficial and may be indicated. Indications for surgery include the failure to respond to chemotherapy in conjunction with evidence of ongoing infection; the need for spinal cord decompression in patients with persistent or recurrent neurologic deficits; or instability of the spine.[3]

Tuberculous Pericarditis

Although infrequent, tuberculous pericarditis is a very serious form of tuberculosis. Infection of the pericardium can result from either hematogenous dissemination of bacilli or contiguous spread from lung or mediastinal nodes. Pathologically, the disease progresses from inflammation to effusion and eventually to fibrous organization. Symptoms are nonspecific and initially in-

clude the insidious onset of fever, weight loss, and night sweats. Subsequently, cardiopulmonary symptoms occur; these include cough, dyspnea, orthopnea, ankle swelling, and chest pain. Physical examination may disclose a pericardial rub or a pulsus paradoxus. A chest x-ray may show a pericardial effusion.

The diagnosis of tuberculous pericarditis depends on direct examination of pericardial fluid or tissue. The pericardial fluid is turbid or hemorrhagic. White blood cell counts typically range from 5,000 to 10,000/μl; lymphocytes are predominant. High protein levels and low glucose levels are typical. AFB smears or cultures of pericardial fluid are positive in about half of cases, but pericardial biopsy with culture has a higher diagnostic yield. The major differential diagnosis includes idiopathic, bacterial, or viral pericarditis and neoplasm.

If left untreated, tuberculous pericarditis has a high mortality, and constriction eventually occurs in many survivors**.** Surgery is indicated if clinical tamponade progresses or recurs despite repeated pericardiocentesis [*see 1:XIII Diseases of the Pericardium, Cardiac Tumors, and Cardiac Trauma*]. However, in the absence of tamponade, medical therapy is generally sufficient. Antituberculous chemotherapy with four drugs should be started immediately and supplemented initially with corticosteroids; corticosteroids should be tapered over a 12-week period [*see* Treatment, *below*]. Corticosteroids have been useful in reducing mortality from tuberculous pericarditis and enhancing clinical response to therapy, but they do not appear to reduce progression to constriction or the need for pericardiectomy.

Central Nervous System Disease

Tuberculous meningitis is a particularly devastating manifestation of tuberculosis, with high mortality (about 40%) and morbidity.[35] Children younger than 5 years of age and HIV-infected persons are at increased risk for tuberculous meningitis. The clinical manifestations, laboratory findings, and outcomes are similar in patients with and without HIV infection.[35,36] Tuberculous meningitis may result from hematogenous seeding of the meninges, or it can be caused by the breakdown of an old submeningeal granuloma with rupture into the subarachnoid space.

Clinical manifestations of tuberculous meningitis result both from the presence of *M. tuberculosis* and from the inflammatory host immune response.[4] Clinical manifestations may include headache, fever, altered mental status, cranial nerve findings, and nuchal rigidity. The intense inflammatory reaction is most prominent at the base of the brain and can have three effects: direct compression of neural tissues, especially cranial nerves; vasculitis, leading to areas of infarction; and obstruction of the free flow of cerebrospinal fluid, leading to cerebral edema, hydrocephalus, or subarachnoid block. CT or MRI may demonstrate basal meningeal enhancement and hydrocephalus. Up to 50% of patients with tuberculous meningitis have abnormalities on chest radiograph indicating old healed tuberculosis or current pulmonary disease or miliary disease. Lumbar puncture is an essential diagnostic test and should be carried out if meningeal signs are present. The CSF opening pressure is usually elevated but on occasion may be normal. CSF examination generally reveals an elevated white blood cell count (often in the range of 100 to 1,000/μl), typically with a lymphocyte predominance, although in early disease, neutrophils can predominate; CSF protein is elevated and CSF glucose level is usually decreased. Acid-fast smears of CSF are insensitive; they are positive in only about 10% of patients with culture-confirmed tuberculous meningitis.[35] CSF cultures may be eventually positive in up to 75% of cases. NAA tests (see below) may be positive but are insensitive in diagnosing tuberculous meningitis; a negative NAA test on CSF does not rule out tuberculous meningitis.[37] The principal considerations in the differential diagnosis include cryptococcal meningitis and other less common forms of fungal meningitis (e.g., histoplasmosis, blastomycosis, cocciodiomycosis), viral meningitis or encephalitis (e.g., from herpes simplex virus, enteroviruses, West Nile virus, and other arboviruses), and, if antibiotics have been given, partially treated bacterial meningitis [*see 7:XXXVI Bacterial Infections of the Central Nervous System*]. Noninfectious diseases in the differential diagnosis include carcinomatous meningitis, neurosarcoidosis, and CNS vasculitis.

Initiation of empirical therapy is crucial for patients with presumed tuberculous meningitis. Corticosteroids are indicated as adjunctive therapy (see below). Without therapy, tuberculous meningitis is universally fatal. The prognosis is worse in young children and in patients who present with altered mental status.[38]

Less common forms of CNS tuberculosis include radiculomyelitis and other infections of the spinal cord or epidural space[39]; and cerebral tuberculomas,[40] which typically present as slowly enlarging mass lesions. Tuberculomas may be initially misdiagnosed as brain tumors before surgical exploration and brain biopsy confirm the proper diagnosis. Tuberculomas may also develop during the course of therapy for tuberculous meningitis; their appearance does not necessarily represent treatment failure.

Abdominal Tuberculosis

Tuberculosis can involve the peritoneum or any intra-abdominal organ. The clinical manifestations depend on the area of involvement. Peritoneal disease is the most common type of abdominal tuberculosis. In the gut, tuberculosis may occur in any location from the mouth to the anus but is most common in the terminal ileum and cecum; other portions of the colon and rectum are less frequently involved.[28] Peritoneal tuberculosis may be secondary to hematogenous spread or, in women, to genital tuberculosis. Ileocecal and anorectal tuberculosis likely arise from the ingestion of tubercle bacilli in association with pulmonary disease. In peritoneal tuberculosis, the onset may be insidious; pain is a frequent presenting manifestation, often accompanied by abdominal swelling and increasing girth, fever, weight loss, and anorexia. Active pulmonary tuberculosis is often not present in patients with peritoneal tuberculosis. Because peritoneal tuberculosis may occur in patients with preexisting disorders, including hepatic cirrhosis with ascites, the symptoms of tuberculosis may be obscured.[28] The findings of ascites, abdominal tenderness, and fever should prompt an evaluation for infection, which should include paracentesis. Examination of peritoneal fluid generally shows an elevation in the white blood cell count with a lymphocytic predominance, elevated protein levels, and decreased glucose levels. AFB smears and cultures of peritoneal fluid are often negative unless extremely large volumes of fluid are examined. Laparoscopy with biopsy is recommended if tuberculosis is suspected; it has a much higher diagnostic yield. The differential diagnosis includes carcinomatosis, lymphoma, and cirrhosis. Tuberculous enteritis often involves the ileocecal region and may mimic Crohn disease or a malignancy. CT scanning and barium examinations are helpful, but colonoscopy and biopsy are required for diagnosis.

Miliary (Disseminated) Tuberculosis

Miliary, or disseminated, tuberculosis is defined as involvement of many organs simultaneously. It can occur as a result of

primary progressive disease or reactivation of latent infection.[4] Miliary tuberculosis is both a radiologic and pathologic term used to describe the hematogenous dissemination of *M. tuberculosis*. Radiologically, the term miliary refers to the pattern often seen on chest radiography, which is described as resembling millet seeds (e.g., a small reticulonodular pattern rather than an infiltrate). Not all patients with disseminated disease have pulmonary involvement, however.

The epidemiology of miliary or disseminated tuberculosis has changed dramatically over time. The incidence of miliary disease decreased markedly after the introduction of effective chemotherapy for tuberculosis. However, the advent of HIV/AIDS brought an increase in the number of cases. Miliary tuberculosis was once a disease primarily of children but now occurs primarily in HIV-infected persons, especially those with low $CD4^+$ T cell counts; it is also occasionally seen in elderly persons or other immunocompromised patients.

The onset of miliary tuberculosis is usually subacute. Symptoms often progress over a period of 1 to 4 months before diagnosis. Fever, anorexia, and weight loss occur in most patients. Respiratory symptoms occur in about half of patients with miliary disease, but hemoptysis is quite rare. Many other symptoms may appear; headache is particularly important because it may reflect coexisting tuberculous meningitis. Variant presentations, which account for a small percentage of cases, include cryptic miliary tuberculosis, in which patients have normal chest x-rays and exhibit problems typical of fever of undetermined origin [*see 7:XXIV Hyperthermia, Fever, and Fever of Undetermined Origin*]. An uncommon occurrence is fulminating miliary disease, which can have a sepsislike picture that includes respiratory failure, acute respiratory distress syndrome, disseminated intravascular coagulation, and multiorgan failure; often, tuberculosis is not considered early in this diagnosis.[41,42]

The physical examination in patients with miliary tuberculosis usually yields nonspecific results. Various pulmonary findings are seen in up to 50% of observed cases, hepatomegaly is seen in 30%, and splenomegaly or lymphadenopathy in 15%. Choroidal tubercles are less common, but they are diagnostically useful if present. Laboratory findings are often nonspecific. The complete blood count may be normal, but dramatic abnormalities have been well documented in this disorder and may range from pancytopenia to leukemoid reactions. Abnormal liver function test results, especially elevation of the alkaline phosphatase level, occur in 30% of cases. Hyponatremia is less common but, if present, should raise the possibility of inappropriate antidiuretic hormone secretion or adrenal insufficiency. AFB sputum smears are positive in only a minority (no more than 30%) of patients who have a miliary pattern on chest radiography. The use of fiberoptic bronchoscopy, bronchial brushings, and transbronchial biopsy to collect specimens may enhance the accuracy of bacteriologic studies, providing confirmation of the diagnosis in patients with miliary disease who have abnormal chest x-rays but negative sputum smears. Liver biopsy is especially helpful, revealing granulomas and providing positive cultures in about 60% of patients. Bone marrow biopsy is positive in about one third of all patients with miliary tuberculosis and has an even higher yield in those with hematologic abnormalities. The differential diagnosis in miliary tuberculosis includes histoplasmosis and other mycotic infections, sarcoidosis and other connective-tissue diseases, and malignant disorders.

Disseminated or miliary disease is fatal without chemotherapy; even with combined chemotherapy, mortality may be as high as 20%.[43,44] Adverse prognostic features include the presence of meningitis, extremes of age (i.e., old age and early childhood), delay in presentation, and the presence of underlying diseases. Clinical improvement with treatment is often very slow, and fever can persist for 1 to 3 weeks.

Other Forms of Extrapulmonary Tuberculosis

Other, less common forms of extrapulmonary tuberculosis include infection of the eye, skin (lupus vulgaris), upper respiratory tract (especially the larynx), pancreas, ear, and adrenal gland. Adrenal disease (often occurring with miliary or disseminated disease) is particularly important to consider and often is a manifestation of advanced disease presenting as signs of adrenal insufficiency. Onset of adrenal tuberculosis is usually insidious but can be acute; the disease should be considered in all patients with active or remote tuberculosis who are doing poorly, particularly if hypotension, hyponatremia, or hyperkalemia is present. Congenital tuberculosis is rare but can result from transplacental spread of *M. tuberculosis* to the fetus or from ingestion of contaminated amniotic fluid. Affected infants have disseminated disease, including involvement of the liver, spleen, lymph nodes, and other organs.

TUBERCULOSIS IN HIV-INFECTED PATIENTS

The interaction between HIV and *M. tuberculosis* is synergistic, each increasing the pathogenicity of the other.[45] HIV infection increases the susceptibility to developing active disease after infection with *M. tuberculosis,* and immune activation by *M. tuberculosis* increases HIV plasma viremia and appears to increase the rate of HIV disease progression and mortality.[46] HIV infection may increase the rate of tuberculosis after treatment completion or cure, in part because of an increased risk of reinfection, especially in highly endemic areas.[47] Dramatic point-source outbreaks of tuberculosis have been reported to occur where HIV-infected persons congregate, both in the United States and in other countries.[48,49] Many of these outbreaks have occurred in health care settings; in the United States, subsequent outbreaks have been prevented by implementation of effective tuberculosis infection control measures.[23,50] Such outbreaks will likely continue to occur in resource-poor areas where such measures have not been implemented. In the United States, HIV-related tuberculosis outbreaks have also been reported in other institutional settings, such as correctional facilities and homeless shelters.[51,52]

Tuberculosis can occur at any stage of HIV infection, but the clinical presentation is affected by the level of immunosuppression. Because *M. tuberculosis* is more virulent than opportunistic pathogens encountered in persons with HIV/AIDS, tuberculosis may be seen at higher $CD4^+$ T cell counts (i.e., > 200 cells/μl) than are generally seen with other opportunistic infections. When tuberculosis occurs early in the course of HIV infection, before severe immunosuppression has developed, the clinical and radiographic features resemble tuberculosis in patients who are HIV seronegative. In patients with more advanced HIV disease and lower $CD4^+$ T cell counts, *M. tuberculosis* tends to produce disease that is more widespread and severe than conventional tuberculosis and that has so-called atypical features [*see Figure 4*]. With progressive immunodeficiency, extrapulmonary involvement becomes increasingly common.

Pulmonary involvement remains common at all stages of HIV disease; however, the radiographic pattern is very different in persons with advanced immunodeficiency, in whom the most

common abnormalities are intrathoracic adenopathy, focal lower or middle lobe infiltrates, and diffuse miliary or nodular infiltrates. This pattern is consistent with a primary tuberculosis–like pattern. Overall, sputum AFB smears are less likely to be positive in patients with pulmonary disease and HIV coinfection than in non–HIV-infected patients, and HIV-infected patients are less likely to have cavitary disease. In one study, 8% of HIV-infected patients with pulmonary tuberculosis had normal chest radiographs.[30] Those with advanced HIV/AIDS frequently have concomitant pulmonary and extrapulmonary or disseminated tuberculosis. Up to 60% of HIV-infected patients with low $CD4^+$ T cell counts (< 200/μl) who develop tuberculosis have involvement of one or more extrapulmonary sites, including diffuse lymphadenitis, disseminated pleural and pericardial disease, or multiorgan involvement. Mycobacteremia and meningitis are also common in patients with advanced HIV infection.

Not surprisingly, given the atypical features of pulmonary tuberculosis in HIV-infected patients, particularly those with low $CD4^+$ T cell counts, delayed or missed diagnoses have been commonly reported. Thus, a high index of suspicion is crucial in making an appropriate diagnosis. The keys to the diagnosis of HIV-related tuberculosis are knowledge of the epidemiology of tuberculosis, recognition of the ways that immunodeficiency changes the clinical presentation, and an assiduous effort to obtain specimens for mycobacterial smear and culture.[53]

Targeted Testing for LTBI

The decrease in tuberculosis cases in the United States has brought a renewed focus on the treatment of LTBI as an important tuberculosis control strategy.[54] Targeted tuberculin testing for LTBI is a critical component of this strategy. Such testing identifies persons who are at high risk for developing tuberculosis and consequently would benefit from treatment of LTBI. (This type of treatment was previously called preventive therapy or chemoprophylaxis.) In immunocompetent persons, the lifetime risk of progression from latent infection with *M. tuberculosis* to active disease ranges from 5% to 10%; by contrast, in persons infected with HIV, the annual risk of disease progression is 10%.

HIV/AIDS is clearly the greatest risk factor for progression to active tuberculosis after infection with *M. tuberculosis*. Other risk factors include infection within the past 2 years (e.g., as indicated by a history of contact with a person known to have tuberculosis), injection drug use, silicosis, and certain other medical conditions and circumstances (e.g., diabetes mellitus, renal failure, certain malignancies, gastrectomy or jejunoileal bypass, solid-organ transplantation, or the use of immunosuppressive drugs; identification of LTBI is of particular importance in patients who are to be treated with TNF-α inhibitors such as infliximab, etanercept, or adalimumab).[22] The risk for progression is also higher in immigrants who have arrived in the United States within the past 5 years from areas where there is a high incidence of tuberculosis; in racial or ethnic minorities; in children 4 years of age or younger; and in children and adolescents who are exposed to adults at high risk.

TUBERCULIN SKIN TESTING

Until recently, the tuberculin skin test was the only available diagnostic test for LTBI, and it remains the most commonly used test. Tuberculin skin testing has a number of important limitations (see below), and new, improved diagnostic tests for LTBI (including those that can distinguish between infection with *M. tuberculosis* and *M. bovis* BCG [BCG vaccination]) are urgently needed.[55] It is hoped that tuberculin skin testing will be replaced with improved diagnostic tests in the coming years.

Tuberculin skin testing should be performed only on persons at increased risk for tuberculosis.[1] False positive results are common when the test is used in populations with a low prevalence of tuberculosis.[23,28] False positives also occur in persons vaccinated with BCG vaccine or in persons who are sensitized to environmental mycobacteria. False negative reactions are common in immunosuppressed persons and in those with overwhelming tuberculosis disease. In addition, testing is inconvenient, in that patients must return 48 to 72 hours after placement to have the result read.

The Mantoux method should be used for tuberculin skin testing; there is no role for multiple-puncture tests, such as the Tine test.[1] The standard test material used in the Mantoux is intermediate-strength (5 tuberculin units) purified protein derivative (PPD). There are two commercially available PPD preparations in the United States, Aplisol and Tubersol; these have similar sensitivity and specificity in at-risk populations, but Tubersol is slightly more specific and therefore may be of benefit when testing low-risk populations (e.g., certain groups of health care workers who are required to undergo regular tuberculin testing).[56] In addition, switching from Tubersol to Aplisol has been associated with false positive results.[57]

In reading a tuberculin skin test, the diameter of induration rather than of erythema should be determined and recorded. The criterion for a positive test (i.e., induration of ≥ 5 mm, ≥ 10 mm, or ≥ 15 mm) varies according to the population group to which the patient belongs, and the choice of criterion is influenced by the patient's likelihood of becoming infected with *M. tuberculosis* and the risk of developing active disease if infected[28] [*see Table 1*]. Anergy testing along with tuberculin testing is not routinely recommended, especially in HIV-infected patients.[1,28] In addition to its use as a diagnostic test for LTBI, a positive test may provide additional support for the diagnosis of active tuberculosis in culture-negative cases when there is a high clinical index of suspicion.

All patients with a positive tuberculin skin test must be evaluated for evidence of active disease with a chest radiograph. In addition, sputum specimens should be tested if symptoms suggestive of tuberculosis are present or abnormalities are found on the chest radiograph.

Repeated tuberculin skin testing will not cause a truly tuberculin-negative person (i.e., one who has not been infected with *M. tuberculosis* or sensitized to other mycobacteria) to become tuberculin positive.[58] In some persons with LTBI, the ability to react to tuberculin skin testing diminishes over time; administration of a tuberculin skin test to such persons can restore reactivity, thereby boosting the response to future tests.[59] Boosting is believed to result from recall of waned, cell-mediated immunity; it is common in persons older than 55 years and in those born outside the United States who have been vaccinated with BCG. Two-step testing is done to avoid interpreting the boost as a recent conversion and new infection in persons who will be undergoing serial testing. If the reaction to the first tuberculin skin test is negative, the test is repeated in 1 to 3 weeks. Two-step testing should be performed when initially testing persons who have not had a test in the previous 12 months and who will be subject to regular testing in the future, such as health care workers and employees and residents of group settings.

NEW DIAGNOSTIC TESTS FOR LTBI

Because of the limitations of the tuberculin skin test, new diagnostic tests for latent tuberculosis infection are needed.[55] A number of tests are under development. Two assays that utilize peripheral blood are commercially available: a whole-blood IFN-γ release assay (QuantiFERON-TB Gold, Cellestis Ltd, Victoria, Australia), which was approved by the Food and Drug Administration in December 2004, and an enzyme-linked immunospot assay (T SPOT-TB, Oxford Immunotec, Oxford, England), which is approved in Europe.[54,60,61] The Centers for Disease Control and Prevention has published guidelines for the use of the first-generation QuantiFERON-TB assay,[62] which is no longer available, and will be publishing guidelines for use of the second-generation assay, QuantiFERON-TB Gold, which uses tuberculosis-specific antigens, in selected patient populations. The advantages of T cell–based IFN-γ assays are that testing can be accomplished with a single patient visit, the test assesses responses to multiple antigens simultaneously, and the test does not boost anamnestic immune responses. Limitations of the currently available tests include the need to draw blood and to process the sample within 12 hours after collection.

It is hoped that the newer-generation tests that use *M. tuberculosis*–specific antigens will have improved utility, which should lead to wider availability and use of these tests.[60] However, prospective studies are needed to determine whether IFN-γ responses are predictive of high risk of progression to active tuberculosis, to gauge the utility of such tests in specialized subgroups of patients (including children and HIV-infected persons), and to ascertain whether treatment of LTBI on the basis of the results of IFN-γ responses will reduce the tuberculosis burden in low-incidence areas such as the United States.[54]

Table 1 Criteria for a Positive Tuberculin Skin Test by Risk Group[97]

Reaction size (induration) ≥ 5 mm, plus any of the following risk factors:
HIV infection
Recent contact with a patient with infectious TB
Fibrotic changes on chest x-ray consistent with prior TB
Organ transplantation, treatment with tumor necrosis factor–α inhibitors (e.g., infliximab, etanercept, adalimumab), or other immunosuppression (treatment with ≥ 15 mg/day of prednisone or an equivalent dose of another corticosteroid for 1 mo or longer*)
Reaction size (induration) ≥ 10 mm, plus any of the following risk factors:
Recent immigration (within the past 5 yr) from a country with a high prevalence of TB
Injection-drug use
Residence or employment† in a high-risk congregate setting: prison or jail; nursing home or other long-term facility for the elderly; hospital or other health care facility; residential facility for AIDS patients; homeless shelter
Employment in a mycobacteriology laboratory
High-risk clinical conditions: silicosis; diabetes mellitus; chronic renal failure; some hematologic disorders (e.g., leukemias and lymphomas); other specific malignancies (e.g., carcinoma of the head or neck, lung carcinoma); weight loss of ≥ 10% ideal body weight; gastrectomy; jejunoileal bypass
Age < 4 yr or, in an infant, child, or adolescent, exposure to a high-risk adult
Reaction size (induration) ≥ 15 mm

*Risk of TB in patients treated with corticosteroids increases with higher dose and longer duration.

†For persons who are otherwise at low risk and are tested at the start of employment, induration of ≥ 15 mm is considered positive.

TB—tuberculosis

Diagnosis

The keys to the diagnosis of tuberculosis are a high index of suspicion and familiarity with the range of clinical presentations that may occur, including atypical ones in HIV-infected patients that often reflect primary disease rather than reactivation of latent tuberculosis infection.[63]

Unfortunately, delay in diagnosis is common; such delays can increase the risk of a poor outcome and lead to further transmission of tuberculosis, including the precipitation of outbreaks in health care and institutional settings.[6,64-66]

CHEST RADIOGRAPHY

Patients presenting with clinical manifestations suggestive of tuberculosis with pulmonary involvement should have a chest radiograph performed. In immunocompetent patients, the chest radiograph may show upper-lobe disease, often with cavitation [*see* Pulmonary Tuberculosis, *above*]. HIV-infected patients, especially those with advanced disease and low $CD4^+$ T cell counts, are less likely to have cavitation visible on chest radiographs, regardless of the duration of symptoms. The longer the time since the onset of symptoms, the more likely it is that cavitation will be present. In HIV-infected patients, especially those with advanced disease who have a low $CD4^+$ T cell count, there is a greater likelihood of atypical findings on chest x-ray that reflect primary disease; such findings may include lower-zone infiltrates or hilar or mediastinal adenopathy [*see* Tuberculosis in HIV-Infected Patients, *above*].

Although the findings on chest radiography may be suggestive of tuberculosis, definitive diagnosis requires identification of *M. tuberculosis* through culture. In addition, a positive culture for *M. tuberculosis* is a prerequisite for susceptibility testing.

MICROBIOLOGY STUDIES

A number of different diagnostic tests for tuberculosis are available. However, AFB smear and culture are critical in the evaluation of a patient with suspected tuberculosis.

Acid-Fast Bacteria Smear Microscopy

The Kinyoun and the Ziehl-Neelsen basic fuchsin stains are the traditional methods used for visualizing mycobacteria in clinical specimens. In the United States and other developed countries, an auramine-rhodamine stain with fluorescent microscopy is used because it is more sensitive and less time consuming than the carbol-fuschin stain (e.g., the Ziehl-Neelson stain). Throughout most of the world, AFB smear microscopy is the major diagnostic tool for tuberculosis. In the United States and other developed countries, AFB culture, which is more sensitive than an AFB smear, is also used in conjunction with smear microscopy. AFB smear microscopy has a sensitivity of only about 50% to 60% in culture-confirmed cases, in part because a positive smear requires a sputum sample containing 5,000 to 10,000 AFB/μl, whereas a positive AFB sputum culture requires only 10 to 100 AFB/μl.[28] Another limitation is that smear microscopy cannot distinguish *M. tuberculosis* from other mycobacteria.

A presumptive diagnosis of tuberculosis can be made in the setting of a positive AFB smear and clinical manifestations con-

sistent with the disease. Culture confirmation is necessary for a definitive diagnosis; NAA tests, which can be performed directly on clinical specimens, can also provide confirmation of *M. tuberculosis* on AFB smear–positive respiratory specimens.

Mycobacterial Culture

A definitive diagnosis of tuberculosis generally depends on the isolation and identification of *M. tuberculosis* from a clinical specimen; most often this is a sputum sample from a patient with pulmonary disease. Conventional culture of mycobacteria with solid media requires incubation for 3 to 6 weeks. Use of broth-based media can result in recovery of a positive culture 10 to 14 days sooner than with solid media.[67] Broth-based media are also preferable because they are more sensitive than solid media, although neither type of medium recovers all isolates.[67,68] For these reasons, it is recommended that a broth system be used for primary mycobacterial culture but that a solid medium also be inoculated.

DNA probes can be used to rapidly identify colonies of *M. tuberculosis* complex (i.e., *M. tuberculosis, M. bovis, M. africanum,* and *M. microti*) and have replaced biochemical tests in most laboratories. Commercially available probes can identify the *M. tuberculosis* complex but do not differentiate *M. tuberculosis* from other members of the complex; they can also identify *M. avium* complex, *M. kansasii*, and *M. gordonae*. Probes provide species identification within a few hours with nearly 100% accuracy if sufficient growth is tested. However, a positive culture is required before the probe can be used for species identification. High-performance liquid chromatography can also be used to determine the mycobacterial species, but it is usually available only at large public health and reference laboratories.

Susceptibility Testing

Initial isolates from all patients should be tested for drug susceptibility to identify an effective antituberculous regimen.[28] In addition, drug susceptibility tests should be repeated if the patient continues to produce culture-positive sputum after 3 months of adequate therapy or if the patient does not respond clinically to therapy. It has been proposed that susceptibility test results for the first-line antituberculous drugs be reported within an average of 28 days of receipt of the specimen in the laboratory; this requires the use of broth-based media for identification and susceptibility testing. According to the National Committee for Clinical Laboratory Standards Subcommittee for Antimycobacterial Susceptibility Testing, isolates of *M. tuberculosis* should be tested for susceptibility to isoniazid (at two concentrations), rifampin, ethambutol, and pyrazinamide (the latter three at one concentration each).[69] Such testing provides comprehensive information regarding the initial four-drug therapy recommended for treatment of most tuberculosis patients in the United States.

If resistance to rifampin or to any two first-line drugs is found, the isolate should be tested for susceptibility to second-line drugs (e.g., capreomycin, ethionamide, kanamycin, ofloxacin, *para*-aminosalicylic acid, rifabutin, and streptomycin) and for susceptibility to ethambutol at a higher concentration than was used initially.[69,70] Second-line drug testing can be done only on solid media, preferably using the agar proportion method. This process is slow; it can take up to 2 months for results to become available.

Nucleic Acid Amplification Tests

NAA techniques can be used to identify mycobacterial DNA or RNA of *M. tuberculosis* in clinical specimens (e.g., sputum or other respiratory specimens) and provide immediate confirmation that a patient has tuberculosis. NAA testing has been most commonly used to confirm the diagnosis of tuberculosis in patients who have positive AFB smears on sputum or other respiratory specimens. Two commercially available tests are approved by the FDA for use on respiratory specimens.[68,71] The tests are rapid, taking less than 6 hours, and are performed directly on clinical specimens. In sputum and respiratory specimens that are AFB smear–positive, NAA tests have sensitivities and specificities greater than 95%; in AFB smear–negative specimens, specificity remains above 95% but sensitivity is much lower, often less than 50%.[24] The FDA has approved NAA tests in conjunction with cultures of respiratory specimens from patients who have not been treated for tuberculosis.[71] NAA tests have been performed on nonrespiratory specimens, although they are not FDA approved for this use. The performance of NAA tests on nonrespiratory specimens has varied; the sensitivity appears to be less than that for respiratory specimens.[68] NAA tests are particularly useful when the positive predictive value of a positive AFB smear of sputum for *M. tuberculosis* is low. This is the case in settings where recovery of nontuberculous mycobacteria is common, such as with HIV-infected patients, especially those with advanced disease. Currently, NAA tests cannot replace conventional methods for the diagnosis and management of tuberculosis. In hospitalized patients, the AFB smear is used to assess infectivity and the need to institute isolation precautions against airborne infection. Culture must be performed to recover the isolate for susceptibility testing. Thus, NAA testing is a supplement to the traditional diagnostic tests, and it results in additional expense—predominantly, laboratory costs for reagents and technicians' time. The increase in laboratory expenditures, however, may be offset by savings elsewhere in the hospital or public health department. Hospitals can benefit from the ability to discharge patients from airborne-infection isolation rooms despite being AFB positive, when negative results on NAA testing show that they do not have tuberculosis. Negative NAA tests also can help avoid unnecessary therapy for tuberculosis and may shorten hospital stays. In public health departments, positive NAA test results can facilitate contact investigations of persons who have tuberculosis.

Additional Diagnostic Tests

Other diagnostic tests may be useful in facilitating the diagnosis of tuberculosis. Sputum induction by ultrasonic nebulization of hypertonic saline may be useful for patients who are not able to expectorate sputum. The yield of an induced sputum test appears to be as good as that of specimens obtained by fiberoptic bronchoscopy, and yield of repeated inductions may be superior.[72,73] Bronchoscopy with bronchoalveolar lavage or biopsy is sometimes performed as a diagnostic test, especially when sputum cannot be obtained or in patients with radiographic abnormalities suggestive of other diagnoses (e.g., bronchogenic carcinoma). It is essential that specimens be submitted to the microbiology laboratory for AFB smear and culture to establish a diagnosis in such cases.

Molecular typing (so-called DNA fingerprinting) of *M. tuberculosis* isolates has proved very useful in furthering the understanding of the epidemiology of tuberculosis. Molecular typing has led to an increase in knowledge regarding the transmission dynamics of *M. tuberculosis*. It has also proved useful in the evaluation of patients with a second episode of tuberculosis, in that it enables one to differentiate relapses from reinfection with a new

strain. Molecular typing is also helpful in evaluating outbreaks and in identifying laboratory cross contamination.[8]

Extrapulmonary Tuberculosis

To establish the diagnosis of extrapulmonary tuberculosis, appropriate specimens should be obtained for AFB staining, mycobacterial culture, and drug susceptibility testing.[27,30] Depending on the clinical circumstances, specimens may include pleural fluid; pericardial or peritoneal fluid; pleural, pericardial, and peritoneal biopsy specimens; lymph node tissue; bone marrow; bone; blood; urine; brain tissue; or cerebrospinal fluid. Blood from patients with HIV infection should be sent for AFB culture when extrapulmonary or disseminated tuberculosis is suspected. Tissue specimens should also be examined microscopically, after routine and AFB staining, but the absence of AFB and of granulomas or even failure to culture *M. tuberculosis* does not necessarily exclude the diagnosis of tuberculosis. In some cases, a presumptive diagnosis of tuberculosis is made on the basis of epidemiologic findings (e.g., close contact of an active case), consistent clinical and radiologic findings, and a positive tuberculin skin test.

Treatment

PRINCIPLES OF TUBERCULOSIS TREATMENT

The goals of antituberculosis therapy are to ensure a cure without relapse, to prevent death, to stop transmission of *M. tuberculosis*, and to prevent the emergence of drug-resistant disease.[4] Therapy is initiated with a multidrug regimen to kill tubercle bacilli rapidly, to minimize or prevent the development of drug-resistant *M. tuberculosis* strains, and to eliminate persistent organisms from host tissue to prevent relapse. Active tuberculosis should never be treated with a single drug, because of the risk of emergence of resistance, and a single drug should never be added to a failing regimen.

The initial therapy for tuberculosis generally consists of a four-drug regimen (isoniazid, rifampin, pyrazinamide, and ethambutol) [*see Table 2*]. Detailed discussion of the pharmacokinetics, pharmacodynamics, and available preparations of these drugs is beyond the scope of this chapter, but reviews of these subjects have been published.[3,74]

Tuberculosis requires prolonged treatment. The minimum length of therapy for the treatment of drug-susceptible tuberculosis is 6 to 9 months with a rifampin-based regimen (so-called short-course therapy). Longer courses of therapy are required for drug-resistant tuberculosis, especially multidrug-resistant disease (i.e., disease caused by *M. tuberculosis* that is resistant to at least isoniazid and rifampin).Treatment of tuberculosis has two phases: initiation (also known as the bactericidal or intensive phase) and continuation (also known as the subsequent sterilizing phase). These phases reflect the current understanding of the pathophysiology of tuberculosis. Three separate subpopulations of *M. tuberculosis* are thought to exist in the host with tuberculosis.[74] The first and largest of the subpopulations consists of rapidly growing extracellular organisms that mainly reside in well-oxygenated cavities (abscesses) containing 10^7 to 10^8 organisms. The second subpopulation resides within poorly oxygenated, closed, solid, caseous lesions (e.g., noncaseating granulomas) containing 10^4 to 10^5 organisms. These organisms are considered semidormant and undergo only intermittent bursts of metabolic activity. The third subpopulation consists of a small number of organisms (fewer than 10^4 to 10^5) believed to be semidormant within acidic environments—both intracellular (e.g., in macrophages) or extracellular within areas of active inflammation and recent necrosis.

Initiation of tuberculosis treatment is usually with a four-drug regimen consisting of isoniazid (also called INH), rifampin, pyrazinamide (PZA), and ethambutol. Isoniazid and rifampin are the two most important antituberculous drugs and are the cornerstones of therapy. PZA is an important first-line drug that is a necessary component for so-called short-course therapy (i.e., 6 to 9 months). Of these agents, isoniazid is the most potent for killing the rapidly multiplying *M. tuberculosis* bacilli (i.e., those in the first subpopulation) during the initial part of therapy; that is, it has early bactericidal activity. Rifampin and ethambutol have less early bactericidal activity than isoniazid but considerably more than PZA, which has weak early bactericidal activity during the first 2 weeks of treatment. The use of drugs that have potent early bactericidal activity reduces the chance of the development of resistance.

The rapidly dividing population of bacilli (i.e., the first subpopulation) is eliminated early in effective therapy, and after 2 months of treatment, about 80% of patients are culture negative. The remaining (i.e., the second and third) subpopulations of *M. tuberculosis* account for treatment failures and relapses and are the reason that prolonged therapy is required for eradication. For the continuation phase of therapy, antituberculous drugs are chosen on the basis of their sterilizing activity, which is defined by a drug's ability to kill bacilli mainly in the second and third subpopulations.The use of drugs that have good sterilizing activity is essential for short-course therapy (e.g., 6-month regimens). Rifampin and PZA have the greatest sterilizing activity, followed by isoniazid and streptomycin. The sterilizing activity of rifampin persists throughout the course of therapy; however, the sterilizing activity of PZA is mainly seen during the initial 2 months of therapy.

Directly Observed Therapy

Successful treatment of tuberculosis depends not only on the correct choice of antimycobacterial drugs but also on the provision of those drugs within a clinical and social framework based on individual patient circumstances.[3] Furthermore, the treatment of tuberculosis is much different from the treatment of other diseases because of the public health implications of the disease. Whether care is provided by a physician in private practice or through a public health program, the provider has the dual responsibility of selecting an appropriate regimen and ensuring that treatment is completed.[3] For that reason, DOT is recommended for all patients diagnosed with active tuberculosis, in that it helps maximize completion rates [*see Figure 6*], decrease risk for emergence of resistance, and enhance tuberculosis control.[75,76] DOT is generally provided by public health agencies.

INITIATION OF THERAPY

The decision to initiate combination antituberculosis chemotherapy (e.g., a four-drug regimen) should be based on epidemiologic information; clinical, pathologic, and radiographic findings; and the results of microscopic examination of AFB-stained sputum smears (or other diagnostic specimens, as appropriate) and cultures for mycobacteria.[3] Given that *M. tuberculosis* is a relatively slow-growing organism and that cultures can take up to 4 to 5 weeks to become positive, empirical therapy with an appropriate multidrug regimen needs to be initiated when there is

Table 2 Recommended Doses and Adverse Effects of Antituberculosis Medications for Adults*

Rank	*Drug (Route)*	*Daily Dose (Maximum Daily Dose)*	*Twice-Weekly Dose (Maximum Dose)†*	*Thrice-Weekly Dose (Maximum Dose)†*	*Adverse Effects*
First-line drugs	Isoniazid (p.o., I.M., I.V.)	5 mg/kg (300 mg)	15 mg/kg (900 mg)	15 mg/kg (900 mg)	Liver enzyme elevation, hepatitis, peripheral neuropathy, central nervous system effects, rash
	Rifampin (p.o., I.V.)	10 mg/kg (600 mg)‡	10 mg/kg (600 mg)‡	10 mg/kg (600 mg)‡	Orange discoloration of secretions and urine, GI upset, hepatitis, immune-mediated toxicity (e.g., thrombocytopenia, renal failure), flulike symptoms, many drug interactions, rash
	Rifabutin (p.o.)	5 mg/kg (300 mg)‡	5 mg/kg (300 mg)‡	5 mg/kg (300 mg)‡	Similar to rifampin; fewer drug interactions
	Pyrazinamide (p.o.)	40–55 kg: 1,000 mg 56–75 kg: 1,500 mg 76–90 kg: 2,000 mg	40–55 kg: 2,000 mg 56–75 kg: 3,000 mg 76–90 kg: 4,000 mg	40–55 kg: 1,500 mg 56–75 kg: 2,500 mg 76–90 kg: 3,000 mg	GI upset; hepatitis; hyperuricemia; arthralgias
	Ethambutol (p.o.)	40–55 kg: 800 mg 56–75 kg: 1,200 mg 76–90 kg: 1,600 mg	40–55 kg: 2,000 mg 56–75 kg: 2,800 mg 76–90 kg: 4,000 mg	40–55 kg: 1,200 mg 56–75 kg: 2,000 mg 76–90 kg: 2,400 mg	Optic neuritis
Second-line drugs	Cycloserine (p.o.)	10–15 mg/kg in two doses (1 g in two doses)§	No data to support intermittent use	No data to support intermittent use	Psychosis, seizures, depression
	Ethionamide (p.o.)	15–20 mg/kg (1 g) h.s., with main meal, or in two divided doses	No data to support intermittent use	No data to support intermittent use	GI upset, hepatotoxicity, hypothyroidism, metallic taste, bloating
	Streptomycin (I.V., I.M.)	15 mg/kg (1 g); 10 mg/kg in patients > 59 yr (750 mg)‖	15 mg/kg (1 g); 10 mg/kg in patients > 59 yr (750 mg)‖	15 mg/kg (1 g); 10 mg/kg in patients > 59 yr (750 mg)‖	Ototoxicity (hearing loss, vestibular dysfunction), nephrotoxicity
	Amikacin-kanamycin (I.V., I.M.)	15 mg/kg (1 g); 10 mg/kg in patients > 59 yr (750 mg)‖	15 mg/kg (1 g); 10 mg/kg in patients > 59 yr (750 mg)‖	15 mg/kg (1 g); 10 mg/kg in patients > 59 yr (750 mg)‖	Ototoxicity (hearing loss, vestibular dysfunction), nephrotoxicity
	Capreomycin (I.V., I.M.)	15 mg/kg (1 g); 10 mg/kg in persons > 59 yr (750 mg)‖	15 mg/kg (1 g); 10 mg/kg in patients > 59 yr (750 mg)‖	15 mg/kg (1 g); 10 mg/kg in patients > 59 yr (750 mg)‖	Ototoxicity (hearing loss, vestibular dysfunction), nephrotoxicity, hypokalemia, hypomagnesemia, eosinophilia
	para-Aminosalicylic acid (PAS) (p.o., I.V.)	8–12 g in two or three doses	No data to support intermittent use	No data to support intermittent use	GI upset, hypersensitivity, hepatotoxicity
	Levofloxacin (p.o., I.V.)	500–1,000 mg	No data to support intermittent use	No data to support intermittent use	GI upset, dizziness, cartilage damage at high doses
	Moxifloxacin (p.o., I.V.)	400 mg	No data to support intermittent use	No data to support intermittent use	GI upset, dizziness, cartilage damage at high doses
	Gatifloxacin (p.o., I.V.)	400 mg	No data to support intermittent use	No data to support intermittent use	GI upset, dizziness, cartilage damage at high doses

*See Table 3 for recommended regimens.
†Must be administered by directly observed therapy only.
‡Dose adjustment may be necessary with concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.
§Serum concentration measurements of cycloserine are often useful for optimizing doses in individual patients; the goal is a peak concentration of 20–35 mg/dl.
‖The usual dose is 750–1,000 mg, given as a single dose 5–7 days/wk; reduced to 2–3 days/wk after the first 2–4 mo or after culture conversion, depending on the efficacy of other drugs in the regimen.
GI—gastrointestinal

high clinical suspicion of active disease. Therapy should be started before culture confirmation and in some cases before AFB smear microscopy results are known. NAA tests [*see* Nucleic Acid Amplification Tests, *above*] may be useful in selected cases, because of their ability to provide an immediate definitive diagnosis (e.g., confirmation of AFB smear–positive respiratory specimens). The threshold for initiating empirical therapy should be low for patients with potentially life-threatening forms of tuberculosis that can progress rapidly, such as tuberculous meningitis, pericarditis, or miliary disease.

TREATMENT REGIMENS

Guidelines published by the American Thoracic Society (ATS), the CDC, and the Infectious Diseases Society of America (IDSA) outline recommended treatment regimens for use in the United States and other industrialized countries [*see Table 3*].

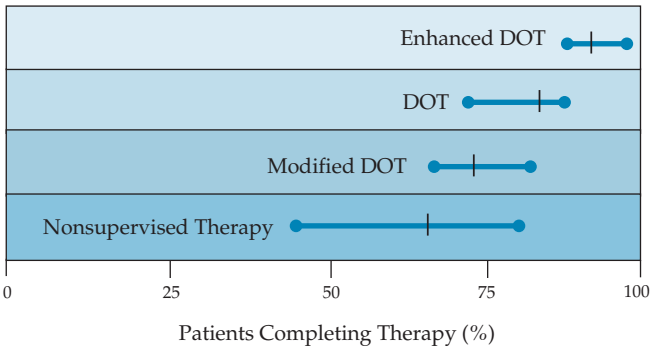

Figure 6 **Impact of directly observed therapy (DOT) on completion rates of therapy for pulmonary tuberculosis.[74] Median completion rates were 61.4% for nonsupervised therapy, 78.6% for modified DOT (i.e., initial inpatient DOT followed by a variety of outpatient strategies, including self-administered medication), 86.3% for DOT, and 91.0% for enhanced DOT (i.e., DOT with multiple incentives and enablers).**

Recommendations are graded and evidence based, using the IDSA–United States Public Health Service rating system.

Drug-Susceptible Pulmonary Disease

When testing confirms drug susceptibility in patients who have been started on an empirical four-drug regimen (e.g., isoniazid, rifampin, PZA, and ethambutol) for pulmonary disease, treatment can be modified accordingly [*see Table 3 and Figure 7*]. PZA can be discontinued after 2 months of therapy (i.e., at the end of the initiation phase). Ethambutol can also be discontinued after 2 months of therapy or as soon as drug susceptibility is confirmed. Isoniazid and rifampin are maintained in the continuation phase (4 more months) for a minimum of 6 months of therapy. Patients at high risk for relapse include those with cavitary pulmonary tuberculosis who remain culture positive after 2 months of therapy.[77] Such patients should have the continuation phase of therapy extended 3 additional months (to 7 months in the continuation phase and a total of 9 months of therapy).

In addition to the total duration of therapy, the number of completed doses is important for treatment success. Doses should be counted and tracked to ensure the proper amount of therapy is delivered. Lack of adherence to antituberculosis therapy is the most common cause of treatment failure, relapse, and the emergence of drug resistance. DOT has been proved to improve completion rates and outcome, and it should be considered the standard of care [*see Figure 6*].[3] Drug-susceptible disease can be successfully treated with antituberculosis therapy administered on an intermittent basis (e.g., twice or thrice weekly), especially in the continuation phase; this tactic facilitates supervision of therapy, thereby helping to improve outcomes. Intermittent therapy (e.g., therapy administered twice or thrice weekly) should be given by DOT only and only to patients with drug-susceptible disease.

HIV-Infected Patients

Because tuberculosis may be the disease that brings an HIV-infected person into the health care system for the first time, all patients diagnosed with tuberculosis should be offered—and strongly encouraged to undergo—HIV serologic testing.[3] The treatment of tuberculosis in patients with HIV coinfection is similar to that in HIV-seronegative patients, with two exceptions. First, HIV-infected patients should not be treated with once-weekly isoniazid-rifapentine in the continuation phase; this regimen is reserved for highly selected HIV-seronegative patients without cavitary disease. In HIV-infected patients, the risk of relapse with this regimen is increased to an unacceptable degree; when relapse occurs, it is often with organisms that have acquired rifamycin resistance.[78] Second, HIV-infected patients with

Table 3 Treatment Guidelines for Drug-Susceptible Pulmonary Tuberculosis in Adults*[3]

	Initial Phase		Continuation Phase			Total Dosage Range (Minimal Duration)	Rating/Evidence†	
Regimen	Drugs	Interval	Regimen	Drugs	Interval		HIV-Negative Patients	HIV-Positive Patients
1	Isoniazid + Rifampin + Pyrazinamide + Ethambutol	Daily or 5 days/wk‡ for 8 wk	1a	Isoniazid + rifampin	Daily or 5 days/wk‡ for 18 wk	182–130 (26 wk)	A/I	A/II
			1b	Isoniazid + rifampin	Twice weekly for 18 wk	92–76 (26 wk)	A/I	A/II§
			1c	Isoniazid + rifapentine	Once weekly for 18 wk	74–58 (26 wk)	B/I	E/I
2	Isoniazid + Rifampin + Pyrazinamide + Ethambutol	Daily or 5 days/wk‡ for 2 wk, then twice weekly for 6 wk	2a	Isoniazid + rifampin	Twice weekly for 18 wk	62–58 (26 wk)	A/II	B/II§
			2b	Isoniazid + rifapentine	Once weekly for 18 wk	44–40 (26 wk)	B/I	B/II

†Rating levels: A, preferred regimen; B, acceptable alternative; C, offer when A and B cannot be given; D, generally should not be given; E, should never be given. Evidence levels: I=randomized clinical trial; II=data from clinical trials that were not randomized or were conducted in other populations; III=expert opinion.
‡5 days/wk administration is always given by directly observed therapy; rating for these regimens is A/III.
§Not recommended for HIV-positive patients with CD4+ T cell counts < 100 cells/μl.

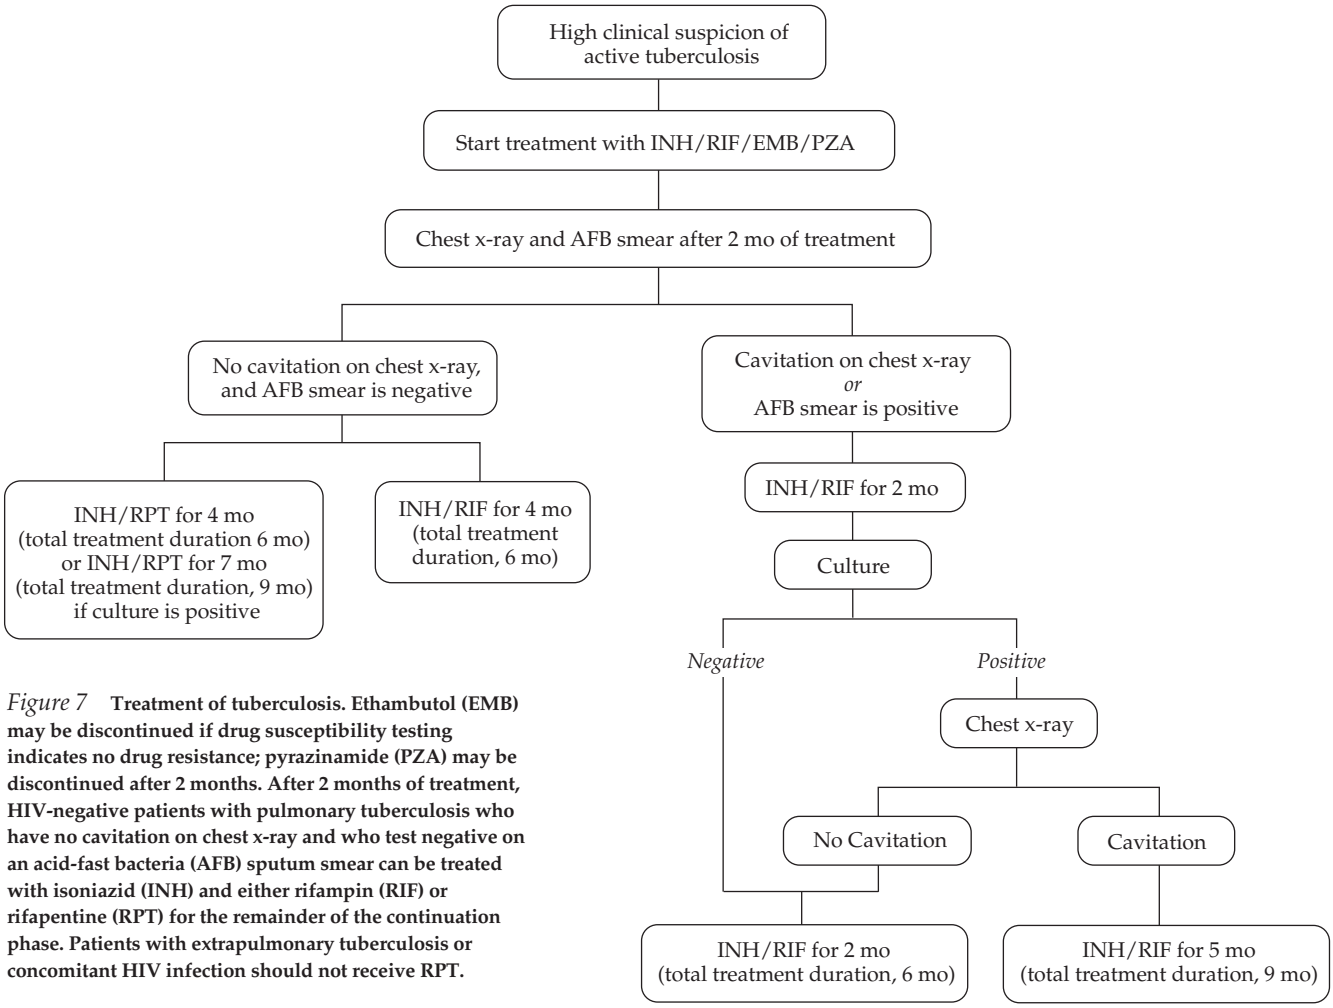

Figure 7 **Treatment of tuberculosis. Ethambutol (EMB) may be discontinued if drug susceptibility testing indicates no drug resistance; pyrazinamide (PZA) may be discontinued after 2 months. After 2 months of treatment, HIV-negative patients with pulmonary tuberculosis who have no cavitation on chest x-ray and who test negative on an acid-fast bacteria (AFB) sputum smear can be treated with isoniazid (INH) and either rifampin (RIF) or rifapentine (RPT) for the remainder of the continuation phase. Patients with extrapulmonary tuberculosis or concomitant HIV infection should not receive RPT.**

$CD4^+$ T cell counts of less than 100/μl should not receive twice-weekly intermittent regimens (e.g., isoniazid-rifampin or isoniazid-rifabutin), because acquired rifamycin resistance has also been reported in this setting.[3,79] Instead, HIV-infected patients with low $CD4^+$ T cell counts should receive daily or thrice-weekly therapy.[3] HIV-infected patients with drug-susceptible pulmonary tuberculosis can generally be treated for 6 months [*see Table 3*]. For HIV-infected patients with tuberculosis who are slow to respond to therapy or who have a suboptimal response (e.g., whose cultures are positive after 2 months of therapy), prolongation of the continuation phase to 7 months (for a total of 9 months of treatment) is suggested.[3]

In the United States, most patients with HIV-related tuberculosis have advanced immunosuppression and high plasma HIV RNA levels at the time of diagnosis.[80] Thus, they meet the criteria for antiretroviral therapy.[81] In addition, the use of antiretroviral therapy during the treatment of tuberculosis in persons with HIV infection may improve tuberculosis treatment outcomes.[3,82] However, strict adherence to antiretroviral therapy is necessary to promote a sustained virologic response; moreover, the use of antiretroviral therapy in HIV-infected patients with tuberculosis is complicated by overlapping toxicity profiles of some antituberculosis and antiretroviral drugs, as well as by complex drug-drug interactions and the occurrence of paradoxical or immune reconstitution reactions.

Paradoxical or immune reconstitution reactions are characterized by exacerbation of symptoms and signs or by radiographic manifestations of tuberculosis. These reactions are more common in HIV-infected patients who are started on antiretroviral therapy early in the course of antituberculosis therapy.[83] Therefore, although there are no data to indicate the best time to start antiretroviral therapy, some experts have recommended delaying its initiation, if possible, until after the patient has received 1 to 2 months of antituberculosis therapy.[3]

The use of antiretroviral therapy during tuberculosis treatment is complex for both the patient and the physician. Thus, there needs to be close coordination of care between the physicians treating each disease. The interaction between rifampin (and other rifamycins) and antiretroviral agents, especially the protease inhibitors, is a major concern and a challenge in treating tuberculosis in HIV-infected patients. Because rifamycins induce the hepatic cytochrome P-450 3A enzyme system, their use leads to reductions in the serum levels of a variety of drugs—in some cases to nontherapeutic ranges. A long list of clinically significant drug-drug interactions involving the rifamycins have been reported, including those with protease inhibitors and nonnucleoside reverse transcriptase inhibitors; there are generally no significant drug-drug interactions with nucleoside reverse transcriptase inhibitors (NRTIs) [*see 7:XXXIII HIV and AIDS*]. Rifampin is the most potent cytochrome P-450 inducer, followed by rifapen-

tine and rifabutin. Conversely, the protease inhibitors are cytochrome P-450 inhibitors that raise rifabutin levels to potentially toxic concentrations and necessitate dose modifications. Rifampin cannot be given with most protease inhibitors, because its use results in low serum levels of these drugs. Rifabutin lowers drug serum levels to a lesser degree than rifampin, and therefore it can be used with certain protease inhibitors.

Possible options in the treatment of tuberculosis in HIV-infected patients include the following: (1) use of a rifampin-based regimen, which can be given to patients receiving antiretroviral therapy with NRTIs and efavirenz; (2) the substitution of rifabutin for rifampin in a multidrug regimen when the patient is receiving antiretroviral therapy with a protease inhibitor; (3) the use of rifampin in a multidrug regimen when antiretroviral therapy cannot be given; and (4) the use of a non–rifamcyin-based regimen in patients receiving antiretroviral drugs, including protease inhibitors. Despite the potential for avoiding drug-drug interactions, however, regimens that do not include a rifamycin are not recommended for patients with HIV infection, because worse outcomes have been reported.[80]

It must be emphasized that recommendations on the use of antiretroviral therapies in HIV-infected patients with tuberculosis continue to evolve. The latest recommendations and information, including acceptable antiretroviral regimens and necessary dose adjustments, are available from CDC on the Internet (www.cdc.gov/nchstp/tb/TB_HIV_Drugs/TOC.htm).[84]

Extrapulmonary Tuberculosis

The basic principles that underlie the treatment of pulmonary tuberculosis also apply to extrapulmonary forms of the disease. A 6-month course of therapy is recommended for treating tuberculosis involving any site except the meninges; for the meninges, a 9- to 12-month regimen is recommended. Prolongation of therapy also should be considered for patients with tuberculosis that is slow to respond, regardless of the site.

The addition of corticosteroids is recommended for patients with tuberculous pericarditis and meningitis, because it improves outcome and decreases mortality.[3,85,86] Evidence-based guidelines for the treatment of extrapulmonary tuberculosis and the adjunctive use of corticosteroids have been developed [*see Table 4*]. Corticosteroids should be given for tuberculous pericarditis during the first 11 weeks of antituberculosis therapy. Corticosteroids do not reduce the risk of the development of constrictive pericarditis, however. For patients with tuberculous meningitis, adjunctive dexamethasone is recommended.

Tuberculosis in Pregnant Patients

Tuberculosis that is discovered during pregnancy should be treated without delay. Because tuberculosis can spread to the fetus, treatment in pregnant women should be initiated whenever the probability of maternal disease is moderate to high.

The initial treatment regimen in pregnant patients consists of isoniazid, rifampin, and ethambutol. Consideration should be given to including PZA in the initial regimen as well: PZA has not been widely used in the United States to treat pregnant women with tuberculosis, but it is recommended for use in this setting by the WHO and the International Union Against Tuberculosis and Lung Disease, as well as some public health agencies in the United States.[3,87] PZA is recommended for use in all HIV-infected pregnant patients and in pregnant patients who are thought to be at high risk for drug-resistant tuberculosis (pending susceptibility test results). If PZA is not included in the regimen, the minimum duration of treatment is 9 months. Supplemental pyridoxine (vitamin B_6), 25 to 50 mg a day, is indicated for all pregnant women taking isoniazid, to prevent peripheral neuropathy. Aminoglycosides and fluoroquinolones should be avoided in pregnancy because of potential adverse effects on the fetus.

Drug-Resistant Tuberculosis

Treatment of drug-resistant tuberculosis, especially MDR-TB, is quite challenging and should be done by, or in close consultation with, an expert in this subject. Recommendations for the treatment of drug-resistant tuberculosis have been developed [*see Table 5*]. Treatment of isolated isoniazid resistance can be accomplished with a 6-month regimen of daily rifampin, PZA, and ethambutol. Treatment of isolated rifampin resistance requires a minimum of 12 months of therapy with a regimen such as isoniazid, PZA, ethambutol, and a fluoroquinolone. Treatment of MDR-TB (resistance to both isoniazid and rifampin) requires 18 to 24 months, depending on the full resistance pattern, and is associated with significantly higher morbidity and mortality than drug-susceptible disease. Treatment of MDR-TB requires the use of second-line drugs, which have less in vitro activity and significantly more toxicity than first-line drugs [*see Table 2*].

Common errors that lead to the emergence of drug resistance include the addition of a single drug to a failing regimen, failure to identify preexisting or acquired drug resistance, initiation of

Table 4 Evidence-Based Guidelines for Duration of Therapy for Drug-Susceptible Extrapulmonary Tuberculosis and Adjunctive Use of Corticosteroids*[3,85]

Site	*Duration of Antimicrobial Therapy (Rating)*	*Adjunctive Corticosteroids (Rating)*	*Corticosteroid Regimens*
Lymph node	6 mo (A/I)	Not recommended (D/III)	Pericarditis: prednisone, 60 mg/day, wk 1–4; 30 mg/day, wk 5–8; 15 mg/day, wk 9–10; 5 mg/day, wk 11
Bone and joint	6–9 mo (A/I)	Not recommended (D/III)	
Pleural disease	6 mo (A/II)	Not recommended (D/III)	
Pericarditis	6 mo (A/II)	Strongly recommended (A/I)	
CNS, including meningitis	9–12 mo (B/II)	Strongly recommended (A/I)	Meningitis: dexamethasone for 6 wk; in children < 25 kg, 8 mg/day × 3 wk; in children > 25 kg and in adults, 12 mg/day × 3 wk; in all patients, dose is tapered over the next 3 wk
Disseminated disease	6 mo (A/II)	Not recommended (D/III)	
Genitourinary	6 mo (A/II)	Not recommended (D/III)	
Peritoneal	6 mo (A/II)	Not recommended (D/III)	

*Preferred duration of therapy for extrapulmonary tuberculosis caused by drug-resistant organisms is unknown.
CNS—central nervous system

Table 5 Potential Regimens for the Treatment of Drug-Resistant Tuberculosis[3]

Pattern of Drug Resistance	*Suggested Regimen (Alternative Choice)*	*Duration of Treatment (mo)*	*Comments*
Isoniazid (± streptomycin)	Rifampin, pyrazinamide, ethambutol; addition of a fluoroquinolone* may strengthen regimen for patients with extensive disease	6	Use at least three other drugs; include rifampin, pyrazinamide, and ethambutol or streptomycin
Rifampin	Isoniazid, ethambutol, and a fluoroquinolone,* plus pyrazinamide for the first 2 mo; an injectable agent† may be included for the first 2–3 mo for patients with extensive disease	12–18	Isoniazid, pyrazinamide, and streptomycin for 9 mo is an alternative regimen; however, prolonged therapy with an injectable agent may not be feasible or desirable, and an all-oral regimen should be as effective; some experts continue pyrazinamide throughout the course of therapy
Isoniazid and rifampin (± streptomycin)	A fluoroquinolone,* pyrazinamide, ethambutol, and an injectable agent,† ± an alternative agent‡	18–24	Extended treatment is needed to lessen the risk of relapse; in patients with extensive disease, the addition of an alternative agent may be prudent to lessen the risk of failure and additional acquired drug resistance; consider resectional surgery as adjunct to chemotherapy
Isoniazid, rifampin (± streptomycin), and ethambutol or pyrazinamide	A fluoroquinolone* (ethambutol or pyrazinamide, if active), injectable agent,† and two alternative agents‡	24	Use the first-line agents to which the strain is susceptible; add two or more alternative agents in patients with extensive disease; consider resectional surgery as adjunct to chemotherapy

Note: treatment of drug-resistant tuberculosis should be carried out by, or in consultation with, a physician with expertise and experience in treating drug-resistant disease [*see Table 2 for dosages*].
*For example, levofloxacin, moxifloxacin, gatifloxacin.
†Injectable agents may include aminoglycosides (streptomycin, amikacin, or kanamycin) or the polypeptide capreomycin.
‡Alternative agents are ethionamide, cycloserine, *para*-aminosalicylic acid, clarithromycin, amoxicillin-clavulanate, and linezolid.

an inadequate primary regimen, failure to identify and address noncompliance, and use of monotherapy for active disease (in cases in which therapy for latent tuberculosis was prescribed but active disease was present).[88] In patients suspected of having MDR-TB (e.g., those who failed to complete an earlier regimen or who followed their therapy erratically, those with recent exposure to an MDR-TB case, or those from extremely high-risk areas), the physician should consider initiating therapy with extended empirical regimens, pending culture results. This is especially the case for patients with extensive pulmonary disease or extrapulmonary disease such as tuberculous meningitis or miliary disease. Documented MDR-TB requires treatment with at least four drugs (and more if possible) to which the organisms are susceptible, such as three oral drugs and one injectable agent [*see Table 5*].

The role of surgery in MDR-TB has not been examined in randomized studies but is thought by some experts to be beneficial in selected cases. In one case series, surgical resection in conjunction with fluoroquinolone therapy was associated with improved microbiologic and clinical outcomes in 205 patients with MDR-TB.[89] Surgery should be deferred until the patient has completed several months of intensive chemotherapy, and it should be performed by an experienced surgeon.[3]

MONITORING RESPONSE TO TREATMENT

For patients undergoing treatment of pulmonary tuberculosis, a sputum specimen for AFB smear and culture should be obtained at least monthly until two consecutive specimens are culture negative.[3] It is essential to obtain an AFB sputum smear and culture after 2 months of therapy, because of their value in predicting risk of relapse. Drug susceptibility tests should be repeated on *M. tuberculosis* isolates from patients whose cultures are positive after 3 months of treatment.

In patients with pulmonary tuberculosis, a repeat chest radiograph should be taken after 2 months of therapy; more frequent chest radiographs are not indicated. However, a chest radiograph taken at the completion of therapy can be useful for providing a baseline against which subsequent films can be compared.

Bacteriologic monitoring is more difficult in patients with extrapulmonary disease. In these cases, the response to treatment often must be assessed clinically because it is not feasible to obtain follow-up cultures.

All patients undergoing treatment of tuberculosis should be seen on a monthly basis; at each visit, they should undergo a clinical evaluation to identify possible adverse effects of the antituberculosis medications and to assess adherence. Baseline liver function tests, creatinine level, and platelet count should be obtained on all patients. In patients taking first-line antituberculosis drugs, ATS/CDC/IDSA guidelines do not recommend monthly liver or renal function tests during treatment unless baseline abnormalities were present or there are clinical reasons to obtain the tests.[3] Patients taking ethambutol should be questioned monthly regarding visual disturbances; monthly testing of visual acuity and color vision is recommended for those treated with dosages higher than 20 mg/kg/day or for those who require ethambutol for more than 2 months.

CONTACT INVESTIGATION AND REPORTING OF TUBERCULOSIS CASES

Physicians are required by law to report tuberculosis cases to their local public health agency. In some hospitals, this is handled by the infection control department, but the physician should ensure that the case has been reported expeditiously, so that the local health department can contact the patient while he or she is still hospitalized. This will help to ensure that the patient is not lost to follow-up after discharge. Discharge planning should be carried out in a collaborative fashion with the involvement of the public health department, which should have the resources and the ability to provide DOT to patients with tuberculosis in the outpatient setting. The local public health agency is

responsible for conducting a contact investigation to identify others who have been exposed to an infectious patient (e.g., in the home, at work, and in other social settings). This can lead to the identification of newly infected contacts, for whom treatment of latent tuberculosis is a priority, and it can lead to other potential cases. In addition, when the patient is a child, the contact investigation can lead to the identification of the source case. Priority for contact investigations should be given to instances in which infants or HIV-infected persons (or other highly immunocompromised persons) have been exposed, given the rapid progression from infection to active disease in these settings.

LTBI

Therapy for latent tuberculosis can markedly reduce the risk of progression to active disease and is recommended for patients who are at increased risk for disease progression. Patients with LTBI (i.e., those who test positive on tuberculin skin testing or other diagnostic tests but whose chest radiograph is negative and who have no signs or symptoms of tuberculosis) who are at increased risk for progression to active disease should be encouraged to undergo therapy.

The CDC and ATS have issued guidelines on the treatment of latent tuberculosis [*see Table 6*]. The preferred regimen is a 9-month course of isoniazid; 6 months of isoniazid is an alternative in HIV-seronegative adults. The recommendation for this duration of therapy comes from reanalysis of data from older trials.[90] Rifampin taken for 4 months is an alternative for the treatment of LTBI and is recommended for adults suspected of harboring an isoniazid-resistant strain of *M. tuberculosis*.

A 2-month regimen of rifampin plus PZA for the treatment of LTBI is not recommended, because of its unacceptably high rate of hepatotoxicity in these patients. A CDC survey suggests that the risk of death with this regimen is nearly 1 in 1,000 persons, and the rate of hospitalization is 3 in 1,000 persons.[91] Rifampin and PZA, however, remain an important component of a multidrug regimen for patients with active tuberculosis. Isoniazid may also be given twice weekly in DOT to facilitate adherence in institutional settings or when resources are available.

Patients receiving therapy for LTBI should have an initial clinical evaluation, followed by follow-up evaluations at least monthly; no more than 1 month's supply of medication should be dispensed at a time. The monthly clinical evaluation should include questioning about side effects and a brief clinical assessment for signs of hepatitis. Although adverse reactions to isoniazid are not common, they can be serious. Hepatotoxicity is the most important side effect. However, at a tuberculosis clinic in Seattle, hepatotoxicity occurred in only 0.15% of patients who completed isoniazid monotherapy for LTBI—a rate much lower than those reported in earlier studies.[92] The rate of isoniazid-related hepatotoxicity has been estimated to be 1 to 3 per 1,000 patients. Age is a risk factor: isoniazid-induced hepatotoxicity is rare in patients younger than 20 years, but the rate increases with advancing age. Risk may also be higher in patients with underlying liver disease (including hepatitis C), in those with a history of heavy alcohol consumption, and in the postpartum period (especially for Hispanic women). Asymptomatic, and generally transient, elevations of the aminotransferase level can occur in 10% to 20% of patients taking isoniazid for LTBI. The risk of fatal hepatitis from isoniazid is currently reported to range from 0 to 0.3 (median, 0.04) per 1,000 patients.[91,92] Death has been associated with continued administration of isoniazid despite onset of hepatitis symptoms. The drug should be discontinued when levels of alanine aminotransferase (ALT) or aspartate aminotransferase (AST) exceed five times normal in asymptomatic patients or three times normal in those with symptoms.

Patients should be advised to discontinue isoniazid at the onset of symptoms that are consistent with hepatitis (e.g., nausea, loss of appetite, and dull midabdominal pain) and to immediately seek medical evaluation should these symptoms occur. Liver function tests should be obtained for any patient who develops symptoms suggestive of hepatitis. We recommend baseline liver function tests for all adult patients at the start of therapy for LTBI. However, ATS/CDC guidelines recommend baseline laboratory testing only for patients whose initial evaluation suggests a liver disorder and for those at increased risk for hepatotoxicity, including HIV-infected patients, pregnant women,

Table 6 CDC Guidelines for the Treatment of Latent Tuberculosis in Adults[97]

Drug	*Dosage and Duration (Maximum Dose)*	*Rating/Evidence Level*		*Comments*
		HIV-Negative Patients	*HIV-Positive Patients**	
Isoniazid	5 mg/kg (300 mg) daily for 9 mo	A/II	A/II	Preferred for adults and children; indicated for HIV-infected patients and those with fibrotic lesions on chest x-ray; in HIV-infected patients, may be given concurrently with antiretroviral treatment; DOT must be used with twice-weekly dosing
	900 mg twice weekly for 9 mo	B/II	B/II	
Isoniazid	5 mg/kg (300 mg) daily for 6 mo	B/II	C/I	Alternative for HIV-negative patients; DOT must be used with twice-weekly dosing
	900 mg twice weekly for 6 mo	B/II	C/I	
Rifampin	10 mg/kg (600 mg) daily for 4 mo	B/II	B/III	Alternative regimen; for contacts of patients with isoniazid-resistant, rifampin-susceptible TB; HIV-infected patients taking protease inhibitors or certain NNRTIs cannot take rifampin and must instead use rifabutin; the combination of rifampin and pyrazinamide is not recommended (D/II) for treatment of latent TB infection because of high risk of hepatotoxicity

*Current data on interactions with HIV-related drugs are available at http://www.aidsinfo.nih.gov/guidelines.
CDC—Centers for Disease Control and Prevention DOT—directly observed therapy NNRTI—nonnucleoside reverse transcriptase inhibitor

women in the immediate postpartum period (i.e., within 3 months after delivery), patients with a history of chronic liver disease (e.g., hepatitis B, hepatitis C, alcoholic hepatitis, or cirrhosis), regular users of alcohol, and patients at risk for chronic liver disease.[1] Baseline laboratory tests should also be obtained in patients who are taking other potentially hepatotoxic medications for chronic medical conditions. Active hepatitis and end-stage liver disease are relative contraindications to the use of isoniazid for treatment of latent tuberculosis. Routine laboratory monitoring (e.g., monthly AST or ALT measurement) during treatment of latent tuberculosis is recommended for persons whose baseline liver function test results are abnormal and for other patients at risk for hepatic disease (see above).

Peripheral neuropathy is also a side effect of isoniazid. It is relatively uncommon, but the risk is increased in persons with a nutritional deficiency, as well as those with diabetes mellitus, HIV infection, renal failure, or alcoholism, and in women who are pregnant or breast-feeding. Pyridoxine (25 to 50 mg a day) is recommended for patients with these risk factors to help prevent neuropathy. Some clinicians routinely give supplemental pyridoxine to all patients taking isoniazid.

VACCINES

BCG vaccination involves use of a live attenuated strain of *M. bovis*. The primary benefit of BCG administration appears to be in preventing disseminated tuberculosis and tuberculous meningitis in young children; variable efficacy has been reported in adults. BCG has had little effect on the global epidemiology of tuberculosis. BCG is not recommended for use in the United States but is widely used outside of the United States, especially in developing countries. Interestingly, in the tropics, administration of BCG has been associated with a decreased risk of leprosy.[93] The vaccine can produce a positive tuberculin test in recipients, and because of the low incidence of new tuberculous infections in the United States, case finding and treatment of latent tuberculous infection are considered more efficient and effective strategies. Interpretation of a tuberculin skin test reaction is not changed for patients who have received BCG,[1] because tuberculin sensitivity tends to wane considerably after BCG vaccination, and BCG is often given in areas where tuberculosis is endemic. Given that many BCG-vaccinated persons come from areas with a high prevalence of tuberculosis, it is important that those who have significant reactions to the tuberculin skin test be evaluated for the presence of disease and managed accordingly. Appropriate follow-up includes a careful medical history, a chest x-ray to rule out disease, and evaluation for treatment of latent tuberculosis. Newer diagnostic tests are needed for distinguishing between infection with *M. tuberculosis* and immunization with BCG.

Hospital-Based Prevention

Tuberculosis infection control efforts, utilizing a hierarchy of measures recommended by the CDC, have proved effective in preventing nosocomial transmission of tuberculosis.[22,93,94] Atop this hierarchy are administrative controls, which include high suspicion for tuberculosis, careful screening of patients, precautions against airborne infection for patients suspected of having tuberculosis, and prompt diagnosis and initiation of effective therapy. Engineering controls and respiratory protection constitute the second and third tiers of the hierarchy of control measures. Guidelines for implementing a tuberculosis infection control program in health care facilities have been published.[95]

III INFECTIONS DUE TO NEISSERIA

Jeanne M. Marrazzo, m.d., m.p.h.

Infections caused by *Neisseria* species are among the most frequently encountered and potentially dangerous diseases. The two major species of concern are *N. meningitidis* and *N. gonorrhoeae.* Both are gram-negative cocci that reside primarily in polymorphonuclear white blood cells and tend to cluster in pairs [*see Figure 1*]. No nonhuman reservoir exists for either organism. Although there is some overlap in the clinical syndromes these two species elicit, they are commonly known for distinctly different presentations.

Infections Caused by *Neisseria meningitidis*

The most clinically relevant classification scheme for *N. meningitidis* utilizes the organism's capsular polysaccharides and includes at least 13 serogroups. The most common of these are A, B, C, X, Y, L, and W135.[1] In addition to serogroup, the organism can be classified by class 1 outer-membrane proteins (OMP) (serosubtype), class 2 or 3 OMP (serotype), and lipooligosaccharide (immunotype).

Invasive disease caused by *N. meningitidis* is a significant source of morbidity and mortality worldwide. Important trends include increased recognition of the Y serogroup's role in outbreaks, consideration of college freshmen as candidates for vaccination, and the relative increase of *N. meningitidis* as a pathogen in children as the success of immunization against *Haemophilus influenzae* type b is increasingly realized.

epidemiology and transmission

N. meningitidis is most commonly found in the setting of asymptomatic nasopharyngeal carriage. The prevalence of nasopharyngeal colonization in the United States is estimated at 5% to 10%.[2] Duration of colonization varies from transient (days) to as long as 2 years, with a median of 9 to 10 months. Development of humoral immunity to the colonizing strain of the organism is common and may last at least 4 to 6 months after exposure.

Transmission results from direct transfer of respiratory or oral secretions and requires prolonged intimate contact. Consequently, habitation in very close quarters (e.g., military barracks, correctional facilities, and college dormitories) can facilitate colonization, the prevalence of which can reach 20% to 40% during outbreaks.[3] Facilitation of transmission within close quarters is also reflected by seasonal patterns in invasive infection. Although disease occurs year-round, the incidence peaks in late winter and early spring. Transmission has also been documented through prolonged exposure to an infected person on an airplane and in laboratory technicians working with isolates on open laboratory benches.[4,5]

Despite longstanding availability of antibiotics and meningococcal vaccine, most areas of the world continue to have stable rates of endemic disease. After *Streptococcus pneumoniae*, *N. meningitidis* is the most common cause of bacterial meningitis worldwide, causing an estimated 25% of cases.[6] In the United States, laboratory-based surveillance for invasive meningococcal disease from 1992 to 1996 revealed an average annual incidence of 1.1 cases per 100,000 population (approximately 2,454 cases a year).[2,6,7] Incidence was highest in infants younger than 1 year, with a rate of 15.9/100,000 for children 4 to 5 months of age. The serogroup associated with the most cases of invasive disease was serogroup C (35%); however, significant geographic variation was seen, and the incidence of disease from serogroup Y increased during the study period.[7] For reasons that are unclear, rates of invasive meningococcal disease in the United States are higher in blacks than in nonblacks.

The risk of invasive meningococcal infection in college students has been summarized by the Centers for Disease Control and Prevention (CDC),[8] which initiated surveillance in this group in 1998. Whereas the incidence in undergraduates overall was lower than that in persons 18 to 23 years of age who were not enrolled in college, rates were relatively high in the approximately 590,000 freshmen who lived in dormitories (4.6/100,000).

Sporadic outbreaks of invasive meningococcal disease also continue to occur in sub-Saharan Africa, in an area extending from Senegal in the west to Ethiopia in the east, known as the meningitis belt. Outbreaks caused primarily by serogroup A occur there during the dry season, from December to June. However, serogroups B and C have caused large epidemics elsewhere, including the United States.[7]

pathogenesis and immunity

The cascade of events from exposure to colonization and from invasion to specific manifestations of clinical disease is complex. Most persons who develop invasive meningococcal disease do so after recent colonization.[1] Concomitant upper respiratory viral infection, cigarette smoking, underlying chronic illness, and preceding *Mycoplasma* infection may facilitate meningococcal infection and colonization. Colonization requires attachment to nonciliated columnar mucosal cells of the nasopharynx. Meningococci secrete proteases that cleave IgA, which may disable a major mucosal defense mechanism; how this mechanism contributes to pathogenesis is unclear, however. Endocytosis and intracellular transport of meningococci-laden vacuoles mediate the organisms' passage to the submucosa.

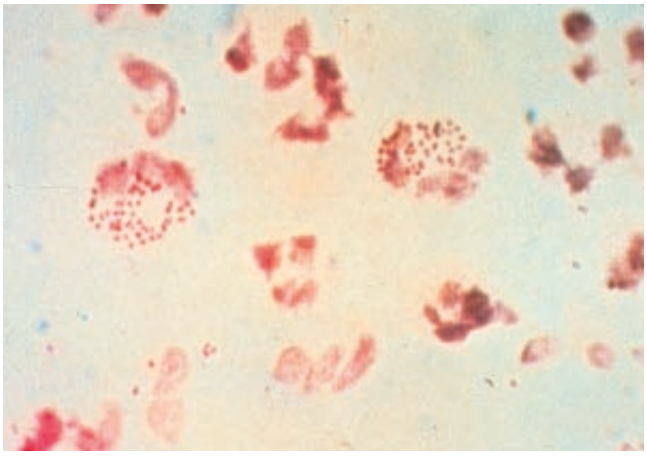

Figure 1 **Gram stain of urethral secretions showing abundant *N. gonorrhoeae* as gram-negative diplococci within polymorphonuclear cells.**

Immunity to meningococcus involves interactions at the nasopharyngeal mucosa, innate immune mechanisms, and acquired antibody.[9,10] The importance of antibody is highlighted by several findings. Natural immunity is acquired after, and boosted by, meningococcal colonization of the nasopharynx. Immunity correlates with bactericidal antibody levels in serum, and the age-specific attack rate of meningococcal disease is reciprocally related to the presence of serogroup-specific antibodies.[9] Further, hypogammaglobulinemia is a risk factor for invasive disease. In military recruits, risk of disease is highest in the absence of bactericidal activity against the prevalent pathogenic strain.[11] Specific antibody directly binds the meningococcus and activates complement-mediated phagocytosis.

Both pathways of the complement system—classic and alternative—appear critical in controlling meningococcal infection.[9] Persons with deficiencies in the terminal complement system (C5, C6, C7, C8, or C9) develop antibody to meningococci, but the rates of meningococcal infection in these individuals are 1,400-fold to 10,000-fold higher than in the general population.[12] Approximately 50% of affected persons have at least one episode of meningococcal infection, and 20% to 25% have more than one episode. Of note, infections in persons with complement deficiency often involve unusual serogroups and are less severe. Persons with deficiencies of properdin (an alternative-pathway component) or factor D are also at increased risk for meningococcal disease, with a case-fatality rate of over 50%. Recurrent meningococcal disease should prompt screening for complement deficiencies,[13] which involves testing the serum for hemolytic whole-complement activity.

Coagulopathy and microvascular thrombosis are hallmarks of meningococcal sepsis. The most visible manifestation of these processes is purpura fulminans [*see Figure 2*]. Dysfunction of the activation pathway of protein C appears to play a key role in these thrombotic events. When activated by its binding to thrombomodulin and the endothelial protein C receptor, protein C normally functions to keep thrombin's procoagulant properties in check. In children with purpuric lesions from meningococcal sepsis, endothelial protein C activation is impaired.[14]

CLINICAL PRESENTATIONS

Meningococcal Bacteremia

Meningococcal bacteremia occurs across a spectrum of clinical presentations, ranging from an acute fulminant disease that is fatal within hours to asymptomatic infection. The presence of *N. meningitidis* in the blood is usually associated with severe illness. However, bacteremia may occasionally be found in persons who appear healthy or who have only mild systemic symptoms (usually fever and, sometimes, upper respiratory symptoms or rash resembling a viral exanthem).

Symptoms associated with so-called benign bacteremia usually resolve before the infection is identified by isolation of meningococcus from blood cultures. This syndrome differs from the so-called chronic meningococcemia associated with low-grade fever, rash, and polyarticular arthritis that can be confused with disseminated gonococcal infection (DGI).

The rash of chronic meningococcemia usually takes the form of a nonspecific maculopapular eruption, but it may be petechial. Unlike persons who experience recurrent meningococcal meningitis (see below), patients with chronic meningococcemia appear immunologically normal and are usually infected with typical serogroups. *N. meningitidis* should be considered in the evaluation of any patient with a chronic arthritis-dermatitis syndrome.

The most notorious presentations of meningococcal disease take two forms: meningococcemia and meningococcal sepsis. The two forms may occur simultaneously.

The term meningococcemia usually denotes bacteremia accompanied by signs of sepsis and frequently by the classic purpuric or petechial rash typical of this syndrome, which occurs in 75% of patients with this disease [*see Figure 2*]. Although the rash of purpura fulminans is obvious, patients presenting early in the course of disease may have more subtle abnormalities of the skin and mucous membranes. These abnormalities include palpebral and conjunctival petechiae and lesions in areas subject to physical pressure, such as the waist and soles of the feet. Because these findings can herald the development of full-blown meningococcemia, they should be carefully sought in persons in whom this illness is a consideration; so that a thorough examination can be performed, the patient should be examined without clothes. Affected patients may also complain of intense, diffuse myalgias in the initial period of their illness. Evolution of individual petechiae to coalescence and eventual frank ecchymosis proceeds apace with the progression of the thrombocytopenia of disseminated intravascular coagulation (DIC).

Meningococcal sepsis is characterized by a rapid progression from general, nonspecific complaints that may resemble a viral illness to hypotension, multiorgan failure, and DIC. Despite the availability of antibiotics and advances in critical care, meningococcal sepsis still carries a mortality of up to 40%.[2] Concomitant adrenal hemorrhage, known as the Waterhouse-Friderichsen syndrome, may also occur. Myocarditis has been noted on histopathologic examination in more than 70% of patients with fatal meningococcemia.[15,16] Meningococcemia may also precipitate pericarditis, sometimes to the point of tamponade. The formation of arterial thrombi can result in peripheral gangrene.

Meningitis

Acute meningococcal meningitis results from hematogenous dissemination of the organism and is usually accompanied by classic signs of bacterial meningeal inflammation: fever, headache, and nuchal rigidity. Other findings typical of meningitis may occur, including photophobia, nausea, vomiting, focal neurologic signs, seizures, and progression to obtundation and coma.[17] From 50% to 75% of patients have a petechial rash suggestive of meningococcemia.[18] The cerebrospinal fluid is typically purulent, with numerous polymorphonuclear neutrophils (PMNs), low glucose (< 50 mg/dl, present in 75% of cases), and an elevated protein concentration. In contrast, the uncommon syndrome of recurrent meningococcal meningitis produces less severe clinical and CSF findings.

Bacteremic Pneumonia

Bacteremic pneumonia from *N. meningitidis* constituted 3% of cases of invasive meningococcal disease reported by Schuchat[6] in 1997 and may be more commonly associated with serogroup Y isolates. However, meningococcal pneumonia probably occurs more frequently than is indicated by detection through positive blood cultures, and this disease has occurred in outbreaks. In a well-described outbreak involving 68 military recruits, most of the individuals had fever, rales, and

Figure 2 **(*a*) The rash of purpura fulminans, seen here with petechiae as well as larger, coalescent hemorrhagic lesions, in a patient with meningococcal sepsis and meningitis caused by serogroup B. (*b*) Closer view of petechiae, some of which have coalesced into purpuric and intracutaneous hemorrhagic lesions.**

pharyngitis.[19] Although disease was multilobar in 40% of the patients, no deaths occurred. Diagnosis by sputum culture is problematic, given the potential confounding effect of upper airway colonization. Instead, most patients are diagnosed either at bronchoscopy or, if they have systemic infection, with positive cultures at nonpulmonary sites.

Other Meningococcal Infections

Uncommonly, *N. meningitidis* can cause syndromes for which *N. gonorrhoeae* is well known, including urethritis in men and cervicitis in women. One proposed mechanism of meningococcal genital infection is acquisition through orogenital sex, which may transmit nasopharyngeal colonizers to genital sites.[20] These syndromes respond well to the antibiotics typically used for gonococcal genital infections (see below).[21] Sex partners should be treated, but no further chemoprophylaxis (e.g., treatment of household contacts) is indicated.

Cases of *N. meningitidis* infecting numerous other body sites have been reported, including endocarditis, cellulitis, conjunctivitis, otitis media, epiglottitis, and arthritis.[2,22,23]

DIAGNOSIS

N. meningitidis is a fastidious aerobic organism that grows best on chocolate agar and is distinguished from *N. gonorrhoeae* by its ability to ferment both maltose and glucose. The bacteria can be isolated from blood in approximately 75% of persons with invasive meningococcal disease and from the CSF in approximately 46% to 94% of persons with meningitis.[17] Sepsis occurs in an estimated 5% to 20% of persons with positive blood cultures. Gram stain of CSF remains a very useful means of detecting the meningococcus; however, its sensitivity is probably no higher than 50% to 70% and, like that of culture, is reduced by recent antibiotic use. Detection assays for polysaccharide antigens using countercurrent immunoelectrophoresis or latex agglutination are frequently applied to CSF. Their advantages include rapid turnaround time, high specificity, and ability to individuate serogroups. Their major disadvantage is relatively low sensitivity (meaning that false negatives occur), particularly if serogroup B is responsible; in addition, they are not reliable when used to detect antigen in urine or serum. The polymerase chain reaction (PCR) has been successfully applied to the detection of *N. meningitidis*, especially in the United Kingdom, but is not commercially available in the United States.[24] Of note, the isolation of meningococci from upper respiratory secretions does not itself indicate meningococcal disease.

COMPLICATIONS AND PROGNOSIS

Meningococcal sepsis confers a mortality of up to 40%, and 11% to 19% of survivors suffer sequelae, including hearing loss, neurologic disability, and amputation because of peripheral gangrene.[25] The case-fatality rate for all invasive meningococcal disease is estimated to be 11%, and it is significantly higher in the presence of bacteremia (17%) than with meningitis alone (3%). Mortality from *N. meningitidis* is most profound in children: in developed countries, invasive meningococcal disease is the leading cause of death in this age group. Among 295 adolescents and young adults with invasive meningococcal disease in Maryland during the 1990s, 22.5% of those 15 through 24 years of age died.[26] Clearly, this disease continues to present a major challenge to physicians, communities, and the public health system.

DIFFERENTIAL DIAGNOSIS

In its earliest stage, the presentation of invasive meningococcal disease can be nonspecific, resembling a typical viral illness with fever and myalgias. Appearance of a rash should prompt consideration of common viral etiologies, including the enteroviruses. The presence of severe systemic illness should bring to mind Rocky Mountain spotted fever (RMSF), vasculitides (polyarteritis nodosa, Churg-Strauss syndrome, and anaphylactoid [Henoch-Schönlein] purpura), and toxic shock syndromes associated with staphylococcal, streptococcal, and, less commonly, clostridial infections. Less common infections that can present in similar fashion include epidemic typhus, infections caused by *Streptobacillus moniliformis* and *Spirillum minus* (rat-bite fever), gonococcemia, septicemia caused by *H. influen-*

Table 1 Chemoprophylaxis for Meningococcal Disease[1]

Drug	*Dosage*	*Relative Efficacy*	*Comments*
Rifampin	Children < 1 mo: 5 mg/kg p.o., q. 12 hr for 2 days Children ≥ 1 mo: 10 mg/kg p.o., q. 12 hr for 2 days Adults: 600 mg q. 12 hr for 2 days	First choice	Not recommended for pregnant women, because it is teratogenic in animals; because reliability of oral contraceptives may be affected by rifampin, alternative contraceptive measures should be considered during its administration
Ciprofloxacin	Adults: 500 mg p.o. once	Alternative	Not generally recommended for persons < 18 yr or for pregnant and lactating women, because it causes cartilage damage in immature laboratory animals; however, ciprofloxacin has been used extensively in children with cystic fibrosis without reported adverse outcomes; CDC recommends it for chemoprophylaxis in children when no acceptable alternative is available
Ceftriaxone	Children < 15 yr: 125 mg I.M. once Adults: 250 mg I.M. once	Alternative	Indicated for pregnant women

zae type b, typhoid fever, and acute *S. aureus* endocarditis. Key pieces of information can help narrow the differential diagnosis. Tick-borne diseases such as RMSF usually occur within specific geographic confines and are generally associated with outdoor exposure to animal or insect vectors during the temperate months, principally in summer. Travel history is important in consideration of typhoid fever, as is information regarding the host's general immune status.

TREATMENT

Emergency Management

Infected patients should be isolated and droplet precautions observed until effective antimicrobial therapy has been given for at least 24 hours.[27] Antibiotic therapy should be started as soon as possible. Earlier initiation of antibiotics has been demonstrated to favorably affect outcome in some, though not all, studies,[28] but the disease is frequently so severe that reasonable measures to impact its early course should be undertaken.

Penicillin has constituted the mainstay of antibiotic therapy of meningococcal disease for several decades. Although β-lactamase–producing strains with high-level resistance (minimum inhibitory concentration [MIC] ≥ 250 μg/ml) exist, and strains with altered penicillin-binding proteins and intermediate resistance (MIC, 0.1 to 1.0 μg/ml) have been isolated clinically, treatment failures with penicillin have not been reported.[29] Similarly, isolates with high-level resistance to chloramphenicol have been reported outside the United States. Given these data, meningococcal isolates from blood and CSF should be routinely evaluated for penicillin susceptibility at a reference laboratory.

Antibiotic Therapy

Until the presence of meningococcus is confirmed, the patient should receive empirical treatment for bacterial meningitis [*see 7:XXXVI Bacterial Infections of the CSF*]. Once *N. meningitidis* is identified in the CSF or blood, monotherapy with penicillin G (300,000 U/kg/day I.V., up to 24 million U/day) or ceftriaxone (50 mg/kg/day, up to 2 g) may be used. For persons who cannot tolerate penicillins or cephalosporins, chloramphenicol is an option; however, hematologic toxicity remains a concern. These antibiotics provide adequate CSF penetration, especially in the presence of meningeal inflammation. Treatment for 10 to 14 days is commonly recommended.[29] Although fluoroquinolones provide excellent activity against *N. meningitidis* and achieve very good CSF levels, their role in the treatment of invasive meningococcal disease requires further study.

Adjunctive Therapy

Adjunctive therapy of meningococcal infection with corticosteroids has been a subject of intense debate. Steroid therapy has not been shown to improve outcomes associated with meningococcal disease and is therefore not recommended. Another strategy under pursuit is repletion of activated protein C, which is severely depleted in severe meningococcemia.[30] One small open-label study showed that compared with predicted outcomes, there were reductions in morbidity and mortality from severe meningococcemia in patients treated with activated protein C.[31] In a large, randomized, placebo-controlled study of patients with sepsis, recombinant protein C reduced mortality but also increased bleeding events.[32] None of the patients in this study had sepsis from *N. meningitidis*. However, protein C depletion appears to be more severe in meningococcal disease than in related conditions that commonly cause sepsis, suggesting that further study is warranted. Recombinant protein C is commercially available, and its use in patients with sepsis from *N. meningitidis* should be considered.

PREVENTIVE THERAPY

Although outbreaks account for only 2% to 3% of all cases of meningococcal disease in the United States, prevention of the spread of disease carries a high priority. The risk of invasive disease in family members of persons with invasive meningococcal disease is increased by a factor of 400 to 800. Further, case clusters cause great alarm in the community. Consequently, assessment of the need for prophylaxis and coordination of its administration are critical steps in the management of invasive meningococcal disease. Assistance in carrying out these steps can be provided by the public health agencies to which cases of meningococcal disease must be reported (see below).

Prophylaxis is recommended for close contacts of infected persons [*see Table 1*]. Close contacts are defined as household members, day care center contacts, and anyone directly exposed to the patient's oral secretions (e.g., by kissing, by mouth-to-mouth resuscitation, during endotracheal intubation, or during endotracheal tube management by health care workers not wearing masks).[33] The likelihood of contracting invasive

disease from close contact is highest in the first few days after exposure; thus, prophylaxis should ideally be administered within 24 hours after identification of the index case and is unlikely to be of value if given beyond 14 days after onset of illness in the index case.[34]

IMMUNIZATION

Vaccine

A quadrivalent polysaccharide vaccine for protection against *N. meningitidis* serogroups A, C, Y, and W-135 (Menomune) is currently available.[35] It is administered subcutaneously as a single 0.5 ml dose, induces protective antibody within 7 to 10 days, and is generally well tolerated. No serious side effects have been reported. The vaccine may be administered to pregnant and lactating women, because no adverse events associated with immunization during pregnancy have been reported. An important consideration is that the vaccine does not provide protection against serogroup B infection, which causes over half of cases in infants younger than one year. Vaccine efficacy against serogroups A and C is estimated at 85% to 100% in older children and adults.[36] Although protective immunity to serogroup A can be conferred in infants older than 3 months, immunity to serogroup C is difficult to attain in children younger than 1 year. No data are available on efficacy of the Y and W-135 polysaccharides in older children and adults, but these polysaccharides are safe and immunogenic. For all serogroups, limited data suggest that the duration of immunoprotection is probably no more than 3 years. Given this, as well as the difficulty of inducing an adequate immune response in infants, routine vaccination of infants is not recommended.

Several new meningococcal conjugate vaccines are under study for serogroups A, C, Y, and W-135, and they are likely to become available in the United States in the next few years.[37] Unlike polysaccharide vaccines, they induce a stronger, longer-lasting immune response that can be boosted by subsequent doses. Serogroup C conjugate vaccines were introduced in the United Kingdom in 1999.

Recommendations for Vaccine Use

Vaccination is recommended for persons at increased risk, for prospective travelers, and for the control of outbreaks.

Persons at increased risk Persons at increased inherent risk include military recruits and persons with terminal complement pathway deficiencies or functional or anatomic asplenia. Persons exposed routinely to *N. meningitidis* through occupational exposure (e.g., clinical or research laboratory personnel) should also consider vaccination.

Prospective travelers Vaccination is recommended for travelers to areas endemic for invasive meningococcal disease, including parts of sub-Saharan Africa during peak periods of disease incidence (generally the dry season, from December to June). In addition, a large international outbreak in pilgrims to the Hajj in Saudi Arabia in 2001 prompted recommendations that travelers to this site also be immunized.[38] Updated recommendations for this and other travel-related immunizations can be obtained at www.cdc.gov/travel.

Control of outbreaks Vaccination may be considered as a means of controlling outbreaks caused by serogroups covered by the vaccine. The Advisory Committee on Immunization Practices (ACIP) recommends that mass vaccination of persons 2 years of age or older be considered when three cases of serogroup C meningococcal disease occur within a 3-month period in a community or organization (e.g., a school), with an incidence of 10 cases per 100,000 population or greater.[39]

Immunization of college freshmen, particularly those living in dormitories, deserves special mention. Although the rate of invasive infection in this group exceeds that of any age group other than children younger than 2 years, it is still below the threshold recommended for initiating meningococcal vaccination campaigns. Thus, ACIP recommends that health care providers and colleges inform students and their parents about the vaccine's availability and potential benefits.[8] Many colleges recommend meningococcal vaccination to incoming freshmen, and some offer the vaccine through their student health service.

Requirements for Reporting Meningococcal Disease

Infection with *N. meningitidis* is reportable by law to most local and state health departments. Public health agencies will assist clinicians in the identification and treatment of exposed contacts; in the case of outbreaks, these agencies may institute other control measures. Physicians should not assume that clinical laboratories will execute reporting. Contact information for reporting communicable diseases can be found through state health departments, Web sites for which can be found at http://www.cdc.gov/mmwr/international/relres.html.

Infections Caused by *Neisseria gonorrhoeae*

Known primarily as a cause of sexually transmitted infections, *N. gonorrhoeae* remains an important cause of cervicitis, urethritis, proctitis, and pelvic inflammatory disease (PID) [*see 7:XXII Sexually Transmitted Diseases*]. No vaccine is available.

EPIDEMIOLOGY

An estimated 600,000 new cases of gonococcal infection occur in the United States each year.[40] These cases are a mix of symptomatic infections, which occur mostly in men, and asymptomatic infections detected through routine testing, largely in women.

The incidence of gonorrhea declined steadily in the United States from 1978 through 1997, but rates increased in 1998 and have not declined since then. In particular, the incidence in adolescents, especially those in large cities, remains high; in addition, sustained outbreaks have occurred recently in men who have sex with men. In the United States in 2000, the highest reported rates of gonorrhea were in women 15 to 19 years of age (715.6 per 100,000 population) and in men 20 to 24 years of age (589.7 per 100,000 population).[41] In 42 states, the incidence of gonorrhea in women remains above the objective of 19 new cases per 100,000 population from Healthy People 2010 (http://www.health.gov/healthypeople/document/html/objectives/25-02.htm), a set of health objectives for the United States developed through the Office of Disease Prevention and Health Promotion of the United States Department of Health and Human Services.

Rates of gonococcal infection have increased among men who report having sex with other men.[42] In a surveillance project at six sexually transmitted disease clinics in five U.S. cities, positivity of urethral gonorrhea in this population was 21% for those who were HIV positive and 12% for those who were HIV

negative. These findings have spurred some government agencies to recommend routine screening at least annually for gonorrhea in this population.[43]

Typing methods for the gonococcus are generally less clinically useful than for meningococcus and are used primarily to study gonococcal epidemiology. Most widely used are auxotyping, which classifies the organism on the basis of nutritional requirements, and protein I-serotyping, which is based on the stable antigenic diversity of its largest surface protein and further classifiable into different serovars by coagglutination assays. These two methods are combined into auxotype/serovar (A/S) classes for nomenclature of many strains (e.g., AHA/IA-1 denotes a strain that requires arginine, hypoxanthine, and uracil for growth and exhibits protein IA with a type 1 coagglutination pattern).[21]

PATHOGENESIS

The pathogenesis of *N. gonorrhoeae* has been closely studied in an experimental model using male human volunteers.[44] Like *N. meningitidis*, the gonococcus possesses a protease that may be important in cleaving IgA at the mucosal surface. Columnar or cuboidal epithelium is the main target for attachment, which is mediated primarily by pili that protrude from the cell surface and by outer membrane proteins termed Opa proteins.[45] Because they require iron for growth, gonococci possess transferrin receptors; they also contain lipo-oligosaccharide (LOS). The toxicity of LOS may be especially important in incapacitating the ciliary function of cells lining the fallopian tubes.[45] Within 24 to 48 hours after attachment, the organism's penetration into submucosa elicits an intense neutrophilic inflammatory response. Submucosal microabscesses form, purulent exudate collects, and the affected epithelium sloughs, resulting in ready detection of intracellular gram-negative diplococci in neutrophils on Gram stain.

The role of systemic antibody in gonococcal infection is unclear, given that individuals may be infected multiple times. Gonococcal strains can differ in the clinical manifestations they induce. Some strains, such as AHU/IA-1, AHU/IA-2 and CU, have been associated with the uncommon finding of asymptomatic urethral infection in men and a higher incidence of DGI.[46]

CLINICAL PRESENTATIONS

N. gonorrhoeae is known primarily for its propensity to cause superficial mucosal infections that are transmitted through sexual contact. In men, these infections most commonly involve the urethra. After an incubation period of 1 to 14 days, 95% of men infected at this site experience dysuria and urethral discharge. The discharge is typically purulent but can be serous or seropurulent, especially early in the course of disease. Mild edema and erythema of the urethral meatus may be seen. If left untreated, infection usually resolves over the course of several weeks, and persistent asymptomatic carriage is thought to be unlikely. In some men with untreated urethral infection, infection may spread to cause epididymitis, prostatitis, seminal vesiculitis, and infections of the Cowper and Tyson glands.[21] The urethra may also be infected in women, but isolated urethral infection is unusual except in women who have undergone a hysterectomy. Urethral infection in women is less frequently symptomatic.

Endocervical Infection

In women, the most common site of infection is the endocervical canal, where *N. gonorrhoeae* may cause mucopurulent cervicitis (MPC). MPC presents as either mucopurulent endocervical discharge or easily induced endocervical bleeding. Cervical ectopy, if present, may appear edematous. However, at least half of women with gonococcal infection of the cervix have neither signs of MPC nor gonococci detected on Gram stain of endocervical secretions. If symptoms develop, they are nonspecific and typical of most lower genital tract infections: abnormal, increased, or malodorous vaginal discharge; bleeding between menses; menorrhagia; pelvic pain; or pain with intercourse. If cervical infection is left untreated, *N. gonorrhoeae* may ascend to infect the upper genital tract—including the endometrium, fallopian tubes, ovaries, or adnexa (PID)—or the perihepatic space (Fitz-Hugh-Curtis syndrome). PID is estimated to occur in 10% to 20% of infected women. Finally, abscesses of Bartholin glands are not uncommon.[47]

Infection at Other Mucosal Sites

Both men and women can be infected at common mucosal sites, including the rectum, pharynx, and conjunctiva. Approximately 35% to 50% of women with endocervical infection are also infected at the rectum, usually without local symptoms. Receptive anal sex is not a prerequisite for rectal infection in women; rather, these infections may result from perianal inoculation with infected cervicovaginal secretions. Men who practice receptive anal sex with other men are also at risk of rectal infection. The presentation of rectal gonococcal infection ranges from asymptomatic colonization detected at routine screening to overt proctitis. Even in symptomatic patients, the range of manifestations is wide, including mild perianal pruritus, painless mucopurulent rectal discharge, mild rectal bleeding, severe rectal pain, tenesmus, and constipation.

Gonococcal infection of the pharynx is rarely symptomatic. Acquired by receptive oral sex (by either fellatio or cunnilingus but more efficiently by fellatio), pharyngeal infection is usually detected through routine screening. In persons with gonococci detected at nonpharyngeal sites, the prevalence of pharyngeal infection ranges from 3% to 7% in heterosexual men, 10% to 20% in heterosexual women, and 10% to 25% in men who have sex with other men.[21]

Gonococcal conjunctivitis occurs uncommonly in adults. It usually results from autoinoculation, particularly in laboratory and medical personnel.

Disseminated Gonococcal Infection

The term disseminated gonococcal infection refers to gonococcal infections that have spread beyond the genitourinary tract. The most common presentation is the acute arthritis-dermatitis syndrome, which is estimated to occur in 0.5% to 3.0% of persons with untreated mucosal gonococcal infection.[48,49] This syndrome may comprise the triad of tenosynovitis, dermatitis, and polyarthralgias without purulent arthritis, or it may appear as purulent arthritis alone. DGI should be strongly considered in any young, sexually active person with acute, nontraumatic oligoarthritis or tenosynovitis.

The arthritis of DGI can affect joints of any size and is typically asymmetrical.[50] With tenosynovitis, major tendon sheaths and their insertions are often tender and inflamed; the clinician should palpate these sites if this diagnosis is at all entertained. The classic rash of DGI usually consists of relatively few (< 20) tender, necrotic pustules on an erythematous base that often resolve within several days if left untreated.

Diagnosis of DGI is made more often in women than in men.

Predisposing factors include recent menstruation, recent pregnancy, and terminal complement deficiency. The gonococcal strains that cause DGI are often those associated with asymptomatic genital disease and with resistance to complement-mediated bactericidal activity of normal human serum. The organism is recovered by culture from normally sterile sites, including blood or joint fluid, in less than 50% of persons with DGI; however, it can be cultured from mucosal sites or from sexual partners in more than 80% of cases. Amplified nucleic acid assays, such as PCR, have increased the yield of *N. gonorrhoeae* detection in joint fluid, but a subset of those affected still have sterile joint fluid in the presence of urogenital gonococci, suggesting that immunomodulatory responses are important in the pathogenesis of DGI.[51,52]

More invasive infection with *N. gonorrhoeae* is uncommon. Endocarditis and meningitis have been reported, however.[53,54]

DIAGNOSIS

N. gonorrhoeae may be diagnosed presumptively by direct visualization on a Gram stain smear of secretions from a compatible clinical site and, specifically, by growth in culture or detection by antigen detection, nonamplified DNA probe, and a nucleic acid amplification test (NAAT). In men with urethral discharge from *N. gonorrhoeae*, the organism is seen on Gram stain in 95% [*see Figure 1*]. Although reasonably specific for detection of endocervical *N. gonorrhoeae* (> 95%), Gram stain is considerably less sensitive (50% to 70%) and thus not recommended as the sole means of diagnosis of endocervical infection. Gram stain of anoscopically obtained rectal secretions has a sensitivity of 70% to 80% and thus may assist in making a specific diagnosis of gonococcal proctitis.[21] Because nongonococcal *Neisseria* species colonize the pharynx, Gram stain of the pharynx is not specific to infection with *N. gonorrhoeae* and thus is not recommended.

Traditional bacterial culture remains the mainstay of microbiologic diagnosis for normally sterile specimens in which invasive disease is suspected, such as blood and joint fluid, and is commonly used for the diagnosis of cervical, urethral, pharyngeal, and rectal infections. Cultures are obtained from these sites with a sterile Dacron swab that is then swept across the surface of a plate containing chocolate agar supplemented with glucose, vancomycin, colistin, and nystatin (Thayer-Martin media) and held in an environment with a high level of CO_2. The organism grows best under aerobic conditions at 35° to 37° C; however, it can also grow under anaerobic conditions. Unlike *N. meningitidis*, it does not ferment lactose. Relative to an expanded diagnostic standard that incorporates results of NAAT, culture for *N. gonorrhoeae* has an estimated sensitivity of 90% and specificity of greater than 99%.[55]

Other tests commonly used to diagnose gonococcal infection are a nonamplified DNA probe and several types of NAAT. The DNA probe is a nucleic acid hybridization test with a sensitivity of approximately 85% and specificity of 98%.[56] Available NAATs include PCR, ligase chain reaction (LCR), transcription-mediated assay (TMA), and hybrid capture tests. In general, the performance of these tests exceeds that of the nonamplification techniques, enhancing sensitivity while maintaining excellent specificity.[56] Further, NAATs have the major advantage of performing well on noninvasive specimens: urine in men and, in women, urine and vaginal swabs. Vaginal swabs may be collected either by patients or by clinicians, which provides opportunities for novel screening strategies. The NAATs in general have sensitivities for detection of *N. gonorrhoeae* of 95% to 99%, with a specificity greater than 99% for cervical and urethral specimens. However, none is currently recommended for use on specimens other than urine, cervical, or urethral samples.[56]

TREATMENT

Recommended treatment of gonorrhea varies according to the site of infection and the likelihood of antibiotic resistance [*see Table 2*]. Currently recommended regimens for the treatment of gonorrhea are available online at www.cdc.gov/std/treatment.[43]

The gonococcus has multiple means of acquiring resistance to antibiotics. Plasmid-mediated mechanisms confer resistance to penicillin by encoding altered penicillin-binding proteins (PBPs). Resistance to tetracyclines is mediated by chromosomal mechanisms. Resistance to fluoroquinolones is conferred by production of an altered DNA gyrase to which these antibiotics are unable to bind and hence are rendered ineffectual. The Gonococcal Isolate Surveillance Project (GISP) annually updates important trends in gonococcal resistance patterns (http://www.cdc.gov/ncidod/dastlr/gcdir). Because these patterns can emerge and progress surprisingly rapidly, physicians should be aware of them. Although some problems begin in relative geographic isolation, they often mark the start of significant nationwide trends.[57-59] For example, recommendations for the empirical use of single-dose fluoroquinolone therapy were prominent in the CDC's 1998 Sexually Transmitted Disease Treatment Guidelines; the 2002 document emphasizes that because up to 14% of gonococcal isolates in Hawaii exhibit resistance to fluoroquinolones, these drugs should not be used in this area.[60,61] Patients in whom physicians should consider the possibility of quinolone-resistant *N. gonorrhoeae* (QRNG) include those who (1) have had failures with fluoroquinolone therapy, (2) have traveled to Hawaii or Southeast Asia (where resistance is endemic) or have sexual partners who may have acquired a gonococcal infection there, and (3) reside in California, where recent data indicate an increasing prevalence of QRNG. Because active surveillance is critical, physicians who encounter documented or suspected cases of QRNG should report this to their local health department. In 2000, 25% of GISP isolates were resistant to penicillin, tetracycline, or both. To date, no isolates resistant to cephalosporins have been detected in GISP. Because persons with gonococcal infection are at risk for other STDs, particularly chlamydial infection, the CDC recommends that treatment regimens for gonorrhea be partnered with an antibiotic effective against *C. trachomatis* as well. Although azithromycin is active against the gonococcus, a dose of 2 g orally is required to effect acceptable cure rates. This is double the dose required to treat chlamydial infection, and such a high dose frequently causes gastrointestinal side effects. Similarly, ciprofloxacin remains effective for gonococcal infections not caused by QRNG, but it is not effective against chlamydial infection. Both infections can be treated with a 1-week course of levofloxacin or ofloxacin, however.

COMPLICATIONS AND PROGNOSIS

The best-known complications of *N. gonorrhoeae* infection include PID and neonatal conjunctivitis (ophthalmia neonatorum). PID in which gonococci play an etiologic role may be more purulent and severe than PID caused by *C. trachomatis*. If left untreated, 10% to 40% of women with gonococcal cervical infection will develop PID.[62] Ophthalmia neonatorum caused by *N. gonorrhoeae* can be severe, resulting in perforation of the

Table 2 Treatment of Gonorrhea[1]

Disease	*Drug*	*Dosage*	*Relative Efficacy*	*Comments*
Uncomplicated infection of the cervix, urethra, or rectum*	Cefixime	400 mg p.o. once	First choice	Quinolones not recommended in areas where resistance is a concern; spectinomycin is used for patients intolerant of cephalosporins and quinolones, it is unreliable against pharyngeal infection, and posttreatment cultures are recommended
	Ciprofloxacin	500 mg p.o. once	Alternative first choice	
	Ofloxacin	400 mg p.o. once	Alternative first choice	
	Levofloxacin	250 mg p.o. once	Alternative first choice	
	Ceftriaxone	125 mg I.M. once	Second choice	
	Spectinomycin	2 g I.M. once	Second choice	
Conjunctivitis (not ophthalmia neonatorum)	Ceftriaxone	1 g I.M. once	—	—
Disseminated gonococcal infection (DGI)	*Parenteral*			Parenteral therapy is given for 24–48 hr after improvement, then followed by oral therapy for 1 wk total antibiotic therapy
	Ceftriaxone	1 g I.M. or I.V. q. 24 hr	First choice	
	Cefotaxime	1 g I.V. q. 8 hr	Alternative	
	Ceftizoxime	1 g I.V. q. 8 hr	Alternative	
	Ciprofloxacin	400 mg I.V. q. 12 hr	Alternative	
	Ofloxacin	400 mg I.V. q. 12 hr	Alternative	
	Levofloxacin	250 mg I.V. q.d.	Alternative	
	Spectinomycin	2 g I.M. q. 12 hr	Alternative	
	Oral			
	Cefixime	400 mg p.o., b.i.d.		
	Ciprofloxacin	500 mg p.o., b.i.d.		
	Ofloxacin	400 mg p.o., b.i.d.		
	Levofloxacin	500 mg p.o., q.d.		
Meningitis	Ceftriaxone	1–2 g I.V. q. 12 hr for 10–14 days	—	—
Endocarditis	Ceftriaxone	1–2 g I.V. q. 12 hr for ≥ 4 wk	—	—
Ophthalmia neonatorum	Ceftriaxone	25–50 mg/kg I.V. or I.M. in a single dose, not to exceed 125 mg	—	Topical antibiotic therapy alone is inadequate

*Treatment of gonorrhea in the adult should always be accompanied by treatment of chlamydial infection (azithromycin, 1 g orally in a single dose, or doxycycline, 100 mg orally b.i.d. for 7 days), and patients should abstain from sex during treatment. Test of cure is not routinely recommended.

globe and blindness. Moreover, accruing evidence suggests that gonococcal infection may profoundly impact global morbidity through its role in facilitating transmission and acquisition of HIV. In men infected with HIV, the presence of gonococcal urethritis was shown to increase the quantity of HIV shed in semen by approximately eightfold.[63,64] Remarkably, treatment with routine antibiotics aimed at *N. gonorrhoeae* resulted in significant reduction of the associated HIV shedding.[64] Similarly, cervical inflammation in women, commonly caused by gonococcal infection, is associated with increased shedding of HIV; treatment of cervicitis reduces this shedding.[65,66] These observations suggest that the inflammation associated with gonococcal infection significantly increases the likelihood that HIV may be more efficiently transmitted through unprotected sex. In persons who are not infected with HIV, the same inflammatory cells elicited by gonococcal infection provide a ready target for HIV infection; thus, risk of HIV acquisition is very likely increased in this setting.[67]

Management of Sexual Partners and Chemoprophylaxis

Persons infected with *N. gonorrhoeae* should be interviewed and counseled about the importance of treatment for their sexual partners. The CDC recommends that sexual partners with whom patients have had sex within the past 60 days be tested and treated for both gonococcal infection and chlamydial infection.[43] If the patient's last sexual contact was more than 60 days before being interviewed, the last partner should be evaluated and treated. For infants, most states require by law that, at birth, an agent be administered to prevent gonococcal ophthalmia neonatorum. Options include single applications of one of several agents, including silver nitrate 1% aqueous solution, erythromycin 0.5% ophthalmic ointment, and tetracycline 1% ophthalmic ointment.

Other *Neisseria* Species

Several typically nonpathogenic *Neisseria* species are found as saprophytes in the upper respiratory tract: the nonchromogens *N. lactamica*, *N. mucosa*, and *N. sicca* and the chromogens *N. flavescens* and *N. subflava*. All of these species can occasionally cause disease.[68,69] Meningitis that is clinically indistinguishable from that caused by *N. meningitidis* has been attributed to each of these species, most frequently to *N. subflava* and *N. mucosa*. Endocarditis has also been attributed to nonpathogenic species, particularly *N. sicca*, *N. mucosa*, and *N. subflava*. Odontogenic infections or bite wounds may also harbor these species.[70] Infections with nonpathogenic *Neisseria* species can be treated effectively with penicillin, but occasionally, strains are resistant. The antimicrobial susceptibility of the strain causing the infection should be used to guide therapy.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

IV INFECTIONS DUE TO GRAM-POSITIVE BACILLI

FREDERICK S. SOUTHWICK, M.D.

Diphtheria

Diphtheria derives its name from the Greek word *diphtheria*, meaning leather hide, which is the character of the pharyngeal membrane that is a hallmark of this disease. Once the cause of major epidemics in Europe and the United States, diphtheria was nearly eradicated by medical discoveries in the late 1800s and early 1900s. Conditions in both developing and developed countries have led to several recent outbreaks and have raised concerns that diphtheria may again become a serious public health problem.

MICROBIOLOGY

Diphtheria is caused by *Corynebacterium diphtheriae*, a gram-positive rod with club-shaped swellings at each end. It is nonmotile and is capable of growing on blood agar plates, causing a narrow band of hemolysis. Most strains produce a highly lethal exotoxin, whose production requires the presence of a bacteriophage that carries a specific determinant for toxin production. The organism produces characteristic metachromatic granules that stain bluish purple with methylene blue. Their snapping division results in angular and palisade arrangements of the cells on smear that frequently take on the appearance of Chinese lettering.[1]

ETIOLOGY AND EPIDEMIOLOGY

Humans are the only natural host for *C. diphtheriae*. The organism is most commonly spread by upper respiratory tract droplets. Persons incubating the disease, those convalescing from the infection, and healthy carriers can spread the disease to others through close contact. Asymptomatic carriage can persist for years within a population. For example, in Russia the clonal strain responsible for a large diphtheria outbreak was carried asymptomatically in the population for at least 5 years before the epidemic.[2] Spread is more common during the colder months of the year, when people tend to be crowded indoors.[3] Persons with *C. diphtheriae* skin lesions can also serve as reservoirs for the organism, and contamination of the environment tends to be greater from skin infection than from upper respiratory tract infection.[4] Because the organism can survive as long as 6 months in fomites and dust, these objects and particles can serve as vehicles for transmission.

Diphtheria toxoid immunization prevents the serious complications of diphtheria, alleviating the clinical manifestations of the disease by blocking the toxin's ability to enter cells. Immunization reduces local colonization of the nasopharynx with toxin-producing strains by reducing their survival advantage. In the United States, with the advent of widespread vaccine administration in the 1940s, the carrier state has dropped to very low levels, and the incidence of diphtheria has steadily declined. Before the initiation of the vaccination program, as many as 125,000 cases and 10,000 deaths were reported annually in the United States. Subsequently, the incidence declined to zero to five cases a year from 1980 to 1990. History indicates that diphtheria outbreaks occur in cycles that may include quiescent periods of up to 100 years. Therefore, the downturn in incidence may represent a normal cycle rather than herd immunity. Occasional outbreaks have been observed in Texas, Washington, and South Dakota.[5] Two outbreaks were associated with urban alcoholics who practiced poor hygiene and lived in crowded environments; a third occurred in a Native-American community. Day care centers can also serve as a site for the spread of diphtheria. Outbreaks in Russia (15,211 cases) and the Ukraine (2,987 cases) are thought to have resulted from the decreased immunization of infants and children, as well as from waning immunity to diphtheria in older people.[6] The resurgence of diphtheria in developed countries raises concern that reductions in the immunization of young children and the failure to revaccinate older adults could lead to a worldwide increase in the incidence of this very serious disease. The finding that only 30% of persons older than 70 years in the United States have protective antibody levels to diphtheria further emphasizes the potential for resurgence.[7]

PATHOGENESIS

C. diphtheriae attaches to mucosal surfaces, particularly in the nasopharynx. Ocular and genital mucosae are less often infected. The skin has become an increasingly common site of infection, particularly in the United States. The diphtheria bacillus rarely invades living tissue but generally remains in superficial layers of the mucosa and skin. The major manifestations of this often serious disease result from production of a potent exotoxin. When iron concentrations are low, diphtheria bacilli possessing the corynebacteriophage containing the *tox* gene produce high concentrations of the toxin. This protein has a molecular weight of 62,000 and consists of two major fragments, designated A and B. Fragment B binds to a specific host cell membrane receptor, resulting in endocytosis of the entire molecule. Fragment B then forms a membrane channel that allows fragment A to enter the cell cytoplasm, block protein synthesis, and induce cell death within hours [*see Figure 1*].[8] Antitoxin antibody can neutralize toxin adsorbed to cells or in the extracellular fluid. However, once the toxin penetrates cells, its toxic effects are irreversible.

In the host, the cytotoxic effects of the toxin are most marked in regions where bacterial growth is heavy and toxin concentrations are highest. Tissue necrosis is associated with an inflammatory response, leading to the formation of an adherent membrane that is greenish-gray to black and consists of fibrin, necrotic tissue, lymphocytes, polymorphonuclear leukocytes, erythrocytes, and bacterial colonies. All cells are susceptible to the lethal effects of the toxin; however, the heart, kidneys, and nervous system are injured most often.

DIAGNOSIS

Clinical Manifestations

The incubation period for respiratory diphtheria is generally 2 to 4 days but can be as long as 7 days. Infection is usually associated with low-grade fever (approximately 38° C [100.4° F]); early in the infection, systemic complaints often are minimal. Symptoms depend on the location and duration of the infection before treatment. Concentrations of bacteria increase over time, resulting in the release of increasing amounts of the cytotoxic exotoxin.

Early recognition and treatment are therefore critical for reducing the complications associated with toxin dissemination.

Respiratory tract infection Pharyngeal infection, the most common form of diphtheria, presents as a sore throat and malaise. Symptoms may be mild in vaccinated patients, whereas unvaccinated patients tend to have more severe disease. Initially, diphtheria pharyngitis results in the development of a patchy white exudate that can be readily removed and is indistinguishable from group A streptococcal or viral pharyngitis. However, as the toxin begins to cause cell necrosis, a thin membrane begins to form that progressively thickens and spreads over the tonsils, posterior pharynx, and uvula [*see Figure 2*]. Initially, the membrane is white and smooth but later becomes gray, with patches of green and black necrosis. Particularly in children, the membrane can spread from the posterior wall up into the nose or down to the larynx or even the tracheobronchial tree.[9] As the membrane spreads, it can interfere with normal airflow and lead to suffocation. Such extensive spread is generally associated with increased release of exotoxin, resulting in myocardial and neurologic complications and greatly increasing mortality. Laryngeal involvement results in hoarseness and may serve as a warning of impending respiratory compromise.[10] Less often, the membrane may be limited to the nasopharynx, causing a serosanguineous nasal discharge. Such limited involvement is less likely to be associated with generalized toxicity. Patients who have no membrane, but only pharyngeal erythema, almost always have milder, uncomplicated disease. Other clinical manifestations include tachycardia, cervical adenopathy, leukocytosis, and proteinuria. Development of the classic bull neck, the result of massive adenopathy, is now uncommon.

Cutaneous diphtheria Although outbreaks of cutaneous diphtheria were originally described primarily in tropical areas, outbreaks over the past 3 decades have been reported in the Pacific Northwest, Midwest, and southern United States. Cutaneous infection may result in greater environmental contamination than respiratory diphtheria and may carry a greater risk of spread to others. Unlike pharyngeal diphtheria, which usually develops in the winter months, cutaneous infections tend to peak in the late summer and early fall. Most cases are reported among residents of Seattle's Skid Road district, who practice poor hygiene and often have preexisting sores.[11] Skin infections have also been described in young schoolchildren. The classic punched-out ulcerative lesion often found in the tropics is rare in temperate climates. When the lesion does develop, it generally begins as a pustule that progresses to an ulcer with a gray-brown membrane at its base. More commonly, diphtheria superinfects preexisting skin lesions, including traumatic breaks in the skin, insect bites, ecthyma, and impetigo. In association with *C. diphtheriae*, other skin pathogens, particularly *Staphylococcus* and *Streptococcus*, are found on culture. These infections tend to be indolent and are rarely associated with signs of intoxication, probably because cutaneous infections induce high levels of antitoxin antibody.

Other sites of infection Less often, *C. diphtheriae* infects the conjunctiva, eye, ear, and vagina. In Seattle, ocular infections in Skid Road residents sometimes accompanied skin involvement.

Complications

Systemic complications are caused by release of the diphtheria exotoxin, which predominantly damages the heart and nervous system.

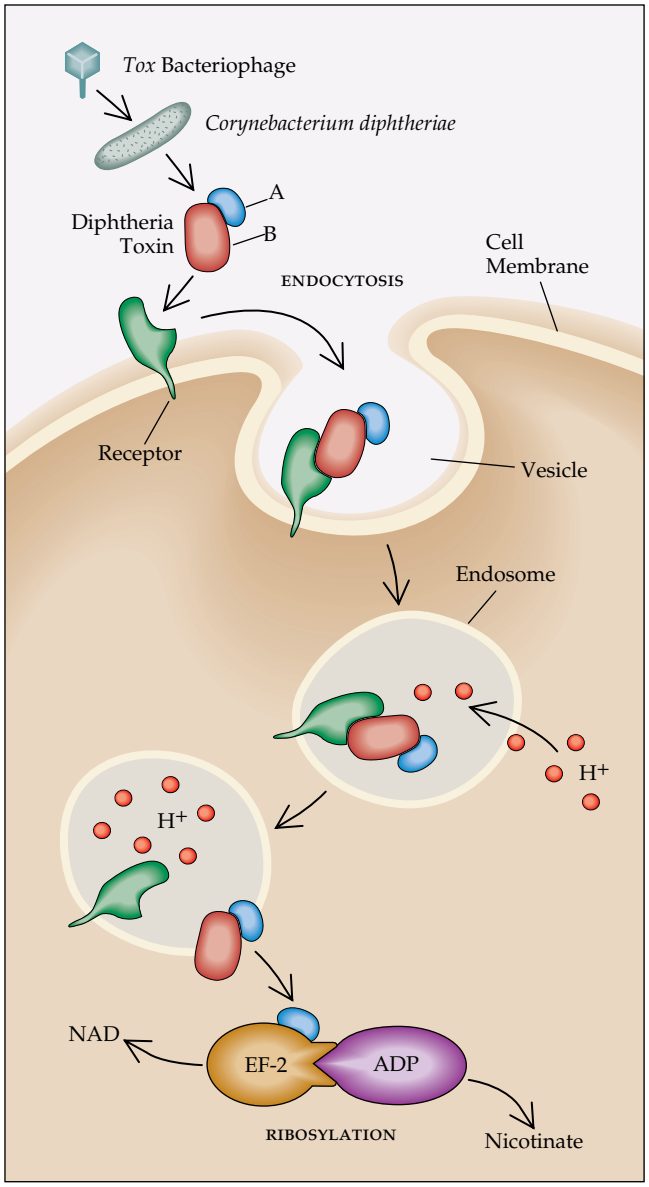

Figure 1 **Mechanism of action of diphtheria toxin. Diphtheria toxin production is encoded by a bacteriophage carrying the *tox* gene that gains entry into *Corynebacterium diphtheriae*. The toxin consists of an A fragment and a B fragment. The B fragment binds to the receptor (heparin-binding epidermal growth factor precursor) on the cell surface, and the whole molecule is then taken into the cell by endocytosis. In the closed environment of the endosome, acidification occurs (H^+). The low pH level causes the B region to unfold and form a membrane channel, allowing the A domain to pass through the membrane into the cytoplasm. The disulfide bond linking the A and B regions is reduced, and the A subunit is then freed to bind to ADP-ribosylate elongation factor–2 (EF-2). Ribosylation interferes with the ability of EF-2 to add amino acids to a peptide chain, blocking protein synthesis and causing cell death. (A—A fragment; B—B fragment; NAD—nicotinamide adenine dinucleotide; ADP—adenosine diphosphate)**

Myocarditis Subtle evidence of myocarditis is found in up to two thirds of patients with respiratory diphtheria.[12] Clinically

significant cardiac dysfunction is observed in 10% to 20% of patients. The severity of cardiac compromise correlates with the extent and severity of respiratory tract involvement. Cardiac toxicity generally occurs within 1 to 2 weeks after onset of the illness, often when pharyngeal symptoms are improving. The electrocardiogram generally reflects the severity of myocardial involvement and should be followed closely in all cases. ST segment and T wave changes and first-degree heart block are found in less severe disease, whereas left bundle branch block and AV block are associated with high mortality. In addition to damaging the Purkinje system, the toxin causes necrosis of cardiac muscle cells that can result in acute heart failure and circulatory collapse. A poor outcome is more likely in patients with extensive pharyngeal membrane and an aspartate aminotransferase level above 80 IU/L.[13] Recovery in more severe cases of myocarditis can result in normalization of the ECG; however, patients usually sustain permanent injury to the myocardium.

Neurologic toxicity Neurologic complications occur in approximately 10% of respiratory cases. As with myocardial involvement, the likelihood of neurologic involvement correlates with the severity of the respiratory infection. Symptoms develop 10 to 28 days after the onset of respiratory complaints. Two types of neuropathy are seen. The first, cranial nerve involvement, is generally limited to the glossopharyngeal and vagus nerves, resulting in difficulty swallowing, aspiration, nasal regurgitation, and loss of the gag reflex. Less often, oculomotor and facial nerves become impaired. The second type of neuropathy tends to occur somewhat later in the course of the illness and resembles Guillain-Barré syndrome. These patients have quadriparesis associated with hyporeflexia. Degeneration of myelin sheaths and axon cylinders is observed in biopsy specimens. After treatment of the infection, slow but complete neurologic recovery ensues.[14]

Physical Examination and Laboratory Tests

Prompt recognition and treatment of respiratory diphtheria are critical for preventing complications and mortality. In the early stages, diphtheria pharyngitis mimics group A streptococcal pharyngitis and mononucleosis. As diphtheria progresses, unlike in pharyngitis and mononucleosis, the exudate changes, becoming darker and forming a membrane that cannot be removed without causing bleeding. Neurologic abnormalities, such as ninth and 10th nerve deficits or ECG changes, should also alert the clinician to the possibility of diphtheria. The microbiology laboratory staff must be notified of the possibility of *C. diphtheriae* because normal throat flora usually overgrow on blood agar plates. Nonnutritive, moist, reducing transport medium is helpful in preventing the overgrowth of competitors, and samples need to be inoculated on Löffler and tellurite media for proper identification. Assays for diphtheria toxin production also need to be performed.

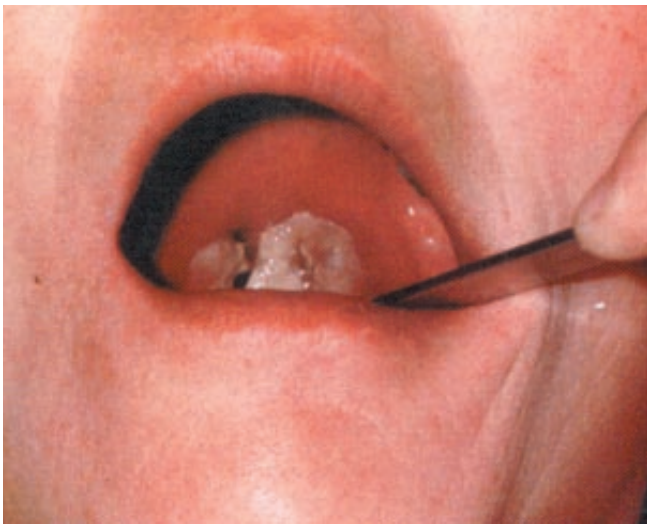

Figure 2 **Diphtheritic membrane extending across the uvula in a 47-year-old woman. Neck edema also has developed.[10]**

TREATMENT

All patients with a clinical diagnosis of respiratory diphtheria should be hospitalized and isolated, because the course of illness is unpredictable. Rapid administration of antiserum is of primary importance. The sooner diphtheria antitoxin is given, the more favorable the outcome. Antitoxin is most effective if given within 4 days after the onset of illness. The antibody blocks entry of toxin into cells and therefore is effective only in neutralizing toxin in the extracellular space before entry into the cytoplasm. Dosage of antitoxin is adjusted to the severity of disease. Patients with extensive involvement of the tonsils and pharynx or larynx, who are expected to have higher concentrations of toxin, should be given at least half the treatment dose of antitoxin by intravenous infusion over 60 minutes. If extensive disease has been present for 3 or more days or if a bull neck has developed, administration of 80,000 to 120,000 units is recommended. For milder disease of shorter duration (48 hours or less), 20,000 to 40,000 units may be used. Antitoxin is given once; repeated doses provide no added benefit. Because antiserum is derived from horse serum, approximately 10% of patients have an allergic reaction. If skin or eye testing demonstrates hypersensitivity, desensitization should be attempted.

Antibiotic Therapy

Antibiotic therapy should be initiated as soon as possible and serves three purposes: (1) it shuts off toxin production; (2) it eradicates other potential pharyngeal pathogens, including group A streptococci; and (3) it eliminates the carrier state, preventing the spread of *C. diphtheriae* to other nonimmunized persons. Erythromycin is considered the treatment of choice. Penicillin is also effective; it is given intramuscularly until the patient is able to swallow, then orally (as penicillin V) for the remainder of the 2-week course [*see Table 1*]. A study of Vietnamese children found penicillin to be more effective than erythromycin.[15] *C. diphtheriae* is generally susceptible to clindamycin and rifampin. However, there has been less experience with the use of these antimicrobial agents.

Other Measures

Extensive pharyngeal and laryngeal membrane formation can lead to upper airway obstruction. Therefore, patients need to be closely monitored, and if signs of obstruction are detected, prompt intubation or tracheostomy must be performed. Sedatives may obscure the development of respiratory difficulties and should be avoided. Patients with myocarditis need cardiac monitoring and should initially be kept at bed rest. Treatment of heart failure with digoxin may result in further impairment of electrical conduction and lead to heart block. Experience with cardiac pacemakers is limited, but pacemakers would be expected to reduce mortality from complete heart block.

Table 1 Antibiotic Treatment of Infections Caused by Gram-Positive Bacilli

Pathogen (Disease)	*Drug*	*Dosage*	*Comment*
Corynebacterium diphtheriae (diphtheria)	Erythromycin	500 mg I.V. or p.o., q.i.d. × 2 wk	First choice
	Penicillin	Penicillin G, 600,000 U I.M. b.i.d., then penicillin V p.o. 250 mg q.i.d. × 2 wk	First choice; in children, penicillin may be more effective than erythromycin
C. urealyticum	Vancomycin	1 g I.V. q. 12 hr × 2–3 wk	Use antibiotic sensitivity testing to guide therapy
C. jeikeium	Vancomycin	1 g I.V. q. 12 hr × 2–3 wk	First choice; use antibiotic sensitivity testing to guide therapy
	Penicillin G + gentamicin	20 million U/day I.V. divided q. 4–6 hr 5 mg/kg/day I.V. divided q. 8 hr	Alternative
C. ulcerans	Erythromycin	500 mg I.V. or p.o., q.i.d. × 2 wk	—
Rhodococcus equi	Vancomycin ± rifampin ± erythromycin, imipenem, amikacin, or ciprofloxacin	1 g I.V. q. 12 hr × 6 wk 600 mg p.o., q.d. 1 g I.V. q. 6 hr 0.5–1 g I.V. q. 6 hr 15 mg/kg I.V. q.d., or divided q. 8–12 hr 500–750 mg p.o. or 400 mg I.V. q. 12 hr	Prolonged therapy often required, relapse common; combination therapy recommended; no one regimen has proved to be more effective
Listeria monocytogenes	Ampicillin ± gentamicin	2 g I.V. q. 6 hr × 3–6 wk 5 mg I.V. q.d. or divided q. 8 hr	Clinical efficacy of gentamicin has not been proved
	Trimethoprim-sulfamethoxazole (TMP-SMX)	20 mg TMP, 100 mg SMX/kg/day I.V., divided q. 6–8 hr × 3–6 wk	Use in penicillin-allergic patients
Nocardia	Sulfisoxazole or sulfadiazine	1.5–2 g I.V. q. 6 hr	May not be available on hospital formulary; follow by oral sulfonamide × 10–11 mo
	TMP-SMX	20 mg TMP, 100 mg SMX/kg/day I.V., divided q. 6–8 hr × 1–2 mo	Follow by oral sulfonamide × 10–11 mo
	Minocycline	100 mg I.V. q. 12 hr	Alternative drug; may cause vertigo
	Imipenem ± amikacin	0.5–1 g I.V. q. 6 hr 15 mg/kg I.V. q.d. or divided q. 8–12 hr	Alternative

Isolation and Treatment of the Carrier State

When diphtheria is suspected, the patient should be isolated until two cultures from the infected site are negative. Cultures should be obtained from all persons who have been in close contact with the patient to determine whether they are pharyngeal carriers. All carriers need to be treated with erythromycin or penicillin for 14 days, and eradication of the carrier state must be documented by follow-up cultures.

PREVENTION

Active immunization using formalin-detoxified diphtheria toxin effectively prevents diphtheria. Preschool children (6 weeks to 7 years of age) should be immunized with three 0.5 ml intramuscular injections of diphtheria-tetanus–acellular pertussis (DTaP) vaccine spaced 4 to 8 weeks apart. A fourth dose should be given 6 to 12 months later. Immunity to the toxin is not lifelong, and if primary immunization was completed before 4 years of age, a booster is recommended at the time of school entry. Subsequently, booster injections need to be given every 10 years to maintain protective immunity. A single dose of vaccine is sufficient for most age groups, with the exception of persons 30 to 49 years of age, who may require three doses to generate protective antibody titers.[16] Surveys indicate that high percentages of adults in the United States and Europe fail to demonstrate a significant immune response to diphtheria toxoid. It has been estimated that epidemic diphtheria is favored when more than 70% of the population lacks protective immunity, a condition now present in many developed countries. A toxoid booster inoculation every 10 years is strongly recommended for all adults.

Nondiphtheria *Corynebacterium* and *Rhodococcus*

In addition to the species *diphtheriae*, the genus *Corynebacterium* contains a large number of species that for decades were considered to be culture contaminants and constituents of the normal human flora. These organisms were previously termed diphtheroids. As the number of immunocompromised hosts and persons with prosthetic devices has increased, the role of nondiphtheria corynebacteria as true pathogens has become evident[17] [*see Table 2*]. *C. urealyticum* and *C. jeikeium* are two nondiphtheria strains that are particularly important nosocomial pathogens.

C. UREALYTICUM

C. urealyticum is a slow-growing, urease-positive organism that is widely distributed on the skin of hospitalized patients. *C.*

Table 1 (*continued*)

Pathogen (Disease)	*Drug*	*Dosage*	*Comment*
Bacillus anthracis (anthrax)	Ciprofloxacin or doxycycline + one or two additional antibiotics: rifampin vancomycin penicillin G ampicillin chloramphenicol imipenem clindamycin clarithromycin	400 mg I.V. q. 12 hr followed by 500 mg p.o., b.i.d. × 60 days 100 mg I.V. q. 12 hr followed by 100 mg p.o., b.i.d. × 60 days 600 mg p.o., q.d. 1 g I.V. q. 12 hr 20 million U/day I.V. divided q. 4–6 hr 2 g I.V. q. 4 hr 1 g I.V. q. 6 hr 500–1,000 mg I.V. q. 6 hr 600 mg I.V. q. 8 hr 500 mg p.o., b.i.d.	Prolonged treatment necessary because spores may persist and later germinate; no one combination regimen preferred; some experts favor the addition of clindamycin, which theoretically may block toxin production; chloramphenicol associated with granulocytopenia
B. cereus	Vancomycin	1 g I.V. q. 12 hr	First-line therapy; duration depends on the type of infection
	Imipenem	500–1,000 mg I.V. q. 6 hr	Alternative
	Clindamycin	600 mg I.V. q. 8 hr	Alternative
	Ciprofloxacin	400 mg I.V. q. 12 hr	Alternative
Other *Bacillus* species	Vancomycin ± gentamicin	1 g I.V. q. 12 hr 5 mg/kg/day I.V. or divided q. 8 hr	First-line therapy; duration depends on the type of infection
	Clindamycin ± gentamicin	600 mg I.V. q. 8 hr 5 mg/kg/day I.V. or divided q. 8 hr	Alternative
	Imipenem	500–1,000 mg I.V. q. 6 hr	Alternative
Erysipelothrix (erysipeloid)	Penicillin G	Benzathine form; single 600,000 U I.M. dose	First-line therapy
	Erythromycin	250–500 mg p.o., q.i.d. × 10 days	Alternative
Erysipelothrix (endocarditis)	Penicillin G	20 million U/day I.V. divided q. 4–6 hr × 4–6 wk	First-line therapy; recommended for endocarditis
	Ceftriaxone	1 g I.V. q.d. × 4–6 wk	For penicillin-allergic patient
	Cefazolin	1.5–2 g I.V. q. 8 hr × 4–6 wk	For penicillin-allergic patient

urealyticum is one cause of alkaline-encrusted cystitis, a urinary tract infection that is severe and difficult to treat.[18] The urea-splitting activity of the organism leads to alkaline urine and the formation of struvite stones. Factors that predispose an individual to this infection include previous urinary tract infections, urologic instrumentation, immunosuppression, underlying inflammation of the bladder, and bladder neoplasia. Less commonly, *C. urealyticum* can cause septicemia, endocarditis, osteomyelitis, and pneumonia. This organism is often resistant to most antibiotics; therefore, vancomycin is recommended for initial treatment pending sensitivity testing [*see Table 1*].

C. JEIKEIUM

C. jeikeium frequently colonizes the skin of hospitalized patients. Patients at highest risk for colonization and subsequent infection with *C. jeikeium* include those receiving broad-spectrum antibiotics and those requiring prolonged hospitalization. In patients with neoplastic disease, other risk factors include prolonged neutropenia and breaks in the integument.[19] In most patients, infection presents as bacteremia. The incidence is highest in neutropenic patients and those who have undergone cardiac surgery.[17] Bacteremia is most often associated with colonization of an intravenous catheter.[20] Prosthetic endocarditis and native valve endocarditis have been reported, as have rare cases of extravascular infections, including cutaneous lesions, pneumonia, peritonitis, prosthetic knee infection, and ventriculostomy infection. Most isolates of this organism tend to be multiply resistant and frequently are sensitive only to vancomycin[21] [*see Table 1*]. Contaminated catheter lines can often be sterilized with antibiotics alone.[20] In patients with prosthetic valve infection, however, the foreign material often has to be removed to control the infection.

RHODOCOCCUS EQUI

Rhodococcus equi, also known as *Corynebacterium equi*, primarily infects immunocompromised hosts with defects in cell-mediated immunity, particularly patients with AIDS[22] and those with solid-organ transplants.[23] Cases in normal hosts have also been reported.[24,25] *R. equi* is found in the soil and at particularly high concentrations in horse manure. Infection is generally acquired through the lungs.

The primary manifestation in most cases is cavitary lung disease resembling tuberculosis, nocardiosis, or fungal infection. Lung consolidation without cavitation is also seen. Bronchoscopy,

Table 2 Clinical Syndromes Caused by Nondiphtheria *Corynebacterium* Species

Species	*Clinical Syndrome*
C. ulcerans	Pharyngitis, skin ulcer, diphtheria
C. pseudotuberculosis (C. ovis)	Suppurative lymphadenitis
C. (Arcanobacterium) haemolyticum	Pharyngitis, scarlatiniform rash
C. pseudodiphtheriticum (C. hofmannii)	Endocarditis, pneumonia, tracheobronchitis, lymphadenitis
C. urealyticum (formerly group D2)	Alkaline-encrusted cystitis, urinary tract infections
C. jeikeium (group JK)	Nosocomial septicemia, wound infection, endocarditis
Rhodococcus equi (C. equi)	Necrotizing pneumonia in patients with AIDS

thoracentesis, or surgery may be required to make the diagnosis, although blood cultures are frequently positive.[24] *R. equi* organisms may be mistaken for contaminating diphtheroids, or because they are modified acid-fast positive, the infection may be misdiagnosed as tuberculosis. Extrapulmonary infections may also occur.

Macrolides and rifampin act synergistically in combination, and regimens containing these two agents are often recommended. These antibiotics achieve high intracellular levels, an important characteristic for clearing *R. equi*, because this pathogen primarily multiplies in cells. The organism is also sensitive to vancomyin and aminoglycosides, and vancomycin is often included in the initial regimen [*see Table 1*]. Cephalosporins should be avoided because of the frequent development of resistance, and multidrug resistance is becoming more common.[26] Short courses of therapy are associated with relapse; therefore, therapy needs to be continued for many weeks. Mortality in AIDS patients is approximately 15%; however, half of the survivors are never completely cured of *R. equi* infection.[22]

Listeriosis

Listeria monocytogenes, a food-borne pathogen, is the cause of listeriosis, a serious and often fatal infection.

MICROBIOLOGY

L. monocytogenes is an aerobic and facultatively anaerobic, non–spore-forming, gram-positive rod. As opposed to corynebacteria, this organism is motile, possessing one to five flagella. *Listeria* organisms grow at a wide range of temperatures (3° to 42° C), which explains its ability to contaminate refrigerated foods. This bacterium can also grow at acidic concentrations of a pH of 5 or higher and salt concentrations of as high as 10% to 12%. *Listeria* organisms can be readily cultured on blood agar plates, where they cause slight zones of β-hemolysis. *Listeria* organisms on occasion can appear somewhat coccoid and, therefore, may be mistaken for diphtheroids or *Streptococcus pneumoniae* on Gram stains of cerebrospinal fluid. There are at least 11 serotypes of *L. monocytogenes*. Serotypes 1b and 4b are most commonly associated with listeriosis.

ETIOLOGY AND EPIDEMIOLOGY

L. monocytogenes is found in soil, dust fertilizer, sewage, stream water, plants, processed foods, and the intestinal tract of many mammals. Investigations of multiple outbreaks indicate that both sporadic and common-source outbreaks of listeriosis are the result of food contamination. Outbreaks have been linked to raw vegetables, Mexican-style cheese, milk, undercooked chicken, and foods purchased in delicatessens.[27] Prepared refrigerated foods stored for prolonged periods and requiring no further high-temperature heating are most likely to be contaminated because *Listeria* organisms can readily multiply on refrigerated foods.

The overall incidence of listeriosis is low: 0.7 cases per 100,000 population. This infection more often occurs in persons older than 70 years (2.1 cases per 100,000); pregnant women (12 cases per 100,000); patients with defects in cell-mediated immunity, including renal transplant recipients; patients receiving high doses of corticosteroids; and patients with AIDS (100 cases per 100,000).[28] At a large referral hospital, *Listeria* organisms were the third most common cause of community-acquired bacterial meningitis in adults (12% of cases).[29] Despite its relatively low incidence, listeriosis concerns public health officials because this disease is associated with a high fatality rate (23%), unlike infections from other food-borne pathogens, such as *Salmonella* organisms, which are rarely fatal. Given the increasing numbers of elderly and immunocompromised patients, the incidence of listeriosis is likely to increase.

PATHOGENESIS

L. monocytogenes has an unusual life cycle[30] [*see Figure 3a*]. Several proteins (internalins[31]) on the surface of the bacterium allow attachment and subsequent ingestion of *Listeria* organisms by host cells. Once internalized, the bacterium is surrounded by host cell membrane, forming a phagolysosome, a closed space that is generally toxic for pathogens. *Listeria* organisms evade destruction by producing the exotoxin listeriolysin O, which lyses the confining membranes. All pathogenic strains of *Listeria* organisms produce listeriolysin O, and their escape into cytoplasm of the host cell is required for pathogenesis. Once in the growth-permissive cytoplasm, the bacteria proliferate, with doubling times of about 1 hour. The *Listeria* surface protein ActA possesses binding sequences to attract actin regulatory proteins that stimulate actin filament assembly.[30,32] About 2 hours after entry into the cytoplasm, actin filaments polarize at one end of the bacteria and provide the force for movement through the cytoplasm [*see Figure 3b*]. Many of the bacteria migrate to the periphery of the cytoplasm, where they push against the host cell's outer membrane to form elongated protrusions or filopods that can be ingested by adjacent cells. Once a bacterium enters the adjacent cell, the life cycle begins anew. *Listeria* organisms, therefore, can spread from cell to cell without directly contacting the extracellular environment. A number of other virulence factors, in addition to ActA and internalins, have been identified, and their contributions to *Listeria* pathogenesis are being defined.

The *Listeria* organism's intracellular lifestyle explains many of this pathogen's unique clinical characteristics.[30] Although the association between contaminated foods and the *Listeria* organism has been well documented, evidence of gastrointestinal disease has been absent in most cases. The *Listeria* organism's capacity to enter the gastrointestinal tract without causing erosive lesions is explained by the ability of this pathogen to stimulate phagocytosis by gastrointestinal cells and macrophages. Subsequently, the *Listeria* pathogen commandeers host cell actin regulatory proteins to spread from cell to cell and eventually enter the bloodstream either in monocytes or as free organisms after cell lysis.

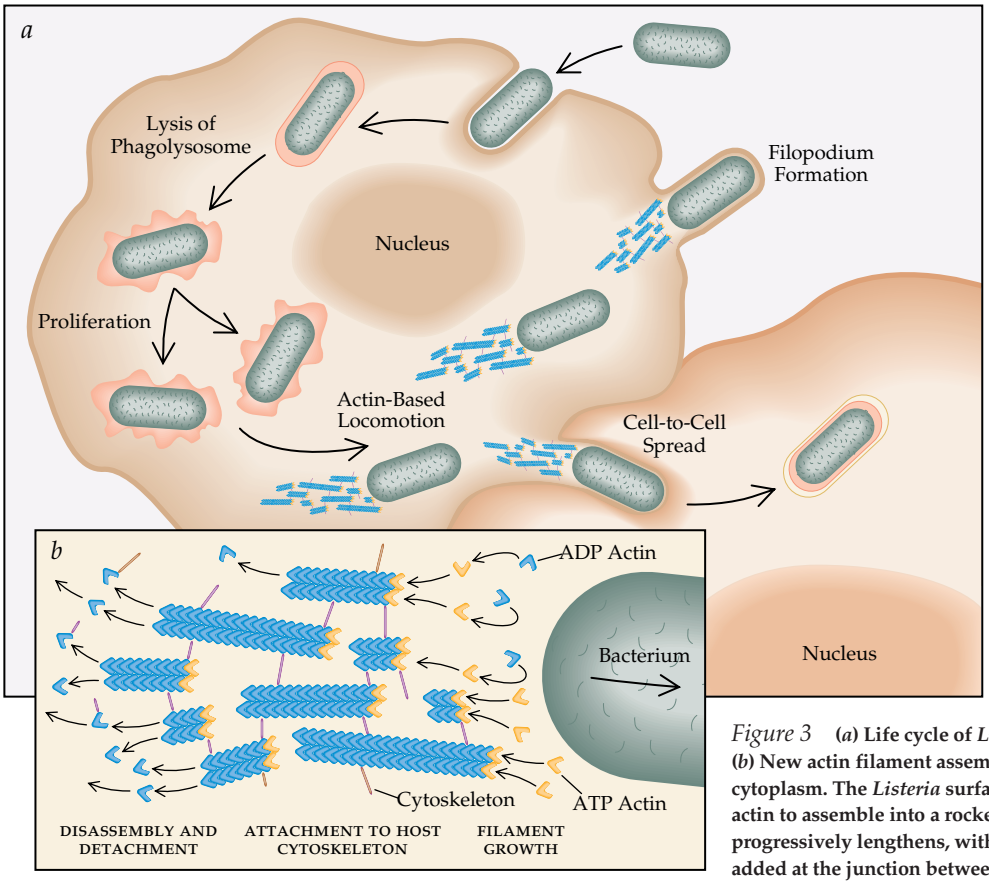

Figure 3 **(*a*) Life cycle of *Listeria monocytogenes* in host cells. (*b*) New actin filament assembly drives the bacterium through the cytoplasm. The *Listeria* surface protein ActA induces host cell actin to assemble into a rocket tail. The actin filament tail progressively lengthens, with new host cell actin monomers being added at the junction between the bacterium and the actin filament tail. The older regions of the actin tail attach to the host cell's cytoskeleton, providing a purchase so that the forces of actin filament lengthening can be applied to the bacterium to drive it through the cytoplasm. Bacteria are able to move at rapid speeds (0.02 to 1.4 µm/sec).[30]**

The ability of the *Listeria* organism to avoid the extracellular environment also explains the increased incidence of listeriosis in immunocompromised patients, neonates, and pregnant women. Increased risk of listeriosis has not been associated with deficiencies of immunoglobulins or complement. However, clinical conditions and therapies (particularly corticosteroids) that lead to deficiencies in cell-mediated immunity, the primary defense for controlling intracellular pathogens, increase the risk for listeriosis. For example, treatment with fludarabine and prednisone in patients with chronic lymphocytic leukemia markedly lowers the $CD4^+$ T cell counts and increases the incidence of listeriosis.[33] Patients with AIDS are most likely to contract *Listeria* infection when their $CD4^+$ T cell counts fall below $40/mm^3$.[34]

Clinical Manifestations

Listeriosis varies in its clinical presentation; primary manifestations most often are sepsis, meningitis, or both. Other extravascular infections are also reported, but they are surprisingly rare.

Infection during pregnancy Nearly one third of individuals who contract listeriosis are pregnant women, with infection occurring most frequently in the third trimester. The symptoms tend to be relatively mild, consisting of a flulike illness with chills, fever, and muscle aches. Back pain, a less frequent complaint, suggests a urinary tract infection; however, urinalysis and urine culture results are normal. Blood cultures, although not always obtained, are positive. Symptoms usually resolve spontaneously without therapy.[35]

Neonatal listeriosis The *Listeria* organism can cross the placental barrier, probably as a result of cell-to-cell spread mediated by host cell actin. The organism may cause amnionitis and precipitate premature labor, leading to septic abortion. Transplacental transmission can also cause the unique clinical syndrome of granulomatosis infantiseptica. The organism can disseminate in utero, forming abscesses and granulomas involving the fetal liver, spleen, lungs, kidneys, brain, and skin.[36] Mortality is high, ranging from 35% to 55%.

Chorioamnionitis is the most common early manifestation of perinatal *Listeria* infection. A Gram stain of the meconium frequently reveals gram-positive bacilli, suggesting the diagnosis. In addition to causing congenital infection, the *Listeria* pathogen can cause meningitis in neonates 7 to 28 days of age. Listerial meningitis is the third most common form of meningitis in neonates, accounting for 5% to 15% of cases.

Adult meningitis and meningoencephalitis Meningitis is the most common manifestation of listeriosis. The *Listeria* pathogen has a predilection for the central nervous system, particularly the meninges. Although the clinical presentation of listerial meningitis is similar to that of other forms of bacterial meningitis (i.e., *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*), several characteristics distinguish *Listeria* infections. Meningeal signs develop less frequently in patients with listerial meningitis than in patients with other forms of bacterial meningitis.[37] However, tremor and grand mal or focal motor seizures are observed with a higher frequency, suggesting more

extensive invasion of the CNS.[30] The CSF response may reflect the intracellular nature of *Listeria* organisms. Compared with the CSF cell counts in other forms of bacterial meningitis, both the total number of white blood cells and the percentage of neutrophils tend to be reduced in patients with listerial meningitis. Because *Listeria* primarily grows in cells, it is less commonly found in Gram stains of CSF (positive in 5% to 33% of cultures versus 80% in other forms of bacterial meningitis).[38]

Meningoencephalitis, a direct invasion of the cerebral cortex, can also result from *Listeria* infection, but it is not a recognized complication of other forms of bacterial meningitis. The ability of the *Listeria* pathogen to cross the meninges and blood-brain barrier is also likely to be the result of endothelial cell or macrophage phagocytosis of the organisms and utilization of the host cell contractile system to migrate to and grow in the brain. *Listeria* organisms most commonly invade the brain stem, causing a syndrome that has been called rhomboencephalitis.[39] The disease is usually biphasic; CNS manifestations are preceded by 7 to 10 days of malaise, fatigue, headache, nausea or vomiting, and fever. These symptoms are followed by the development of multiple cranial nerve deficits, particularly of the sixth and seventh nerves. Brain stem damage can also cause hemiparesis, ataxia, and respiratory dysfunction, often followed by respiratory arrest. In cases of meningoencephalitis, CSF monocyte counts may reach 80% to 90%. In some cases, the CSF may contain no cells or only a few cells and have normal protein and glucose levels. Magnetic resonance imaging reveals areas of increased resonance and is the best way to visualize the brain stem. Computed tomography with contrast generally shows areas of increased uptake with or without ring enhancement.

The diagnosis of both listerial meningitis and meningoencephalitis frequently is delayed. A monocytic response in the CSF and a negative CSF Gram stain can lead the clinician to confuse listerial meningitis and meningoencephalitis with herpes and other forms of viral encephalitis, viral meningitis, tuberculous meningitis, Lyme disease, syphilis, cryptococcal meningitis, Wegener granulomatosis, or CNS sarcoidosis. Particularly in the immunocompromised host, the possibility of *Listeria* infection must always be considered as a possible cause of CNS infection.

Bacteremia Bacteremia without meningitis or focal infections occurs in 5% to 30% of adult cases. There are no distinctive clinical features except for peripheral monocytosis, which is present in a small percentage of patients. Diagnosis is based on blood culture findings.

Miscellaneous infections Like many other pathogens that are able to enter the bloodstream, the *Listeria* organism can cause focal infections at many extravascular sites, including bones, normal and prosthetic joints, eyes,[40] spinal cord, pleura, peritoneum, and liver.[41] Isolated brain abscesses have also been reported.[37] In rare cases, the *Listeria* organism causes endocarditis, myocarditis, and mycotic aneurysms. Although *Listeria* enters via the gastrointestinal tract, symptomatic gastroenteritis is uncommon. However an outbreak of febrile gastroenteritis associated with contaminated delicatessen precooked turkey was reported in Los Angeles.[42]

Laboratory Tests

L. monocytogenes can be readily cultured, although a diphtheroid-like organism discovered in blood or CSF cultures is frequently misinterpreted as a contaminant. Diphtheroids can be rapidly differentiated from *Listeria* organisms by using a microscopic bacterial motility test. Decreasing motility is indicative of *Listeria* organisms. Gram stains of cerebrospinal or meconium fluid showing gram-positive rods strongly suggest *Listeria* infection. In an immunocompromised host, treatment of listeriosis should be initiated pending the laboratory staff's final diagnosis.

Table 3 Dietary Recommendations for Preventing Food-Borne Listeriosis

General recommendations
Thoroughly cook raw food from animal sources
Wash raw vegetables thoroughly
Keep uncooked meats separate from vegetables and cooked foods
Avoid consumption of unpasteurized milk or foods made with raw milk
Wash hands, knives, and cutting boards after handling uncooked foods
Additional recommendations for high-risk persons*
Avoid soft cheeses (e.g., Mexican style, feta, Brie, Camembert, and blue veined); hard cheeses, cream cheese, cottage cheese, and yogurt can be eaten
Leftovers or ready-to-eat foods (e.g., hot dogs) should be reheated until they are steaming hot
Pregnant women and immunosuppressed persons should consider avoiding foods from delicatessen counters or thoroughly cooking cold cuts before eating

*High-risk persons include immunocompromised persons, pregnant women, neonates, and the elderly.

PREVENTION AND TREATMENT

Preventive Measures

It is not possible to eliminate the large reservoir of *Listeria* organisms found throughout the environment. Physicians can help prevent disease by instructing patients at risk on how to minimize the multiplication of *Listeria* organisms in foodstuffs and how to kill the organisms on potentially contaminated foods. Patients need to avoid unsterilized dairy products, undercooked meats, and prepared foods that have been refrigerated but not resterilized by high-temperature reheating. More detailed preventive instructions are provided by the Centers for Disease Control and Prevention (CDC) [*see Table 3*].

Antibiotic Therapy

No clinical trials comparing various antibiotic regimens have been published. Bacteriostatic drugs, such as chloramphenicol and tetracycline, are associated with high failure rates in patients with listeriosis and cannot be recommended. Ampicillin is generally recommended as the treatment of choice, and the *Listeria* pathogen is generally sensitive[43] [*see Table 1*]. In immunosuppressed patients, relapse has been reported after 2 weeks of penicillin therapy. The poor response to bacteriostatic drugs and the slow response to ampicillin therapy probably result from the *Listeria* organism's ability to survive and grow in cells. The intracellular level of ampicillin may not be sufficient for complete sterilization. Immunosuppression reduces the host's ability to clear infected cells. The exact duration of antibiotic treatment required to prevent relapse is not known; however, 3 to 6 weeks of therapy is probably prudent for immunosuppressed patients. Antibi-

otics that penetrate cells poorly, such as aminoglycosides, may be synergistic in vitro but are unlikely to prove efficacious in the living host. Although some experts have recommended that an aminoglycoside be added to ampicillin, the *Listeria* organism grows in cells in the presence of extracellular gentamicin concentrations of 10 to 20 µg/ml. Furthermore, addition of gentamicin to ampicillin therapy has failed to improve outcome in a mouse infection model.[44] Therefore, aminoglycosides are unlikely to work in patients with listeriosis and certainly should be avoided in kidney transplant recipients and other patients with renal dysfunction. On the other hand, trimethoprim-sulfamethoxazole, a drug combination that readily enters cells and is bactericidal for *Listeria* organisms, may prove to be the most effective agent for treating *Listeria* infection. Trimethoprim-sulfamethoxazole has proved to be effective in patients with listeriosis and penicillin hypersensitivity [*see Table 1*].[39] Tissue culture and animal studies suggest that levofloxacin may also be effective; however, treatment of human *Listeria* infection with this quinolone has not been reported.[45]

Listeria infection in the CNS is associated with a high mortality despite appropriate antibiotic treatment. In patients with meningoencephalitis, mortality ranges from 36% to 51%. Survivors often have permanent neurologic sequelae. Mortality in patients with meningitis is somewhat lower (26%), but it is higher in patients with seizures and in those older than 65 years.[37] Early recognition and rapid institution of antibiotics are critical for improving outcome.[39]

Nocardiosis

MICROBIOLOGY

Nocardia species are thin, aerobic, gram-positive bacilli that form branching filaments that tend to fragment into coccobacilli. Gram stain is often taken up, variably resulting in an irregular, beaded appearance in exudates [*see Figure 4*]. *Nocardia asteroides* is the most common *Nocardia* species to cause human disease in the United States (80% to 90% of cases). *N. brasiliensis*, *N. otitidiscaviarum*, and *N. farcinica*[46] are rarer human pathogens. All four organisms are commonly found in soil. In addition to being gram positive, they are modified acid-fast positive. This characteristic helps differentiate *Nocardia* species from the *Actinomyces* organism, a gram-positive, anaerobic pathogen that also forms branching filaments. The *Nocardia* organism grows slowly on blood agar plates and Sabouraud dextrose agar. In sputum specimens, other organisms often overgrow, obscuring *Nocardia* colonies. Colonies generally have an orange pigment and appear heaped up and folded. They can also be white or pink. Colony characteristics suggestive of the *Nocardia* organism may not develop for 2 to 4 weeks. Samples should be obtained when the patient is not taking antibiotics. Modified Thayer-Martin medium and buffered charcoal–yeast extract agar can be used to enhance recovery of *Nocardia* species.

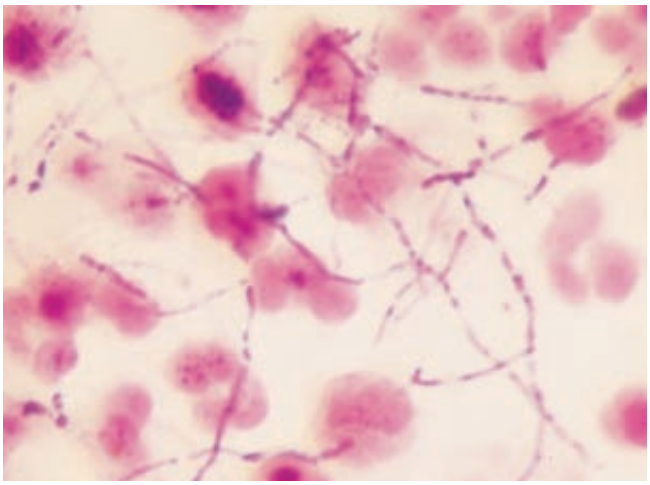

Figure 4 **Gram stain of joint fluid containing *Nocardia asteroides*.**

ETIOLOGY AND EPIDEMIOLOGY

Nocardiosis is relatively rare, infecting approximately 1,000 persons a year in the United States. Often found in soil, *Nocardia* organisms most often infect immunocompromised hosts and primarily cause pulmonary infections, brain abscesses, and skin infections.

PATHOGENESIS

In most cases, the *Nocardia* organism gains entry to the host through the respiratory tract. Inhaled bacteria elicit a neutrophil response that inhibits but does not kill the organism. *Nocardia* organisms are phagocytosed by neutrophils and incorporated into phagolysosomes. In this closed membrane space, the organism is able to survive for prolonged periods. Like *Mycobacterium tuberculosis*, pathogenic *Nocardia* species produce superoxide dismutase, a product that inactivates the toxic oxygen by-products of the neutrophils and macrophages. In addition, both *M. tuberculosis* and *Nocardia* species synthesize a second product: a mycolic acid that inhibits the fusion of lysosomes with the phagolysosomal compartment. This inhibitory activity prevents the release of toxic proteases and other antibacterial products that would otherwise reach the intracellular bacteria. The host defenses utilized to protect against nocardiosis are multifactorial and include neutrophils, macrophages, and cell-mediated and humoral immunity. Patients at risk for nocardiosis include those with chronic granulomatous disease (which compromises the ability of neutrophils to produce toxic oxygen by-products) and those with dysgammaglobulinemia. The highest percentage of cases occur in patients with impaired cell-mediated immunity, including renal and cardiac transplant patients,[47] other patients on high-dose corticosteroids, patients with Cushing disease, cancer patients,[48] and those with AIDS who have $CD4^+$ T cell counts below 250 cells/mm^3.[49] Patients with chronic pulmonary disorders, particularly alveolar proteinosis, are also at increased risk. Approximately one third of those who acquire nocardiosis have no identifiable predisposing condition.

DIAGNOSIS

Clinical Manifestations

Nocardiosis has no pathognomonic characteristics, and delays in diagnosis are common. This infection must always be considered in the immunocompromised host.

Pulmonary nocardiosis Pulmonary infection is the most common manifestation of nocardiosis, occurring in approximately two thirds of cases. In most cases, pulmonary disease is subacute in onset, mimicking pulmonary tuberculosis. Patients complain of productive cough, pleuritic chest pain, dyspnea, fever, anorexia, and weight loss. Occasionally, hemoptysis de-

velops, particularly in patients with large cavitary lung lesions; if left untreated, the disease tends to run a chronic waxing-and-waning course. Chest x-ray findings are variable and include the following, in order of most to least frequent: pulmonary nodules or mass lesions, areas of consolidation, cavitary lesions, interstitial infiltrates, and pleural effusions. In addition, CT may demonstrate areas of low attenuation in consolidations, multiple nodules, and chest wall extension of the infection. AIDS patients are more likely to have multiple pulmonary nodules, cavitary lung lesions, and upper lobe infiltrates.[49] On occasion, the infiltrate spontaneously resolves, particularly in patients with normal immune function. A brain abscess may develop later as a consequence of transient dissemination of the organism.

CNS infection In approximately one third of patients with nocardiosis, the CNS becomes infected. Brain abscess is the most common CNS infection. The lesions are often multilocular and can occur in any region of the brain.[50] CT or MRI with contrast demonstrates ring-enhancing lesions, as observed with other causes of pyogenic brain abscess. In AIDS patients, brain abscess is often accompanied by an abnormal chest x-ray, which suggests the diagnosis.[51] With other patients, abnormalities on chest x-ray are not always present. However, when abnormalities are detected, the combined findings of a lung nodule on chest x-ray and ring-enhancing CNS lesions are often mistaken for lung carcinoma with metastasis. Patients treated with surgical drainage of their abscesses have a higher survival rate than those who are not.[50] Nocardial meningitis is a less common CNS manifestation and is often associated with brain abscess (40% of meningitis cases). Patients with nocardial meningitis typically have subacute to chronic meningitis characterized by fever, stiff neck, and headache. CSF analysis demonstrates a predominance of polymorphonuclear neutrophils, a low CSF glucose level, and an elevated protein level. CSF cultures are often negative, particularly in the first 3 days of the disease, and patients fail to fully respond to empirical antibiotic therapy. Appropriate treatment is often delayed, and mortality is high (50% to 60%).

Cutaneous infection Cutaneous involvement is uncommon and is generally caused by *N. brasiliensis*. A break in the skin caused by trauma, an insect bite, a thorn bush scratch,[52] and even a cat scratch can result in local invasion by *Nocardia* organisms. A pustule or a moderately erythematous, nonfluctuant nodule develops at the site of inoculation. Regional adenopathy is generally found. The presence of multiple subcutaneous nodules indicates dissemination of the organism and more often occurs in the immunocompromised patient. In the tropical regions of South and Central America, ulcerations and large tumorlike lesions called mycetomas occur on the lower legs and are caused by *N. asteroides*.

Other infections Dissemination occurs in approximately 40% of pulmonary *Nocardia* infections and can result in localized infection in any organ. Septic arthritis, osteomyelitis, endophthalmitis, sinusitis, peritonitis, and purulent pericarditis have all been reported.

Laboratory Tests

Invasive procedures are generally required to obtain infected tissue samples. The histopathology of biopsy specimens usually reveals an acute inflammatory response with a predominance of neutrophils. Tissue necrosis with minimal fibrosis often results in the formation of multilocular abscesses with minimal capsular formation. Gram stain or Brown-Brenn stains often reveal gram-positive beaded branching forms. *Nocardia* species can also be visualized by using a modified acid-fast stain. The organism is not well seen after hematoxylin-eosin or periodic acid–Schiff stain. Culture is the definitive way to prove the diagnosis. For sputum cultures, selective media may be required to prevent the overgrowth of more rapidly growing mouth flora. For the diagnosis of meningitis, large volumes of CSF should be obtained for culture.

Nocardia organisms are slow growing and are difficult to identify on routine culture. When a potential case is encountered, it is important for the clinician to alert microbiology and pathology laboratory staffs that *Nocardia* is a possible pathogen, so that cultures can be incubated for a longer period.

TREATMENT

Sulfonamides alone and trimethoprim-sulfamethoxazole remain the treatments of choice. High intravenous doses of these agents are required: sulfadiazine (1.5 to 2 g every 6 hours) or trimethoprim-sulfamethoxazole (20 mg/kg/day of trimethoprim and 100 mg/kg/day of sulfamethoxazole given in three divided doses) to maintain serum sulfonamide levels in the 12 to 15 mg/dl range. Once substantial improvement is documented, oral treatment can be substituted after 1 to 2 months of intravenous therapy. For sulfa-allergic patients, possible alternatives need to be determined on the basis of sensitivity testing. Minocycline, imipenem, amoxicillin–potassium clavulanate, and amikacin alone or in various combinations have been successful in individual patients [*see Table 1*].[53] Because of the intracellular nature of nocardiosis and the organism's slow growth rate, 12 months of antibiotic therapy is required to prevent relapse. In cases of abscess formation in the brain, subcutaneous tissue, or other organs (except the lung), surgical drainage is also required for cure.

PROGNOSIS

The overall mortality from nocardiosis is approximately 25%. Otherwise healthy persons with pulmonary nocardiosis have a better prognosis (15% mortality). Fatality rates are higher in patients with bacteremia,[54] patients with acute infection (symptomatic for less than 3 weeks), patients receiving corticosteroids or cytotoxic agents, patients with disseminated disease involving two or more noncontiguous organs, and patients with meningitis.

Anthrax

Bacillus anthracis causes infections primarily in animals, particularly herbivores. However, contact with animals or animal products can produce *B. anthracis* infections in humans. Although *B. anthracis* was once the cause of severe epidemics, our understanding of this pathogen's epidemiology and the vaccination of domestic animals have resulted in a marked reduction of naturally acquired anthrax in the United States. In developing countries, however, outbreaks associated with exposure to animals and animal products continue to be reported. In October 2001, anthrax spores were used in a bioterrorist attack in the United States.[55] This attack emphasized the need for all health care personnel to be familiar with the clinical manifestations, diagnostic approach, treatment, and prevention of anthrax. The identification of a single case of *B. anthracis* is now a cause for alarm.[56]

MICROBIOLOGY

B. anthracis is an aerobic, gram-positive rod that forms endospores. The spores are highly resistant to adverse conditions and are able to survive at extreme temperatures, at high pH and salinity levels, and in disinfectants. The organism can be readily cultured on standard blood and nutrient agar plates. For contaminated specimens (e.g., stool), selective media or decontamination methods can be used that take advantage of the spores' ability to resist heat, ethanol, and various antibiotics. The spores germinate when they are exposed to an environment rich in amino acids, nucleosides, and glucose, such as the blood or tissues of a mammalian host. Once germination occurs, the organism multiplies rapidly. On blood agar plates, vegetative bacteria form gray-white colonies and are nonhemolytic. A fluorescent antibody stain can be used to identify the organism.

ETIOLOGY AND EPIDEMIOLOGY

Anthrax is primarily a disease of herbivores (cattle, sheep, horses, goats, and swine). Humans become infected as a result of contact with infected animals (agricultural exposure) or through exposure of infected animal products (industrial exposure). The October 2001 bioterrorist attack through the United States mail system has emphasized the danger of anthrax spores as a biologic weapon. Accidental laboratory-related infections have also been reported. *B. anthracis*, like all *Bacillus* species, is a saprophyte that grows in the soil, and animals generally contract the infection through contact with soil. Because domestic animals in the United States are vaccinated against anthrax, agricultural exposure is rare, and the diagnosis of anthrax in the United States or other developed countries should immediately raise the possibility of a bioterrorist attack.

Most cases of anthrax in the United States have occurred as a result of contact with animal products imported from Asia, the Middle East, and Africa. Wool, goat hair, and animal hides are the most common sources of infection. Persons who work in the early stages of processing these materials are exposed to the highest inoculum of spores and are most likely to contract disease. Processed materials have also caused human disease. Cases have been traced to shaving-brush bristles, wool coats, yarn, goat-skin bongo drums, and heroin preparations. The largest recent outbreak of anthrax occurred in Sverdlovsk (now Yekaterinburg), Russia, in 1979, resulting in approximately 96 inhalation cases and 64 deaths. Accidental aerosol release of anthrax spores from a germ-warfare facility is suspected, and polymerase chain reaction (PCR) analysis of tissue samples from 11 victims has identified multiple strains of *B. anthracis* in each sample, consistent with infection by a manufactured preparation of bacterial spores.[57] In October 2001, *B. anthracis* spores were sent in at least five letters to Florida, Washington, D.C., and New York City, resulting in 22 cases of anthrax (11 cases of confirmed inhalational anthrax and 11 cases of cutaneous disease [seven confirmed and four suspected]). Several cases developed as a consequence of cross-contamination of mail, and a number of postal workers were infected by spores aerosolized during mail processing.[55]

PATHOGENESIS

Spores gain entry into the epidermis through abrasions in the skin and can be inhaled into the lungs as 1 to 5 µm particles. Once in the host, the spores germinate, multiply, and produce toxins that cause tissue edema and necrosis. In the lungs, spores are ingested by macrophages, where many are lysed and destroyed. However, surviving spores are transported to the mediastinal lymph nodes, where they germinate, multiply rapidly, and quickly enter the vascular system, causing bacteremia. Extrapolation from monkey experiments indicates that inhalation of 2,500 to 55,000 spores is required to cause fatal disease in 50% of humans. However other experimental data suggest that the inhalation of as few as 1 to 3 spores may be sufficient to cause disease, and two cases of fatal inhalation anthrax in New York City and Connecticut suggest that in some individuals, fatal doses may be quite low.[56] Coating of anthrax spores to prevent their aggregation improves their ability to infect the lung (such spores are termed weaponized). The spores used in the United States attack were weaponized, which explains the efficiency of infection. Another major epidemiologic concern is the duration of risk for contracting disease after the inhalation of spores. In Sverdlovsk, cases occurred up to 43 days after exposure,[58] and in monkey experiments, viable spores were found in mediastinal lymph nodes 100 days after the spores were inhaled.[59]

Figure 5 **Typical dark, necrotic, painless pruritic skin lesion of anthrax on the wrist of a shepherd from Morocco.**

Three toxin components are synthesized on the bacterial surface and account for the major pathologic consequences of infection: protective antigen, lethal toxin, and edema toxin. Protective antigen binds host cell receptors and transports either lethal or edema toxin in the cells, which can cause cell swelling and death. Lethal toxin has a protease activity that cleaves specific kinases, which in turn may induce cell lysis.[60,61]

DIAGNOSIS

Clinical Manifestations

Skin infection Skin disease is the most common manifestation of anthrax, and half of the victims (11 of 22) in the United States bioterrorist attack presented with cutaneous disease. In the absence of exposure to animals or animal products, the diagnosis of cutaneous anthrax should immediately raise the possibility of a bioterrorist attack. One to 7 days after inoculation of spores into the skin, a small papule develops and progresses to a vesicle over the ensuing few days. Erythema and nonpitting edema often surround the vesicle. Initially, the vesicular fluid is serous and contains large numbers of organisms. Once the vesicle ruptures, a black eschar becomes evident at the base of the ulcer [*see Figure 5*]. Anthrax derives its name, which is taken from

the Greek word for coal, from these characteristic black lesions. Despite the erythema and swelling, lesions are not painful but may be mildly pruritic. Lymphangitis, lymphadenopathy, fever, and malaise may accompany the skin infection. After 1 to 2 weeks, the skin lesion dries and a permanent scar is formed. Lesions occur primarily on exposed regions of the body. The arms are the most frequent site of infection; the face and neck are also commonly involved. Lesions are usually single but may occur at multiple sites as a result of simultaneous inoculations.[62]

Respiratory infection (Woolsorters' disease) Unlike cutaneous anthrax, which is rarely fatal, inhalational anthrax is usually a fulminant disease with a high mortality. The index case in the United States bioterrorist attack presented as typical inhalational anthrax, followed quickly by sepsis and meningitis.[63] The pulmonary form of disease is usually biphasic in its presentation.[64] From 1 to 5 days after inhalation of spores, the patient has symptoms suggestive of a viral syndrome: nonproductive cough, malaise, fatigue, myalgia, and mild fever. Occasionally, the sensation of chest heaviness is reported. Other manifestations reported in the United States bioterrorist cases included sweats, often drenching; nausea and vomiting; abdominal pain; headache; confusion; and sore throat.[65] Rhonchi may be heard on pulmonary auscultation. Within 2 to 4 days, symptoms temporarily resolve but are rapidly followed by the second, more severe stage of the disease. This stage involves the sudden onset of severe respiratory distress with dyspnea, cyanosis, and diffuse diaphoresis, accompanied by fever, tachycardia, and tachypnea. On pulmonary auscultation, moist, crepitant rales are evident, and findings are consistent with pleural effusion. Chest x-ray often demonstrates a widened mediastinum. Infiltrates or consolidation may also be seen, and pleural effusions are commonly found.[65] Death often occurs within 24 hours and may be preceded by septic shock. A Russian patient was described as dying suddenly, in midsentence. Recent experience in the United States suggests that early aggressive antibiotic therapy may modify the outcome, and death rates were reduced from above 85% to below 50%.[56] Autopsy usually reveals hemorrhagic necrosis of the thoracic lymph nodes, drainage from the lungs, and hemorrhagic mediastinitis. A high index of suspicion is critical because any delay in diagnosis and treatment greatly increases the likelihood of a fatal outcome.

Gastrointestinal infection Gastrointestinal anthrax has not been reported in the United States. It occurs primarily in developing countries, usually after ingestion of contaminated meat. The incubation period is usually 3 to 5 days. Patients initially have nausea, vomiting, anorexia, and fever. Acute abdominal pain, hematemesis, and bloody diarrhea follow rapidly. Findings on examination suggest an acute surgical abdomen, and there is moderate leukocytosis with immature band forms. Rapid progression to toxemia and shock leads to death within 2 to 5 days after the initial onset of symptoms.

An oropharyngeal form of anthrax has also been described. Inflammatory lesions that resemble the cutaneous lesions develop on the posterior pharynx, hard palate, or tonsils. Tissue necrosis and edema are accompanied by sore throat, dysphagia, fever, regional lymphadenopathy, and toxemia.

Meningitis Anthrax meningitis can result from bacteremia precipitated by cutaneous, respiratory, or gastrointestinal infection. This complication is relatively rare, occurring in fewer than 5% of patients. In the index case in the United States bioterrorist attack, the patient presented to the emergency department with confusion, and gram-positive rods were identified in his CSF.[63] The onset of meningeal symptoms usually occurs simultaneously with the primary lesion or within several days after its onset. Meningitis is hemorrhagic and rapidly fatal (within 6 days).

Patient History and Laboratory Tests

A careful epidemiologic history is the single most important means of suggesting the diagnosis. A history of contact with herbivores or products from these animals, particularly if the products come from outside the United States, should raise the possibility of anthrax. The sudden appearance of several cases of severe acute febrile illness with a fulminant fatal outcome should raise the possibility of a bioterrorist attack. Certain occupational groups are at higher risk of being exposed to anthrax spores disseminated in the mail: post-office workers, members of the news media, and politicians and their staffs. Therefore, the occupational history can provide a critical clue for recognizing early inhalational and cutaneous anthrax.

The physical appearance of the skin lesions is characteristic, and Gram stains and cultures of the ulcer base are frequently positive. A history of exposure to dust from a contaminated animal product can usually be obtained in the prodromal phase of the respiratory illness, when symptoms are mild. In the absence of a thorough history, the disease is initially mistaken for a viral respiratory illness or bronchitis. Patients with gastrointestinal disease have a history of eating undercooked, often spoiled, meat.

Gram stain of the peripheral blood may reveal gram-positive bacilli, and in cases of meningitis, the CSF Gram stain is often positive. Blood cultures are positive in most cases of inhalational anthrax, and specimens for culture should be drawn immediately. The microbiology laboratory must be alerted to the possibility of anthrax, or the organism may be identified only as a *Bacillus* species and the pathogen misinterpreted as a contaminant. In the United States, the public health Laboratory Response Network, consisting of 81 clinical laboratories, has been established to specifically identify bioweapon pathogens, and all suspected samples should be referred to one of these laboratories for confirmatory diagnosis.[56]

In addition to microbiologic-study results, a chest x-ray showing a widened mediastinum, infiltrates, and pleural effusions suggests inhalational anthrax. A chest CT scan is also helpful in this disease, revealing hyperdense hilar and mediastinal nodes, mediastinal edema, and infiltrates and pleural effusions. Thoracentesis may reveal hemorrhagic pleural fluid.

A variety of rapid-assay kits are available to detect *B. anthracis* spores on environmental surfaces. However, none of these kits has been independently evaluated or endorsed by the CDC or the Food and Drug Administration, and many false positive results were reported during the United States bioterrorist attack.[56]

Enzyme-linked immunosorbent assays are available that measure antibody titers against lethal and edema toxins. A fourfold rise in titers over 4 weeks or a single titer of 1:32 is considered positive. This assay is not helpful during the acute illness. In patients receiving antibiotic prophylaxis, the antibody response may be blunted.

TREATMENT AND PROGNOSIS

Antibiotic therapy should be immediately initiated in all patients deemed at high risk who have fever or a systemic illness

consistent with inhalational anthrax. Any delay in therapy increases the risk of a fatal outcome. First-line antibiotics are intravenous ciprofloxacin or doxycycline combined with one or two other antibiotics with activity against the pathogen [*see Table 1*]. Because anthrax strains may have constitutive and inducible β-lactamases, monotherapy with penicillin or ampicillin is not recommended. When meningitis is suspected, doxycycline should not be used, because of its poor CNS penetration. Once the patient is stable, oral antibiotics can be given, with ciprofloxacin (500 mg twice daily) or doxycycline (100 mg twice daily) being the treatment of choice. Because of the risk of delayed germination of spores in the host, therapy should be continued for 60 days. Oral ciprofloxacin or doxycycline for 60 days is recommended for cutaneous disease. Excision of skin lesions is contraindicated because of the increased risk of precipitating bacteremia. However, after appropriate antibiotic therapy, excision and skin grafting may be necessary.[66]

Before antibiotics became available, cutaneous disease was associated with a mortality of 10% to 20%. With appropriate antibiotic treatment, fewer than 1% of patients die. Despite appropriate antibiotics and respiratory support, inhalational anthrax in the past was almost always fatal. However, experiences in Russia and the United States demonstrated that with early systemic antibiotic therapy, mortality can be reduced to approximately 50%. Gastrointestinal disease also is associated with a high mortality (25% to 100%).

PREVENTION

Postexposure prophylaxis is critical for the prevention of secondary cases. The selection of patients for prophylaxis depends on the environmental setting and the conditions of the spore release. Nasal swab cultures are insensitive and should not be used to determine whether an individual should receive prophylactic antibiotics. Nasal swab cultures are recommended only as an epidemiologic tool to determine the extent of exposure in a specific area or building. In cases of suspected exposure to *B. anthracis*, the preventive regimens of choice are oral fluoroquinolones (e.g., ciprofloxacin, 500 mg twice daily; levofloxacin, 500 mg a day; or ofloxacin, 400 mg twice daily) or, if fluoroquinolones are contraindicated, doxycycline (100 mg twice daily). Prophylaxis should be continued until exposure is excluded. If exposure is confirmed, prophylaxis should be continued for 60 days. In persons thought to be heavily exposed, prophylaxis for 100 days may be considered.[67]

A killed vaccine derived from a component of the anthrax exotoxin is available and is recommended for all industrial workers at risk for exposure to contaminated animal products. As a result of increased concerns about biologic warfare and bioterrorism, military personnel are now vaccinated. Postexposure vaccination, although not approved by the FDA, has been shown to provide additional protection in animal studies and is recommended as an option by the CDC. In such cases, the vaccine is considered an investigational new drug and should be administered with informed consent.[68]

Anecdotal reports in the lay press have associated anthrax vaccine with a high incidence of serious reactions. Nevertheless, although mild localized reactions occur in up to 30% of anthrax vaccine recipients, to date, with the exception of two cases of optic neuritis,[69] and one of delayed anaphylaxis,[70] serious adverse reactions have not been reported.[71]

For decontamination after anthrax exposure, exposed skin should be washed extensively with soap and water. Because of the potential danger of secondary aerosolization, decontamination of exposed environments is recommended. Decontamination is technically difficult and requires expert analysis that takes into account the nature of the exposure and the environmental conditions.[56]

Infections and Disorders Due to Other *Bacillus* Species

Bacillus organisms are found in soil, dust, decaying organic matter, and water. Some species are part of the normal flora, particularly in patients who have had prolonged hospitalizations. Despite their widespread distribution, these organisms rarely cause infection and are more often isolated as a contaminant. Risk factors associated with serious *Bacillus* infections include use of intravascular catheters; intravenous drug abuse; sickle cell disease; and immunosuppression caused by malignancy, neutropenia, corticosteroid therapy, or AIDS.[72] Because these organisms are frequently resistant to third-generation cephalosporins, prolonged antibiotic treatment regimens that include these agents may select out for *Bacillus* organisms.

B. cereus is the most frequent *Bacillus* species to cause invasive infection, followed by *B. subtilis* [*see Table 4*].

DIAGNOSIS

Clinical Manifestations

With the exception of *B. cereus* eye infections, *Bacillus* infections are rare and cannot be clinically distinguished from those caused by other pyogenic organisms. Pneumonia can develop in the compromised host, and necrotizing pneumonia caused by *B. cereus* has been reported in patients with acute leukemia and hepatic malignancy. Fatal pseudomembranous tracheobronchitis and pneumonia have been reported in a patient with aplastic anemia.[73]

Bacterial endocarditis caused by *Bacillus* species is a well-recognized complication of intravenous drug abuse. The tricuspid valve is most often involved, and the course of illness tends to be indolent. *Bacillus* species are among many pathogens that infect prosthetic valves.[74] Indwelling catheters may become colonized with *Bacillus* organisms, resulting in positive blood culture results.

High-grade bacteremia can be complicated by fatal meningoencephalitis in the immunocompromised host.[75] Necrotizing fasciitis can be caused by *B. cereus*.

In rare cases, meningitis may result from *Bacillus* bacteremia, but more often, it has followed inadvertent inoculation of organ-

Table 4 Clinical Syndromes Caused by *Bacillus* Species

Species	*Clinical Syndrome*
B. alvei	Meningitis, pneumonia, empyema, bacteremia
B. cereus	Ophthalmitis, bacteremia, pneumonia, osteomyelitis, endocarditis, soft tissue infection
B. sphaericus	Peritonitis, pleuritis, lung infection, meningitis, bacteremia
B. subtilis	Meningitis, otitis, mastoiditis, urinary tract infection, bacteremia, endocarditis, ventricular shunt infection

isms into the CSF during spinal anesthesia.[76] Because of their hardy growth characteristics, *Bacillus* species are common laboratory contaminants. Pseudobacteremia caused by contamination of alcohol swabs and rubber stoppers on blood culture bottles and pseudomeningitis caused by *Bacillus* contamination of commercial culture media have been reported.[77]

Motor vehicle accidents in which injuries result from direct contact with the road may result in *B. cereus* soft tissue and bone infections that necessitate extensive surgical debridement and amputation for cure. Close-range gunshot wounds and injection of contaminated heroin have also been complicated by *B. cereus* soft tissue infection.[78,79]

Ocular infections *B. cereus* is a primary pathogen for ocular infections. This species is one of the most common agents associated with posttraumatic endophthalmitis. When *B. cereus* is the causative agent, an intraocular foreign body is often present. Injuries caused by metal fragments and injuries associated with contamination by soil and dust increase the risk of infection by *B. cereus*. The onset of infection is rapid and leads to destruction of the vitreous and retinal tissue, causing loss of vision 12 to 48 hours after inoculation. Patients frequently become systemically ill, with fever and leukocytosis. Endophthalmitis and panophthalmitis can also be related to intravenous drug abuse. Early diagnosis and treatment are critical for preventing permanent structural changes and blindness.[80]

Food poisoning *B. cereus* produces two enterotoxins, diarrheal toxin and emetic toxin, that are responsible for two food-poisoning syndromes. The emetic form is associated primarily with the ingestion of contaminated fried rice.[81] From 1 to 6 hours after ingestion, the person experiences vomiting and symptoms identical to those of staphylococcal food poisoning. A case of fulminant fatal hepatic failure and rhabdomyolysis associated with ingestion of *B. cereus* emetic toxin has also been reported.[82] The diarrheal form has a longer incubation period (10 to 12 hours), and manifestations are related to lower rather than upper gastrointestinal symptoms. Symptoms include abdominal pain, profuse watery diarrhea, tenesmus, and nausea. This syndrome is usually self-limited and lasts 12 to 24 hours. Outbreaks are generally associated with ingestion of contaminated meat, vegetables, and mayonnaise.[83]

TREATMENT

B. cereus is resistant to penicillin and other β-lactam antibiotics, including cephalosporins; it is sensitive to vancomycin, gentamicin, imipenem, and ciprofloxacin. Clindamycin, erythromycin, chloramphenicol, and tetracycline have also been shown to be active. Other *Bacillus* species are susceptible to penicillins and cephalosporins. Pending speciation and susceptibility testing, vancomycin or clindamycin with or without gentamicin is the empirical treatment of choice when infection with *Bacillus* species is suspected [*see Table 1*].

If *Bacillus* bacteremia develops in immunocompromised patients with long-term indwelling catheters, antibiotic therapy must be instituted and the catheter removed to prevent recurrence of the infection.[84] In addition to antibiotic treatment, the deep-seated soft tissue infection associated with necrotizing fasciitis requires aggressive surgical debridement.[85]

For intraocular infections, systemic therapy is usually supplemented with intravitreous clindamycin and gentamicin administered by an ophthalmologist. Intravitreous dexamethasone and early vitrectomy have been recommended for the management of sight-threatening endophthalmitis by *B. cereus*.[80]

For patients with food poisoning, antibiotics are not required, because the disease is self-limited. Supportive care may include intravenous fluids if the patient becomes severely dehydrated.

Infections Due to the *Erysipelothrix* Organism

Human infections by the *Erysipelothrix* organism are rare and are always caused by *E. rhusiopathiae* (formerly *E. insidiosa*). This aerobic gram-positive bacillus grows on routine nonselective media and is nonhemolytic, nonmotile, and catalase negative. Because of the cell wall's high lipid content (about 30%), *E. rhusiopathiae* is resistant to desiccation and may tolerate salting, pickling, and smoking. The organism is capable of growing over a broad temperature range (4° to 42° C) and is widespread in nature. *E. rhusiopathiae* can infect mammals, birds, fish, shellfish, and insects. Human infection results from handling dead infected animal parts. Infection can also result from cat bites.[86] Most cases of skin infection occur during the summer and early fall. Infection is almost always the result of occupational exposure of slaughterhouse workers, butchers, fishers, farmers, and veterinarians. The organism is usually traumatically inoculated. Bacilli remain extracellular and are often located deep in the skin near capillaries, where the organism can gain entry into the bloodstream.[87]

DIAGNOSIS

Clinical Manifestations

Erysipeloid Between 2 and 7 days after skin inoculation, a purplish-red, nonvesicular area arises with a sharply defined, raised, serpiginous border. Lesions most often develop on the face and hands. Proximal regions of the hand and fingers are involved, whereas the distal phalanges are usually spared. Lesions spread peripherally at a slow pace (1 cm/day). Over time, the central part of the lesion begins to heal, resulting in a pale center surrounded by a fiery-red outer border. Lesions itch or burn and are rarely associated with lymphangitis or lymphadenitis. Fever and systemic complaints are rare.

Endocarditis Endocarditis is rare but may occur on both deformed and normal heart valves. The onset is acute or subacute and most often involves the aortic valve. In approximately 40% of cases, a skin lesion is noted just before or at the time of diagnosis, suggesting the possibility of *E. rhusiopathiae*.[88] Often, the skin lesion has healed by the time endocarditis becomes apparent. Mental-status changes associated with multiple cerebral hemorrhages may also accompany this form of endocarditis.[89]

Patient History and Laboratory Tests

An appropriate epidemiologic history will suggest the diagnosis. Morphologically, the skin lesions resemble erysipelas (caused by group A streptococci). However, the rate of progression of *Erysipelothrix* infection is considerably slower, and unlike erysipelas, this skin lesion is not associated with tenderness or lymphadenopathy. Injection and culturing of nonbacteriostatic normal saline is rarely successful. Biopsy of a full-thickness skin specimen from the advancing border of the lesion and culturing in glucose-containing broth result in the highest yields. PCR assays for erysipelas have proved to be useful in swine and have been applied to humans.[90] Diagnosis of endocarditis depends on isolation of the organism from blood cultures.

TREATMENT

The treatment of choice for erysipeloid is penicillin; a single injection of 600,000 units of penicillin G benzathine generally is curative. For penicillin-allergic patients, oral erythromycin (250 to 500 mg every 6 hours) is effective. This skin infection is usually self-limited and lasts about 3 weeks; however, antibiotic treatment hastens the healing. Bacterial endocarditis is best treated with intravenous penicillin G. For penicillin-allergic patients, intravenous cefazolin or ceftriaxone is recommended [*see Table 1*].[90,91] Most strains are resistant to vancomycin, which therefore should not be used for empirical therapy for endocarditis if *E. rhusiopathiae* is a possibility. Despite appropriate therapy, the mortality associated with endocarditis is 30% to 40%.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

V ANAEROBIC INFECTIONS

Anthony W. Chow, m.d., f.a.c.p, f.r.c.p.c.

General Considerations

anaerobic bacteria and oxygen tolerance

Obligate anaerobes require reduced oxygen tension (< 10%) for growth; they do not survive as surface growths on solid medium in ambient air (i.e., 20% oxygen). In contrast, facultative bacteria can grow in air with or without 10% carbon dioxide, whereas microaerophilic or capnophilic bacteria grow poorly in ambient air, but they grow better in air with reduced oxygen tension (i.e., 10% oxygen and 10% carbon dioxide). Obligate anaerobes vary greatly in their sensitivity to oxygen. Extremely oxygen-sensitive anaerobes, such as spirochetes and some *Clostridium* species, cannot tolerate even 0.5% oxygen. As a general rule, clinical isolates commonly recovered from anaerobic infections are relatively aerotolerant, able to survive in 2% to 8% oxygen.

obligate anaerobes in the normal flora

Quantitatively, obligate anaerobes are the predominant normal flora on mucocutaneous surfaces—especially the oral cavity, skin, and gastrointestinal and genital tracts—where they outnumber facultative bacteria by a factor of 10 to 10^3 [*see Table 1*]. The major genera of obligate anaerobes and their distribution in the normal flora vary according to body site [*see Table 2*]. These indigenous bacteria have unique ecologic niches at different body sites. For example, in the oral cavity, *Actinomyces viscosus* (along with the aerobes *Streptococcus sanguis, S. mutans,* and *S. mitis*) preferentially colonizes the tooth surface; in contrast, *Veillonella parvula* and *S. salivarius* have a predilection for the tongue and buccal mucosa.[1] *Bacteroides vulgatus, B. thetaiotaomicron, B. fragilis*, and *B. distasonis* are primarily indigenous in the colon[2]; *Prevotella bivia* and *P. disiens* are primarily resident in the female genital tract.[3] In addition, this ecosystem is readily influenced by a variety of physiologic and other host factors, such as age, pregnancy, menses, diet, underlying disease, hospitalization, and antimicrobial therapy [*see Table 3*].

pathogenesis of anaerobic infections

Host Conditions

Anaerobic infections characteristically are polymicrobial (mixed) and include both anaerobic and facultative organisms. The organisms tend to be acquired endogenously. The particular mix of pathogens reflects the combined influence of the complex commensal flora at a specific body site and the unique microbiota of the underlying conditions. Because these organisms are generally of low pathogenicity, anaerobic or mixed infections generally develop as a consequence of either structural alterations in the normal mucosal barrier or tissue ischemia with lowered oxidation-reduction potential. Knowledge of the anatomic location of the primary source of infection and the underlying condition of the host, therefore, is essential in predicting the probable organisms causing anaerobic and mixed infections associated with the indigenous microflora.

Microbial Synergy

Two thirds of anaerobic infections involve both anaerobes and facultative bacteria. The infectivity of obligate anaerobes in these instances is often facilitated by the coexistence of facultative organisms. Such examples of microbial synergy are particularly well demonstrated in periodontal infection and in various animal models of intra-abdominal and subcutaneous abscesses.[4,5] For example, microbial synergy is common between *Bacteroides* species and aerobic bacteria or anaerobic cocci and between most *Peptostreptococcus* species and *Pseudomonas aeruginosa* or *Staphylococcus aureus.* Anaerobes may require symbiotic facultative bacteria for providing necessary growth factors, lowering the oxidation-reduction potential of the environment, or impairing local host defenses. Conversely, the presence of obligate anaerobes may benefit coexisting facultative bacteria by growth enhancement,[6] protection from phagocytosis (e.g., succinic acid production by *Bacteroides* species),[7] or protection from β-lactam antibiotics (e.g., β-lactamase production).[8] Infective synergy between anaerobes and facultative bacteria is best demonstrated within tissues in which bacterial clearance is normally slow (e.g., subcutaneous abscesses or fibrin clot in intraperitoneal infection) or is hampered by underlying disease. An understanding of the dynamic interactions between different components of a complex flora in mixed infections has important therapeutic implications. Microorganisms in mixed infections may respond to antimicrobial agents differently than do those in monomicrobial infections, and it may not be necessary to eradicate every bacterial species in mixed infection to achieve a cure.

Virulence Factors

A number of microbial virulence factors are considered important in the pathogenesis of anaerobic infections [*see Table 4*].

Extracellular or membrane-bound enzymes Obligate anaerobes possess a number of extracellular or membrane-bound

Table 3 Effect of Host Conditions on the Indigenous Microflora at Various Body Sites

Site	*Host Condition*	*Change in Normal Flora*
Gingiva	Dental caries and periodontal disease	Increased motile anaerobic gram-negative bacilli and spirochetes
Oropharynx	Hospitalization, antibiotics, or serious illness	Increased facultative gram-negative bacilli
Upper small bowel	Achlorhydria, vagotomy, pyloroplasty	Increased *E. coli, B. fragilis,* and *Bifidobacterium*
Small bowel	Regional enteritis, decreased motility, or stasis secondary to blind loop, obstruction, diverticuli, irradiation, etc. Disrupted anatomic continuity after bowel resection or bypass surgery	Colonic flora
Large bowel	Colonic resection with ileostomy	Decreased anaerobes and some facultative bacteria
Vagina	Parturition, hysterectomy, or irradiation	Increased *E. coli* and *B. fragilis*

Table 4 Microbial Virulence Factors Important in Mixed Anaerobic Infections

Microbial Factor	*Pathogenic Effect*
Histolytic enzymes (e.g., collagenase, fibrinolysin, hemolysins, hyaluronidase, protease, lipase, ribonuclease, deoxyribonuclease; *Bacteroides fragilis, Porphyromonas gingivalis, Prevotella melaninogenica*)	Tissue destruction
Hemolysins (*Clostridium perfringens*)	Hemolysis
Enterotoxins (*C. perfringens, C. difficile*)	Alteration of cell function with diarrhea or cell death
Neurotoxins (*C. tetani, C. botulinum*)	Blockade of neuromuscular junctions with either spasticity (tetanus) or paralysis (botulism)
Endotoxin (gram-negative anaerobes; *B. fragilis, Fusobacterium nucleatum, P. intermedia, Veillonella parvula*)	Direct toxicity; Hageman factor, complement activation
Heparinase (*P. gingivalis, Bacteroides* species, *Fusobacterium* species)	Promotion of coagulation and tissue ischemia
Capsular polysaccharide (*B. fragilis, P. melaninogenica, Peptostreptococcus* species)	Inhibition of phagocytosis; abscess formation
IgA protease (*P. melaninogenica, P. gingivalis, P. intermedia*)	Impairment of secretory and mucosal immunity
Succinic acid (*B. fragilis*)	Inhibition of phagocytosis
β-Lactamase (*B. fragilis, P. melaninogenica, P. gingivalis, F. nucleatum*)	Antibiotic resistance
Oxygen-scavenging enzymes (e.g., superoxide dismutase, catalase, peroxidase; *P. gingivalis, B. fragilis, C. perfringens*)	Oxygen tolerance
Surface ligands and charge (*P. gingivalis, P. intermedia, F. nucleatum, Actinomyces naeslundii*)	Adherence and bacterial interaggregation
Bacteriocin and metabolites (e.g., fatty acids, H_2S, NH_3; *Propionibacterium acnes, B. fragilis, F. necrophorum*)	Inhibition of other normal flora

enzymes that promote tissue destruction. These include lipases, proteases, nucleases, and heparinases.[9] Membrane-bound enzymes, such as superoxide dismutase[10] and β-lactamases,[8] may be important for protecting virulent organisms from the toxic effects of oxygen and β-lactam antibiotics, respectively. Catalase may serve a function similar to that of superoxide dismutase. Organisms lacking these enzymes are susceptible to killing by toxic oxygen radicals and common antibiotics in the environment.

Capsular polysaccharide *B. fragilis, Prevotella melaninogenica,* and a number of *Peptostreptococcus* species are encapsulated and exhibit increased virulence in abscess formation and systemic invasion.[11] Interestingly, organisms that are normally nonencapsulated and unable to induce abscesses by themselves during experimental infection may become heavily encapsulated after participating in a mixed infection with other aerobic and anaerobic bacteria.[5] These heavily encapsulated strains are able to induce abscesses thereafter when inoculated alone. This phenomenon may help explain how nonpathogenic organisms that are part of the normal host flora can become pathogens. The capsular materials of *B. fragilis* and *P. melaninogenica* have been extracted and purified. These large-molecular-weight polysaccharides have been demonstrated to inhibit phagocytosis in vitro and to promote abscess formation in several animal models.[12] In addition, several oral anaerobes (e.g., *P. melaninogenica, P. gingivalis,* and *P. intermedia*) can secrete IgA proteases that may impair secretory and local mucosal immunity.[13]

Lipopolysaccharide Like their aerobic counterparts, anaerobic gram-negative bacteria possess lipopolysaccharides (LPS) in their outer cell membrane. However, the structure and biologic activity of LPS from several anaerobic bacteria are distinctly different from those of the classic LPS of Enterobacteriaceae. For example, LPS of *B. fragilis* and *P. intermedia* lack 2-keto-3-deoxyoctanoic acid and L-glycero-D-mannoheptose, and they have little endotoxic potency.[14] The LPS of *F. nucleatum* and *V. parvula,* on the other hand, have biochemical and biologic properties similar to those of classic endotoxin.

Fatty acids and other metabolites *B. fragilis* and other anaerobes produce various short-chain fatty acids that are deleterious to mammalian cell function. Infections with *B. fragilis* are associated with the production of high concentrations of succinic acid, which impairs the generation of the respiratory burst and profoundly reduces phagocytic killing and chemotactic responses of neutrophils.[15] This effect is most evident at the low pH and the low Eh (redox potential) conditions present in abscesses and mixed infections. Succinic acid production may represent an important virulence mechanism by *Bacteroides* species in the pathogenesis of synergistic mixed infections.

Toxins Several *Clostridium* species produce potent exotoxins. The most important of these is *C. perfringens* α-toxin, which is a lecithinase that exhibits hemolytic, necrotizing, and lethal properties.[16] α-Toxin disrupts membranes containing phospholipid-lecithin complexes, including human cell and mitochondrial membranes, and has direct myocardial depressant properties. A second clostridial exotoxin, β-toxin, is a potent cytotoxin that has cytolytic activity, particularly against endothelial cells. Toxin production at a site of injury allows rapid invasion and destruction of healthy tissues. The paucity of leukocytes in the exudate of clostridial myonecrosis may reflect the presence of these cytotoxins.

C. difficile, the major cause of antibiotic-associated diarrhea and enterocolitis, produces two high-molecular-weight enterotoxins, toxin A (enterotoxin) and toxin B (cytotoxin).[17] Both toxins inactivate Rho proteins, a family of small guanosine triphosphate–binding proteins that regulate actin cytoskeleton and various signal transduction processes. Toxin A causes intestinal fluid secretion, mucosal injury, and inflammation. Toxin B has no demonstrable effect on cell permeability and fluid secretion, but like toxin A, it disrupts tight junctions in human epithelial cell monolayers. Toxin B is 10 times more potent on a

Table 5 Anaerobic Bacteria Associated with Specific Infections[57-86]

Site	*Infections Likely to Involve Anaerobes*	*Anaerobes Recovered (Percentage of Infections)*	*Predominant Isolates*

	Diabetic foot ulcer	63	
	Breast abscess	79	
	Bite wound infections	53	
Blood	Primary bacteremia	4	*B. fragilis* group, *F. necrophorum, Peptostreptococcus* species, *C. perfringens, C. septicum*

molar basis than toxin A in mediating damage to human colonic mucosa.[18]

Tetanus toxin (tetanospasmin) is produced in a tetanus-infected wound and is transported intra-axonally along motor nerves to the spinal cord. Here, the toxin alters normal control of the reflex arc by suppressing the inhibitory neurotransmitter γ-aminobutyric acid (GABA), producing severe muscle spasms. Like tetanospasmin, botulinum toxin also binds irreversibly to presynaptic nerve endings of cranial and peripheral nerves. Once bound, botulinum toxin prevents the release of the neurotransmitter acetylcholine, producing flaccid paralyses.

Specific Anaerobic Infections

Anaerobic bacteria can cause infections throughout the body. These infections can be conveniently divided into three categories on the basis of unique clinical, microbiologic, and epidemiologic features. These include infections caused by (1) *Bacteroides* and other mixed anaerobes, (2) *Actinomyces* species, and (3) *Clostridium* species.

INFECTIONS CAUSED BY *BACTEROIDES* AND OTHER MIXED ANAEROBES

Epidemiology

Anaerobic infections caused by *Bacteroides* and mixed anaerobes may involve any organ and may occur in persons of all ages. Obligate anaerobes are particularly prevalent in infections of the head and neck, lung and pleural space, intra-abdominal organs, the female genital tract, and necrotic skin and soft tissues. Predisposition to these infections is increased by local ischemia or tissue necrosis, such as from trauma, bites, surgical manipulation, irradiation, or neoplasm.

Etiology

The predominant obligate anaerobes commonly isolated from anaerobic or mixed infections at different anatomic sites include *Bacteroides, Prevotella, Porphyromonas, Fusobacterium, Peptostreptococcus, Actinomyces*, and *Clostridium* [*see Table 5*]. All members of the genus *Bacteroides* are thin, pleomorphic, gram-negative bacilli that are nonmotile and nonsporulating. The *B. fragilis* group dominates in the colonic microflora, whereas *Porphyromonas* and

Prevotella species reside primarily in the oropharynx. *B. fragilis* [*see Figure 1a*], the encapsulated member of the *B. fragilis* group, is by far the most common in anaerobic infections. Other members of this group include *B. ovatus*, *B. thetaiotaomicron*, *B. distasonis*, and *B. vulgatus.*

Prevotella melaninogenica (formerly *B. melaninogenicus*) is recognized in the laboratory by the production of a dark pigment. The most prevalent *Porphyromonas* species isolated from oral and periodontal infections are *P. gingivalis* and *P. asaccharolyticus*.

Fusobacterium species are gram-negative bacilli with typically pointed ends. They generally reside in the oropharynx or the gastrointestinal tract. Among these, *F. nucleatum* [*see Figure 1b*] is the most important species in head and neck and pleuropulmonary infections.

Peptostreptococcus species are small gram-positive cocci that are common in mixed infections at all body sites but particularly the oral cavity and the female genital tract. *Veillonella* species are anaerobic gram-negative cocci that are occasionally isolated from mixed infections, but their pathogenicity is uncertain.

Among the nonsporulating anaerobic gram-positive bacilli, *Propionibacterium acnes* is occasionally isolated in blood cultures but almost always as a skin contaminant. Another nonsporulating anaerobic gram-positive bacillus with low pathogenicity is *Lactobacillus,* a dominant member of the normal vaginal flora. *Lactobacillus* species occasionally can cause serious infections, including bacteremia.[19] Clinically important *Actinomyces* and *Clostridium* species are discussed separately (see below).

Clinical Presentations

Head and neck infections Orofacial anaerobic infections are commonly odontogenous in origin and include periapical abscesses, gingival and periodontal infections, and orofacial fascial space infections.[1] The clinical manifestations of these infections are largely dictated by the anatomic location and the extent and routes of spread. An aggressive form of gingivitis is Vincent angina, or trench mouth. This is a fulminant form of necrotizing, ulcerative gingivitis associated with severe pain, tissue destruction, foul breath, and a putrid discharge. Masticator-space infection generally originates from a molar or premolar tooth of the mandible and is characterized by pain and swelling at the angle of the jaw and by severe trismus. Extension of infection into the sublingual and submandibular spaces bilaterally may cause swelling of the base of the tongue and potential airway obstruction (Ludwig angina).[20] Extension of infection into the posterior compartment of the lateral pharyngeal space may be complicated by thrombophlebitis of the jugular vein (Lemierre syndrome).

Obligate anaerobes are also commonly present in chronic sinusitis, otitis media and mastoiditis, and tonsillar and peritonsillar abscesses. Acute sinusitis is seldom caused by anaerobic organisms unless it is associated with a dental infection. *Fusobacterium* and anaerobic gram-positive cocci are also commonly isolated in chronic or recurrent maxillary sinusitis. *Fusobacterium necrophorum* and *P. melaninogenica* are most frequently recovered from tonsillar and peritonsillar abscesses.

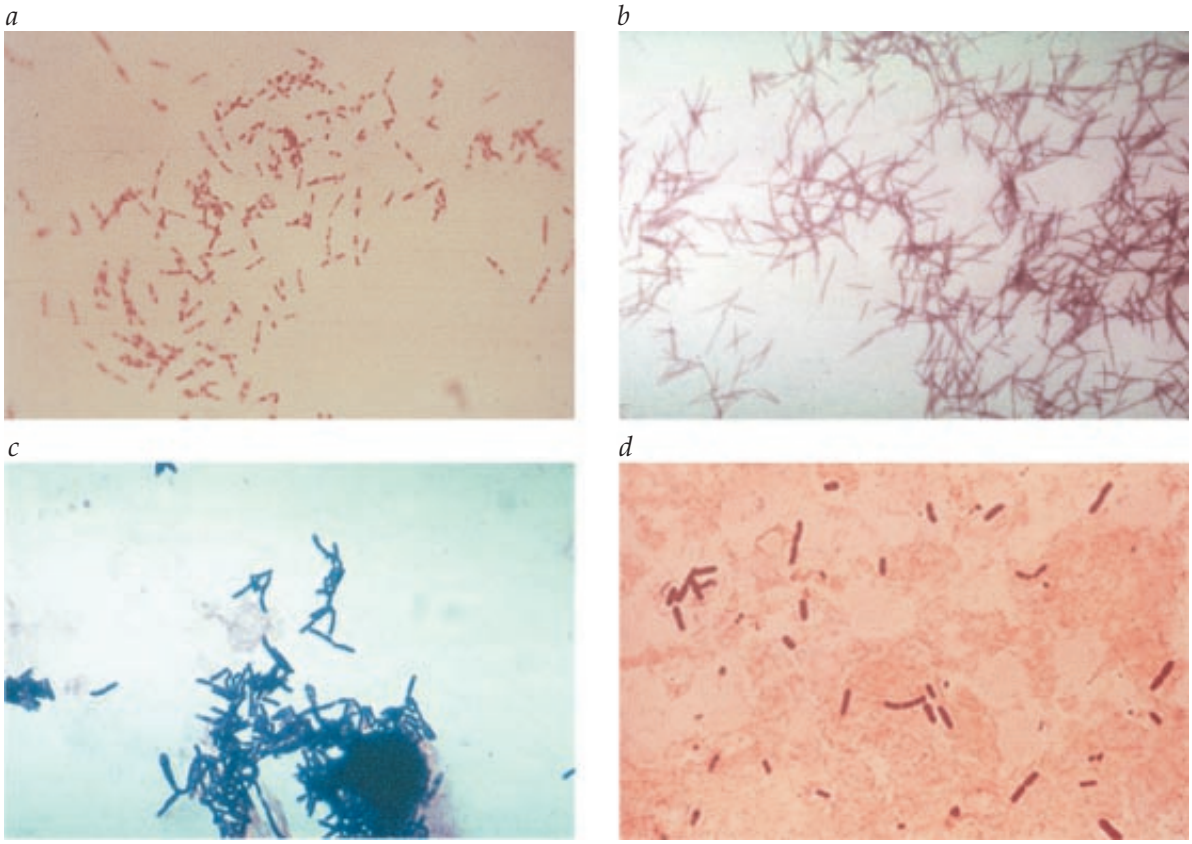

Figure 1 **Gram stains of representative obligate anaerobes commonly isolated in anaerobic infections (magnification: × 1,000). (*a*) *Bacteroides fragilis* from a pelvic abscess. (*b*) *Fusobacterium nucleatum* from an anaerobic pleuropulmonary infection. (*c*) *Clostridium perfringens* from myonecrosis. (*d*) *Actinomyces israelii* from cervicofacial actinomycosis.**

Intracranial infections Anaerobic bacteria are frequent pathogens in intracranial infections, particularly brain abscess caused by hematogenous dissemination from chronic and suppurative pulmonary foci; they are also frequently isolated in patients with cyanotic congenital heart disease. Contiguous spread from chronic otitis media, mastoiditis, or sinusitis may result in subdural empyema, epidural abscess, or suppurative thrombophlebitis of cortical vessels or venous sinuses. Purulent meningitis seldom involves anaerobic bacteria except in the newborn. Cerebral abscesses of sinus or dental origin are more probably caused by *S. milleri,* either alone or in mixed culture with other oropharyngeal aerobes and anaerobes. Otogenic cerebral abscesses, on the other hand, frequently involve *B. fragilis*, *Proteus* species, and streptococci.

Pleuropulmonary infections Anaerobic pleuropulmonary infections include aspiration pneumonitis, putrid lung abscess, necrotizing pneumonia, and empyema. Pneumonitis is usually the initial lesion; related symptoms in the early phases may be indistinguishable from symptoms of acute bacterial pneumonia of other causes. If the initial lesion remains untreated, however, pulmonary abscess may ensue after 8 to 14 days. Approximately one half of patients with lung abscess develop putrid-smelling expectorations. The subsequent clinical course depends largely on the nature of the underlying pulmonary pathologic condition. About 10% of patients with anaerobic infections of the lung parenchyma develop empyema. Necrotizing pneumonia is characterized by multiple small cavities within a pulmonary segment or lobe. The course is often fulminant, with rapid extension into adjacent segments. Anaerobic pleuropulmonary infections are typically polymicrobial. Predominant anaerobic isolates include *Peptostreptococcus* species, *F. nucleatum,* and the saccharolytic black-pigmented anaerobic gram-negative bacilli *(P. melaninogenica* and *P. intermedia)*. Aerobic and microaerophilic streptococci (e.g., *S. intermedius*) are also frequently isolated. Aerobes such as *S. aureus*, *Escherichia coli, Klebsiella pneumoniae,* and *P. aeruginosa* are more likely to be isolated along with anaerobic bacteria in hospital-acquired infections than in community-acquired aspiration pneumonia.

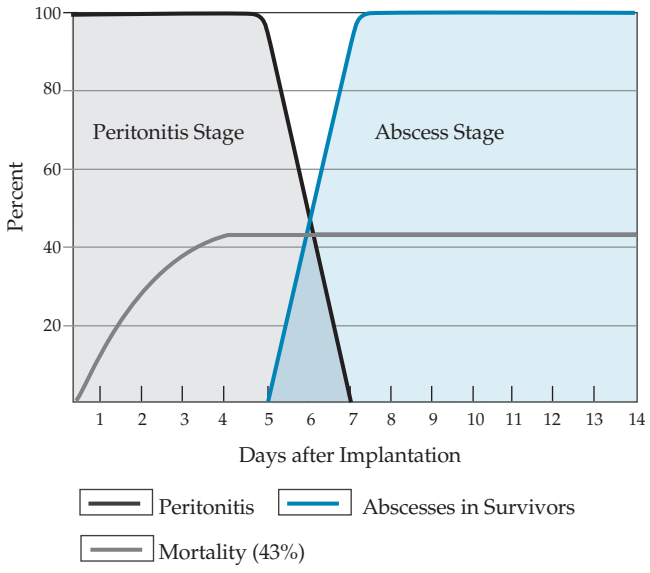

Figure 2 **Biphasic disease model of mixed infection in intra-abdominal sepsis.[25]**

Intra-abdominal infections Intra-abdominal sepsis most commonly results from bacterial contamination of intraperitoneal or retroperitoneal spaces after intestinal perforation. The initial event is peritonitis, either generalized or localized, with subsequent abscess formation. Common predisposing conditions include penetrating trauma, perforated appendicitis or diverticulitis, inflammatory bowel disease, intestinal malignancy with strangulation or obstruction, and anastomotic leak after intestinal surgery. Although a multiplicity of anaerobic and facultative bacteria may be isolated in intra-abdominal infections—particularly *B. fragilis, Peptostreptococcus* species, *Clostridium* species, Enterobacteriaceae, and *Enterococcus faecalis*—it is not always clear which components are the primary pathogens and which are merely symbionts or commensals. Animal studies of experimental peritonitis simulating intestinal perforation suggest that such infections follow a biphasic process[21] [*see Figure 2*]. Early peritonitis and bacteremia are related to aerobic coliform bacteria, whereas late abscesses are caused by anaerobes, often in synergy with facultative bacteria. The therapeutic implications of these studies are clear: both microbial components of intra-abdominal sepsis should receive appropriate antimicrobial attention.

Female genital tract infections Mixed aerobes and anaerobes are particularly important in closed-space infections such as vulvovaginal, adnexal, or tubo-ovarian abscesses and in postsurgical and postpartum infections. Other common gynecologic and obstetric infections involving mixed aerobic and anaerobic flora include acute and chronic salpingitis, infections associated with contraceptive intrauterine devices, postpartum or post–cesarean section wound infections, endometritis, and amnionitis. The most common anaerobes found include *Prevotella* species (especially *P. bivia, P. disiens,* and *P. melaninogenica*), *Peptostreptococcus* species, and *Actinomyces* species. The most common facultative pathogens are Enterobacteriaceae, especially *E. coli*, and aerobic or microaerophilic streptococci. *B. fragilis* is not a common organism in the normal vagina, but its prevalence is increased in posthysterectomy and post–cesarean section infections and in pelvic infections associated with malignancy and immunosuppressive therapy. Bacterial vaginosis also appears to be a polymicrobial infection involving both aerobes and anaerobes.[22] In addition to *Gardnerella vaginalis,* high concentrations of *Prevotella*, *Peptostreptococcus*, and *Mobiluncus* (a motile anaerobic curved gram-negative bacillus) can be regularly isolated from vaginal secretions.

Necrotic skin and soft tissue infections Necrotic wound and soft tissue infections are especially likely to develop in areas that are regularly exposed to fecal or oral contamination and that have been injured by trauma, ischemia, or surgery. Obligate anaerobes are particularly prevalent in infected pressure ulcers, diabetic foot infections, human bites, and infected pilonidal cysts. Clinical manifestations include crepitant cellulitis, synergistic necrotizing cellulitis or gangrene, myonecrosis, and necrotizing fasciitis. The range of bacterial isolates in such infections is enormous. Anaerobes, including *Bacteroides*, *Peptostreptococcus*, and *Clostridium* species, are almost universally present in mixed cultures.

Anaerobic bacteremia and endocarditis Polymicrobial bacteremia is particularly prevalent in infections of the gastrointestinal tract and the female genital tract, as well as infections of den-

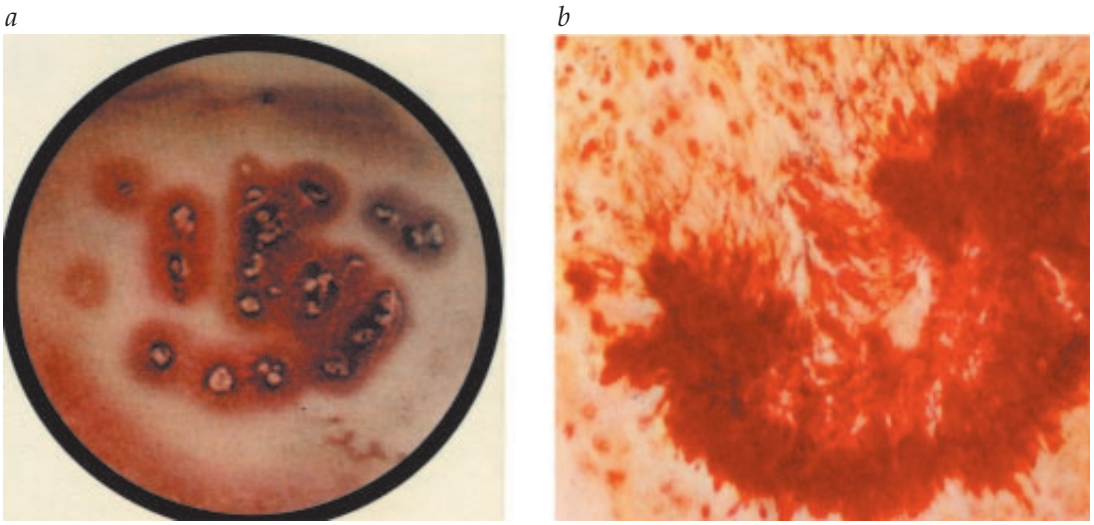

Figure 3 **Sulfur granules are a characteristic feature of *Actinomyces* infection. (*a*) Gross appearance in exudates. (*b*) Histologic appearance in infected tissue.**

tal origin. Anaerobic bacteremia originating from the female genital tract and odontogenous sources tends to be transient and self-limited. In contrast, anaerobic bacteremia originating from the gastrointestinal tract or from necrotic soft tissue tends to be recurrent and persistent in the absence of surgical drainage. The clinical manifestations of anaerobic bacteremia and the specific organisms involved depend to a large extent on the portal of entry and the nature of the underlying disease. For example, *B. fragilis* is most common in bacteremia of gastrointestinal and necrotic soft tissue origin.[23] Bacteroidaceae bacteremia of the female genital tract and of odontogenous origin rarely involves *B. fragilis;* more commonly, *Peptostreptococcus* is isolated. *Fusobacterium*, when isolated, is usually oropulmonary or pelvic in origin. Several clinical features are particularly distinctive in anaerobic bacteremia. Excessive jaundice with hyperbilirubinemia has been noted in 10% to 40% of cases.[24] Suppurative thrombophlebitis may be present in 5% to 12% of cases, primarily involving the pelvic, hepatic, mesenteric, and portal veins. Although anaerobic bacteria can cause endocarditis, such infections appear to be exceedingly rare.

INFECTIONS CAUSED BY *ACTINOMYCES*

Epidemiology

Actinomycosis is a relatively rare condition but has a worldwide distribution with no predilection for age, race, season, or occupation. However, a male-to-female predominance of 1.5:1 to 3:1 has been reported in many series. Predisposing factors include dental caries and extractions, gingivitis and gingival trauma, diabetes mellitus, immunosuppression, malnutrition, and local tissue damage caused by neoplastic disease or irradiation. In children, the development of actinomycosis should arouse suspicion of an underlying immunodeficiency state, particularly chronic granulomatous disease.

Etiology

Actinomyces species are nonsporulating strict or facultative anaerobes with a variable cellular morphology that ranges from diphtheroidal forms to coccoid filaments [*see Figure 1c*]. They are normal constituents of the oral, gastrointestinal, and genital flora. The term actinomycosis literally translates as "ray fungus," which reflects the organism's characteristic filamentous, fungus-like appearance in infected tissues. However, *Actinomyces* species are true bacteria with filaments that are much narrower than fungal hyphae. They require an enriched culture medium, such as brain-heart infusion broth, for growth; cultures should be observed for at least 14 to 21 days to allow adequate detection. Human actinomycosis is primarily caused by *A. israelii*. Other species known to cause human disease include *A. odontolyticus, A. naeslundii,* and *A. graevenitzii*. *A. bovis* causes the disease known as lumpy jaw in cattle but does not cause human disease. Actinomycosis is typically a polymicrobial infection; *A. actinomycetemcomitans* and *Haemophilus aphrophilus* are the most common coisolates. However, the significance of these coexisting bacteria in the pathogenesis of actinomycosis remains unclear.

Clinical Presentation

Actinomycosis is a chronic disease characterized by abscess formation, draining sinus tracts, fistulas, and tissue fibrosis. It can mimic a malignancy or granulomatous disease. A hallmark of actinomycosis is the tendency to spread without regard for anatomic barriers, including the fascial planes or the lymphatics; the development of multiple sinus tracts is also characteristic. Pain is generally an uncommon feature, particularly in chronic cases. Another characteristic is the presence of sulfur granules within infected tissue. The granules are 100 to 1,000 µm in diameter and are hard in consistency. They are often visible to the naked eye or by microscopy with low magnification [*see Figure 3a*]. The granules are composed of an internal tangle of mycelial fragments and a rosette of peripheral clubs [*see Figure 3b*]. Filaments within a granule are often visible on Gram or methenamine-silver stain, though more calcified granules may be difficult to identify. Cervicofacial involvement is the most common manifestation, accounting for 50% of all cases; thoracic, abdominal, pelvic, and disseminated infections occur less frequently.

Cervicofacial actinomycosis Fistulization from the perimandibular region is the most easily recognized manifestation of cervicofacial actinomycosis. Characteristic lesions usually develop slowly, over weeks to months, with adherence to overlying

skin giving it a bluish or reddish appearance. This is often mistaken for cellulitis but, in fact, more likely represents venous congestion. Over time, sinus tracts invariably form on the skin surface or oral mucosae, eventually erupting to express a thick yellow or serous exudate, which yields the characteristic sulfur granules. A characteristic inflammatory, cicatricial scarring eventually results. Less commonly, actinomycosis may present as an acute suppurative infection with a rapidly progressive, fluctuant, and pyogenic mass. At this stage, the patient may experience pain and trismus that appear disproportionate to the local (visible) inflammation.

Thoracic actinomycosis Pulmonary actinomycosis usually results from aspiration of organisms from the oropharynx. The disease has an insidious onset and a subacute course. Typical symptoms include cough, hemoptysis, chest wall discomfort, fever, and weight loss. Pulmonary osteoarthropathy is less common. The radiographic findings are variable and include patchy infiltrates, mass lesions, or cavitation. The infection may extend directly into the pleural space, ribs, and chest wall to produce empyema, osteomyelitis, and draining fistulous tracts. Less frequently, thoracic actinomycosis can extend to the mediastinum and present as pericarditis. The differential diagnosis includes carcinoma, tuberculosis, nocardiosis, and systemic mycosis. Because *A. israelii* is part of the normal oral flora, culturing the organism from sputum or bronchoscopic washings per se is not diagnostic of infection. Definitive diagnosis requires percutaneous needle aspiration, bronchoscopic biopsy, or open lung biopsy.

Abdominal actinomycosis Gastrointestinal actinomycosis generally originates from damaged intestinal mucosa. Any portion of the intestinal tract may be involved, but ileocecal infection is most frequent. The disease can spread to the omentum, mesenteric lymph nodes, and intra-abdominal viscera and can produce fistulous invasions of the abdominal wall or perineum. Presenting manifestations include pain and fever, palpable mass lesions, and draining sinus tracts. Carcinoma, tuberculosis, and Crohn disease are prominent considerations in the differential diagnosis. Unless draining sinus tracts are present, surgery is required for definitive diagnosis. If the bladder is involved, sulfur granules may be present in the urine. A careful search for the characteristic histopathology may be needed to establish the diagnosis, even when excisional biopsy is performed. It is important to confirm the diagnosis, because actinomycosis requires postsurgical administration of antibiotics to prevent recurrent disease.

Pelvic actinomycosis Pelvic actinomycosis is often associated with the use of intrauterine devices (IUDs) for contraception.[25] The pathogenesis of pelvic actinomycosis is not certain, but the disease likely results from upward spread of organisms from the perineum via the intestinal tract. Clinically, pelvic actinomycosis may present as endometritis, salpingo-oophoritis, or tubo-ovarian abscess; bladder invasion or systemic infection arising from a vaginal focus is rare. Optimal management of asymptomatic women with chronic *Actinomyces* colonization is uncertain. Removal of IUDs has been suggested, but the role of antibiotics is unclear. Pelvic inflammatory disease is the major consideration in the differential diagnosis. Surgery is generally required to establish the diagnosis. Actinomycosis of the male genitourinary tract is rare, but infections of the prostate have been reported.

Disseminated infection Disseminated actinomycosis most often occurs by hematogenous spread from a pulmonary focus. Any body site can be involved, including soft tissues, bone, the brain, and visceral organs.

INFECTIONS CAUSED BY CLOSTRIDIA

Clostridia are sporulating gram-positive bacilli; all species are obligate anaerobes, but some (e.g., *C. perfringens*) are relatively aerotolerant. Clinically important *Clostridium* species can be categorized into three major groups: histotoxic species (*C. perfringens*, *C. novyi*, *C. septicum*, *C. bifermentans*, and *C. sordellii*), enterotoxigenic species (*C. perfringens* and *C. difficile*), and neurotoxic species (*C. tetani* and *C. botulinum*).

Diseases from Histotoxic Clostridia

Most invasive infections caused by histotoxic clostridia originate from the gastrointestinal tract and are precipitated by trauma or underlying intestinal disorders. *C. perfringens* is the species that most commonly causes human disease [*see Figure 1d*], but isolation of *C. perfringens* may simply represent contamination of a wound surface. The spectrum of disease produced by *C. perfringens* and other histotoxic clostridia is broad, ranging in severity from relatively benign and localized conditions (e.g., a Welch abscess within a wound cavity) to fulminant infections associated with sepsis and high mortality (e.g., clostridial myonecrosis or parturient endometritis). *C. septicum* infections are particularly likely to occur in patients with underlying malignancies. *C. tertium* bacteremia occurs especially in neutropenic patients.

Soft tissue infections Clostridial crepitant cellulitis is a moderately serious gas-forming infection of the skin and subcutaneous tissues that does not involve muscle or produce a toxemic state, as does clostridial gas gangrene (clostridial myonecrosis; see below). It develops primarily in devitalized tissue in inadequately debrided wounds. The infection extends gradually through tissue planes and is accompanied by the formation of large quantities of gas, which is easily palpated as crepitus (more than is usually evident in cases of clostridial myonecrosis). A thin, dark, gray-brown, foul exudate is produced. There is relatively little local pain or change in the overlying skin. Diagnosis is usually based on a Gram stain revealing plump, gram-positive bacilli (without spores) and variable numbers of polymorphonuclear leukocytes. Of note, crepitant cellulitis is more commonly caused by non–spore-forming anaerobes than by clostridia [*see* Necrotic Skin and Soft Tissue Infections, *above*]. A more serious complication is necrotizing fasciitis caused by *C. sordellii* with toxic-shock manifestations in black tar heroin users.[26]

Clostridial myonecrosis Clostridial myonecrosis (i.e., gas gangrene or clostridial myositis) is a fulminant and rapidly progressive infection caused by *C. perfringens*. It initially involves injured or devitalized muscle and then aggressively invades contiguous normal muscle. Predisposing conditions include penetrating war wounds, surgery on the biliary tract or colon, infarcted bowel from an incarcerated hernia, arterial disease, and intramuscular injection of epinephrine. Spontaneous nontraumatic cases have also been reported. The incubation period is short, ranging from 8 to 72 hours. Onset is acute. Local pain is the earliest symptom, followed by pallor, apprehension, marked tachycardia, moderate fever, and lethargy. Hypotension, shock, and oliguria quickly supervene. There is extensive intravascular hemolysis, evidenced by the appearance of so-called port-wine

urine. The overlying skin is swollen and exquisitely tender and becomes dark yellow or bronze. In an involved extremity, the skin is pale and cold because of ischemia. Crepitus is present but not prominent. A thin, brownish discharge with a foul odor is evident; tense blebs containing dark, thin fluid often develop. The overall mortality in gas gangrene is 15% to 30%. Gas gangrene of the abdominal wall has a mortality of 50%.

Uterine infection and septic abortion Almost all cases of clostridial uterine infection are caused by *C. perfringens,* which is present in the genital tract in 5% of healthy women. Infection occurs in the setting of incomplete abortion, premature rupture of membranes, or operative termination of pregnancy. The organisms may enter and remain confined to the myometrium, or they may spread hematogenously, as occurs in the septicemic form of clostridial uterine infection. The incubation period is short, usually 12 to 72 hours, and is followed by vaginal bleeding, low-grade fever, and lower abdominal pain. The onset of systemic symptoms, such as vomiting, diarrhea, marked tachycardia, high fever, and chills, is abrupt. A foul-smelling vaginal discharge is present, the uterus and adnexa are tender, and perforation of the uterus may lead to pelvic peritonitis. Jaundice and hemoglobinemia may result from massive intravascular hemolysis. Hypotension, shock, and renal shutdown are common in such cases. Mortality in patients with intravascular hemolysis from postabortal *C. perfringens* uterine infection is approximately 50%. A variant of this infection is fulminant endometritis caused by *C. sordellii* in parturient young women, which is marked by profound leukocytosis and shock and which produces significant mortality.[27]

Diseases from Enterotoxigenic Clostridia

Food poisoning *C. perfringens* ranks second only to *S. aureus* in causing outbreaks of food poisoning in the United States.[28] Most strains of *C. perfringens* that are associated with food poisoning are heat-resistant type A organisms. The vehicle is usually a meat product that has been stewed or boiled and then left for a few hours before serving or rewarming. The initial cooking kills contaminating vegetative forms but not heat-resistant spores of *C. perfringens*. During cooling, the spores germinate and multiply in the anaerobic environment. Large numbers of viable organisms are then ingested. These organisms multiply and sporulate in the small intestine. Sporulation is associated with the elaboration of an enterotoxin that produces ileal fluid accumulation and diarrhea. Abdominal cramps and diarrhea develop about 8 to 12 hours after ingestion of contaminated food. Nausea occurs occasionally, but vomiting does not occur. Fever, headache, and systemic symptoms are absent. The illness is mild and runs its course in 24 hours.

Enteritis necroticans In developing countries, intestinal infection with *C. perfringens* type C can produce a β-toxin that causes a severe hemorrhagic, inflammatory, or ischemic necrosis of the jejunum known as enteritis necroticans or pigbel.[29] The infection primarily affects chronically ill persons who consume pig intestines (chitterlings).

***C. difficile*–associated diarrhea and colitis** *C. difficile* accounts for about 25% of all cases of diarrhea in patients receiving antibiotics. *C. difficile* is acquired in the gastrointestinal tract early in infancy, often in neonatal nurseries. Up to 78% of neonates harbor the organism, but the carrier rate declines to less than 50% in older children and to about 5% in healthy adults. Despite the high carrier rate, infants and young children are highly resistant to the effects of *C. difficile* toxins, possibly because their intestinal mucosa is relatively immature and lacks toxin receptors. The carrier rate is much higher in debilitated adults, and the organism is transmitted person-to-person in health care facilities. About 20% of all hospitalized patients acquire the organism, but two thirds remain asymptomatic.

At least 300,000 cases of *C. difficile*–associated diarrhea (CDAD) occur in the United States every year.[30] Patients receiving tube feedings are at particular risk. CDAD was first observed in patients receiving clindamycin, but many other antibiotics can cause diarrhea. The risk is highest from clindamycin, the cephalosporins, and ampicillin and lowest for vancomycin, metronidazole, and the aminoglycosides. There is also an increased risk of CDAD associated with the use of proton pump inhibitors in hospital inpatients.[31] In rare instances, CDAD may develop in patients who have not been hospitalized or exposed to antibiotics. For example, cancer chemotherapy predisposes to *C. difficile* infection even in the absence of antibiotic therapy.

The clinical presentation of CDAD is quite variable. The symptoms range from mild diarrhea to severe colitis with fever, leukocytosis, abdominal cramps, and bloody diarrhea. The onset may be within the first few days of antibiotic therapy or as late as 6 weeks after antibiotics have been discontinued. Endoscopy reveals pseudomembrane formation in about half of cases. Toxic megacolon may occur in severe cases, particularly in patients who have received antimotility agents. Intestinal perforation may occur but is uncommon.

Diseases from Neurotoxic Clostridia

Tetanus All of the clinical features of tetanus are caused by a potent neurotoxin—tetanospasmin—produced by *C. tetani*. The toxin travels to the spinal cord and suppresses the inhibitory neurotransmitter GABA in the neuromuscular junction, resulting in severe muscle spasms.

Tetanus is now rare in industrialized countries because of widespread immunization. In the United States, fewer than 50 cases are reported annually, mostly in inadequately immunized older adults.[32] In developing countries, tetanus is still a major problem, causing the deaths of an estimated one million persons annually, half of whom are newborns. *C. tetani* is commonly found in the soil, in the intestines of domestic animals, and occasionally in human feces. The organism is commonly introduced by a laceration or puncture wound that is usually sustained outdoors. Tetanus may also occur in association with pregnancy (postpartum and postabortion tetanus), injection of illicit narcotics, surgery (postoperative tetanus), burns, vaccination, intramuscular injections, chronic skin ulcers, dog bites, and umbilical stump infection in newborns (neonatal tetanus). In 10% to 20% of patients with tetanus, there is no history of injury or evidence of an infected lesion.

The disease is characterized by generalized rigidity and intermittent, intense muscle spasms. The incubation period ranges from 1 to 55 days, but onset of symptoms occurs within 14 days after the initial injury in over 80% of patients. The usual presenting symptoms are restlessness; pain caused by muscle spasm; and stiffness of the back, neck, thighs, and abdomen. When muscle spasms occur, the characteristic clinical features are determined by the relative strengths of the opposing muscles: the greater strength of the masseter over the opposing digastricus and mylohyoid results in trismus; the greater strength of the ex-

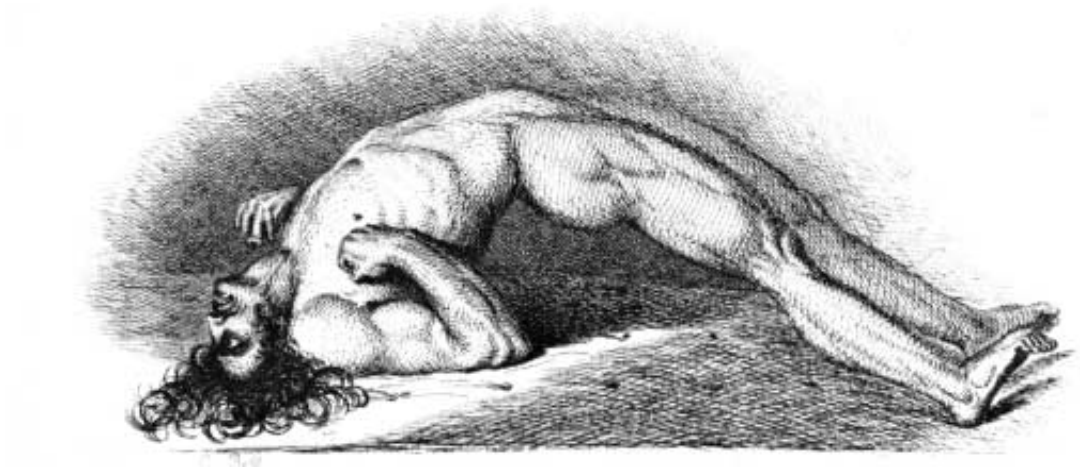

Figure 4 **Spasms in a wounded soldier with tetanus are illustrated in this drawing by Scottish surgeon and anatomist Sir Charles Bell in his book *The Anatomy and Philosophy of Expression*, published in 1832. The classic signs of tetanus—risus sardonicus, trismus, and opisthotonos—are shown.**

tensor groups over the flexors in the lower extremities produces characteristic extension at the hips and knees; and the greater strength of the biceps results in flexion of the forearms. This combination of flexion of the upper extremities and extension of the lower extremities is termed opisthotonos [*see Figure 4*].

Difficulty in opening the mouth (trismus, or lockjaw) is the first symptom in more than 50% of patients. Dysphagia, caused by spasm of pharyngeal muscles, may be an early symptom. Deep tendon reflexes are hyperactive, but the plantar responses are flexor. As the process progresses, violent spasms of the paraspinal, abdominal, and limb musculature occur, but the patient remains conscious. Trismus and stiffness of the facial muscles produce risus sardonicus, a characteristic sneering expression. Sudden stimuli (e.g., bright light or noise) can precipitate tonic seizure accompanied by diaphragmatic, intercostal, glottal, or laryngeal spasm; such spasms can result in hypoxia and respiratory arrest. Fever may be caused by the marked muscular rigidity and spasms alone. Severe sympathetic hyperactivity, evidenced by labile hypertension or hypotension, tachypnea, tachycardia, arrhythmias, profuse sweating, and marked intermittent vasoconstriction, may occur singly or in varying combinations. After the manifestations of tetanus have peaked, they persist at the same level for about a week and then gradually diminish over several weeks. Residual stiffness may persist for several more weeks. In patients who have survived moderate to severe tetanus, respiratory assistance has been required for 2 to 4 weeks; the average hospital stay has been 5 to 8 weeks. The major complications of tetanus are respiratory arrest secondary to tetanic spasms, pneumonia secondary to aspiration, pulmonary emboli, cardiac problems related to sympathetic overactivity or to cardiomyopathy, and fractures of thoracic vertebrae caused by violent spasms.

Botulism About 100 cases of botulism are reported in the United States each year, but a surge in cases associated with black tar heroin and the threat of international bioterrorism have renewed interest in a disease that was first recognized in the early 17th century.[33]

As with tetanus, all the clinical manifestations of botulism are caused by a potent neurotoxin produced by *C. botulinum.* The organism has been isolated from soil everywhere in the world. The spores are very hardy, resisting dryness and extremes of temperature. Spores that are introduced into food, wounds, or the human intestinal tract can germinate and elaborate botulinum toxin. Although seven antigenically distinct forms of the toxin (serotypes A through G) have been identified, just three types (A, B, and E) account for nearly all human disease. Botulism occurs in three main forms: food-borne botulism, wound botulism, and infant botulism.

Food-borne botulism results from the ingestion of home-processed foods that are improperly cooked or refrigerated. The vegetative organisms produce the toxin, which is heat labile and can be destroyed by boiling for 10 minutes or by heating to 80° C for 30 minutes. However, if contaminated food is not heated sufficiently, the toxin resists gastric acid and intestinal trypsin and is absorbed from the intestinal tract. About half the cases of food-borne botulism are caused by type A toxin; the rest are divided evenly between types B and E.

Wound botulism typically follows severe trauma, such as a crush injury involving an extremity. However, heroin use has become the leading predisposing factor in the United States; most cases have occurred in California after subcutaneous injection of black tar heroin from Mexico. About 80% of wound botulism is caused by type A toxin; most of the rest is caused by type B toxin.

Infant botulism is caused by the ingestion of *C. botulinum* spores rather than preformed toxin. The spores then germinate, colonizing the intestinal tract with toxin-producing organisms. Although the source of the spores eludes detection in most cases, honey has been implicated in about 15% of cases. Toxin type A and type B each accounts for about half the cases of infant botulism.

The symptoms of food-borne botulism usually begin 18 to 36 hours after ingestion of the toxin; the incubation period for wound botulism is typically longer. Although food-borne botulism may be heralded by gastrointestinal symptoms such as nausea, vomiting, abdominal cramps, and diarrhea (earlier stage) or constipation (later stage), neurologic manifestations soon predominate. In wound botulism, gastrointestinal symptoms are absent and the wound may appear surprisingly benign. Cranial nerve symptoms such as blurred vision and diplopia are usually the earliest neurologic complaints, followed by dysphagia, dysarthria, and dry mouth. Symmetrical motor paralysis ensues, characteristically progressing in a descending fashion that be-

gins with the arms and then involves the respiratory muscles and lower body. Autonomic dysfunction can produce constipation, urinary retention, and orthostatic hypotension. Sensory deficits are absent, and mentation is normal. Respiratory arrest occurs in severe cases; mechanical ventilation and respiratory support may be required for weeks to months before full recovery. Infant botulism presents as lethargy, constipation, poor feeding, and floppiness, typically in the second month of life.

NEWLY RECOGNIZED ANAEROBES

Molecular tools such as 16S ribosomal DNA sequencing are continuing to identify new genera and species of clinically relevant anaerobic bacteria.[34,35] For example, the anaerobic gram-negative bacillus *Bilaphila wadsworthia* is now known to be an important pathogen and is frequently isolated from gangrenous appendicitis.[36] Newly described anaerobic cocci, gram-positive non–spore-forming rods, and clostridia have also been isolated from various infections.[35,37]

Diagnosis of Anaerobic Infections

CLINICAL CLUES TO ANAEROBIC INFECTIONS

Apart from actinomycosis and clostridial myonecrosis, infections involving obligate anaerobes are generally indistinguishable from infections caused by other pathogens. Clinical manifestations are largely determined by the organ system involved and by the extent and chronicity of the infection. The two most helpful clinical clues are the presence of local tissue ischemia or necrosis and the proximity of infection to mucosal surfaces where obligate anaerobes normally reside. A putrid, foul-smelling discharge is virtually diagnostic of infection involving anaerobes, although the absence of foul odor does not rule out this possibility. Similarly, crepitus or black discoloration of affected tissue is only suggestive evidence.

MICROBIOLOGIC DIAGNOSIS OF ANAEROBIC INFECTIONS

A well-performed Gram stain of appropriately collected clinical material is a very useful diagnostic tool. Anaerobic infections are typically polymicrobial, and the characteristic cellular morphology of certain anaerobic pathogens may be recognized by an accomplished microscopist [*see Figure 1*]. The finding of so-called sterile pus by conventional culture methods in the face of a positive Gram stain should be considered presumptive evidence of an anaerobic infection. In the final analysis, however, the accurate diagnosis of anaerobic infection depends on the ability of the laboratory to isolate these fastidious organisms from clinical material likely to yield meaningful bacteriologic data.

Specimen Collection and Transport

One of the major handicaps in the recovery of anaerobic bacteria is improper specimen collection and transport. Care must be taken to avoid specimens that may be contaminated by commensal flora of mucocutaneous surfaces where anaerobes normally reside (e.g., throat swabs, expectorated sputum, voided urine, bronchoscopic and nasotracheal aspirates, vaginal secretions, feces, colostomy effluent, or superficial wound swabs). Blood and other body fluids that are normally sterile and aseptically obtained should be routinely cultured for anaerobic bacteria. Other clinical materials likely to yield meaningful bacteriologic data for anaerobic infections include specimens from tissue biopsy or curettage or from deep wounds during surgery.

Proper specimen transport to preclude aeration is critical for microbiologic confirmation of an anaerobic infection. Many fastidious organisms are extremely oxygen sensitive and cannot withstand even a brief moment of exposure to air. Furthermore, in mixed infections, the presence of facultative organisms that grow faster than anaerobes frequently precludes recovery of the latter. Several commercially available systems for anaerobic transport of clinical specimens have been evaluated and have been shown to provide excellent recovery of fastidious anaerobes.[38] If commercial anaerobic transport vials are not available, specimens should be collected with a sterile needle and syringe. Air in the syringe is carefully expelled. The needle is capped to minimize aeration, and the specimen should be promptly delivered to the clinical laboratory. If swabs are to be used, they should be prepared, stored, and transported in gas-filled containers under anaerobic conditions. Immediate processing of specimens by the laboratory also improves recovery, but in practice, this is often not feasible.

RADIOLOGIC AND IMAGING STUDIES

Noninvasive tests such as computed tomography, magnetic resonance imaging, ultrasonography, and gallium or indium scanning are most useful for localization of suppurative infections in the central nervous system and in intra-abdominal and pelvic organs. The sensitivity and specificity of these tests in the detection of abscess and the differentiation from tumor, hematoma, and other noninflammatory space-occupying lesions in various sites remain to be determined by careful prospective study. In general, it may be said that a positive scan is highly suggestive, particularly when supported by the clinical picture; however, a negative scan is much less useful in ruling out infection.

SPECIFIC ANAEROBIC INFECTIONS

Actinomycosis

The diagnosis of actinomycosis depends on identification of the organism by smear or culture and by characteristic histopathology from tissue biopsy. The identification of sulfur granules establishes the diagnosis of actinomycosis [*see Figure 3*]; however, sulfur granules may constitute no more than 1% of total tissues in a given lesion and, hence, are easily missed by routine tissue staining. Similar granules may be seen with other microorganisms, notably *Nocardia brasiliensis* and *Streptomyces madurae* (both of which can cause mycetoma), as well as *S. aureus* (a cause of botryomycosis). However, these other granules do not have peripheral clubs, which appear to be specific to *Actinomyces* species. Not all *Actinomyces* species form sulfur granules (e.g., *A. odontolyticus* does not), and a peripheral fringe of clubs may be absent in certain instances, such as in a tonsillar crypt infection or in pelvic actinomycosis associated with an IUD. Additionally, *Actinomyces* species can be morphologically differentiated from *Nocardia;* moreover, *Nocardia* is acid fast in modified acid-fast stains, whereas *Actinomyces* is not.

Clostridial Myonecrosis versus Crepitant Cellulitis

Surgical exploration is necessary to distinguish myonecrosis from anaerobic cellulitis. In gas gangrene, the involved muscle looks cooked and lacks contractility, whereas in clostridial cellulitis, the muscle is visibly healthy. A presumptive diagnosis is based on a typical Gram stain of the wound drainage or aspirate that reveals many clostridia but few leukocytes. The presence of gas in subcutaneous tissue is not pathognomonic of clostridial

infection. Patients with diabetes mellitus are particularly prone to crepitant cellulitis caused by enteric bacteria or *Bacteroides* species. Perineal phlegmons, which result from extension of perirectal abscesses caused by mixed anaerobic and facultative organisms, may also involve subcutaneous gas formation. Crepitus from trapped air after traumatic injury can usually be distinguished from anaerobic cellulitis or myonecrosis by the fact that the former does not spread.

C. difficile–Associated Diarrhea

The diagnosis of CDAD is established by demonstrating the toxins of *C. difficile* in stool specimens by immunoassays. Toxins A and B can be detected using specific antibodies. In approximately 5% to 20% of patients, more than one stool specimen is required to detect *C. difficile* toxin. Consequently, when enzyme-linked immunosorbent assay results are negative but clinical suspicion is high, tests should be repeated using the tissue culture cytotoxicity assay. Some clinical laboratories utilize screening tests that detect the presence of *C. difficile* in fecal specimens, either by culture or by detecting the presence of glutamate dehydrogenase, a metabolic enzyme expressed at high levels by all strains of *C. difficile*, both toxigenic and nontoxigenic.[39] Although these rapid screening tests may be cost-effective in some instances where large volumes of fecal specimens are processed, they are more suitable for excluding rather than establishing the diagnosis of CDAD because of their high negative (approximately 98%) but low positive (approximately 60%) predictive values.

Tetanus

The diagnosis of fully developed tetanus presents little difficulty. Acute strychnine poisoning is the only disease that resembles tetanus. A greater problem in the differential diagnosis occurs earlier in the course of the illness, when trismus is the principal manifestation. Trismus may occur in patients with intraoral disease, especially dental or jaw infections, and is occasionally seen in patients with trichinosis. Hepatic encephalopathy is sometimes associated with prominent muscle stiffness and rigidity. However, the associated liver disease is usually obvious. Furthermore, a sudden stimulus, such as jarring a bed rail, is likely to cause spasms in a patient with tetanus but not in a patient with hepatic encephalopathy. Trismus may also develop as an acute reaction to phenothiazines (the so-called grimacing syndrome). Unlike trismus from tetanus, the masseter muscle spasm in this drug reaction is painful and intermittent, and to some degree it can be overcome voluntarily. This drug reaction is readily reversed with intravenous diphenhydramine.

Botulism

Because botulism is uncommon, the diagnosis may not be entertained despite characteristic clinical findings. Clustering of cases in a family or community and a history of eating home-canned or spoiled foods may be important clues. The differential diagnosis includes Guillain-Barré syndrome, Eaton-Lambert syndrome, myasthenia gravis, cerebrovascular accidents, tick paralysis, and chemical intoxication. In patients with botulism, results of complete blood counts, blood chemistries, CNS imaging studies, and cerebrospinal fluid analysis are all normal. Rapid repetitive electromyography, however, is highly suggestive of botulism if it demonstrates a pattern of facilitation. A positive diagnosis can be established by demonstrating botulinum toxin in serum or stool specimens; the toxin may also be detected in food samples.

Management of Anaerobic Infections

Successful treatment of anaerobic infections requires rational antibiotic selection in conjunction with judicial surgical resection and drainage. The choice of antibiotics should be guided by culture results and antibiotic susceptibility data.

Several methods for antimicrobial susceptibility testing of obligate anaerobes have been validated by the National Committee for Clinical Laboratory Standards.[40] Both agar dilution and microbroth testing methods are appropriate, whereas the E-test, which utilizes a predefined gradient of antibiotic concentrations on a plastic strip, offers a more expensive but practical and fairly accurate alternative for susceptibility testing of individual anaerobic isolates. In light of the growing concern of emerging antibiotic resistance among anaerobic bacteria, the need for more regular susceptibility testing of clinical isolates of anaerobic bacteria has become evident.[41] Susceptibility testing is particularly important in clinical settings where there has been a suboptimal response to empirical antibiotic regimens. Certainly, antimicrobial susceptibility testing should be routinely performed on organisms that are frequently resistant to antibiotics commonly used as empirical therapy, such as members of the *B. fragilis* group; pigmented *Prevotella*, including *P. bivia* and *P. disiens;* and certain *Fusobacterium* species. In the absence of specific culture or susceptibility data, initial antibiotic therapy must be chosen empirically and directed against the pathogens most likely to be present in a particular clinical setting [*see Table 5*], in accordance with predicted in vitro susceptibility patterns [*see Table 6*].

PREDICTED ANTIMICROBIAL SUSCEPTIBILITY

Although penicillin G has been considered the agent of choice for a number of mixed infections at various sites above the diaphragm (particularly oropulmonary and head and neck infections), β-lactamase production and treatment failure have been increasingly reported.[42] β-lactamase production is increasingly recognized in oral isolates of *P. intermedia, F. nucleatum,* and *Peptostreptococcus micros*.[42,43] Among the cephalosporins, only cefoxitin, cefotetan, and ceftizoxime have an enhanced antianaerobic spectrum. These agents appear to have comparable activity against *B. fragilis,* with resistance rates ranging from 10% to 20%; none are as active as clindamycin or metronidazole. Among the penems, imipenem-cilastatin, meropenem, and erzapenem are the most broadly active.[44] The monobactam aztreonam is inactive against anaerobes, as well as gram-positive aerobes.

All strains of *B. fragilis* produce β-lactamases and are resistant to penicillin, but extended-spectrum penicillins in combination with β-lactamase inhibitors (e.g., ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam) are active against most strains. Increasing resistance of *B. fragilis* to cefoxitin and clindamycin has also been reported, and they are no longer the agents of choice in intra-abdominal infections.[45] Cefotetan, ceftizoxime, piperacillin-tazobactam, imipenem, and meropenem remain active. Antibiotic susceptibilities of the non-*fragilis* species of the *B. fragilis* group are more variable than those of *B. fragilis*. Only metronidazole, imipenem, and chloramphenicol are predictably active against nearly all isolates.[46]

Erythromycin and ketolides are relatively inactive against *Fusobacterium* species and most *B. fragilis* strains. Similarly, the first- or second-generation quinolones (e.g., norfloxacin, ciprofloxacin, enoxacin, ofloxacin, and levofloxacin) are relatively inactive as single-agent therapy for anaerobic or mixed infections. However, the third-generation quinolones moxifloxacin and gatifloxacin have good in vitro activity against most anaerobes, including

†Similar combinations currently available, including amoxicillin-clavulanate and ticarcillin-clavulanate, are comparably active.

B. fragilis,[47] whereas gemifloxacin is less active.[48]

Metronidazole has excellent activity against *B. fragilis*, *Fusobacterium* species, and *Clostridium perfringens*. *Peptostreptococcus* and *Bacteroides* species other than *B. fragilis* are only moderately sensitive, whereas nonsporulating gram-positive bacilli are relatively resistant. Metronidazole lacks activity against aerobic bacteria and should not be used as a single agent for empirical therapy, because most infections involving anaerobic bacteria are in fact mixed infections. On the other hand, metronidazole is the only agent with consistent bactericidal activity against *B. fragilis*. Metronidazole crosses the blood-brain barrier well, so it is particularly useful for treating anaerobic brain abscess or infective endocarditis.

Tetracycline and its analogues can no longer be recommended for the empirical treatment of anaerobic infections because of the substantial resistance acquired by *B. fragilis* and virtually all classes of other anaerobic bacteria. Tetracycline remains useful in the treatment of actinomycosis, however. Trimethoprim-sulfamethoxazole has only limited activity against anaerobic bacteria. Vancomycin is effective against some gram-positive anaerobes (particularly *C. difficile*), but it has no activity against gram-negative anaerobes. Aminoglycosides are uniformly inactive against obligate anaerobes.

EMPIRICAL ANTIMICROBIAL THERAPY

The recommended regimens for empirical therapy for various anaerobic or mixed infections vary according to the site of infection [*see Table 7*]. In general, therapy should be directed at both the aerobic and anaerobic components of the suspected microflora. Monotherapy with a broad-spectrum single agent (e.g., ceftizoxime, cefotetan, ampicillin-sulbactam, ticarcillin-clavulanate, piperacillin-tazobactam, imipenem-cilastatin, meropenem, or ertapenem) may be used to minimize toxicity and reduce cost. Parenteral administration, relatively high dosages, and prolonged duration of treatment (3 to 6 weeks) are usually required because of the extent of tissue necrosis and the tendency for relapse with these infections. There are insufficient published data to evaluate the efficacy of empirical therapy with the newer

Empirical Antimicrobial Regimens for Suspected Anaerobic or Mixed Infections

quinolones (e.g., moxifloxacin and gatifloxacin) against severe anaerobic or mixed infections, despite their favorable in vitro susceptibility profiles.

SURGICAL DRAINAGE

Surgical drainage of abscesses and resection of necrotic tissue may be the decisive therapeutic modality for most suppurative anaerobic infections. However, several exceptions are noteworthy. In lung abscess, nonsurgical treatment alone is often effective, perhaps because of spontaneous drainage and expectoration of abscess contents through the tracheobronchial tree. Certain cerebral abscesses, even when well encapsulated, may also respond to antibiotics alone. A similar favorable experience has been noted with hepatic and tubo-ovarian abscesses. Although abscesses do not always require drainage, it is not clear what factors reliably predict a favorable response to antibiotics alone. When necrotic tissue is present, however, surgical excision is invariably required.

HYPERBARIC OXYGEN AND OTHER ADJUNCTIVE MEASURES

Hyperbaric oxygen therapy, consisting of 100% oxygen at 2 to 3 atm administered for approximately 2 hours, has been used as an adjunct to surgical debridement and antibiotics in the treatment of clostridial gas gangrene and other necrotizing soft tissue infections. Despite enthusiasm for hyperbaric oxygen therapy, there have been no controlled trials of its use in humans, and its precise role in the management of these infections remains to be defined. Nevertheless, hyperbaric oxygen therapy has been recommended for selected cases of necrotic soft tissue infections and for recalcitrant anaerobic osteomyelitis of the maxilla or mandible. Other adjunctive measures useful for the management of anaerobic infections include topical wound irrigation with 3% hydrogen peroxide solution to control foul-smelling discharge and administration of fibrinolytic agents (e.g., trypsin) to prevent intra-abdominal abscess formation postoperatively.[49]

Actinomycosis

High-dose penicillin remains the drug of choice for actinomycosis. For severe infections, a 4- to 6-week course of intravenous penicillin G should be followed by oral penicillin V (2 to 4 g/day in four divided doses) for 6 to 12 months. For mild infections, a 2-month course of oral penicillin V is generally appropriate. Oral amoxicillin (500 mg three times daily) is equally effective. Acceptable alternatives to penicillin include the tetracyclines, erythromycin, and clindamycin. Agents generally deemed to have poor activity against *Actinomyces* species include oral cephalexin; oxacillin and dicloxacillin; the first- and second-generation fluoroquinolones; metronidazole; aminoglycosides; and aztreonam.[50] For patients with penicillin allergy, tetracycline probably offers the best alternative, especially in milder disease. Therapy does not need to be directed against other commensal flora that are recovered along with *Actinomyces* species, because antibiotic regimens effective against *Actinomyces* alone are usually curative. Surgical intervention may be necessary in more complicated cases.

Clostridial Myonecrosis

Aggressive surgical debridement is mandatory for suspected gas gangrene to determine the extent of infection and to eliminate all necrotic tissue. The procedure includes multiple incisions for drainage; fasciotomy for decompression of muscle compartments; and excision of necrotic muscle. If the process is extensive and if irreversible changes have occurred in an extremity, amputation becomes necessary. Early use of hyperbaric oxygen therapy may limit the zone of frank muscle necrosis, reducing the extent of the surgical debridement. Simple drainage, with fasciotomy where indicated, is usually sufficient for treating clostridial cellulitis. Antibiotic therapy is required to treat bacteremia and prevent the spread of infection. The combination of penicillin G and clindamycin is recommended, because the latter rapidly inhibits toxin synthesis. When a Gram stain indicates a polymicrobial infection, monotherapy with broad-spectrum agents, such as piperacillin-tazobactam, imipenem, or meropenem, is indicated. Alternatively, an aminoglycoside (e.g., gentamicin), a newer cephalosporin (e.g., cefotaxime), or a fluoroquinolone (e.g., ciprofloxacin) may be added initially.

C. difficile–Associated Diarrhea

Symptomatic patients should receive oral metronidazole or vancomycin. Either agent, given at a dosage of 500 mg three times daily for 10 days, produces a clinical cure in 94% of patients. Metronidazole is considerably less expensive, but some *C. difficile* strains are resistant to the drug. Because vancomycin is active against all isolates and is not absorbed in the upper gastrointestinal tract, it may be preferable for severely ill patients. Orally administered bacitracin alleviates symptoms as effectively as metronidazole or vancomycin but is less effective in eradicating *C. difficile* and its toxins from the stools. For patients with CDAD who cannot tolerate oral therapy, intravenous therapy with vancomycin plus metronidazole or intravenous therapy with metronidazole alone has been recommended.

Regardless of the treatment regimen, symptoms recur in about 20% of patients.[51] Relapse is less likely to occur in patients who mount a serum antibody response to toxin A during the initial episode. Patients with recurrent symptoms should be retreated with oral metronidazole or vancomycin. Various regimens, including prolonged and tapering courses of vancomycin, have been suggested.[52] Cholestyramine resin, which binds the toxin in the intestine, may be useful for some patients. It is administered in conjunction with oral vancomycin for 1 to 2 weeks (4 g three or four times daily). Administration of the yeast *Saccharomyces boulardii* may improve the results of antibiotic therapy in some patients who experience relapses of *C. difficile* colitis.[53] Attempts to reconstitute the normal colonic flora by the administration of donated stool directly through a colonoscope have also been tried, with some success.[51] Prevention of antibiotic-associated diarrhea by the coadministration of *Lactobacillus* GG was evaluated in one randomized clinical trial but was unsuccessful during 21 days of follow-up.[54]

Tetanus

Treatment of tetanus is aimed at controlling muscle spasms, managing dysautonomia, neutralizing circulating toxin, eliminating the continuing source of the toxin, and preventing respiratory complications. Patients with tetanus should be monitored in an intensive care unit. External stimuli (e.g., noise or bright lights) that may precipitate muscle spasms must be kept to a minimum. A urinary catheter is required. Because of the danger of precipitating pharyngeal or laryngeal spasms by oral feedings, fluids and electrolytes are initially administered intravenously. Later, when the danger of aspiration is reduced, a nasojejunal tube may be used, provided that a cuffed endotracheal tube or tracheostomy tube is in place. Antitoxin treatment with human tetanus immune globulin (500 to 1,000 units) is administered intramuscularly; it neutralizes circulating toxin only.

The use of muscle relaxants is essential. Intravenous diazepam (40 to more than 200 mg a day, titrated according to need) is the drug of choice because it acts rapidly as a muscle relaxant and produces a sedative effect without inducing depression. If severe spasms cannot be controlled by diazepam, assisted ventilation and neuromuscular blockade may be necessary. Beta blockers, such as propranolol and labetalol, are used to control sympathetic overactivity.

The value of antimicrobial agents in the treatment of tetanus is doubtful. The only beneficial effect would be to clear the wound of vegetative cells of *C. tetani* that could produce additional toxin. Penicillin has been the traditional drug of choice, but metronidazole is now preferred. If feasible, wound debridement is carried out to eliminate the site of toxin elaboration. Surgical wound care should be performed only after the initial doses of tetanus immune globulin and antibiotics have been administered and after muscle spasms have been controlled. The wound should be thoroughly irrigated and left open. Because clinical tetanus does not establish natural immunity, the patient should be immunized with the first dose of adsorbed tetanus toxoid before discharge.

Botulism

Antitoxin should be administered promptly to neutralize any circulating botulinum toxin before it binds to cholinergic synapses. The currently recommended dose is one vial of intravenous trivalent (types A, B, and E) antitoxin, which is of equine origin and available from the Centers for Disease Control and Prevention (404-639-2206 during business hours; 404-639-2888 at other times). Hypersensitivity reactions can occur in up to 7% of recipients; such reactions may be severe. A human botulism immune globulin is being developed for the treatment of infant botulism. Wound botulism should be managed with surgical debridement and intravenous penicillin. Patients with severe botulism require mechanical ventilation and metabolic support.

Table 8 Recommendations for Tetanus Prophylaxis in Routine Wound Management

History of Immunization with Adsorbed Tetanus Toxoid	*Clean, Minor Wounds*		*All Other Wounds**	
	Td†	*TIG*	*Td*†	*TIG*
Unknown or fewer than three doses	Yes	No	Yes	Yes
Three or more doses‡	No§	No	No‖	No

*Such as, but not limited to, wounds contaminated with dirt, feces, soil, saliva, etc.; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.
†For children younger than 7 yr, DTP (DT, if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For persons 7 yr of age or older, Td is preferred to tetanus toxoid alone.
‡If only three doses of fluid toxoid have been received, then a fourth dose of toxoid, preferably an adsorbed toxoid, should be given.
§Yes, if more than 10 yr since last dose.
‖Yes, if more than 5 yr since last dose.
DT—diphtheria and tetanus toxoids adsorbed (dose of diphtheria toxoid is higher than that in Td, dose of tetanus toxoid is the same)
DTP—diphtheria and tetanus toxoids and pertussis vaccine adsorbed Td—tetanus and diphtheria toxoids adsorbed TIG—tetanus immune globulin

Prevention

SURGICAL PROPHYLAXIS FOR POSTOPERATIVE WOUND INFECTIONS

Anaerobic infections can be prevented by avoiding conditions that predispose to tissue invasion by commensal microflora. In traumatic wounds, the most effective prophylaxis is thorough debridement and cleansing of the wound, elimination of foreign bodies and dead space, and the reestablishing of good circulation. Preoperative mechanical cleansing of the bowel with a low-residue or liquid diet followed by cathartics, enemas, and luminal antibiotics can reduce the incidence of postoperative wound infections after colorectal surgery. Parenteral perioperative antibiotics are used in gastrointestinal and gynecologic surgery when there is heavy contamination with normal microflora at the operative site; examples of such surgeries include elective colorectal surgery, cesarean section after premature rupture of membranes, vaginal hysterectomy in a premenopausal woman, and radical pelvic or head and neck surgery for malignancy. Several studies have shown significant reduction in the frequency of postoperative infections, from about 20% to 30% down to 4% to 8%. Cefoxitin is the agent of choice for prophylaxis of postsurgical intra-abdominal wound infections.[55] A first-generation cephalosporin, such as cefazolin, is as effective as some second- or third-generation cephalosporins. In surgery on contaminated or so-called dirty sites, early treatment rather than prophylaxis is essential for reducing the incidence of postoperative morbidity.

INFECTION CONTROL MEASURES FOR *C. DIFFICILE*–ASSOCIATED DIARRHEA

Enteric precautions, strict adherence to hand washing, and restrictions on the use of antibiotics are necessary to control the intrahospital spread of CDAD. The use of environmental disinfectants containing hypochlorite can reduce the incidence of *C. difficile* acquisition and the subsequent development of disease. However, antibiotic therapy for asymptomatic carriers is not beneficial.

WOUND CARE AND ACTIVE IMMUNIZATION FOR TETANUS

About two thirds of tetanus cases in the United States occur after puncture wounds, lacerations, and other penetrating trauma. Prompt and thorough wound debridement is of paramount importance in preventing trauma-induced tetanus. Prophylactic antibiotics do not reliably prevent the development of tetanus. The United States Public Health Service has issued specific recommendations for wound management and tetanus prophylaxis[56] [*see Table 8*]. Active immunization should be promoted for the general public. Infants should receive diphtheria-pertussis-tetanus (DPT) vaccine at 2 months of age. Two additional doses are given at 4 and 6 months of age. A booster injection of DPT is given at 18 months of age and again 4 years later. At 16 years of age, a booster dose of combined adult-type tetanus and diphtheria toxoids is administered. Thereafter, immunity is maintained by booster injections every decade. About 70% of Americans have protective levels of tetanus antibodies (> 0.15 IU/ml). Nearly 90% of children are protected, but the rate declines rapidly after 40 years of age, decreasing to less than 30% after 70 years of age. Adults who have not been immunized should receive two doses of alum-precipitated tetanus toxoid intramuscularly, 1 month apart, followed by a booster dose after 1 year. Thereafter, immunity is maintained by booster injections every decade.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VI SYPHILIS AND THE NONVENEREAL TREPONEMATOSES

Michael Augenbraun, m.d.

Syphilis

Syphilis is an infectious disease with complex acute and chronic manifestations that is transmitted primarily through sexual contact. The disease has been recognized for many centuries, although its origin remains unknown.

epidemiology

Transmissible syphilis in the United States has become increasingly concentrated in a few geographic areas, particularly in the southeastern part of the country [*see Figure 1*]. It disproportionately affects minority populations and occurs more frequently in men than in women. Recent outbreaks have been reported in homosexual men. Sexual transmission rates from infected to uninfected persons may range from 30% to 60%.[1-3]

The incidence of syphilis was declining from the 1940s through the 1980s, but a sharp and surprising increase occurred in the late 1980s. By 1990, the Centers for Disease Control and Prevention (CDC) reported the largest number of primary and secondary cases of syphilis in 40 years.[4] This increase was strongly linked to the epidemic use of crack cocaine. With the increased incidence of primary syphilis came an increase in the numbers of cases of congenital syphilis.[5]

Just as surprising as the increase in the number of syphilis cases in the late 1980s has been the rapid decline in the number of syphilis cases in the latter half of the 1990s.[6] The reasons for this decline are unclear, but by 1999 there had been an 87% decline from the peak number of cases in 1990. This was the lowest reported rate since the collection of reliable statistics began [*see Figure 2*].

As a result of the low incidence rates of primary and secondary syphilis, its geographic confinement to a limited number of areas, the continued efficacy of penicillin therapy, and the reliability of serologic diagnostic tests, the CDC has initiated a program intended to eliminate syphilis in the United States.[7] The stated goal is to reduce primary and secondary cases to 1,000 or fewer in a given year and to increase the number of syphilis-free counties to 90% by the year 2005. The CDC hopes to achieve this goal through the use of enhanced surveillance, greater cooperation with community groups in the remaining areas of high morbidity, and rapid outbreak response.

etiology

Syphilis is transmitted primarily through sexual contact between infected and uninfected partners. Passage through the placenta in an infected pregnant woman may result in congenital disease. Although the disease can also be transmitted through nonsexual contact with infectious lesions, laboratory accidents, and the administration of contaminated blood products, these methods of transmission are relatively rare. Humans are the only known host of *Treponema pallidum*.

pathogenesis and disease course

T. pallidum is a bacterium belonging to the order Spirochaetales. This order also includes similar familiar bacteria genera, such as *Leptospira* and *Borrelia*. All of these organisms are slender, helically coiled, gram-negative bacteria. Treponemal species other than *T. pallidum* may live as commensals in the oral cavity or the genital tract (e.g., *T. denticola* and *T. oralis*).

T. pallidum probably gains entry to the subcutaneous tissues through small abrasions in overlying skin and mucous membranes. The organism does not possess well-recognized virulence factors, such as lipopolysaccharide. Once penetration of the epithelium occurs, organisms replicate locally at the site of inoculation and spread to regional lymph nodes. Depending on factors such as inoculation load and history of previous syphilis infection, the incubation period from exposure to clinical disease can range from 3 weeks to 3 months.

The characteristic first lesion of primary syphilis [*see Table 1*] is the chancre [*see Figure 3*]. It is a typically indurated and nontender ulcerative lesion, often accompanied by a nontender, nonsuppurative regional lymphadenopathy. In some patients, the chancre is inconspicuous, and in others it can be more than 1 to 2 cm in diameter. Although not common, multiple chancres may occur, particularly in HIV-infected persons. In the absence of effective therapy, the chancre resolves within 2 to 8 weeks. Healing may take longer in immunocompromised persons.

Spirochetemia develops soon after the appearance of the primary chancre, but clinical evidence of dissemination is rarely seen at the same time. Signs and symptoms of dissemination and secondary syphilis include fever, malaise, diffuse lymphadenopathy, patchy alopecia, headache, and classic hyperpigmented macular-papular rash on the palms and soles [*see Figure 4*]. Condylomata lata and mucous patches may appear in a variety of locations, such as the genitals and the gluteal and nasolabial folds [*see Figure 5*]. Other anatomic sites, such as the eyes, gastrointestinal mucosa, liver, and bones, may also be involved.

The clinical manifestations of secondary syphilis [*see Table 1*] resolve after weeks to months even without therapy, and the disease enters the latent stage. During the early latency period, the signs and symptoms of secondary syphilis may recrudesce. This period generally lasts 1 year after infection but can extend to 4 or 5 years.[8]

Latent syphilis is, by definition, recognized only by the presence of a reactive serologic test. During this period, the organisms evade any meaningful host immunologic responses. Although infected persons mount both significant cell-mediated and humoral responses to infection, neither response is adequate for control. Many reasons have been postulated for this phenomenon, including the lack of immunogenic proteins and polysaccharides in the outer membrane of *T. pallidum,* as well as the organism's ability to cloak itself with host proteins.[9]

Once syphilis enters the latent phase, the course of disease is variable. Although the majority of infected persons will never suffer undue consequences, data from the Oslo[8] study suggests that years later, tertiary disease [*see Table 1*] will develop in approximately one third of these individuals, manifesting as neurosyphilis, cardiovascular syphilis, or gummatous (benign) syphilis. The pathology associated with tertiary syphilis is quite varied, and there is substantial overlap between clinical entities. Chronologically, meningeal and meningovascular

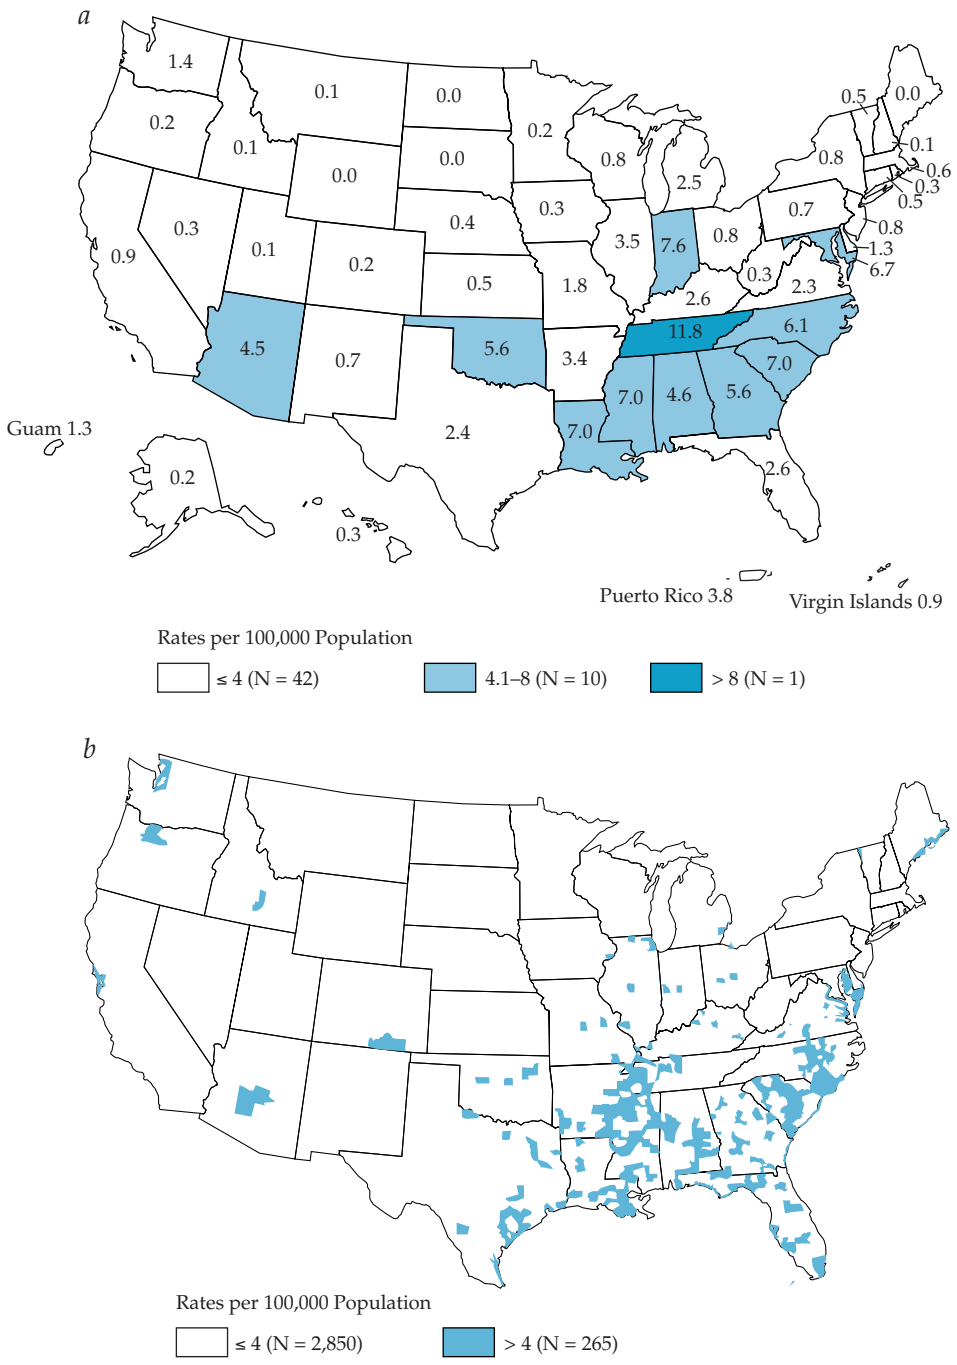

Figure 1 **Rates of primary and secondary syphilis by (*a*) state and (*b*) county.**

symptoms (i.e., stroke) may be the earliest manifestations of symptomatic neurosyphilis. In later stages, parenchymatous disease with associated cognitive and long-tract signs becomes prominent. As in cardiovascular and gummatous syphilis, the lesion in CNS syphilis is endarteritis.

DIAGNOSIS

Depending on the stage of disease, the diagnosis of syphilis may be made by visualizing the organisms, by serologic studies, by pathology, or by clinical presentation. None of these methods is entirely sensitive or specific.

Clinical Manifestations

Primary syphilis In primary syphilis, the chancre [*see* Pathogenesis, *above*] typically occurs at the site of inoculation and thus may be seen anywhere in the genital region (i.e., penis, scrotum, inner thigh, buttocks, vaginal labia, cervix, or anus). Lesions may be single or multiple. Often, they occur where tissue proximates infected sites—so-called kissing lesions.

Typically, the chancre is indurated with a raised but clean margin. It is nontender. It may have a gray-white exudative covering, particularly if the lesion is secondarily infected. More commonly, it is clean without bleeding. There is associated

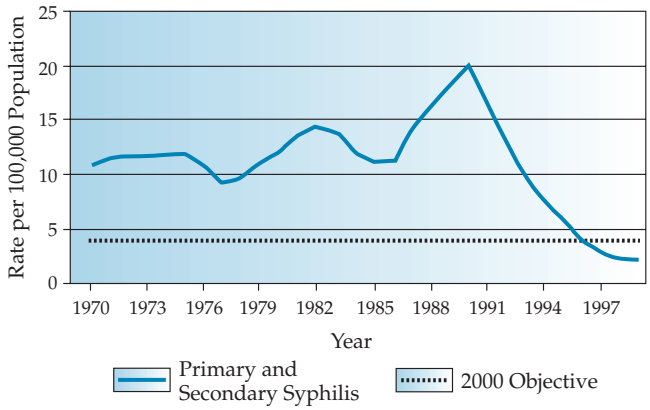

Figure 2 **Reported rates of primary syphilis in the United States over 3 decades. The highest rate occurred in the late 1980s and early 1990s, after which there has been a steep decline in the number of syphilis cases.**

nontender and nonsuppurative regional lymphadenopathy. Cervical or rectal chancres may result in deep pelvic noninguinal adenopathy.

Secondary syphilis The widely varied clinical manifestations of secondary syphilis reflect the capacity of *T. pallidum* to disseminate virtually anywhere in the body within weeks of the appearance (and resolution) of the primary chancre. With spirochetemia, which develops after the first chancre [*see* Pathogenesis, *above*], comes a host of systemic symptoms that are relatively nonspecific, including headache, malaise, fatigue, arthralgias, myalgias, and diffuse painless lymphadenopathy. The finding of enlarged epitrochlear lymph nodes in the absence of any upper extremity pathology is considered to be highly suspicious for secondary syphilis.

The rash of secondary syphilis is one of the most common signs of the disease. The classic finding is maculopapular hyperpigmented lesions 3 to 10 mm in diameter, often with fine peripheral scaling on the palms and soles. There are so few clinical entities that cause these lesions that the presence of the lesions is nearly pathognomonic. Rash will be seen in 75% to 100% of patients at some point in the course of infection. However, the rash of secondary syphilis does not always fit this classic pattern. It may present in any of a variety of ways—macular, maculopapular, papular, pustular, or plaques of varying size—on virtually any site of the body. Raised, moist, nontender plaques known as condylomata lata may form in intertriginous areas, such as in the gluteal fold, under the breasts, and in the inguinal area. Similar mucous patches may form on

Table 1 Clinical Manifestations of Syphilis in Adults

Stage	*Manifestations*
Primary	Chancre and inguinal lymphadenopathy
Secondary	Rash, diffuse lymphadenopathy, fever, alopecia, condyloma latum, and mucous patches
Early latent	None (secondary syphilis may recur)
Late latent or latent syphilis of unknown duration	None
Tertiary	
Neurosyphilis	
Asymptomatic	None
Meningitis	Headache, cranial nerve palsies, delirium, seizures, and findings of raised intracranial pressure
Meningovascular	Hemiparesis, hemiplegia, aphasia, and seizures
Parenchymatous	
General paresis	Memory loss, personality changes, cognitive dysfunction, confusion, and seizures
Tabes dorsalis	Lightning pains, ataxia, pupillary abnormalities, and impaired proprioception
Cardiovascular	Aortic aneurysm, aortic regurgitation, chest wall mass, and hoarseness
Gummatous	Chronic inflammation with focal destructive lesions in nearly any tissue or organ of the body

Figure 3 **Indurated, nontender ulcerative chancres are the first lesions of early syphilis.**

Figure 4 **A hyperpigmented maculopapular rash on the palms and soles is a classic sign of spirochetemia.**

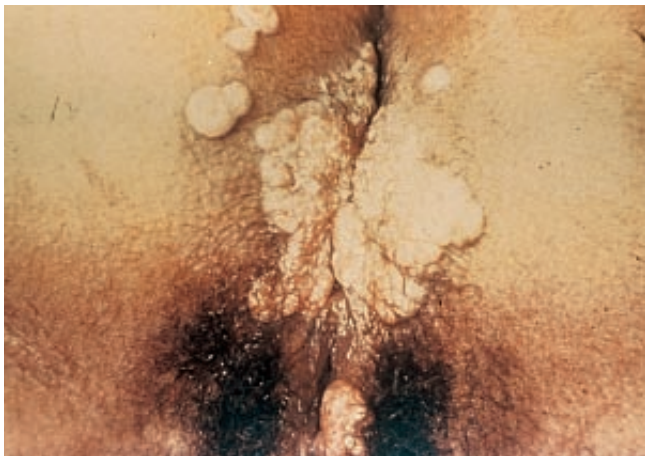

Figure 5 **Highly infectious condylomata lata appear on genitalia and gluteal folds.**

mucosal surfaces, such as the nares, mouth, vagina, and anus. These lesions can be confused with chancres but are not, strictly speaking, ulcers. They teem with spirochetes and are highly infectious. Secondary syphilis can also involve hair follicles, leading to patchy alopecia of scalp hair, as well as thinning of the eyebrows, eyelashes, and beard.

Skeletal manifestations of secondary syphilis can include osteitis, arthritis, and bursitis.[10] Syphilitic hepatitis with hepatomegaly and an elevated alkaline phosphatase level may occur.[11] Various forms of nephropathy, including glomerulonephritis and nephrotic syndrome, have also been noted in secondary syphilis.[12] Gastritis with attendant abdominal pain, nausea, and vomiting can result from infiltration of the gastric mucosa by spirochetes.[13] Both anterior and posterior uveitis can occur and may be either asymptomatic or associated with altered vision.[14, 15] Some of these cases come to light after failure to respond or after worsening of symptoms with steroids.

Involvement of the CNS occurs early in syphilis.[16] At least 40% of lumbar puncture samples from patients with secondary disease (more in some series) have been found to have CSF abnormalities. *T. pallidum* may actually be recovered from up to 30% of these samples. Whereas symptomatic parenchymatous neurosyphilis is often associated with late-stage syphilis, meningeal involvement may be seen during or shortly after the nonneurologic symptoms of secondary syphilis. This condition is characterized by findings typical of a bacterial meningitis, including headache, stiff neck, photophobia, nausea, and vomiting. Cranial neuropathies associated with ocular and otic deficits, as well as facial nerve palsies, can occur. In some instances, papilledema associated with hydrocephalus has been reported, as have delirium, seizures, aphasia, and hemiplegia. Most patients no longer demonstrate the rash of secondary syphilis at the time these symptoms develop.

Latent syphilis By definition, latent syphilis is not associated with any clinical finding. Early latency delineates that period after the resolution of secondary disease during which the signs and symptoms of secondary disease may recur. Although this latency period may last as long as 5 years, the majority of cases of latent syphilis occur within the first to second year, followed by tertiary syphilis.

Neurosyphilis It is presumed that in the majority of patients with primary or secondary syphilis who experience invasion of the CNS by spirochetes, resolution of this aspect of infection occurs with or without the administration of systemic antibiotics. A small number of these patients have continuing CNS involvement with asymptomatic CSF changes and are at high risk for progressive symptomatic neurologic disease for a period of years. It is difficult to ascertain which individuals may be at risk, and anyone with presumably latent syphilis may harbor CSF changes suggesting continued neurosyphilis.

Late symptomatic neurosyphilis may present as one of several clinical syndromes that occur within the following conditions (the syndromes often overlap):

1. Meningovascular neurosyphilis. *T. pallidum* tends to cause endarteritis, which can compromise vascular supply to portions of the CNS and cause infarctions that clinically resemble any other cerebrovascular accident. These events can occur anywhere along the neuroaxis, including the cerebrum, the cerebellum, the brain stem, and the spinal cord. Signs and symptoms therefore correspond to the portion of the CNS involved. The time elapsed from primary syphilis to meningovascular syphilis is usually 5 to 12 years but may be as long as several decades.
2. Parenchymatous neurosyphilis. Direct involvement of the CNS parenchyma results in a wide range of clinical syndromes characterized pathologically by fibrosis and atrophy. General paresis is a meningoencephalitic syndrome that may be similar in presentation to many psychiatric and neurologic disorders. Patients exhibit emotional lability, delusions, paranoia, and memory loss and may progress to dementia, delirium, and seizures. They may have difficulty with speech, and their pupils may become constricted and unresponsive to light and painful stimuli (Argyll Robertson pupil). They may lose the capacity for facial expressions and are noted to have trembling of the lips and tongue. In tabes dorsalis, there is a pronounced involvement of the dorsal roots and the posterior columns of the spinal cord. Patients complain of shooting pains in the back and lower extremities, where they also notice paresthesias. These paroxysms of pain can be referred to other locations, including the abdomen and the throat. Patients lose proprioception and vibratory sense and develop a wide-based gait. Optic atrophy may occur. Knee and ankle reflexes are diminished or lost entirely, plantar responses are flexor, and ataxia is usually present. Symptomatic parenchymatous disease develops 15 to 25 years after primary infection. The long-term outlook in general paresis without treatment is grim. Death may occur within months or, more likely, 4 to 5 years after the onset of symptoms. Untreated tabes dorsalis leads to eventual incapacitation, although it has been known to remit spontaneously.

Cardiovascular syphilis After the introduction of antibiotics, cardiovascular syphilis became extremely rare. *T. pallidum* can cause endarteritis of the aortic vasa vasorum, leading to progressive medial necrosis and loss of elastic tissue, dilatation, and, eventually, aneurysm. The proximal thoracic aorta and the aortic arch are most commonly involved, whereas involvement of the abdominal aorta is extremely rare. Symptoms usually develop when the aneurysm begins to encroach upon or erode adjacent structures, such as the chest wall, the superior vena cava, the recurrent laryngeal nerve, the trachea, and the

mainstem bronchi. These aneurysms rarely dissect. In 30% of cases, aortic root dilatation leads to aortic regurgitation in which there is no evidence of aortic stenosis. Uncommonly, the coronary artery ostia may be involved, causing ischemic heart disease. Cardiovascular syphilis is usually preceded by a latent period of 15 to 30 years.

Gummatous (benign) syphilis As with neurosyphilis and cardiovascular syphilis, the incidence of late gummatous syphilis has declined dramatically since the introduction of effective antimicrobial agents. The hallmark of this disease are gummas, which are indolent, destructive granulomatous lesions of soft tissue and bone [*see Figure 6*]. They can lead to dramatic scarring and disfigurement. They are primarily immunologically mediated responses. Although almost any part of the body may be involved, gummas most frequently occur in soft tissue and skeletal structures. Gummas do not develop until decades after infection. They appear slowly, often as a nodule with minimal attendant inflammation. Central coagulative necrosis develops, with softening and involution of the lesion. Eventually, fibrosis occurs, with deep scarring. Involvement of the nasal septum can lead to collapse of the nasal structures. Perforation of the hard palate may occur. Skeletal lesions can lead to fractures.

Laboratory Tests

Primary syphilis Clinical appearance of a genital ulcer is not adequate to establish its etiology. Dark-field microscopy of lesion exudate is a reliable diagnostic method. Incident light through a microscope fitted with polarizing lenses allows the viewer to identify the corkscrew morphology of treponemes as white against a black background [*see Figure 7*]. Exudate for dark-field microscopy can be collected from the base of a chancre that has been cleaned with saline and to which gentle pressure has been applied. Examination must be performed promptly because any drying of the specimen reduces the sensitivity of the test. Therapy, intentional or not, with antibiotics active against *T. pallidum* will rapidly reduce the yield of a dark-field specimen. Nonpathogenic treponemes in the oral cavity reduce the specificity of dark-field microscopy on lesions from this area. A direct fluorescent antibody test (DFA-TP) can also be performed on lesion exudate when the immediate collection of a specimen is not possible. Nucleic acid amplification tests have been developed for *T. pallidum,* but these tests should be considered research tools.

Figure 6 **Granulomatous lesions called gummas are particularly destructive to soft tissue and bone.**

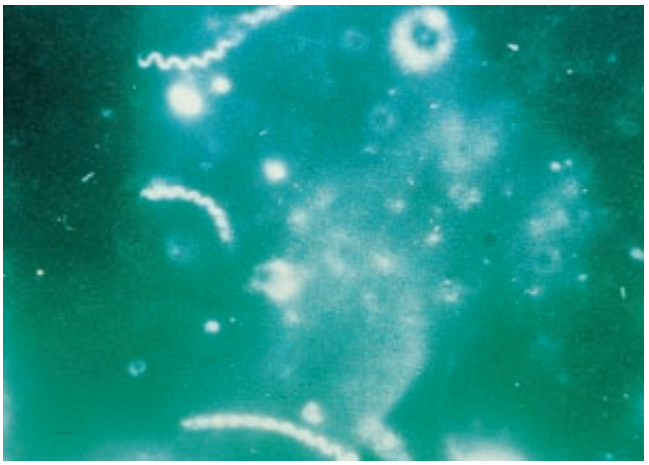

Figure 7 **In dark-field microscopy, treponemes appear white against a black background.**

Besides dark-field microscopy, the most commonly used tests for primary syphilis are serologic tests. Syphilis serology testing requires the use of two tests performed in sequence—one for screening and the other for confirmation. Screening tests are characterized by high sensitivity but variable specificity. They make use of standardized amounts of cardiolipin, cholesterol, and lecithin, to which *T. pallidum*–directed immunoglobulins (IgG or IgM) have an affinity. These tests include the Venereal Disease Research Laboratory (VDRL) test, rapid plasma reagin (RPR) test, unheated serum reagin (USR) test, and toluidine red unheated serum test (TRUST). All are flocculation tests in which visible (macroscopic, microscopic, or both) clumping occurs when test reagents are added to serum from a patient with syphilis. Results may be reported qualitatively or quantitatively. For quantitative results, testing is performed on sequentially diluted serum. The final dilution in which a reaction occurs is reported. In primary syphilis, the sensitivity of any of these nontreponemal serologic tests (NTSTs) ranges only from 78% to 86%. They may also be erroneously reactive in association with a number of other clinical factors, including older age, pregnancy, a history of intravenous drug use, and collagen vascular diseases.[17]

Treponemal-specific tests such as the fluorescent treponemal antibody absorption (FTA-ABS) and the *T. pallidum* particle agglutination (TP-PA) tests use fluorescent antibody and hemagglutinating antibody, respectively, to detect patients' antibodies to *T. pallidum*. In these cases, a suspension of *T. pallidum* serves as the antigenic target. These tests are not routinely quantified. Depending on the strength of the reaction, they may be reported as reactive, nonreactive, or inconclusive. In primary syphilis, these tests can become reactive before the NTSTs. False positive results occur in a small percentage of those tested, so these tests should not by themselves be used for screening. They are best used to confirm a reactive NTST.

Secondary syphilis Dark-field microscopy may be useful for examining exudate from condylomata lata and mucous patches, but ordinarily, this test has limited utility in the diagnosis of secondary syphilis. Serologic tests remain the standard for diagnosing syphilis at this stage. Because these tests quanti-

tatively reflect the degree of immune response associated with infection, the highest NTST titers are generally seen during secondary syphilis. The likelihood of a false negative test in secondary syphilis is remote. An exception to this occurs in the event of the so-called prozone phenomenon, in which extremely high concentrations of reaginic antibodies block the flocculation process. This effect may be expected in no more than 2% of cases and can be overcome by performing repeated tests on diluted samples.

CSF findings in meningitis associated with secondary syphilis are nonspecific, except with use of the CSF-VDRL. A positive finding is invariably indicative of neurosyphilis unless there has been significant contamination of the CSF with blood. Sensitivity of the CSF-VDRL ranges only from 30% to 70%, so a negative test does not rule out neurosyphilis.[18] Other abnormalities of the CSF that may occur with or without a reactive CSF-VDRL include a mononuclear pleocytosis with counts of 10 to 500 cells/mm^3 and an elevated protein level of 46 to 200 mg/dl.

Latent syphilis As disease activity wanes and immunologic mechanisms exert some control, the height of titer in the NTST declines. Titers of between 1:1 and 1:16 are not uncommon. Higher titers suggest but do not confirm the presence of disease activity. The treponemal serologic tests are also reactive.

Neurosyphilis The laboratory diagnosis of neurosyphilis depends on the analysis of serologic tests and the CSF examination. The treponemal serologic test is almost always positive in neurosyphilis but it is not a specific marker for disease, because it is generally reactive for the life of the infected individual, whether treated or not. The NTSTs, generally regarded as sensitive but nonspecific in the evaluation of primary syphilis, are nonreactive in 25% to 30% of cases of neurosyphilis.[19]

CSF evaluation remains the gold standard by which neurosyphilis is diagnosed. Because lumbar puncture is associated with some morbidity, efforts have been made to define subgroups of patients with latent syphilis (i.e., asymptomatic with serologic evidence of disease) who may be at risk for asymptomatic neurosyphilis and therefore at a higher risk for progression to symptomatic late neurosyphilis. Current guidelines suggest that patients with latent syphilis in the setting of HIV and patients with latent syphilis whose titers rise or fail to decline after 2 to 3 years of therapy are at risk.[20] Some experts recommend CSF evaluation in latent syphilis if the serologic titer is at least 1:32.

CSF analysis is warranted in any patient with serologic evidence of syphilis and neurologic, ophthalmologic, otic, or psychiatric disease. Tests conducted on the CSF should include a quantitative CSF-VDRL, a cell count with differential, and a protein assay. The VDRL is the only nontreponemal test that is standardized for CSF. In 25% to 30% of neurosyphilis cases, this test may be nonreactive. It is otherwise extremely specific and by itself may be diagnostic of neurosyphilis. The CSF cell count can range from 5 to 200 cells/mm^3, with a lymphocytic predominance. The CSF protein concentration is also usually increased, although levels should not exceed 200 g/dl. Lymphocytic pleocytosis and increased CSF protein concentrations are nonspecific for neurosyphilis and may be seen in a wide range of pathologic processes. The diagnosis of neurosyphilis in which the results of only these tests are abnormal rests on these findings and clinical suspicion. In some instances when tabes dorsalis has run its course, the CSF is completely normal.

Cardiovascular syphilis As with other forms of tertiary syphilis, the nontreponemal serologic test for late cardiovascular syphilis may be nonreactive, whereas the treponemal-specific test is almost always reactive. Although a chest x-ray may be normal, it can also show a mediastinal mass consistent with the thoracic aortic aneurysm. Calcification of the aneurysm is often seen on radiograph but is not specific for syphilis.

Gummatous syphilis Clinical suspicion is the most important tool in the diagnosis of late gummatous syphilis. Nontreponemal serologic tests are nonreactive in a sizable number of cases. The treponemal serologic tests should always be reactive. Interestingly, spirochetes are not often demonstrated in biopsied tissue. Dark-field microscopy is of little use. More sensitive tests based on nucleic acid amplification may detect treponemal DNA in these lesions.[21]

DIFFERENTIAL DIAGNOSIS

Primary Syphilis

Any clinical condition likely to cause a genital ulcer should be considered in the differential diagnosis when primary syphilis is suspected. The most common cause of genital ulcer disease in the United States is herpes simplex virus type 2 (HSV-2). The ulcers of HSV-2 are usually preceded by prodromal symptoms of burning and tingling, and they pass through a series of predictable stages, including papules, vesicles, pustules, and ulcers, before healing. The ulcers are tender and shallow, with an erythematous base. Lesions are often multiple and can coalesce to form large irregularly shaped ulcers. The course of illness varies, depending on whether it is a primary infection or a recurrence of established infection. The former may last as long as 3 weeks, whereas the latter usually resolves after 10 days. Diagnosis may be made on clinical grounds or with viral culture. Regional lymphadenopathy is common. Worldwide, the other common infectious cause of genital ulcer is chancroid, caused by *Haemophilus ducreyi* [*see 7:XXII Sexually Transmitted Diseases*]. Chancroid is seen sporadically in the United States, usually in conjunction with focal urban outbreaks, but is a common cause of genital ulcer disease in developing countries. Chancroid lesions are painful and indurated, with ragged margins. Gram stain of exudate may reveal gram-variable rods that characteristically line up together in patterns referred to as a school of fish or railroad tracks. Special nutrient media with antibiotic supplements should be used for isolation of *H. ducreyi.*

Secondary Syphilis

It would be nearly impossible to list all the conditions to which secondary syphilis bears some resemblance. A rash of any description, whose etiology may be construed as allergic, infectious, or immune mediated may potentially be syphilitic. Thus, syphilis testing for any patient with a rash of unknown etiology is warranted. The finding of a palmar rash or a rash on the soles of the feet—classic for syphilis—may be seen in a limited number of conditions, including Rocky Mountain spotted fever, atypical measles, and meningococcemia. A rash accompanying any of these alternative diagnoses would ordinarily be associated with more severe systemic illness than is seen with secondary syphilis. Syphilis needs to be considered in the differential diagnosis for aseptic meningitis. More typical causes for this problem may include enteroviruses, HSV-1, and medication-associated aseptic meningitis.

Latent Syphilis

In 1% to 2% of the general population, nontreponemal serologic tests such as the RPR, VDRL, and USR may be falsely reactive. In these circumstances, the treponemal serologic tests, such as the FTA-ABS and TP-PA, are nonreactive. An increased risk of this finding is commonly associated with older age, pregnancy, collagen vascular disease, and intravenous drug use.

Neurosyphilis

Although the pattern of classic meningovascular or parenchymatous neurosyphilis may be recognizable, the clinically varied manifestations of CNS syphilis require the clinician to consider it with nearly any presentation. A wide array of stroke syndromes caused by thrombotic or hemorrhagic mechanisms should be included in the differential diagnosis. Neurosyphilis should be considered in a relatively young person with a history of sexually transmitted diseases who otherwise has no risk factors for a cerebrovascular accident (e.g., atherosclerosis or hypertension) and suffers a stroke. Diabetic neuropathy has been said to mimic tabes dorsalis. Neurosyphilis should be considered in the differential diagnosis of any patient presenting with a dementia.

Cardiovascular Syphilis

Cardiovascular pathology leading to ischemia is more likely to result from atherosclerotic disease than from syphilis. Likewise, aortic aneurysm formation secondary to long-standing hypertension would be more common than syphilitic aneurysms. Aortic regurgitation often follows aortic stenosis. Besides syphilitic aortitis, pure valvular regurgitation without stenosis may be seen in patients with congenital valvular disease (e.g., Marfan syndrome), healed infective endocarditis, or other cardiac trauma.

Gummatous Syphilis

The lesions of late benign syphilis may be easily confused with other granulomatous processes, such as tuberculosis, sarcoid, fungal infection, and, occasionally, neoplastic disease.

TREATMENT

Penicillin remains the antimicrobial agent of choice in all stages of syphilis [*see Table 2*]. The studies that established this therapeutic standard were conducted decades ago. They used varying formulations of penicillin not currently available and would not meet present standards for randomization, blinding, sample size, and other aspects of good study design. These studies provide a weak basis for conclusions about optimal management today.

Primary and Secondary Syphilis

Therapy for primary syphilis should serve two overlapping goals: (1) to reduce and eliminate the capacity of the infected person to transmit disease and (2) to achieve the microbiologic eradication of *T. pallidum* from the host to resolve clinical manifestations and avoid long-term sequelae.

Sexual transmission of syphilis occurs almost exclusively during the early stages of disease, when contact with infectious lesions is most common. Penicillin eliminates infectivity relatively easily. Early studies of penicillin demonstrated the ability of the drug to rapidly convert dark-field–positive lesions to dark-field–negative lesions and hasten their resolution.

All the clinical manifestations of primary and secondary syphilis will resolve without therapy. However, the resolution of clinical manifestations does not ensure the eradication of *T. pallidum*. In such circumstances, patients are assumed to remain infected and to have entered the latent stage of disease. Studies of therapeutic efficacy rely on changes in serologic markers that may or may not reflect microbiologic activity of disease. There is general agreement today that a fourfold (two dilution) decrease in the NTST titer should occur as early as 3 months and as late as 12 or even 24 months after successful therapy. This notion is based on clinical experience and data from a study and subsequent reanalysis of the data.[22,23] The criteria for failure and the need for retreatment in both of these studies were poorly defined. Although it has thus been easy to create general categories for the patterns of response expected after therapy, few studies since the introduction of penicillin have followed patients long enough to establish the risk of disease progression.

Penicillin therapy For the past 3 decades, benzathine penicillin G (2.4 million units given once I.M.) has been the standard regimen for the treatment of primary syphilis and is currently recommended by both the CDC and the World Health Organization (WHO).[20,24] Studies have demonstrated the efficacy of benzathine penicillin but have also suggested a 3% to 10% failure rate by the serologic criteria mentioned above.[22] Where comparative data exist, this single injection appears to be nearly as effective, if not as effective, as a variety of more complicated regimens.[25] The ease and cost-effectiveness of a single injection clearly favors its use over multiple-injection–based therapies or therapies requiring hospitalization for intravenous treatment.

Nonpenicillin therapy It is advantageous to have alternative therapies to penicillin not only for the possibility of resistant *T. pallidum* but also to treat patients who are allergic to penicillin [*see* Complications, *below*]. There have been few comparative trials that have examined the role of nonpenicillin therapies. Tetracyclines have been used for decades as an alternative to penicillin, and the CDC currently recommends doxycycline (100 mg orally twice a day for 14 days) as second-line therapy in primary syphilis.[17] Retreatment rates after tetracycline therapy are higher than those after penicillin therapy.[22] Clinical experience supports the use of tetracyclines as alternatives to penicillin for cases of early stage syphilis in which penicillin cannot be used.

Erythromycin congeners, primarily the potentially hepatotoxic estolate form, have also been studied and appear to be as effective as tetracyclines in the treatment of early stage syphilis.[22] However, oral absorption of erythromycin is erratic, and the difficulty of achieving adequate serum levels with the widely used base form makes this an unreliable choice for primary syphilis treatment. Questions regarding erythromycin resistance have also been raised. A high-dose amoxicillin-probenecid combination is another possible alternative, although compliance with such a complex oral regimen makes it difficult to recommend.

The role of first-generation cephalosporins for the treatment of primary syphilis has also been examined.[26,27] Some efficacy was demonstrated for these agents, but at least one study suggested an unacceptably high failure rate.[28] Given the unclear role of these agents in the treatment of penicillin-allergic patients,

Table 2 Treatment of Syphilis

Stage	*Drug*	*Dose*	*Relative Efficacy*	*Cost/Day ($)*	*Comment*
Primary, secondary, and early latent syphilis	Benzathine penicillin G	2.4 million U I.M. once	Drug of choice	0.75–0.99	—
	Doxycycline	100 mg p.o. twice a day for 14 days	—	0.05–0.12	Therapy for nonpregnant patients who are allergic to penicillin
	Tetracycline	500 mg p.o. four times a day for 14 days	—	0.10–0.24	
	Ceftriaxone	1 g I.M. or I.V. daily for 8–10 days	—	60.00–69.99	Optimal dose has not been defined
	Azithromycin	2 g p.o. once	—	10.00–19.99	—
Late latent or latent syphilis of unknown duration	Benzathine penicillin G	2.4 million U I.M. once a wk for 3 wk (total 7.2 million U)	Drug of choice	0.75–0.99	May be associated with gastrointestinal upset
	Doxycycline	100 mg p.o. twice a day for 28 days	—	0.05–0.12	Therapy for nonpregnant patients who are allergic to penicillin
	Tetracycline	500 mg p.o. four times a day for 28 days	—	0.10–0.24	
Tertiary syphilis (gummatous and cardiovascular)	Benzathine penicillin G	2.4 million U I.M. once a wk for 3 wk	Drug of choice	0.75–0.99	—
	Doxycycline	100 mg p.o. twice a day for 28 days	—	0.05–0.12	Therapy for nonpregnant patients who are allergic to penicillin
	Tetracycline	500 mg p.o. four times a day for 28 days	—	0.10–0.24	—

*Monthly cost.

interest in them waned. The third-generation cephalosporin ceftriaxone is a suitable alternative agent for syphilis treatment. In vitro and animal-model data suggest that ceftriaxone has good antitreponemal activity.[29-31] Favorable pharmacokinetics and ceftriaxone's ability to penetrate the blood-brain barrier also make it an attractive choice for therapy. In small groups of patients with primary syphilis, ceftriaxone appeared to be effective.[32,33] Despite its perceived efficacy, ceftriaxone probably should not be given as a single dose for the treatment of primary syphilis, because it would not remain at treponemicidal levels for an acceptable period of time. The proper dosage and duration of therapy are matters of conjecture.

The azalide antibiotic azithromycin has many properties that suggest its usefulness as therapy for primary syphilis. It is active against *T. pallidum* in vitro and has been effective in experimental models of syphilis.[34,35] Although plasma concentration of azithromycin may be nearly unmeasurable, high levels are achievable in tissue.[36] Its extremely long half-life makes it ideal therapy for *T. pallidum*, an organism with a prolonged doubling time. In a number of small studies, azithromycin in varying doses appeared effective for incubating, primary, and secondary syphilis.[37,38]

Latent Syphilis

The successful treatment of latent syphilis is made problematic by a lack of clear and readily measurable clinical end points. By definition, there is no chancre or rash, the resolution of which would suggest response. The objective of therapy is the prevention of long-term sequelae. Except for waiting perhaps decades to see if late-stage disease develops, changes in serologic titers are the only indication of efficacy. Unfortunately, by its very nature, late latent syphilis elicits little in the way of an inflammatory response. Thus, nontreponemal serologic test results are often very low, and their decline after therapy may be proportionately slow. Seroreversal may never be achieved.

Because early latent syphilis occurs shortly after secondary syphilis appears to resolve, it should respond appropriately to similar single-dose and multiple-dose regimens. In most clinical settings, patients with latent-stage disease are unable to reliably give any history suggestive of recent primary disease and are usually treated as having late latent-stage disease.

Studies have suggested that penicillin, which is effective in primary disease, would be effective for latent disease as well. A variety of penicillin regimens were compared and patients followed over a wide range of periods,[39] and benzathine penicillin G provided equivalent duration of in vivo drug levels with fewer injections. Although there are no data directly supporting the current recommendation of three weekly injections of 2.4 million units of benzathine penicillin G (total, 7.2 million units), this therapy appears reasonable on the basis of theoretical assumptions regarding the slow doubling time of *T. pallidum* and the need for extended duration of therapy. The recommended regimen has been used effectively for decades and only rarely results in progression of disease.

There are virtually no useful data on the treatment of latent syphilis with nonpenicillin therapies. Recommendations of 28 days of tetracycline, chloramphenicol, or erythromycin are largely without clinical data to support their effectiveness.

Late Symptomatic Syphilis (Excluding Neurosyphilis)

Incidences of gummatous syphilis and cardiovascular syphilis have declined so dramatically in the penicillin era that it has been difficult to collect enough cases to conduct a study of

Table 2 (continued)

Stage	Drug	Dose	Relative Efficacy	Cost/Day ($)	Comment
Neurosyphilis	Aqueous crystalline penicillin G	18–24 million U/day, given as 3–4 million U I.V. every 4 hr for 10–14 days	—	10.00–19.99	—
	Procaine penicillin G and probenecid	Penicillin, 2–4 million U/day I.M. for 10–14 days; plus probenecid, 500 mg p.o. four times a day for 10–14 days	—	Penicillin, 2.00–2.99; probenecid, 10.00–19.99*	Can be used if compliance is good
	Ceftriaxone	2 g I.M. or I.V. daily for 10–14 days	—	60.00–69.99	Limited supporting data
Congenital syphilis	Aqueous crystalline penicillin G	100,000–150,000 U/kg/day, given as 50,000 U/kg/dose I.V. every 12 hr during the first 7 days of life and every 8 hr thereafter for a total of 10 days	—	10.00–19.99	—
	Procaine penicillin G	50,000 U/kg/day I.M. once a day for 10 days	—	2.00–2.99	—
Nonvenereal treponematoses (yaws, endemic syphilis, and pinta)	Benzathine penicillin G	Adults, 1.2 million U I.M. once; children, 600,000 U I.M. once	—	0.75–0.99	—
	Doxycycline	100 mg p.o. twice a day for 14 days	—	0.05–0.12	—
	Tetracycline	500 mg p.o. four times a day for 14 days	—	0.10–0.24	—

newer therapeutic modalities. A few studies conducted on small groups of patients soon after the introduction of penicillin demonstrated that penicillin therapy probably halts the progression of gummatous disease, although existing damage to skin, mucous membranes, soft tissue, and skeletal structures is likely irreparable. The therapeutic efficacy of penicillin for cardiovascular syphilis has never been clearly established[40] because of the difficulty of establishing a diagnosis and determining the efficacy of therapy in individuals with already advanced disease (i.e., cardiac structural damage). Despite suggestions that penicillin appeared to have some efficacy in preventing the progression of otherwise uncomplicated aortitis, carefully controlled studies comparing various therapies have never been conducted. In over 4 decades, there have been no studies examining the newer, long-acting preparations of penicillin, nor have there been studies of alternatives to penicillin.

Given the relative safety and ease of use of penicillin therapy for the treatment of cardiovascular syphilis, the WHO and the CDC recommendations appear reasonable, provided that patients are adequately evaluated for other complications of syphilis, such as neurosyphilis, and that adequate clinical and serologic follow-up can be performed.

Neurosyphilis

Frank symptomatic neurosyphilis, like cardiovascular syphilis and gummatous syphilis, has to a certain extent disappeared from clinicians' experience because of the success of therapies for primary and latent-stage disease. Although there is a significant body of work describing and essentially confirming the efficacy of penicillin in the treatment of neurosyphilis, this literature, like much of the syphilis-treatment literature, is compromised by poor posttreatment follow-up and poorly defined outcomes. Nonetheless, penicillin appears to be effective against neurosyphilis, in many instances improving or halting the inexorable progression of neurologic symptoms.

In the 1970s, the CDC recommended either 7.2 million units of benzathine penicillin G I.M. over 3 weeks or 9 million units of aqueous procaine penicillin G over 15 days as therapy for neurosyphilis. The former regimen was also recommended as treatment for late latent syphilis and probably offered some assurance that adequate therapy would be provided for patients with unappreciated asymptomatic neurosyphilis. Serious questions about the efficacy of these regimens, particularly of 7.2 million units of benzathine penicillin G for neurosyphilis, emerged almost simultaneously with their recommendation. Reports detailed the inability of the regimen to achieve acceptable spirocheticidal levels in CSF,[41-45] as well as treatment failures.[46-48] The response of patients with reported treatment failures to increased doses of penicillin has led the CDC to recommend prolonged courses of aqueous or procaine penicillin G for the treatment of neurosyphilis.

Despite the new CDC recommendations for therapy, there are no data from randomized, controlled trials that demonstrate superior efficacy of the new recommendations over previous recommendations. Some experts still contend, also in the absence of supporting data, that lower-dose regimens may be appropriate for asymptomatic neurosyphilis.

The efficacy of high-dose intravenous therapy for neurosyphilis in certain circumstances is also questionable. It is probable that advanced parenchymal disease (e.g., paresis or tabes dorsalis) will not improve after even the most aggressive therapy and may in fact progress. In patients with neurosyphilis and concomitant HIV infection, disease progression

may be seen after therapy.[49] Controversy also exists regarding the efficacy of procaine penicillin G.[49]

Ceftriaxone is an attractive alternative to penicillin in the treatment of neurosyphilis.[32,33,50] It has a long half-life, penetrates the CNS well, and has been shown in vivo and in vitro to have activity against *T. pallidum*. Although there are few well-designed trials supporting the clinical efficacy of ceftriaxone for the treatment of neurosyphilis, infectious disease specialists in the United States commonly use it as an alternative to penicillin.[51]

High-dose amoxicillin (2 g orally three times a day) combined with probenecid has been proposed as an alternative outpatient regimen for neurosyphilis because it has been documented to achieve treponemicidal levels of β-lactam antibiotic in the CSF.[52-54] No randomized, controlled studies have been done to evaluate this regimen for this purpose.

Both chloramphenicol and doxycycline have been examined in individual cases and in small groups of patients with neurosyphilis.[55,56] Limited data suggest that these drugs may have efficacy in the treatment of neurosyphilis, but there is not enough evidence to make final recommendations.

Oral steroids are a frequent adjunct in the therapy of sensorineural deafness complicating neurosyphilis,[57,58] but no controlled trials have been properly conducted to evaluate this practice.

Serologic Follow-up

In the treatment of syphilis, the lack of a microbe that can be cultured, the problem of latency, and the uncertainty of therapeutic efficacy combine to foster a unique clinical reliance on quantitative changes in serologic markers to determine response to and adequacy of therapy. Few, if any, infectious diseases require similar follow-up after treatment.

Current standards of care require patients with primary syphilis to return for clinical and serologic evaluation at 3, 6, and 12 months after therapy.[20] Patients with latent syphilis are followed less frequently, perhaps at 6-month intervals for up to 24 months. HIV-coinfected patients are followed more regularly. Recurrence of disease or lack of resolution of signs or symptoms of disease after treatment may be considered evidence of treatment failure. As a measure of disease activity, a two-tube, or fourfold, dilution increase in the NTST during follow-up is also widely accepted as a marker of treatment failure. In all of these instances, distinguishing treatment failure from reinfection may be difficult. At the opposite end of the therapeutic spectrum, cure may reasonably be assumed to have occurred if the NTST becomes nonreactive after therapy. Unfortunately, this development may occur slowly if at all.

A two-tube, or fourfold, dilution decrease in the NTST after treatment has become accepted as the measure of success. This finding will occur more rapidly after treatment for primary syphilis. Cumulative data and clinical experience over several decades indicate that in immunocompetent patients treated with standard regimens of benzathine penicillin G or tetracycline, the NTST should decline by two or three dilutions within 6 and 12 months of treatment, respectively. The proportion of patients expected to be seronegative within 12 to 24 months is less certain, but the weight of evidence suggests that at least 90% of patients with primary or secondary syphilis should serorevert within 1 or 2 years, respectively.

The treponemal-specific serologic tests revert to negative within 3 years in up to 25% of successfully treated patients with first-episode primary syphilis, so that a negative treponemal antibody test result does not always exclude a past history of syphilis.[20,59] However, seroreversal of the treponemal antibody test results occurs rarely, if ever, after treatment of syphilis at the secondary stage or beyond or after treatment of a second episode of primary syphilis. Some data suggest a higher prevalence of nonreactive treponemal antibody tests in HIV-infected patients after treatment of syphilis.[60] It is possible that HIV-infected persons serorevert more often than non–HIV-infected persons, but the issue is unresolved.

Serologic response after treatment in latent disease may be even more problematic than in primary disease. Long-term studies are not available. Another confounding issue is variation in the definition of late syphilis, which determines the dose or duration of therapy of latent infection. Most early writers defined late infection as syphilis of 4 years' duration, on the basis of observations that relapses of secondary syphilis in untreated individuals ceased after this interval. The usual cutoff in the United States, by contrast, is 1 year, after which sexual transmission is rare and classic tertiary syphilis begins to appear.[61] In 1986, the WHO defined late latent syphilis as infection of 2 years' duration.[24] All these definitions are arbitrary, and there are insufficient data for choosing among them on the basis of documented differences in the clinical or serologic response to various treatment regimens. Moreover, the duration of infection cannot be determined accurately in most asymptomatic seropositive patients, further confounding interpretation of the serologic response to treatment in most published studies.

Older data and the accumulated experience of recent years indicate that NTST results decline more slowly after treatment of late syphilis than after treatment of early syphilis and that these tests often remain reactive indefinitely, usually at low titer. Serologic titers in late latent syphilis and in tertiary syphilis decline slowly after treatment, and nonreactive tests will develop in only a minority of patients after upwards of 5 years.[25] The serologic response to the treatment of symptomatic late-stage syphilis may also result in only gradual declines in the NTST. Whether this reflects failure to achieve biologic cure or is merely a serologic phenomenon (so-called immunologic memory) is unresolved. For clinical application, a reasonable guideline is that failure of the NTST to decline by two or more dilutions within 12 months of treatment of late syphilis and any subsequent rise in titer are indications for comprehensive reevaluation and retreatment.

CSF abnormalities in neurosyphilis are also slow to respond after therapy. When reactive, the CSF-VDRL may remain so for years. Other parameters of inflammation, such as cell count and protein level, should resolve more rapidly. It appears to be a reasonable and acceptable practice to repeat CSF examination in patients treated for neurosyphilis at 3-month to 6-month intervals after therapy to ensure an appropriate response. Although the CDC suggests retreatment if CSF abnormalities persist after 2 years, there is no evidence that this condition is clearly indicative of treatment failure or that retreatment will result in an improved response. It is unclear whether serologic response can be expected to differ in all clinical settings, and it would be prudent to consider more frequent serologic follow-up for the HIV-infected patient treated for any stage of syphilis.

Despite considerable effort to develop guidelines for expected serologic response after treatment, it must be remembered that microbiologic response and serologic response are not synonymous. *T. pallidum* has been isolated by rabbit inoculation of lymph nodes of both patients and rabbits and has been identi-

fied histologically or immunochemically in aqueous humor after penicillin therapy that resulted in clinical and serologic resolution. Relapse (especially of neurosyphilis) has been reported after apparently adequate penicillin treatment of HIV-infected patients with primary syphilis.

Management of Sexual Partners and Incubating Syphilis

Syphilis treatment is not complete until treatment of sexual partners of the index case has been considered. The CDC recommends that sexual contacts exposed to an index case of primary, secondary, or early latent syphilis receive presumptive therapy within 90 days regardless of the serologic test results. For persons exposed more than 90 days before, therapy should be based on the serologic test results. The need for therapy for contacts of patients with latent or late-stage syphilis should be based on clinical evaluation.

High-risk sexual activity (as indicated by the recent acquisition of such sexually transmitted organisms as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*) carries with it the risk of simultaneous acquisition of syphilis. Because the incubation period of syphilis may be much longer than that of diseases caused by these other organisms, neither clinical nor serologic evidence of syphilis may be present at the time of presentation for clinical care. It would therefore be advantageous for therapies directed toward *C. trachomatis* or *N. gonorrhoeae* to also adequately treat syphilis. Treatment with standard doses of ceftriaxone for gonorrhea will probably abort incubating syphilis. The same cannot be said for single-dose therapy with quinolone antibiotics that do not have activity against *T. pallidum.* Activity of single-dose cefixime against *T. pallidum* is uncertain. Spectinomycin is not active in this instance.[62] Although data are lacking to support a 7-day course of doxycycline, this therapy may in fact be effective. Single-dose azithromycin may also be useful for this purpose.[38]

COMPLICATIONS

Jarisch-Herxheimer Reaction

The Jarisch-Herxheimer reaction is an acute systemic syndrome characterized by fever, chills, headaches, myalgias, tachycardia, tachypnea, and nausea that occurs within the first few hours after the treatment of syphilis—usually secondary syphilis. It may result from the release of pyrogenic endotoxins from treponemes adversely affected by therapy. Treatment with anti-inflammatory agents during the first 24 to 48 hours is warranted. Some clinicians advocate the use of preemptive steroid therapy to mitigate any reaction in which additional end-organ damage (e.g., ocular or cardiovascular) may be problematic, but this practice is not supported by available data. In pregnancy, a Jarisch-Herxheimer reaction may precipitate premature labor or fetal distress.[63] Pregnant women should be advised to seek obstetric evaluation if they note contractions or decreased fetal movements after syphilis treatment.

Penicillin Allergy and Desensitization

In the United States, 5% to 10% of the population may have a history of penicillin allergy, and life-threatening complications may result in 2% to 13% of related allergic events.[64] Despite the relatively high risk of adverse events, there are certain clinical situations in which nonpenicillin therapies for syphilis are not acceptable and penicillin must be used (i.e., congenital syphilis, syphilis in pregnancy, and neurosyphilis).

Even where a history of penicillin allergy exists, the drug may not necessarily be contraindicated. A history of allergy may be inaccurate. Additionally, with the passage of time after an allergic event, many patients may stop expressing penicillin-specific IgE. Penicillin skin testing is a well-established means of securing the patient's true allergy status. The penicilloyl hapten moiety that is the largest product of penicillin metabolism is referred to as the major determinant and, conjugated to polylysine, is commercially available for skin testing. The remaining metabolites are referred to as the minor determinants and are available only at certain academic centers. Even in this setting, the quality criteria for their production have not been standardized. Major determinant skin testing, along with that for benzathine penicillin G (considered a minor determinant), should identify 90% to 97% of patients with penicillin allergy. Nearly all allergic patients will be identified if the other minor determinants are also used.[65] Patients who have a positive response to any of the major or minor determinants should undergo either oral or intravenous desensitization.[66]

Desensitization is usually performed only in a hospital setting. Syphilis treatment regimens may be initiated immediately after the successful completion of desensitization. Unless penicillin therapy is continued indefinitely after desensitization, patients should be considered potentially allergic.

SPECIAL SITUATIONS

Syphilis in Pregnancy

Routine screening and confirmatory serologic tests should reveal syphilis in pregnant women. In pregnancy, quantitative nontreponemal tests reflective of previously treated syphilis may not be specifically indicative of syphilis. An increase in titer in this setting should be considered nonspecific.

The treatment of syphilis in pregnancy must not only cure disease in the adult and prevent sexual transmission but also prevent fetal infection via transplacental passage of *T. pallidum* [*see* Congenital Syphilis, *below*]. These goals can be achieved with therapeutic regimens recommended for the nonpregnant individual. Studies have been conducted in small groups of pregnant women with syphilis using 2.4 to 4.8 million units of various forms of penicillin, often over the course of at least 1 week.[67-73] In each case, the incidence of congenital syphilis was exceedingly low. It was observed that where failures occurred, mothers had been treated late in pregnancy. More studies support the contention that treatment late in pregnancy carries a greater risk for congenital disease than treatment earlier in pregnancy.[74,75] No other factors appear to conclusively increase the risk of congenital syphilis after appropriate therapy of the mother, provided that currently recommended doses are used and that the serologic and clinical markers of disease do not suggest relapse or reinfection. Follow-up in this manner is no more difficult than would be expected after the treatment of the nonpregnant patient with syphilis.

Congenital Syphilis

Diagnosis The CDC recommends that, in screening for congenital syphilis, the mother's serum be tested rather than cord blood. Reactive standard serologic tests in the infant may reflect passive transfer of antibody. Although there is interest in the use of tests for IgM antibodies in the infant, such tests may be insensitive, and nonreactive tests should be interpreted with caution. Demonstration of the presence of *T. pallidum* by direct

microscopic examination in the umbilical cord, placenta, nasal discharge, or skin lesions is considered definitive for diagnosis.

Any rise in the incidence of secondary syphilis is invariably accompanied by a rise in the incidence of congenital syphilis. In most cases, the newborn is asymptomatic. Symptomatic disease may occur early or later after birth. In the perinatal period, involvement of the mucocutaneous tissues may be seen, characterized by rhinitis and a desquamative, vesicular, or bullous rash of the skin, particularly on the palms and on the soles of the feet. Hepatic disease can also occur and may result in significant morbidity and mortality. Hepatomegaly, splenomegaly, and hematologic abnormalities occur in this setting. Osteochondritis and perichondritis lead to the classic findings of the so-called saddle-nose deformity and saber shins. After 6 to 12 months, the child enters a latent phase of disease not unlike that seen in adults. Late-stage disease in children may manifest as interstitial keratitis, eighth-nerve deafness, arthropathy, and dental malformations.

Treatment Except where adequate treatment and follow-up of the mother with syphilis can be documented more than 1 month before delivery, some therapeutic intervention will be necessary for the infant. No well-controlled study has determined the appropriate dose of penicillin for the infant suspected of having congenital syphilis, but for those with symptomatic disease at birth, 50,000 U/kg of I.V. aqueous crystalline penicillin G every 12 hours for 10 days or 50,000 U/kg of I.M. procaine penicillin G every day for 10 days appears to be satisfactory. These doses are somewhat arbitrary but are based on doses that may be used to treat bacterial meningitis and would also safely provide at least the standard spirocheticidal levels in the CSF. Because of the difficulty of ruling out active disease in the newborn, many experts recommend the same course of treatment for infants whose mothers' treatment histories are negative or unclear or who received nonpenicillin therapy during pregnancy or within 4 weeks of delivery.

For many years, a single dose of benzathine penicillin for the newborn was considered adequate therapy for congenital syphilis once neurosyphilis had been ruled out. However, reports of treatment failures have cast doubt on this assumption.[76] Benzathine penicillin continues to be recommended as an option in a variety of settings, particularly when the infant is asymptomatic and neurosyphilis has been excluded, but questions exist about the adequacy of maternal therapy and whether follow-up of the child can be assured.[20,77] There are no data to support the contention, largely based on clinical experience, that in low-risk situations these therapies result in nearly universal prevention of congenital syphilis. It is doubtful that most infants receiving this therapy have syphilis at all.

There are no clinical trials examining the role of other antibiotics for the treatment of congenital syphilis. Nonpenicillin therapies recommended for syphilis in adults cannot automatically be recommended for syphilis in infants. Tetracyclines are contraindicated in pregnancy and in infants because of their toxicity to deciduous teeth and long bones and because of concern that they may cause maternal hepatotoxicity, particularly when there is preexisting renal dysfunction.[78] Case reports of symptomatic congenital syphilis in instances in which women received erythromycin during pregnancy as therapy for syphilis suggest that this drug is not a suitable alternative to penicillin.[79-81] These clinical observations are supported by studies demonstrating that placental transfer of erythromycin may not be consistent.[82,83] Issues of compliance and gastrointestinal disturbance in pregnant women treated with erythromycin, although not studied, raise additional questions about this drug's role in pregnancy.

As in adults, serologic follow-up after treatment in infants is essential to ensure the adequacy of response. The ideal frequency of such follow-up is poorly defined, and recommendations range from every month to every 3 months during the first 6 months, with continued follow-up through 12 to 24 months, depending on response.

Syphilis in Children

Penicillin therapy Children with primary, secondary, or early latent syphilis should be treated with benzathine penicillin G (50,000 U/kg I.M., to 2.4 million units in a single dose). Children with late latent syphilis or syphilis of unknown duration should also receive benzathine penicillin G (50,000 U/kg I.M., to 2.4 million units administered as three doses at 1-week intervals). In both cases, a CSF examination should be performed to rule out neurosyphilis.

Alternative therapy The American Academy of Pediatrics recommends that tetracyclines be considered as an alternative to penicillin for both primary and latent disease after 9 years of age.[84] Erythromycin may be considered in early aquired syphilis even in children younger than 9 years (500 mg orally four times a day for 14 days). Follow-up must be ensured. Newer therapies, such as ceftriaxone and azithromycin, may also be effective. There are no studies to support any of these recommendations. Early interest in chloramphenicol as therapy for syphilis has waned because of the drug's well-known side effects.

Syphilis and HIV

Risk behaviors that contribute to the transmission of syphilis are often the same as those that contribute to the transmission of HIV, and therefore, coinfection is common. Each infection has been demonstrated to have some effect on the other. Substantial evidence suggests that early stage syphilis enhances the transmission of HIV.[85,86] Presumably, the inflammatory milieu of syphilitic lesions can serve either as a portal of entry of HIV or as the route through which HIV may be transmitted to an uninfected partner.

In coinfected persons, the deleterious effect of HIV on the immune system can alter the natural history, diagnosis, and management of syphilis. Since the earliest years of the HIV epidemic, case studies have reported on individuals who failed to respond to conventional doses of penicillin therapy and who often progressed rapidly from primary syphilis to neurosyphilis.[87,88] Other important findings have included seronegative secondary syphilis,[89] a likelihood of higher-titer NTSTs by stage,[90] and an increased incidence of biologic false positive NTSTs.[21,91]

A study prospectively followed both HIV-seronegative and HIV-seropositive patients with primary syphilis who received either conventional penicillin therapy or an enhanced regimen of high-dose amoxicillin and probenecid. No neurologic complications and no differences in response to therapy were noted between the groups.[52,92] Except for a tendency for HIV-infected persons to present with multiple chancres, as opposed to a single chancre in non–HIV-infected individuals, no significant differences were noted in presentation or rapidity to resolution of primary syphilis findings. In another study, the CSF white

blood cell count, protein, and VDRL were slower to resolve after therapy in HIV-infected individuals than in non–HIV-infected individuals.[93] Clinical failures were not noted.

The propensity for *T. pallidum* to invade the CNS early during infection and the likely importance of immune mechanisms for its control suggest possible mechanisms for the risk of neurosyphilis in coinfected persons. This issue is further complicated by the likelihood for HIV-infected persons to have CSF abnormalities even in the absence of discernible CNS pathology.[94] Many experts recommend that HIV-infected persons with latent syphilis or primary syphilis undergo a CSF evaluation and that those with CSF abnormalities be treated accordingly.

Nonvenereal Treponematoses

The nonvenereal treponematoses—yaws, endemic syphilis, and pinta—are a group of infections distributed throughout tropical and semitropical areas of the world. They are primarily noted to cause a variety of skin and skeletal lesions. There is little biologic difference between the treponemes that cause these conditions.[95] Their distinguishing nomenclature is based primarily on the clinical disease that characterizes each. Each is linked to poor hygiene and person-to-person transmission and disproportionately affects children. As a result of mass treatment programs conducted in the 1950s and the 1960s, initiated primarily by the WHO in conjunction with local authorities, the incidences of all of the nonvenereal treponematoses are today quite low.

YAWS

Epidemiology

Yaws is a disease primarily affecting individuals who live in rural areas of the tropics. It is seen in parts of South America, Africa, Southeast Asia, and Oceania. In the Western Hemisphere, yaws occurs sporadically in small regions of Colombia, Haiti, Suriname, and Guyana. Propagation depends on a hot, humid climate. Persons younger than 15 years appear to be most at risk for acquisition of this infection. It is known by a number of names in different parts of the world, including frambesia, pian, bouba, and parangi.

Pathogenesis

T. pallidum subspecies *pertenue* is associated with yaws. Transmission occurs through skin-to-skin contact, where abrasions or other defects allow spirochetes to enter and cause infection. The incubation period of yaws is like that of syphilis. Within 9 days to 3 months, a granulomatous papule forms in the area of inoculation. This papule gradually enlarges and becomes either hyperkeratotic or frankly ulcerative, often with the development of an overlying amber crust of bacterial superinfection. As with syphilis, even in the absence of specific treatment, these primary lesions resolve.

Diagnosis

The diagnosis of yaws should be suspected in anyone with skin or bone lesions who has spent time in a tropical region.

Clinical manifestations Systemic symptoms of fever, arthralgias, and regional lymphadenopathy occur in conjunction with the development of a diffuse rash similar in appearance to the primary lesion. Osteitis and periosteitis can occur involving the fingers (polydactylitis), tibia (saber shin), and the paranasal maxillae. Secondary lesions may resolve and then relapse over the course of many years. Gummatous lesions with significant dermal scarring and destruction of underlying bone occur years after infection. Whether CNS involvement occurs is debatable.

Laboratory tests Dark-field microscopy of both primary and secondary lesions may yield spirochetes. Nonspecific treponemal serologic tests (e.g., VDRL or RPR) and treponemal-specific serologic tests (e.g., FTA-ABS or TP-PA) should be reactive in cases of yaws, but these tests cannot distinguish between yaws and other treponematoses.

Differential Diagnosis

The differential diagnosis includes syphilis, eczema, psoriasis, scabies, pyoderma, tuberculosis, leprosy, and ecthyma, as well as other processes.

Treatment

Penicillin remains the treatment of choice. For primary disease, doses of benzathine penicillin, 1.2 million units I.M. once in adults and 600,000 units I.M. once in children, should be adequate. Tetracyclines and chloramphenicol are acceptable alternatives. Close contacts of the patient should also be treated.

ENDEMIC SYPHILIS

Epidemiology

Unlike yaws, endemic syphilis, or bejel, is epidemiologically restricted to the arid regions of the Middle East and North Africa. Like the other treponematoses, endemic syphilis is transmitted by close personal contact and affects primarily children living in rural areas.

Pathogenesis

Endemic syphilis is caused by the spirochete *T. pallidum* subspecies *endemicum*. The primary lesion of endemic syphilis usually occurs at a site of inoculation on the oral mucosa and is often unappreciated. This has led to the suspicion that contaminated utensils and drinking vessels may be involved in the spread of the disease.

As in the case of yaws, gummatous late-stage lesions result in destruction and deformation of the mucosa and bony structures, particularly of the mouth and nasal structures. Long bones are sometimes involved. Hyperkeratosis of the soles of the feet occurs. CNS disease is uncommon.

Diagnosis

The diagnosis of endemic syphilis should be considered in any person from an endemic area who has skin or bone disease.

Clinical manifestations Secondary lesions, which may be the first manifestation of infection to be noticed, occur on and around the oral mucosa as well as on other moist, nonkeratinized epithelium and in the intertriginous areas. In rare cases, lesions are disseminated across the surface of the body. Diffuse lymphadenopathy and osteitis are also seen in this circumstance.

Laboratory tests Dark-field microscopy of primary and secondary lesions will be positive for spirochetes, and serologic testing will also be reactive.

Differential Diagnosis

The differential diagnosis of endemic syphilis includes many of the conditions considered in the differential diagnosis of yaws.

Treatment

As in the case of yaws, a single I.M. injection of 1.2 million units of benzathine penicillin is effective to eradicate disease.

PINTA

Epidemiology

Pinta (Spanish for blemish) occurs only in the Western Hemisphere and only in rural areas of southern Mexico and parts of Colombia. All age groups are susceptible to infection.

Pathogenesis

The organism that causes pinta, *T. carateum*, is transmitted through contact of broken skin with infectious lesions.

Within a few weeks of inoculation, a small papule develops at the infection site. The initial papule is followed rapidly by the appearance of other small, pruritic, erythematous papules around the site of the lesion.

Diagnosis

Pinta should be suspected in anyone with characteristic dermal lesions who has been in an endemic area.

Clinical manifestations Papules may coalesce to form squamous plaques. They may then persist for some time before resolving and leaving areas of hypopigmentation. Within 3 to 12 months, a disseminated form of skin lesion known as a pintid appears, which is similar to the initial lesion. These also may coalesce. Diffuse lymphadenopathy is common. Eventually, longstanding lesions leave atrophic and hypopigmented patches, particularly in the area of the wrists, elbows, and ankles.

Laboratory tests Except in the late stages of disease, lesions should yield dark-field microscopic results positive for spirochetes. Standard serologic tests for syphilis are usually reactive except during the earliest phases of disease.

Differential Diagnosis

Conditions with which pinta may be confused include tinea versicolor, vitiligo, and chloasma.

Treatment

The same penicillin doses used for yaws and endemic syphilis should be effective for pinta. Tetracyclines and chloramphenicol are acceptable alternatives. Lesions may be slow to heal. The hypopigmented, or achromic, lesions of late-stage pinta may never improve despite therapy.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

VII LYME DISEASE AND OTHER SPIROCHETAL ZOONOSES

David C. Tompkins, m.d.
Benjamin J. Luft, m.d., f.a.c.p.

Lyme Disease

Lyme disease is a vector-borne zoonosis caused by *Borrelia burgdorferi,* which is a thin, spiral, motile, extracellular bacterium belonging to the family Spirochaetaceae. The hallmark of infection is erythema migrans, an annular erythematous skin lesion that usually appears at the site of the tick bite.

HISTORY

In 1976, Steere and colleagues noted an association between erythema migrans and a cluster of patients with knee arthritis in Old Lyme, Connecticut; they called this syndrome Lyme arthritis.[1] In the subsequent decade, these investigators defined the multisystem nature of the disease and modified its name to Lyme disease.

Isolation of the Lyme disease pathogen was not accomplished until 1981, when Burgdorfer and colleagues demonstrated a new spirochete in *Ixodes* ticks collected on Shelter Island, New York.[2] In 1982, spirochetes were identified in the midgut of the adult form of the deer tick *I. dammini,* and were named *B. burgdorferi*. Conclusive evidence that *B. burgdorferi* causes Lyme disease came in 1984, when *B. burgdorferi* was cultured from the blood of patients with erythema migrans, from the rash itself, and from the cerebrospinal fluid of a patient with meningoencephalitis and a history of erythema migrans.

EPIDEMIOLOGY

In the United States, surveillance for Lyme disease was begun by the Centers for Disease Control and Prevention (CDC) in 1982. Since that time, the number of reported cases has increased dramatically; nevertheless, as many as 90% of Lyme disease cases may be going unreported. Lyme disease has been reported in 49 of the 50 states, but most cases occur in the Northeast, the Midwest, and northern California. Nine states account for more than 90% of the nationally reported cases, with Connecticut leading the group. The other states are Rhode Island, New York, Pennsylvania, Delaware, New Jersey, Maryland, Massachusetts, and Wisconsin.[3,4] The rising incidence of Lyme disease in the United States may be explained by multiple factors, including an increase in the numbers of ixodid ticks, the expansion of residential areas into previously rural woodlands (habitats favored by ixodid ticks and their hosts), an exploding deer population, and increased recognition.

The Lyme disease pathogen, *B. burgdorferi*, is maintained in and transmitted by ticks of the *I. ricinus* complex, including *I. scapularis* in the northeast and north central United States [*see Figure 1*], *I. pacificus* on the West Coast of the United States, *I. ricinus* in Europe, and *I. persulcatus* in Asia.[5] In Europe, three genospecies of the *B. burgdorferi sensu lato* complex are pathogenic, including *B. burgdorferi sensu stricto*, *B. garinii*, and *B. afzelii*. *B. burgdorferi* is the only pathogenic species in North America. The varying relative distribution of these genospecies from region to region throughout Europe and Asia may account for the relative variability of disease syndromes associated with Lyme disease. In the United States, most patients have symptomatic illness,[6,7] whereas in Europe most patients are asymptomatic.

In field studies in Connecticut and New York, *B. burgdorferi* has been found in 10% to 50% of nymphal and adult *I. scapularis* ticks.[8,9] Although *B. burgdorferi* has been demonstrated in mosquitoes and deer flies, only ticks of the *I. ricinus* complex seem to be important in the transmission of the spirochete to humans.[10] An enzootic cycle of infection is maintained through passage of *B. burgdorferi* back and forth between ticks and their hosts. Infected nymphal ticks transmit *B. burgdorferi* to mice, which serve as a reservoir from which uninfected larvae may acquire infecting organisms. In this manner, a high rate of infection can be maintained in the tick population when the organism, ticks, mice, and deer are all present in the environment.

In temperate climatic zones, the seasonal variation of onset of Lyme disease is explained by the ecology of the predominant tick vectors. The ixodid tick has a three-stage life cycle (larva, nymph, and adult) that spans 2 years. Larvae hatch from fertilized eggs in late spring and feed once for 2 or more days in midsummer. Preferred hosts include a broad range of small mammals. The next spring they molt into nymphs and feed again for 3 or 4 days, with the same host range. After this second blood meal, the nymphs molt into adults. Adult *I. scapularis* organisms have a narrower host range, with a preference for deer. Mating occurs on deer, and the female deposits her eggs and the cycle begins anew.[11] During their 2-year life cycle, ticks typically feed once during each of the three stages, usually the late summer for larval ticks, the following spring for nymphs, and autumn for the adults. *I. scapularis* nymphs appear to be the most important vector for transmission of *B. burgdorferi*. According to laboratory studies, a minimum of 36 to 48 hours of attachment of the tick is required for transmission. In the United States, most cases involving *B. burgdorferi* occur between May and August, which corresponds with increased outdoor human and nymphal tick activity.

Figure 1 ***Ixodes scapularis*, also known as deer tick or black-legged tick, is the vector of Lyme disease. Adult ticks are approximately 2.5 mm in size—about the size of a sesame seed.**

The risk of infection in a given area depends largely on the density of the tick population, as well as on their feeding habits and animal hosts, which have evolved differently in different locations. In the northeastern and north central United States, *I. scapularis* ticks are abundant, and a highly efficient cycle of *B. burgdorferi* transmission occurs between immature larval and nymphal *I. scapularis* ticks and white-footed mice. This results in high rates of infection in nymphal ticks and a high frequency of Lyme disease in humans during the late spring and summer months.[12,13] The proliferation of deer, which are the preferred host of the adult tick, was a major factor in the emergence of epidemic Lyme disease in the northeastern United States during the late 20th century.

I. scapularis and other ticks in the *I. ricinus* complex may transmit multiple pathogens. *I. scapularis* is also a vector for *Anaplasma phagocytophila,* which causes human granulocytic ehrlichiosis [*see 7:XVII Infections Due to Rickettsia, Ehrlichia, and Coxiella*] and *Babesia microti,* which causes babesiosis [*see 7:XXXIV Protozoan Infections*]. The proportion of *I. scapularis* or *I. ricinus* ticks coinfected with both *B. burgdorferi* and *A. phagocytophila* is generally low, ranging from less than 1% to 6% in six geographic areas. A higher prevalence of tick coinfection (26%) has been reported in Westchester County, New York. The proportion of *Ixodes* ticks coinfected with *B. burgdorferi* and *Babesia microti* has ranged from 2% in New Jersey to 19% on Nantucket Island, Massachusetts. In patients with a confirmed tick-borne infection, coinfection rates as high as 39% have been reported. The most commonly recognized coinfection in most of the eastern United States is Lyme disease and babesiosis, accounting for approximately 80% of coinfections.[14]

CLINICAL MANIFESTATIONS

Lyme disease is a progressive infectious disease with a wide array of clinical manifestations. In general, three stages of the illness can be distinguished: early localized disease, early disseminated disease, and persisting late disease.

Infection begins locally in the skin after a feeding tick inoculates *B. burgdorferi*. In most persons, the initial sign of infection is the development of erythema migrans.[15] Even at this early phase of infection, the clinical expression of the disease is highly variable. Some persons are relatively asymptomatic, whereas others experience fever, arthralgias, myalgias, conjunctivitis, meningismus, or multifocal erythema migrans, and still others develop more dramatic signs of infection, including acute meningitis, myocarditis with or without conduction block, hepatitis, myositis, or frank arthritis. Up to 50% of infected persons will progress to symptomatic late disease if not treated during the acute phase of the infection. In the chronic phase of the illness, localized inflammatory processes may occur in one or more organ systems, particularly the nervous system and the musculoskeletal system.

Erythema Migrans

The most common manifestation of early localized Lyme disease is erythema migrans, which occurs in up to 85% of patients and develops 3 to 30 days (typically within the first 7 to 10 days) after the bite. The lesion generally appears at the site of a tick bite and is frequently located around the knees, in the axilla, or in the groin.[16]

Erythema migrans usually begins as a red macule or papule, which expands over the course of days to weeks, presumably as the spirochetes spread centrifugally through the skin [*see Figure 2*]. Secondary cutaneous lesions may develop from hematogenous dissemination of spirochetes. Local symptoms include pruritus, tenderness, or paresthesias but are generally rare or absent in secondary lesions. Erythema migrans may also appear as a target lesion with variable degrees of central clearing and occasionally with vesicular or necrotic areas in the center.

In an observational cohort study in 10 endemic states, 118 patients with microbiologically confirmed erythema migrans presented a median of 3 days after symptom onset. Early erythema migrans commonly had homogeneous or central redness rather than peripheral erythema with partial central clearing. The most common associated symptoms were low-grade fever, headache, neck stiffness, arthralgia, myalgia, or fatigue.[17] Subsequent episodes of erythema migrans have been reported in patients who received appropriate antimicrobial therapy for an initial episode, whereas primary failure of antibiotics is rare, occurring in only about 0.14% of patients.[18]

Lymphocytoma

Borrelial lymphocytoma is an uncommon early manifestation of Lyme disease (occurring in approximately 5% of cases), occurring more often in children than in adults.[19] It is a tumorlike nodule that typically appears on the ear lobe, nipple, or scrotum and is characterized by a dense lymphocytic infiltrate in the dermis or subcutaneous tissue.[20] Borrelial lymphocytoma is usually caused by *B. garinii* and *B. afzelii* and is seen more frequently in Europe than in the United States. The lymphocytoma may occur with other manifestations of infection, such as meningitis, choroiditis, or arthritis. Histopathologically, lymphocytoma may be difficult to differentiate from lymphoma. IgG or IgM antibodies against *B. burgdorferi* are found in the serum of 80% of all patients with borrelial lymphocytoma. Direct detection of *B. burgdorferi* or specific DNA in lesional skin by culture or polymerase chain reaction is helpful to the diagnosis. In a study from Slovenia, 36 cases of borrelial lymphocytoma were detected during the period 1986 to 1990; patients were treated with antibiotic therapy, and all had complete recovery within an average of 3 weeks.[21]

Acrodermatitis Chronica Atrophicans

In European patients, especially elderly women with *B. afzelii* infection, a chronic, slowly progressive skin condition called acrodermatitis chronica atrophicans may develop on sun-ex-

Figure 2 **An erythema migrans lesion has enlarged over several days and now has a red border with clearing in the center.**

posed acral surfaces. The organism has been cultured from such lesions as long as 10 years after the onset of the disease.[22] These lesions may be preceded by erythema migrans and may represent a late or chronic stage of infection. Early lesions have erythematous nodules or plaques with central clearing and involve the extensor areas of the extremities or joints. Later lesions become atrophic and poikilodermatous, resembling scleroderma or lichen sclerosus et atrophicus.

Carditis

Within several weeks after the onset of Lyme disease, about 4% to 10% of untreated patients develop acute cardiac involvement—most commonly, fluctuating degrees of atrioventricular block; occasionally, acute myopericarditis or mild left ventricular dysfunction; and rarely, cardiomegaly or fatal pancarditis.[23] Diffuse T wave changes, ST segment depression, and arrhythmias also are frequently observed. Patients may complain of dizziness, palpitations, dyspnea, chest pain, or syncope.[24,25] Although temporary pacing is frequently required for complete heart block, permanent pacing is rarely needed.[26] Recovery from the acute cardiac manifestations of Lyme disease is usually complete.

In Europe, *B. burgdorferi* has been isolated from endomyocardial biopsy samples from several patients with chronic dilated cardiomyopathy.[27,28] However, this complication has not been observed in the United States.[29] A study from the Netherlands noted improvement in left ventricular ejection fraction in eight of nine *B. burgdorferi*–seropositive patients with idiopathic dilated cardiomyopathy who were treated with antibiotics.[30] Further studies are warranted to clarify the role of *B. burgdorferi* in acute and chronic heart failure.

Musculoskeletal Features

In the United States, arthritis is the predominant manifestation of disseminated *B. burgdorferi* infection, with about 60% of untreated patients developing joint manifestations, usually weeks to years after the initial infection. Months after the onset of illness, patients begin to have intermittent episodes of joint swelling and pain—primarily in the large joints and, occasionally, in the temporomandibular joint.[23] Musculoskeletal features include arthralgia; intermittent episodes of migratory arthritis, usually monoarthritis or asymmetrical oligoarthritis; and chronic arthritis, usually of the knees.[31] Patients with Lyme arthritis usually have higher *Borrelia*-specific antibody titers than patients with any other manifestations of the illness, including late neurologic manifestations.[32] In an observational cohort study of 15 patients with Lyme arthritis, fibromyalgia, or both, symptoms of Lyme arthritis resolved with antibiotic therapy, whereas symptoms of fibromyalgia persisted in 14 of 15 patients treated with antibiotic therapy.[33]

Although most patients respond favorably to antibiotic therapy, about 10% of adults and fewer than 5% of children with arthritis associated with Lyme disease develop inflammatory joint disease that persists for longer than 1 year, which may eventually lead to joint destruction. In about 10% of patients, particularly those with *HLA-DRB1*0401* or related alleles, knee arthritis persists for months or even years.[32] Autoimmunity may develop within the inflammatory milieu of affected joints in these patients because of molecular mimicry between an immunodominant T cell epitope of the outer surface protein A (OspA) of *B. burgdorferi* and human lymphocyte function–associated antigen–1, an adhesion molecule that is highly expressed on T cells in synovium.[34]

Neurologic Involvement

Lyme disease is associated with both acute and chronic neurologic abnormalities, affecting both the central and peripheral nervous systems. All the neurologic syndromes associated with *B. burgdorferi* infection can occur without previous erythema migrans.[35] Clinical data support the hypothesis that *B. burgdorferi* invades the nervous system early in the course of the infection. There is a high frequency of nonspecific complaints that may be referable to central nervous system involvement in patients with erythema migrans. In one series of 314 patients with erythema migrans, 64% had headache and 48% complained of a stiff neck.[36] Additional evidence of early invasion of the nervous system is that within the first 3 months after infection, approximately 12% to 15% of patients experience acute meningitis, cranial neuritis, or painful radiculitis, alone or in combination.[37]

The distinguishing features of meningitis in Lyme disease are evident on CSF analysis: a mild CSF pleocytosis largely consisting of polymorphonuclear leukocytes or mononuclear cells, a modest elevation of the CSF protein level, and a normal CSF glucose level. Meningoencephalitis may be a prominent feature, manifesting as difficulty with memory and concentration and emotional lability.[38] MRI abnormalities have been observed in more severely affected patients. In the absence of local antibody production, the diagnosis of chronic *B. burgdorferi* CNS infection is questionable, although this infection has been demonstrated to occur in rare cases.

Cranial neuropathies may occur with or without meningitis. Any cranial nerve may be affected by Lyme disease, but the seventh nerve (unilaterally and bilaterally) is by far the most frequently affected, with involvement in up to 10% of patients.[38] Lyme disease may be responsible for approximately 25% of new-onset Bell palsy in an endemic area, with the palsy sometimes developing before positive serology for Lyme disease.[39] Bell palsy in Lyme disease is presumably a peripheral neuropathy, given that no antibody has been found in the CSF of some patients who have been tested.

Lyme disease can cause a painful radiculitis that is manifested by neuropathic symptoms such as numbness, tingling, and burning. This radiculoneuropathy may affect the limbs or the trunk. Fifty percent of patients with this radiculitis have associated cranial nerve palsies. The peripheral nerve damage in Lyme disease is usually an axonopathy rather than a demyelinating syndrome.[40]

Acute or subacute myelitis can occur and is associated with spastic paraparesis and CSF pleocytosis.[41] In rare cases, mononeuritis and a Guillain-Barré–like syndrome have been reported. Acute painful radiculoneuritis is the most striking early-stage neurologic syndrome. In the United States, a subtle form of Lyme encephalopathy, which seems to represent CNS infection, has been reported; it manifests predominantly with cognitive abnormalities. Less common neurologic manifestations include sudden sensorineural hearing loss, cerebellitis, intracranial aneurysm, and myelitis.

DIAGNOSIS

In patients in the United States, the diagnosis of Lyme disease is usually made on the basis of the characteristic clinical findings; a history of tick exposure in an area where the disease is endemic, and, except in patients with erythema migrans, an antibody response to *B. burgdorferi* by enzyme-linked immunosorbent assay (ELISA) and Western blot (immunoblot) testing, interpreted according to the criteria of the CDC and the Association of State

and Territorial Public Health Laboratory Directors.[42,43] In endemic areas, the presence of the characteristic rash is often appropriate to trigger initiation of antibiotic therapy without serologic confirmation. Also, antibiotic treatment of early localized disease may blunt the antibody response.

Microscopy

B. burgdorferi, a loosely coiled spirochete that is approximately 0.2 µm wide and 10 to 30 µm long, is readily visible in skin-biopsy specimens observed by phase-contrast or dark-field microscopy. The organism can also be detected with acridine orange, Giemsa, or silver (Warthin-Starry or a modified Dieterle) stains or by fluorescent antibody techniques. In addition to being identified in skin, spirochetes have been observed in other tissues, such as the myocardium, synovium, and the nervous system, but the yields have been very poor because of low numbers of spirochetes. The routine use of skin biopsies of erythema migrans lesions for diagnosis of *B. burgdorferi* infection is limited by the need for special media and by the protracted periods needed for culture growth. Demonstration of *B. burgdorferi* from skin biopsies of erythema migrans by culture or PCR is generally not indicated, except perhaps in cases of reinfection when serology may not be helpful.

Culture

In patients presenting with erythema migrans, culture of the involved skin in Barbour-Stoenner-Kelly medium is virtually 100% specific and reasonably sensitive (57% to 86%) for *B. burgdorferi*.[44] The yield from plasma samples is lower, and only occasionally have CSF samples in patients with meningitis yielded culture growth.

In patients with late-stage infection who develop arthritis, PCR testing is greatly superior to culture in the detection of *B. burgdorferi* in joint fluid.[45] *B. burgdorferi* has not been isolated from the CSF of patients with chronic neuroborreliosis, and *B. burgdorferi* DNA has been detected in CSF samples in only a small number of such patients. The Lyme urine antigen test has provided grossly unreliable results and, therefore, should not be used to support the diagnosis of Lyme disease.[46]

Serology

Within 3 to 4 weeks after the onset of borrelial infection, an increase in the IgM response to one or more spirochetal antigens can be detected in most patients; the IgM response usually peaks after 6 to 8 weeks and then gradually declines. Humoral responses of IgM to other antigens gradually develop as the disease progresses. Although there are differences in antigenic responses between patients from North America and patients from Europe, antibodies against one or more of the major protein antigens (i.e., OspC [23 kd], 31 kd, 34 kd, 60 kd, or 66 kd) develop as the infection continues. Specific IgG and IgA responses gradually increase during the second and third months of infection and, once established, may remain detectable for years.

Some epitopes of antigenic components of *B. burgdorferi*, such as proteins with molecular masses of 41 kd and 60 kd, are common to *Treponema pallidum*, oral treponemes, and even *Escherichia coli*.[47] Such cross-reactivity may result in a significant titer on ELISA screening (see below). False positive reactions have also been reported when sera from patients with juvenile rheumatoid arthritis, rheumatoid arthritis, systemic lupus erythematosus, infectious mononucleosis, or subacute bacterial endocarditis were analyzed for antibodies to *B. burgdorferi*.

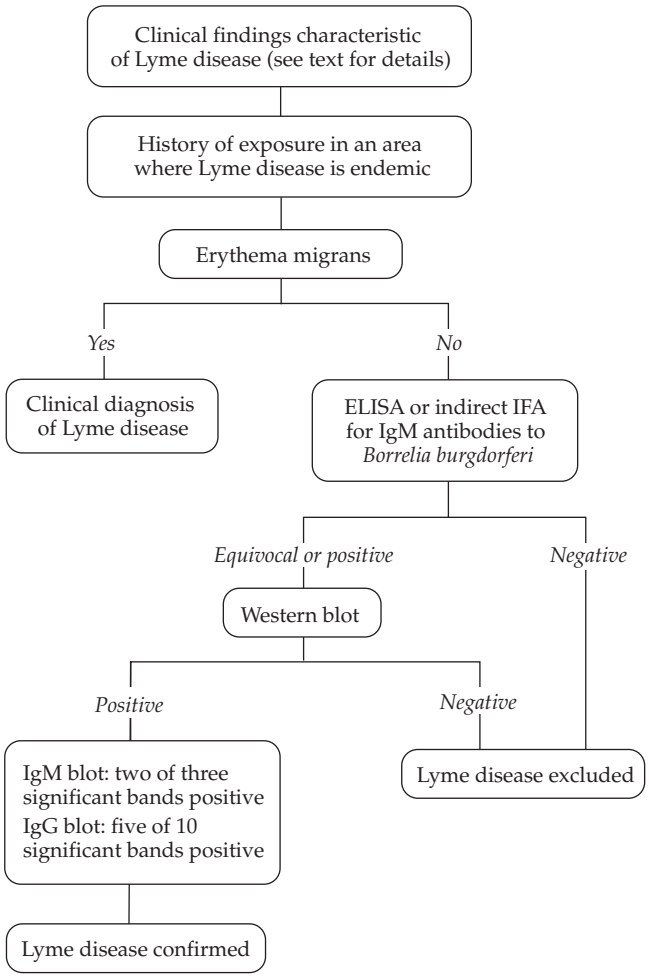

Figure 3 **Diagnosis of Lyme disease. (ELISA—enzyme-linked immunosorbent assay; IFA—immunofluorescence assay)**

Serodiagnostic tests are insensitive during the first several weeks of infection. In the United States, only about 20% to 30% of patients have positive responses, usually of the IgM isotype, during this period.[48] By convalescence, 2 to 4 weeks later, about 70% to 80% of treated patients have seroreactivity. After 1 month, the majority of patients with active infection have IgG antibody responses. In persons who have been ill for longer than 1 month, a positive IgM test result by itself is likely to be false positive; therefore, such a response should not be used to support the diagnosis in this setting.[49] In patients with acute neuroborreliosis, especially those with meningitis, the intrathecal production of IgM, IgG, or IgA antibody against *B. burgdorferi* may often be demonstrated by antibody-capture enzyme immunoassay, but this test is less often positive in patients with chronic neuroborreliosis.[50]

Two-step serologic testing Immunofluorescence assays (IFAs) and ELISAs are the two most commonly used methods for the detection of antibodies to *B. burgdorferi*. ELISAs are more sensitive than IFAs and offer the advantage of easier screening of large numbers of samples. Although *B. burgdorferi* antibody tests are potentially useful and constantly improving, they have limited sensitivity (primarily in early disease) and specificity, and they have not yet been standardized.[51] These limitations have led

to erroneous diagnoses and may have contributed to fundamental misunderstandings of Lyme disease. Therefore, a straightforward two-step serologic approach has been proposed by the CDC [*see Figure 3*]: a positive or equivocal first test, usually an ELISA or indirect IFA, is followed by an immunoblot test on the same serum sample, which can detect IgM and IgG antibodies to individual *B. burgdorferi* antigens.[42,52]

The following two criteria are used for interpretation of the immunoblot test:

- The IgM blot is positive if two of the three following bands are present: 23 kd (OspC), 39 kd, and 41 kd.
- The IgG blot is positive if five of the 10 following bands are present: 18 kd, OspC, 28 kd, 30 kd, 39 kd, 41 kd, 45 kd, 58 kd, 66 kd, and 93 kd.

If the immunoblot test result is negative, the reactive ELISA or IFA result was very probably false positive. Neither ELISA nor immunoblot testing permits detection of fourfold rises in antibody titer (seroconversion).

Some patients lack diagnostic serum levels of specific antibodies but have neurologic involvement and, as a result, have diagnostic levels of antibody in their CSF, because *B. burgdorferi* organisms reaching this immunologically privileged site remain viable and induce a local immune response.[53,54] Intrathecal production of antibody against *B. burgdorferi* may be demonstrated by using the following formula:

$$\frac{\text{Anti–}B.\ burgdorferi\ \text{titer in CSF} \times \text{serum IgG concentration}}{\text{Anti–}B.\ burgdorferi\ \text{titer in serum} \times \text{CSF IgG concentration}}$$

If the ratio is greater than 1, localized production of anti-*Borrelia* antibodies has occurred.

After antibiotic treatment, antibody titers fall slowly, but IgG and even IgM responses may persist for many years after treatment. Thus, even an IgM response cannot be interpreted as a demonstration of recent infection or reinfection unless the appropriate clinical characteristics are present.

New serologic tests An ELISA has been developed on the basis of a conserved immunodominant portion (C6) of the *B. burgdorferi* variable surface antigen (VlsE).[55] This assay can be used in vaccinated and unvaccinated patients. The C6 Lyme ELISA is important because it detects both IgM and IgG antibodies in patients with Lyme disease but not in uninfected vaccine recipients.[56] This assay, when used together with an assay for another immunodominant antigen from OspC, may have the same level of specificity and sensitivity as the two-step approach (see above).[57]

TREATMENT

The primary goals of therapy for Lyme disease are the control of inflammation and the eradication of the infection. Lyme disease is most responsive to antibiotics early in the course of the disease: erythema migrans typically resolves promptly and later-stage disease is prevented.[58,59] Early localized infection that is limited to a single skin lesion, with mild or no systemic symptoms, is uniformly responsive to short-course oral therapy with a number of agents [*see Table 1*]. Of the antibiotics studied to date, the most effective agents for this stage of disease have been amoxicillin, 500 mg three times a day; doxycycline, 100 mg twice daily; and cefuroxime axetil, 500 mg twice a day. Each of these agents is taken for 14 to 21 days.[60] An advantage of doxycycline is its efficacy against human granulocytic ehrlichiosis, a possible coinfection. Amoxicillin should be used in children and pregnant women. About 10% of patients with early-stage Lyme disease experience a Jarisch-Herxheimer reaction (higher fever, redder rash, or greater pain) during the first 24 hours of antibiotic therapy. Patients should be warned of the reaction; if it occurs, the symptoms may be treated with anti-inflammatory agents

Table 1 Antibiotic Therapy for Lyme Disease

Disease Stage or Manifestation	*Agents and Dosage**	*Comments*
Early localized infection with a single skin lesion and mild or no systemic symptoms	Amoxicillin, 500 mg p.o., t.i.d. × 14–21 days Doxycycline, 100 mg p.o., b.i.d. × 14–21 days Cefuroxime axetil, 500 mg p.o., b.i.d. × 14–21 days	Doxycycline is also effective for human granulocytic ehrlichiosis, a possible coinfection; amoxicillin should be used in children and pregnant women; Jarisch-Herxheimer reactions occur during the first 24 hr of antibiotic therapy in about 10% of patients
Carditis with AV nodal block (PR interval > 0.3 sec)	Ceftriaxone, 2 g/day × 14–21 days Penicillin G, 20 million units in four divided doses a day × 14–21 days	Oral regimens are for first-degree AV block < 0.3 sec; for higher-degree AV block (> 0.3 sec), intravenous administration should be used for at least part of the treatment course
Facial palsy with normal CSF findings	Amoxicillin, 500 mg p.o., t.i.d. × 21–30 days Doxycycline, 100 mg p.o., b.i.d. × 21–30 days Cefuroxime axetil, 500 mg p.o., b.i.d. × 21–30 days	Most experts prefer a 30-day course of treatment to reduce the likelihood of late neurologic relapses
Meningitis and other neurologic disorders	Ceftriaxone, 2 g/day × 14–28 days Penicillin G, 20 million units in four divided doses a day × 14–28 days	Clearing of inflammatory CSF findings may lag behind bacteriologic cure
Arthritis	Amoxicillin, 500 mg p.o., t.i.d. ≥ 2 mo Doxycycline, 100 mg p.o., b.i.d. ≥ 2 mo Cefuroxime axetil, 500 mg p.o., b.i.d. ≥ 2 mo Ceftriaxone, 2 g/day ≥ 1 mo Penicillin G, 20 million units in four divided doses a day ≥ 1 mo	Arthritis may persist despite appropriate antibiotic treatment; if PCR tests of joint fluid are negative, patients with persistent arthritis may be treated with anti-inflammatory agents or arthroscopic synovectomy

*All treatment is with single agents.
AV—atrioventricular CSF—cerebrospinal fluid PCR—polymerase chain reaction

such as aspirin. Although carditis resolves spontaneously, patients who have atrioventricular nodal block with a PR interval greater than 0.3 second should receive an intravenous regimen as at least part of the antibiotic course (e.g., ceftriaxone, 2 g/day, or penicillin G, 20 million units in four divided doses a day) for 14 to 21 days. Cardiac monitoring is recommended, but the insertion of a permanent pacemaker is not necessary.[61]

Isolated facial palsies resolve completely or almost completely in nearly all patients. Patients who have facial palsy should undergo a careful neurologic evaluation, including a lumbar puncture and CSF examination. If facial palsy is the only clinical abnormality and CSF findings are normal, current practice is to administer oral antibiotics for 21 to 30 days. Most experts prefer a 30-day course of treatment, however, because of the late neurologic relapses that occasionally occur after shorter courses of therapy. Patients with evidence of active neuroborreliosis should receive a 2- to 4-week course of intravenous ceftriaxone or penicillin G.

Arthritis does not always respond to antibiotic therapy.[62] About 10% of patients in the United States have persistent joint inflammation for months or even several years after 2 months or more of oral antibiotic therapy or 1 month or more of intravenous antibiotic therapy.[62] Patients who have persistent arthritis despite appropriate treatment and negative PCR test results of joint fluid may be treated with anti-inflammatory agents or arthroscopic synovectomy.

B. burgdorferi has not been linked statistically to congenital anomalies, and no increased risk of an adverse outcome of pregnancy has been associated with asymptomatic seropositivity or history of previous Lyme disease.[63] It is appropriate to maintain a lower threshold for institution of aggressive antibiotic therapy for suspected Lyme disease during pregnancy, but women should be reassured that no cases of fetal Lyme disease have occurred with currently recommended antibiotic regimens.

Despite receiving appropriate treatment for Lyme disease, a small percentage of patients continue to have subjective symptoms—primarily, musculoskeletal pain, neurocognitive difficulties, or fatigue—that may last for years. This disabling syndrome, which is sometimes called chronic Lyme disease, is similar to chronic fatigue syndrome or fibromyalgia.[64] In a large study, however, pain and fatigue were no more common in Lyme disease patients than in age-matched control subjects who had not had the disease.[65] In a study of patients with post–Lyme disease syndrome who received either intravenous ceftriaxone for 30 days, followed by oral doxycycline for 60 days, or intravenous and oral placebo preparations for the same duration, there were no significant differences between the two study arms in the percentage of patients who said that their symptoms had improved, gotten worse, or stayed the same.[66] There is no evidence that treatment of asymptomatic seropositive patients is beneficial.

PREVENTION

Primary prevention strategies will help reduce the number of Lyme disease cases, and some strategies may also prevent other tick-borne illnesses, including babesiosis and human granulocytic ehrlichiosis in the United States and tick-borne encephalitis in Europe. The first line of defense is avoidance of tick-infested habitats when possible; use of personal protective measures (e.g., repellents and protective clothing) in tick-infested habitats and checking for and removing attached ticks; and modifications of landscapes in or near residential areas. Tick control (burning or removing vegetation, acaricide use, and deer elimination) reduces *I. scapularis* populations by up to 94%, and acaricide application to wildlife decreases nymphal *I. scapularis* populations by up to 83%. Transmission of borrelial infection requires a period of 24 to 72 hours of tick attachment. Therefore, removal of ticks within 24 hours will usually prevent infection. If an engorged tick is found, a single 200 mg dose of doxycycline administered within 72 hours is effective at preventing the development of Lyme disease.[67] A vaccine for Lyme disease (LYMErix), consisting of recombinant OspA and approved by the Food and Drug Administration for persons 15 to 70 years of age, was introduced in the United States in 1998 but was withdrawn from the market in 2002 because of low sales.

Leptospirosis

Leptospirosis is a worldwide zoonosis acquired by contact with infected animals or by exposure to contaminated soil or freshwater. A variety of animals can be chronically infected and shed viable organisms that can persist in the environment, leading to human infection. The importance of environmental and occupational exposure is reflected by several of the synonyms for this disease: rice-field fever, cane-cutter fever, swamp fever, and mud fever. Clinically, leptospirosis can range from asymptomatic infection to severe multisystem disease with significant mortality. Leptospirosis cases are often undiagnosed because of the protean manifestations of infection, lack of awareness by clinicians, and limited diagnostic tools.[68]

MICROBIOLOGY

The genus *Leptospira* consists of tightly coiled spirochetes that are thin (0.1 μm) and vary in length from 6 to 20 μm [*see Figure 4*]. *Leptospira* can be cultured on artificial media, but initial cultures may take weeks to grow.[69]

In the past, the genus *Leptospira* was divided into two species, the pathogenic *L. interrogans* and the nonpathogenic *L. biflexa,* on the basis of serologic reactivity to the lipopolysaccharide O antigen. A large number of serovars have been identified within each of these species. The classification of the genus *Leptospira* has undergone extensive reorganization with the application of DNA-relatedness techniques. Thirteen named species and four unnamed genomospecies are now recognized.[70] The complete genetic sequence of *L. interrogans* serovar *lai* has been determined.[71]

EPIDEMIOLOGY

A wide variety of mammals can become infected with *Leptospira* and serve as reservoir hosts. Particularly important in human infection are rodents, livestock, and pets.[72,73] Animals are often infected early in life and develop persistent infection of the proximal renal tubules. Infected animals are frequently asymptomatic and shed viable spirochetes in the urine for extended periods, contaminating water and soil. *Leptospira* can persist in a warm, moist environment for several weeks—a fact that correlates with the higher incidence of human infection in tropical areas, particularly during the rainy season. In temperate regions, where survival of the organism in the environment is limited by temperature, the incidence of leptospirosis is seasonal, peaking in the summer and early fall. In the United States, the greatest number of cases have been reported in Hawaii, but cases occur throughout the country. Studies have demonstrated leptospiruria in 41 of 500 healthy dogs in Kansas and 35% of Texas cattle.[74,75]

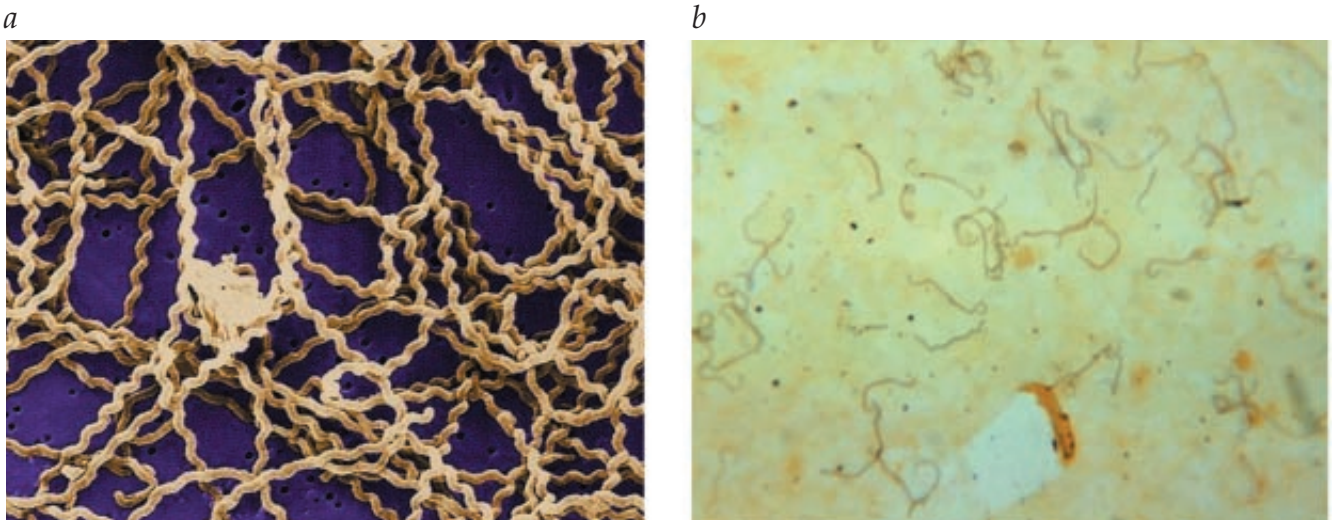

Figure 4 **(*a*) A scanning electron micrograph reveals numerous corkscrew-shaped *Leptospira* spirochetes atop a 0.1 µm polycarbonate filter. (*b*) *Leptospira* spirochetes are visible on a photomicrograph of a liver smear, using a silver-staining technique, taken from a patient with a fatal case of leptospirosis.**

Human infection can result from direct contact with urine or tissues of infected animals; such exposure occurs in veterinarians, dairy workers, hunters, and animal handlers. The more common exposure is to contaminated water and soil.[76] Outbreaks of leptospirosis have been reported related to ecotourism and adventure sporting events.[77,78]

PATHOGENESIS

Leptospires enter the body through minor cuts and abrasions, mucous membranes, and conjunctiva and by inhalation of infected aerosols. Infection spreads throughout the body via the bloodstream. Motility and the ability to migrate through tissues are felt to be important to the pathogenesis of *Leptospira*, allowing the spirochete to establish initial infection and to disseminate to sites of end-organ damage.[71] A variety of hemolysins and phospholipases and a sphingomyelinase have been identified and may have a role in the ability of this organism to move through tissues. The mechanism by which *Leptospira* causes tissue damage is not fully understood, but a systemic vasculitis may facilitate migration of the organism into a variety of tissues, accounting for the broad spectrum of clinical illness.[79] In addition, the host immune response is felt to contribute to tissue damage and the clinical severity of disease.[80] In animals with experimental infections that mimic the more severe icteric Weil disease and hemorrhagic syndromes, the livers and kidneys demonstrate large numbers of leptospires and associated tissue inflammation. Several leptospiral proteins have been identified with homology to host proteins important in hemostasis, which may activate hemolytic pathways and contribute to the hemorrhagic complications seen in severe disease.[81]

DIAGNOSIS

Clinical Manifestations

Infection with *Leptospira* can result in a spectrum of clinical manifestations. Asymptomatic infection is not uncommon, and subclinical or very mild disease that does not lead to medical attention has been reported in several studies.[82,83] When symptomatic, leptospirosis has classically been described as a biphasic illness, with a self-limited septicemic phase followed (although not invariably) by an immune phase. Symptoms of infection develop after an incubation period of 2 to 20 days (mean, 10 days). Illness begins abruptly with high fevers, chills, rigors, headache, myalgias, abdominal pain, nausea, vomiting, diarrhea, and cough. Conjunctival suffusion and muscle tenderness, particularly of the calf and lumbar areas, have been cited as distinctive examination findings. Less common physical findings include lymphadenopathy, splenomegaly, and hepatomegaly.[84] The acute illness lasts 5 to 7 days. *Leptospira* can be recovered from the blood and cerebrospinal fluid during the first week of illness, although symptoms of meningitis are not prominent.

The septicemic phase may be followed by a period of improvement in symptoms and absence of fever lasting several days. The onset of the immune phase of illness coincides with the development of specific antibody to *Leptospira* and the clearance of organisms from the blood and CSF. Leptospires remain detectable in the kidney, urine (leptospiruria), and aqueous humor for several weeks. The immune phase of leptospirosis is often more severe than the septicemic phase and is potentially fatal. The immune phase lasts 4 to 30 days and is characterized by aseptic meningitis, uveitis, iritis, rash, hemorrhagic pneumonitis, and hepatic and renal involvement.[71,84-88] Mortality in patients with severe disease results from multiorgan failure and pulmonary hemorrhage.

The septicemic and immune phases of leptospirosis are illustrated by the meningeal findings. Early in infection, patients often have severe retro-orbital headaches and photophobia. CSF studies reveal a neutrophilic pleocytosis, with counts ranging from 10 to 1,000 cells/µl. *Leptospira* can often be demonstrated in the CSF by culture and PCR. During the immune phase of illness, approximately 25% of patients will develop an aseptic meningitis characterized by headache, vomiting, and signs of meningeal irritation. CSF analysis reveals a lymphocytic pleocytosis, and *Leptospira* can no longer be isolated.

Acute renal failure is reported in 16% to 40% of cases and is associated with tubular necrosis and interstitial nephritis. Jaundice develops in approximately 40% of patients and does not seem to result from hepatocellular damage but, rather, from cholestasis.[84] Serum bilirubin levels may be very elevated (usually to less than 20 mg/dl), with more moderate elevations in

transaminase concentrations (less than 200 IU/L) and mild elevation of the alkaline phosphatase level.[89] Bilirubin levels may take days to weeks to normalize. Pulmonary involvement occurs in up to 70% of cases, and symptoms may range from cough, dyspnea, and hemoptysis to respiratory failure. Severe hemorrhagic pneumonitis and acute pulmonary distress syndrome may occur in the absence of hepatic and renal failure.[90] Radiographs reveal patchy alveolar infiltrates that may progress to large areas of consolidation that are thought to represent pulmonary hemorrhage. Significant pulmonary involvement is a poor prognostic sign and is associated with increased mortality.[84]

Weil disease is the most severe form of *Leptospira* infection, with a mortality of up to 40%. It may develop during the immune phase of a biphasic illness or progress directly from the acute phase without the characteristic brief improvement in symptoms to fulminant illness. Weil disease is characterized by high fevers and the rapid onset of liver failure, acute renal failure, hemorrhagic pneumonitis, cardiac arrhythmias, and circulatory collapse.[71,91]

General Laboratory Studies

During the initial septicemic phase of illness, results of routine laboratory tests are not specific; the neutrophil count may be normal or elevated. During the immune phase of illness, the laboratory values are consistent with the specific end-organ dysfunction. Liver dysfunction is often characterized by markedly elevated serum bilirubin levels with less pronounced increases in serum transaminase and alkaline phosphatase levels. Renal function can deteriorate rapidly, with evidence of interstitial nephritis on biopsy. Renal injury may be compounded by associated hypovolemia. In patients with evidence of meningitis, CSF assays reveal a neutrophilic pleocytosis early and, later, a lymphocytic pleocytosis (usually below 500 cells/μl); modest elevation in protein levels (50 to 100 mg/ml); and a normal glucose level.

Specific Laboratory Studies

Leptospirosis can be diagnosed in three ways: by the direct demonstration of organisms in blood, urine, or tissues; by culture; or serologically.

Microscopy Dark-field microscopy of blood or urine and silver staining of infected tissues have been used to directly visualize leptospires, but both techniques have limited sensitivity and specificity.[92] Approximately 10^4 leptospires/ml are necessary for one cell/field to be visible by dark-field microscopy.[93] Immunostaining has been shown to enhance the ability to directly demonstrate leptospires in tissue; however, the reagents are not commercially available.[94,95]

Culture *Leptospira* grows slowly in the laboratory, which can limit the utility of culture for diagnosis. *Leptospira* can be isolated from a variety of body fluids using commercially available semisolid, albumin-polysorbate media. Antibiotic use may limit the sensitivity of culture, and the timing of specimen collection is important. During the first 7 to 10 days of illness, the spirochete can be recovered from blood, particularly during periods of fever, and from CSF. The culture media should be inoculated with several drops of the patient's blood or CSF at the bedside. Alternatively, blood specimens can be collected in heparin or sodium oxalate (citrate anticoagulation is inhibitory); these should be inoculated within 24 hours. Recovery of leptospires from the urine begins after the first week of illness, and as with blood and CSF, inoculation of media should be done promptly (in less than 1 hour after collection). The cultures are incubated at 30° C and are not reported as negative until after a minimum of 6 to 8 weeks. Identification at the species level is available from a few reference laboratories.

Serology The mainstay for the diagnosis of leptospirosis has been by serology, using a microscopic agglutination test (MAT).[96] The end point is the highest dilution of serum in which 50% agglutination occurs. The MAT uses live organisms, which are coincubated with the patient's serum and examined by dark-field microscopy for agglutination. A fourfold rise in paired titers or a single titer of greater than 1:800 in a patient with an appropriate history supports the diagnosis. Many patients will have a negative test result during the acute illness, and seroconversion may be delayed as long as 30 days after the onset of clinical illness. The MAT is technically complex to perform and to interpret. In addition, live cultures must be maintained for all the serovars required as antigens.

Because of the complexity of the MAT, rapid screening tests for leptospiral antibody have been developed. IgM antibody becomes detectable during the first week of illness and is more sensitive than MAT when the first specimen is taken early in the illness. Commercially available IgM dipstick assays have been shown to perform well.[97,98]

DNA amplification An attractive method to confirm a diagnosis of leptospirosis is PCR, which is more sensitive than culture and is particularly useful in early infection, before significant antibody titers develop. *Leptospira* DNA has been amplified from blood, urine, and various tissues.[94,99] However, the PCR test is currently limited to research laboratories.

TREATMENT

Antibiotic therapy does not appear to have a clear advantage over placebo for treatment of leptospirosis but does tend to reduce mortality, duration of fever, length of hospitalization, and extent of leptospiruria.[100] Most practitioners treat patients with severe disease with parenteral penicillin (1.5 million units every 6 hours), ampicillin (1 g every 6 hours), or ceftriaxone (1 g daily), each for 7 days. Mild infections can be treated with oral doxycycline (100 mg every 12 hours), ampicillin, or amoxicillin. Jarisch-Herxheimer reactions have been reported after treatment with penicillin and ampicillin.[101,102]

PREVENTION

Prevention of leptospirosis can be achieved by limiting high-risk exposure with appropriate protective measures. These include not swimming in potentially contaminated freshwater, wearing rubber gloves and goggles when handling animals, and not walking barefoot. Weekly doxycycline prophylaxis has been shown to be effective at preventing symptomatic infection in persons at high risk for exposure.[103]

Relapsing Fever

Relapsing fever, caused by spirochetes of the *Borrelia* genus, is a febrile illness characterized by recurrent episodes of fever and septicemia separated by afebrile periods. Two forms of the disease are recognized: louse-borne and tick-borne.

Figure 5 ***Ornithodorus*, or soft tick, is the vector of the *Borrelia* species that causes tick-borne relapsing fever. Adult ticks are approximately 2.5 mm in size—about the size of a sesame seed.**

EPIDEMIOLOGY

Louse-borne relapsing fever (LBRF) is caused by infection with *B. recurrentis*. This spirochete is transmitted from person to person by the human body louse (*Pediculus humanus*), and humans are the only known reservoir for this organism.[104] LBRF usually occurs in epidemics that are associated with social catastrophes, such as war and famine, which foster the conditions (e.g., crowding and poor hygiene) that allow lice to flourish and spread from person to person. In addition, LBRF is endemic in areas of central and eastern Africa and Peru.[105] Humans become infected by crushing the lice, which releases the spirochetes and permits them to penetrate the skin or mucous membranes.

Tick-borne relapsing fever (TBRF) is caused by at least 15 different species of *Borrelia*, each of which is associated with a distinct member of the soft ticks of the genus *Ornithodoros*. In contrast to *Dermacentor* and *Ixodes* ticks, which are teardrop shaped with mouth parts visible dorsally, *Ornithodoros* ticks have an oval body shape and mouth parts located on the ventral surface (not visible dorsally) [*see Figure 5*]. Adult *Ornithodoros* ticks are about the size of a sesame seed. Animal reservoirs for these *Borrelia* species include rodents and small animals, such as squirrels, rabbits, chipmunks, owls, and lizards. *Ornithodoros* ticks are obligate blood feeders that typically inhabit caves, decaying wood, rodent burrows, and animal shelters. Their bite often goes undetected because they feed rapidly (over 5 to 20 minutes) at night and have a painless bite.[106] Infection of humans occurs when the tick releases saliva or excrement during feeding. TBRF has been reported worldwide, with the exception of Antarctica, Australia, and certain areas in the southwestern Pacific. Most cases in the United States occur west of the Mississippi River, particularly in the mountain and high-desert areas.[107] Human infection occurs with activity that brings the person into the tick's environment (e.g., camping and cave exploration).

PATHOGENESIS

After entering the bloodstream, *Borrelia* spirochetes multiply and can reach levels of 10^5 to 10^8 organisms/μl. These periods of spirochetemia are associated with fever and systemic symptoms. With the development of a specific antibody response, the spirochetes are cleared from the blood, becoming sequestered in internal organs, and patients become asymptomatic. In response to immune pressure, the *Borrelia* organisms undergo modifications of their outer-surface proteins that allow the spirochetes to reemerge into the circulation; reemergence results in recurrence of symptoms.[108] This process of antigenic variation in response to specific antibody formation can occur for a number of cycles and is responsible for the relapsing course of clinical disease. The number of febrile relapses is higher for tick-borne infection than for louse-borne infection.

CLINICAL MANIFESTATIONS

The incubation period of relapsing fever can range from 4 to 18 days and averages about 1 week. In both TBRF and LBRF, illness begins with the abrupt onset of fevers (usually above 39° C [102.2° F]), rigors, myalgias, arthralgias, and severe headache.[107,109] Physical findings include conjunctival suffusion, petechiae, abdominal tenderness with hepatosplenomegaly, and altered sensorium. A truncal rash that can be petechial, macular, or papular is common during the primary febrile episode. Almost a third of patients develop neurologic complications, including meningitis, cranial nerve palsies, coma, and seizures.

The primary febrile episode is unremitting until it terminates abruptly after 3 to 6 days. After a period of well-being lasting 7 to 10 days, symptoms recur. Each relapse is usually shorter in duration and less severe in intensity. LBRF often is associated with a single relapse, whereas TBRF often is associated with multiple symptomatic relapses.

Mortality from relapsing fever ranges from 2% to 40% and is higher with LBRF. Death is often from complications of myocarditis, with associated arrhythmias, hepatic failure, and cerebral hemorrhage.

DIAGNOSIS

The febrile periods of illness are associated with high-level spirochetemia, and dark-field microscopy or Giemsa or Wright staining of blood smears can directly demonstrate *Borrelia* [*see Figure 6*]. Detection of spirochetes is improved with lysed thick smears or acridine orange staining.[110,111] Spirochetes are rarely seen on blood smears obtained when the patient is afebrile. Culture is difficult and not readily available. Serology is of limited value, in part because of the antigenic variability of the organisms. Currently available assays target antigens common to other spirochetes and bacteria and do not have a high sensitivity. Serologic tests for both syphilis and Lyme disease may be positive.[112]

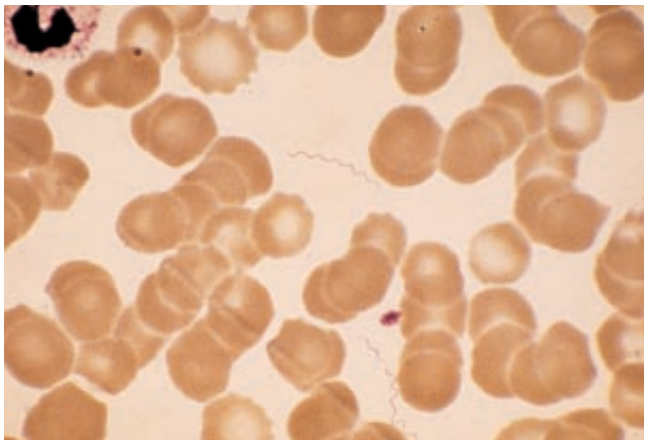

Figure 6 **In this thin Wright stain of peripheral blood from a patient in the febrile stage of relapsing fever, several spirochetes can be seen.**

TREATMENT

The *Borrelia* species that cause relapsing fever are susceptible in vitro to penicillins, tetracyclines, macrolides, cephalosporins, and chloramphenicol.[113] LBRF can be successfully treated with a single oral dose of 500 mg of tetracycline. Young children and pregnant women may be treated with a single dose of erythromycin (500 mg).[114] TBRF requires a 5- to 10-day course of antibiotics; shorter courses of treatment are associated with a higher rate of treatment failures. Tetracycline and erythromycin are felt to be equally effective. In patients with meningitis or encephalitis, a 14-day course of parenteral penicillin G, ceftriaxone, or cefotaxime is generally used. Jarisch-Herxheimer reactions are common within the first several hours after initiating antibiotic therapy and may be severe, with rigors, high fever, and hypotension. For this reason, it is recommended that all patients be kept under observation for several hours after the first dose of antibiotics.

Rat-Bite Fever

Rat-bite fever is a systemic febrile illness that results from infection with *Streptobacillus moniliformis* in North America and Europe and with *Spirillum minus* in Asia. These bacteria are transmitted to humans by the bite of a rat or other small rodent. Illnesses from the two organisms are similar, but each has unique clinical features [*see Table 2*].

Table 2 Characteristics of Rat-Bite Fever

	Streptobacillus moniliformis *Infection*	Spirillum minus *Infection*
Incubation period	10 days (1–22 days)	1–4 wk
Bite site	Healed by the time symptoms appear	Swollen, painful; may ulcerate
Onset	Chills, fever, joint symptoms	Fever without joint symptoms
Joint symptoms	Asymmetrical polyarthritis common; occasional frank septic arthritis	Usually absent
Course	Relapsing course uncommon	Relapsing course common

STREPTOBACILLUS MONILIFORMIS INFECTION

S. moniliformis is a pleomorphic gram-negative bacillus that is frequently part of the nasopharyngeal flora of rats and other small rodents.[115] Infection typically is transmitted by the bite or scratch of rats (also mice and squirrels) or by carnivores that prey on rodents. Despite the term rat-bite fever, approximately 30% of rat-bite fever cases occur in patients who have no history of being bitten by rats. Transmission may occur from handling rats at home and the workplace (pet shops, laboratories). Consequently, rat-bite fever should be in the differential diagnosis of unexplained febrile illness or sepsis in patients with any history of rat exposure. Illness can also result from oral ingestion of the organism—for example, eating food that is contaminated with rodent droppings (Haverhill fever).

Clinical Features

The usual incubation period after a rodent bite is less than 10 days (range, 1 to 22 days). Onset of illness is abrupt, with fever, chills, headache, vomiting, and severe migratory arthralgias and myalgias.[116] In contrast to *S. minus* infection, ulceration at the initial bite site and regional lymphadenopathy are usually absent with *S. moniliformis* infection. Within several days after the onset of the fever, a nonpruritic, maculopapular, petechial, vesicular or pustular rash develops on the extremities, with involvement of the palms and soles. An asymmetrical polyarthritis occurs in a significant number of patients; frank septic arthritis may develop. The large joints are most commonly involved (i.e., knees, ankles, wrists, shoulders, and hips).[117]

Fever associated with *S. moniliformis* infection tends to subside after several days, even without specific therapy. The other clinical manifestations usually resolve over the next several weeks. Rare, potentially fatal complications include cardiac involvement (e.g., endocarditis, myocarditis, and pericarditis), meningitis, pneumonia, and abscesses in a variety of solid organs. Two cases of fulminant sepsis and death in previously healthy persons have been reported.[118]

Diagnosis

S. moniliformis can be readily grown using enriched media. The mainstay of diagnosis is culture. In addition, pleomorphic gram-negative bacilli can be demonstrated on Gram stains of blood, joint fluid, and abscess aspirates. Antibody detection by ELISA and PCR of bacterial 16S ribosomal RNA in tissue samples have been described, but these tests are currently still limited to research centers.[119]

SPIRILLUM MINUS INFECTION

S. minus, a short, thick, gram-negative, tightly coiled spirochete, is the cause of rat-bite fever in Asia. Approximately 25% of rats in endemic areas are carriers of *S. minus,* and the major route of transmission of infection to humans is through the occurrence of rat bites.[120]

Clinical Features

The original rat bite heals promptly, but 1 to 4 weeks later, the site of the bite becomes swollen, indurated, and painful, and it may ulcerate. In contrast to *S. moniliformis* infection, *S. minus* infection usually includes regional lymphadenitis. Headache, fever, chills, and malaise accompany the formation of the ulcer.[121] A sparse, dusky-red maculopapular rash appears on the trunk and extremities in many cases. The severe arthritis and myalgias seen in *S. moniliformis* infection are rare in disease caused by *S. minus*.

Symptoms of *S. minus* infection subside after a few days but recur several days later. Without specific antibiotic therapy, fevers lasting 3 to 4 days recur at regular intervals between afebrile periods lasting 3 to 9 days. This relapsing course can persist for several months; in rare instances, fever relapses have occurred for a year or more. More serious complications include endocarditis, myocarditis, meningitis, conjunctivitis, hepatitis, and pleural effusions. Mortality without antibiotic therapy ranges from 6% to 10%.

Diagnosis

Leukocytosis is often present with *S. minus,* and up to 50% of patients will have a false positive test for syphilis. *S. minus* cannot be grown on artificial media. Initial diagnosis relies on visualization of spirochetes in blood, exudates, or lymph node tissue on culture staining or dark-field microscopy. Intraperitoneal inoculation of mice has been used to establish the diagnosis.[121,122] No specific serologic test is available.

TREATMENT

Both *S. moniliformis* and *S. minus* infections are effectively treated with penicillin given for 10 to 14 days.[123] Initial therapy for severely ill patients should be parenteral, but once the patient becomes stable, the course may be completed with oral penicillin or ampicillin. A Jarisch-Herxheimer reaction has been reported with initial therapy for *S. minus* infection. Oral tetracycline is appropriate for penicillin-allergic patients.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VIII INFECTIONS DUE TO ESCHERICHIA COLI AND OTHER ENTERIC GRAM-NEGATIVE BACILLI

Michael S. Donnenberg, m.d.

This chapter describes infections caused by *Escherichia coli* and related members of the family Enterobacteriaceae, excluding genera that principally cause enteric infections. Infections caused by *Salmonella, Shigella*, and *Yersinia* are described elsewhere [*see 7:IX Infections Due to the Enteric Pathogens Campylobacter, Salmonella, Shigella, Yersinia, Vibrio, and Helicobacter*]. The family Enterobacteriaceae comprises facultative anaerobic gram-negative bacilli that ferment sugars. These organisms are often motile because of the presence of peritrichous flagella (i.e., flagella that are distributed around the entire cell). Many Enterobacteriaceae species reside principally in the gastrointestinal tract of vertebrates, though some are found primarily in the environment. They are oxidase negative and catalase positive and are capable of reducing nitrate to nitrite. They cause a variety of diseases, including diarrhea, urinary tract infections (UTIs), and nosocomial infections.

Escherichia coli Infections

E. coli, the most common facultative anaerobe in the human intestine, is distinguished from other members of the family Enterobacteriaceae primarily on the basis of *E. coli's* ability to ferment lactose and to produce indole and its inability to hydrolyze urea. Several virulence factors are shared by most members of the species; these include the ability to produce a highly reactive lipopolysaccharide in the cell wall, the ability to produce type 1 mannose-binding fimbriae, and, in many strains, the ability to produce an antiphagocytic capsule and to sequester iron.

E. coli and *Salmonella* diverged from a common ancestor about 100 million years ago.[1] Ample time for diversifying selection and a prodigious capacity for genetic exchange have fostered a tremendous degree of genetic diversity in *E. coli* strains. Thus, it is not surprising that this species has the ability to cause a diverse array of infectious diseases. In fact, the organisms that are commonly referred to as *Shigella* are actually members of the species *E. coli*,[2] but because of historical and clinical considerations, they are often discussed separately [*see 7:IX Infections Due to the Enteric Pathogens Campylobacter, Salmonella, Shigella, Yersinia, Vibrio, and Helicobacter*]. The ability of *E. coli* to cause a variety of clinical syndromes by a plethora of mechanisms is entirely dependent upon unique virulence attributes that are encoded by distinct sets of virulence genes. Each group of *E. coli* that causes a particular clinical syndrome by a recognized pathogenic mechanism may be referred to as a pathotype [*see Table 1*]. With the advent of genomic sequencing, it has become evident that different strains of *E. coli,* which are so alike in most characteristics that they could easily be regarded as identical in clinical microbiology laboratories, are remarkably different in genetic content. For example, a strain isolated from a woman with pyelonephritis, a strain isolated from a child with hemorrhagic colitis, and a laboratory strain originally isolated from an asymptomatic volunteer share only 39% of their genes; in contrast, 47% of the total number of genes in the three strains is unique to one strain only.[3,4] It is not known what roles the overwhelming majority of these genes play in the biology of the organism or in the pathogenesis of infections.

Because each pathotype of *E. coli* produces disease that has more or less distinct epidemiologic, pathogenetic, and clinical features, the discussion of specific pathotypes is organized on the basis of whether the infections caused by those pathotypes occur within or outside of the GI tract.

DIARRHEA

Six pathotypes of *E. coli* cause diarrhea [*see Table 1*].[5] Of these, the epidemiologic, pathogenetic, and clinical features of enteroinvasive *E. coli* are the same as those of *Shigella,* and they are described elsewhere [*see 7:IX Infections Due to the Enteric Pathogens Campylobacter, Salmonella, Shigella, Yersinia, Vibrio, and Helicobacter*].

Diarrhea Due to Enterotoxigenic E. coli

Epidemiology Enterotoxigenic *E. coli* (ETEC) is a common cause of watery diarrhea in children in developing nations and in people of all ages who visit these countries. ETEC infections are spread through ingestion of contaminated food and water in regions where sanitation is inadequate. A relatively large inoculum is required to produce illness; therefore, person-to-person transmission is not significant for this organism.

Pathogenesis ETEC produces either a heat-labile toxin (LT), a heat-stable toxin (ST), or both. LT has the same three-dimensional structure, receptor, and mechanism of action as cholera toxin [*see 7:IX Infections Due to the Enteric Pathogens Campylobacter, Salmonella, Shigella, Yersinia, Vibrio, and Helicobacter*]. Like cholera toxin, LT toxin induces a chain of events that leads to an elevation in the intracellular concentration of cyclic adenosine monophosphate (cAMP) and the opening of the cystic fibrosis transmembrane conductance regulator [*see Figure 1*]. The efflux of chloride ions into the intestinal lumen is accompanied by sodium ions and water, and diarrhea ensues. ST is a small disulfide-rich peptide that resembles the endogenous hormone guanylin. Like its homologue, ST causes increases in the levels of cyclic guanosine monophosphate (cGMP), which also lead to electrolyte efflux and fluid efflux through the cystic fibrosis transmembrane conductance regulator. For these toxins to reach their targets in sufficient quantity and for a sufficient duration to induce symptoms, the organisms must adhere to the intestinal mucosa.[6] This binding is accomplished through an antigenically and morphologically diverse array of pilus and nonpilus adhesins known as colonization factor antigens.[5]

Diagnosis After ingestion of food or water that is contaminated with large numbers of ETEC organisms, there is an incubation period of 0 to 2 days before the onset of symptoms. The disease begins abruptly with the onset of watery diarrhea without blood or mucus. Nausea, vomiting, abdominal cramps, and fever are rarely prominent. The disease is self-limited, lasting 3 to 5 days in travelers.[5] The endemic disease is sometimes more severe, occasionally inducing cholera-like purging in children residing in developing countries. Immunity appears to be strain specific and may reflect protective responses against particular

Table 1 Clinical, Epidemiologic, Pathogenetic, and Therapeutic Aspects of Infection with Various Pathotypes of *E. coli*

Pathotype	*Clinical Features*	*Epidemiologic Features*	*Virulence Factors*	*Management*
Enterotoxigenic	Watery diarrhea	Childhood diarrhea in developing countries; traveler's diarrhea	Pili, heat-labile and heat-stable enterotoxins	Fluid replacement; fluoroquinolone or rifaximin can be used alone or in combination with loperamide
Enteropathogenic	Watery diarrhea, vomiting	Infants in developing countries	Bundle-forming pilus, attaching and effacing effect	Fluid replacement
Enterohemorrhagic	Watery diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome	Food-borne and water-borne outbreaks in developed countries	Shiga toxins, attaching and effacing effect	Fluid replacement, supportive care; antibiotics and antimotility agents are contraindicated
Enteroaggregative	Diarrhea with mucus	Childhood diarrhea, traveler's diarrhea	Pili, cytotoxins	Fluid replacement; antibiotic treatment for patients with AIDS?
Diffuse-adhering	Diarrhea	Older children?	Unknown	Fluid replacement
Extraintestinal	UTI, neonatal meningitis, nosocomial infections	Sexually active women, neonates, hospitalized patients	Fimbriae of types 1, P, and others; hemolysin; capsule; iron-acquisition systems	Antibiotics for symptomatic patients and in selected patients with asymptomatic UTI; antibiotic therapy guided by susceptibility testing for other infections

UTI—urinary tract infection

colonization-factor antigens and toxins. The diagnosis of ETEC infection is often suspected on the basis of epidemiology and the clinical presentation but is rarely confirmed. Microbiologic diagnosis requires the use of bioassays to identify LT and ST toxins or the use of DNA probing techniques or polymerase chain reaction to detect the genes that encode these toxins; these tests are performed on *E. coli* organisms recovered from the stool.

Treatment As with all diarrheal disease, the initial management of ETEC infection involves ensuring adequate fluid repletion [*see 4:III Diarrheal Diseases*]. Several well-conducted clinical trials have demonstrated that traveler's diarrhea that is partly caused by ETEC responds rapidly to treatment with any of several regimens containing antibiotics, with or without antimotility agents.[7,8] Ciprofloxacin, taken every 12 hours for 3 days in combination with loperamide, is a particularly effective regimen.[9] Rifaximin, a nonabsorbable agent, is approved by the Food and Drug Administration for traveler's diarrhea caused by noninvasive strains of *E. coli*. Studies have found rifaximin to be comparable in efficacy to ciprofloxacin.[10] Azithromycin is another effective alternative.[11] Rifaximin can be used as a single agent or in combination with loperamide. ETEC organisms are generally susceptible to fluoroquinolones; however, should resistance to fluoroquinolones increase, rifaximin may prove to be an important alternative to ciprofloxacin for the treatment of traveler's diarrhea. For adults traveling to countries where ETEC is endemic, these medications can be provided before they travel, for prompt use if symptoms occur. Travelers should also be counseled to seek medical care if diarrhea is accompanied by blood or fever or if it persists despite treatment. Travelers can reduce the risk of acquiring ETEC by fastidiously avoiding all food that is not served steaming hot, fruit that they have not peeled, and beverages that are not bottled [*see CE:VII Health Advice for International Travelers*]. Bismuth subsalicylate tablets, taken four times a day, also provide some protection, but difficulty with compliance limits the use of this therapy.[7] The prospects for developing an ETEC vaccine are limited by the antigenic heterogeneity of the organisms.

Diarrhea Due to Enteropathogenic E. coli

Enteropathogenic *E. coli* (EPEC) strains are characterized by the ability of these organisms to bind intimately to the apical surface of enterocytes, where they destroy microvilli and induce the formation of cellular pedestals, which then embrace the bacteria [*see Figure 2*]. This histopathologic appearance is known as the attaching and effacing effect.[12] EPEC strains are distinguished from enterohemorrhagic *E. coli* (EHEC) strains by the inability of the former to produce Shiga toxin (see below). Although rare outbreaks involving contaminated food or water may strike individuals of any age,[13-15] most EPEC infections occur in infants in developing countries.[16] However, atypical EPEC strains lacking the bundle-forming pilus found in typical strains have recently been identified as a cause of diarrhea in children in developed countries as well.[17,18]

Diarrhea Due to Enterohemorrhagic and Other Shiga Toxin–Producing E. coli

Epidemiology The Shiga toxin–producing *E. coli* strains constitute a heterogeneous group of organisms, of which EHEC is a subset. Like EPEC organisms, EHEC organisms induce the attaching and effacing effect on epithelial cells. Of the many Shiga toxin–producing *E. coli* strains that have been described in the literature, EHEC of serotype O157:H7 is the most important, having caused both the largest number of outbreaks and the outbreaks involving the greatest number of patients.[19-21] There are approximately 0.9 cases of EHEC O157:H7 infections per 100,000 persons annually in the United States.[22] The reservoir for EHEC is infected cattle, but the organism can be found in a variety of other ruminants. The disease often appears in outbreaks associated with the consumption of contaminated food. Undercooked

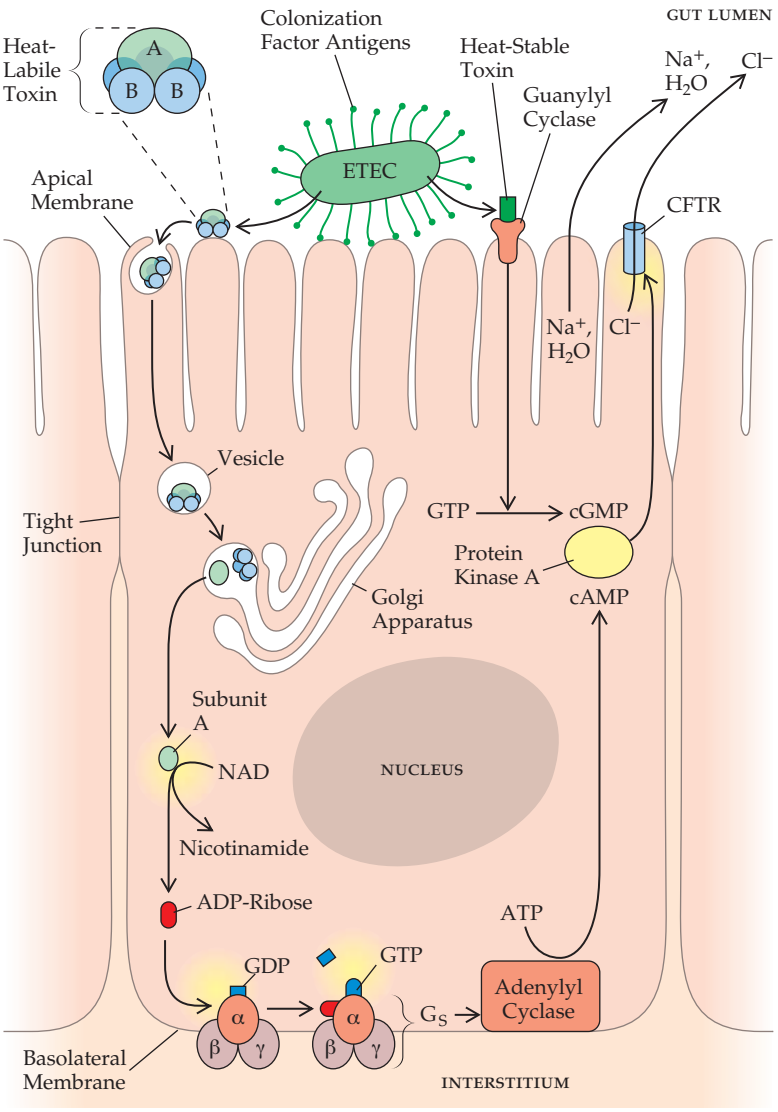

Figure 1 **The pathogenesis of enterotoxigenic *Escherichia coli* (ETEC) infections. ETEC organisms adhere to intestinal epithelial cells by one of several adhesins known as colonization factor antigens. No damage is caused to the epithelial cells. ETEC produces either a heat-labile toxin (LT), a heat-stable toxin (ST), or both. LT is composed of a pentamer of receptor-binding B subunits that are noncovalently attached to a single enzymatically active A subunit. After binding its glycolipid receptor and entering the enterocyte, LT is transported retrograde in membrane-bound vesicles to the Golgi apparatus. The A subunit reaches its target in the basolateral cell membrane, which is the alpha subunit of the stimulatory heterotrimeric G protein receptor (G_A), and catalyzes the adenosine diphosphate (ADP) ribosylation of the target. The modified alpha subunit is locked in its guanosine triphosphate (GTP)–bound active form, which forces it to constitutively activate adenylyl cyclase. The elevated levels of cyclic adenosine monophosphate (cAMP) that result lead to activation of protein kinase A (PKA) and to phosphorylation and opening of the cystic fibrosis transmembrane conductance regulator (CFTR). ST activates a distinct but convergent pathway. A disulfide-rich peptide, ST resembles the endogenous peptide hormone guanylin. Like its homologue, ST binds to and activates membrane-bound guanylyl cyclase–C, causing elevations in the levels of cyclic guanosine monophosphate (cGMP). As is the case with LT, this leads to electrolyte and fluid efflux through the CFTR.[5,29] (Cl^-—chloride; GDP—guanosine diphosphate; GTP—guanosine triphosphate; NAD—nicotinamide-adenine dinucleotide).**

ground beef has been associated with many outbreaks and is the leading risk factor for sporadic cases, but a variety of other foods and beverages, including other beef products, lettuce, sprouts, fruit, fruit juices, and milk, have been implicated. The disease has a low inoculum and can spread from person to person, particularly in day care centers or within the families of young children. An outbreak of EHEC infection resulting from airborne dispersal of bacteria after a country fair emphasizes the highly infectious nature of this pathogen.[23] It can also be spread through contamination of the water supply or through contamination of swimming pools, lakes, or water parks, and it can be contracted directly from infected animals at farms and petting zoos.[19,24-26]

Pathogenesis Animal models have demonstrated that the diarrhea caused by EHEC infection depends on the attaching and effacing effect.[27] However, the severe systemic complications of EHEC infection are caused by the expression of Shiga toxins and are independent of the attaching and effacing effect. Shiga toxins are encoded by bacteriophages related to the classic lambda phage; these bacteriophages stably infect the bacteria.[28] The three-dimensional structures of these toxins resemble those of LT toxin and cholera toxin, but the receptors, enzymatic activities, and targets are entirely different. Shiga toxins catalyze the depurination of ribosomal RNA, leading to a cessation of protein synthesis and to cell death [*see Figure 3*].[29] Microvascular endothelial cells, such as those of the kidney, are particularly sensitive to the toxin.

Diagnosis The classic presentation of EHEC infection begins with watery diarrhea and severe cramps and progresses to bloody diarrhea. Fever is low grade or absent. However, symptomatic disease may range from heme-negative watery diarrhea to frank hematochesia. The severe cramps, the absence of fever, or the presence of blood can lead clinicians to confuse EHEC infections with a variety of noninfectious illnesses, including intussusception, inflammatory bowel disease, and bowel ischemia; this in turn can lead to unnecessary diagnostic procedures or surgical intervention.[30] The dreaded complication of EHEC infection is the hemolytic-uremic syndrome (HUS), which sometimes manifests itself as thrombotic thrombocytopenic purpura. HUS ensues in approximately 5% to 10% of those patients with EHEC O157:H7 infection several days after the onset of diarrhea. It carries a high risk of death or permanent renal impairment. Various studies have demonstrated that children, the elderly, those who have consumed antimotility agents, and those with high white cell counts have an increased risk of HUS.[31,32] Antibiotic therapy

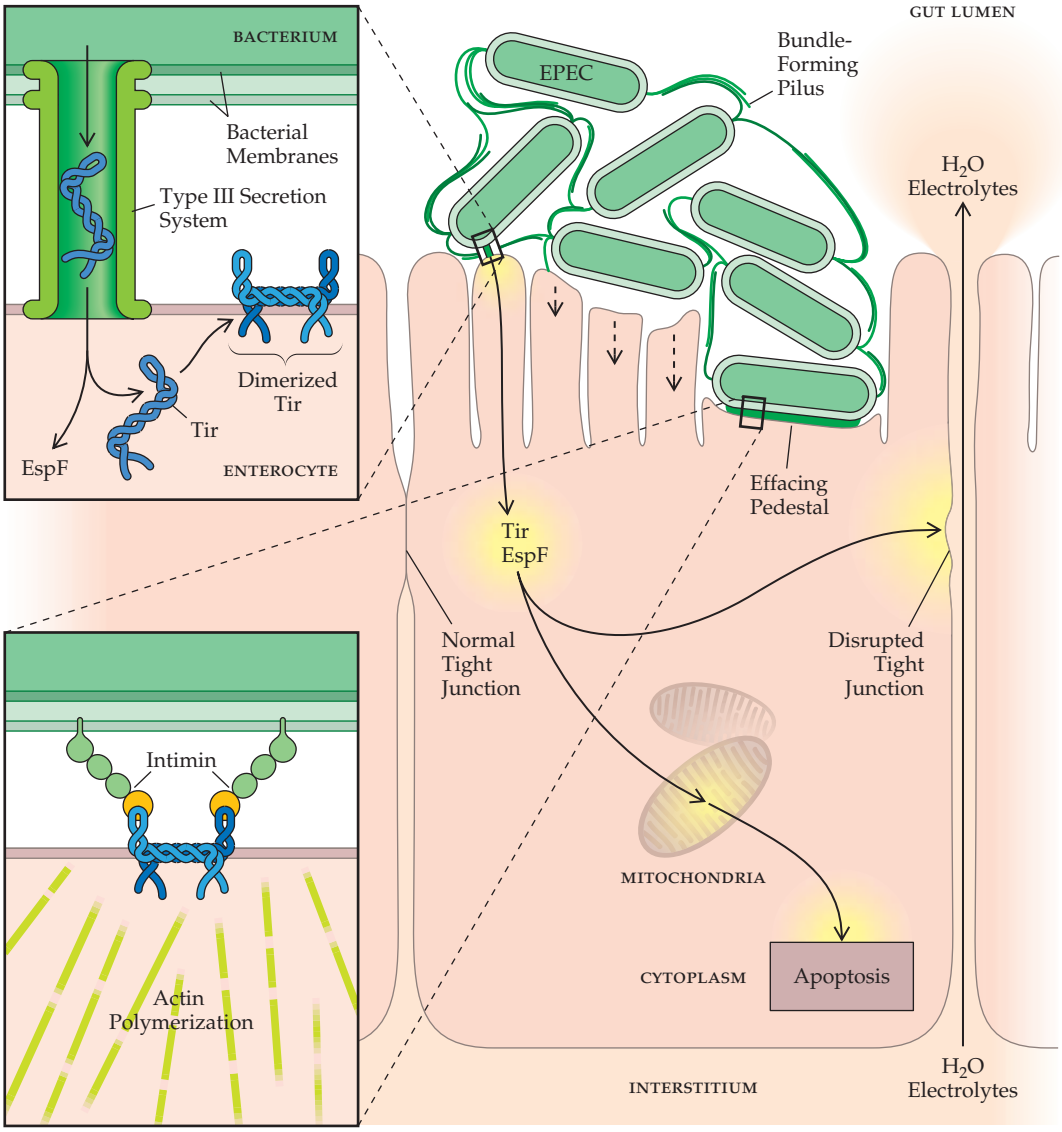

Figure 2 **The pathogenesis of enteropathogenic *E. coli* (EPEC) infections. Typical EPEC strains produce a plasmid-encoded bundle-forming pilus that is required for reversible aggregation of the bacteria and for full virulence.[63] The bacteria are able to inject into host cells a number of proteins, including Tir and EspF, through a specialized chromosome-encoded type III secretion system. Tir forms a dimer in the host cell membrane, where it serves as a receptor for the bacterial outer membrane protein adhesin intimin, a protein of multiple domains that is also essential for virulence. Binding of intimin triggers Tir to activate the cellular machinery for actin polymerization, leading to the formation of the characteristic attaching and effacing pedestals to which the organisms adhere. EspF causes loss of intestinal barrier function through disruption of tight junctions and induces host cell death through apoptosis.[12]**

may also be a risk factor for HUS. Studies on animal models have shown that many antibiotics induce the production of Shiga toxins[33]; clinical studies have reported an association between antibiotic therapy and an increased risk of HUS,[34] although some studies have found no such association.[35] It is possible that some antibiotics increase the risk of HUS, whereas others decrease the risk. However, prospective, randomized studies will be required to test this hypothesis.

HUS is characterized by microangiopathic hemolytic anemia, which results from Shiga toxin–induced damage to endothelial cells, leading to activation of coagulation in the microvasculature. The kidney is particularly susceptible, but ischemic necrosis of the bowel, brain, eye, or virtually any organ can occur.

The diagnosis of EHEC infection is extremely important, both for the patient (to prevent unnecessary interventions and provide appropriate care) and for public health, because any patient with EHEC could represent the index case of a large outbreak—the detection and interruption of which depend critically upon timely diagnosis and reporting. Fortunately, unlike most strains of *E. coli*, O157:H7 ferments sorbitol slowly, enabling the identification of these organisms on specific indicator plates. However, not all microbiology laboratories offer this test, and many of those that perform it do so only on request. Therefore, the recognition of sporadic cases and outbreaks of EHEC infection depends largely on the acumen of the astute clinician, who must suspect the diagnosis and request the test.

The diagnosis of *E. coli* infection caused by Shiga toxin–producing organisms other than O157:H7 is more difficult, because these organisms do not have a distinguishing phenotype that can be assayed in most laboratories. Colonies cultured from the stool of patients with suspected non-O157:H7 Shiga toxin–producing *E. coli* infection should be sent to referral laboratories, state health laboratories, or the Centers for Disease Control and Prevention for assays to detect Shiga toxins or the genes that encode them.

Treatment The treatment of EHEC infection is supportive and includes oral rehydration, observation, and, if necessary, hospital admission for the management of complications. Until proved safe and effective, antibiotics should be regarded as contraindicated in patients with known or suspected EHEC infection. Antimotility agents are also contraindicated in these patients, because their use is associated with a possible risk of HUS[31] and with a theoretical risk of increasing the duration of toxin exposure.

The risk of EHEC infection can be reduced by routine adherence to good hygienic practice in food preparation. Ground beef should always be cooked to an internal temperature of 68.3° C (well done or until the juices run clear).[21] A broad array of efforts

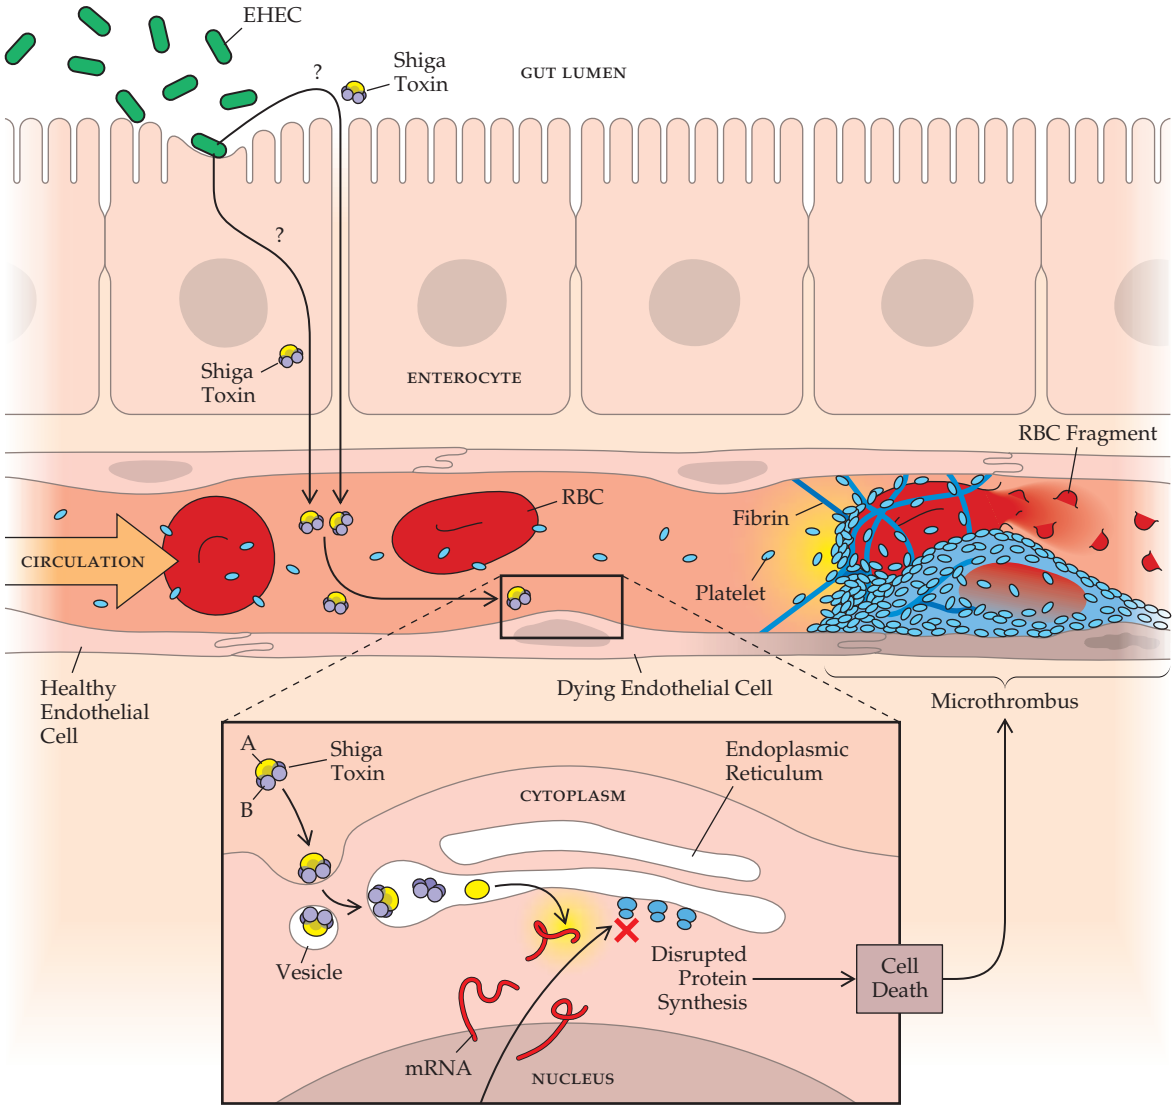

Figure 3 **The pathogenesis of enterohemorrhagic *E. coli* (EHEC) infections. Like EPEC, EHEC strains express intimin and Tir and employ the type III secretion system, which cause the attaching and effacing effect on cells. However, EHEC also produces Shiga toxins, which are encoded by bacteriophages that stably infect the bacteria. Shiga toxins are similar in quaternary structure to the heat-labile toxin of ETEC; they are composed of a pentamer of receptor-binding B subunits that are noncovalently bound to a single enzymatic A subunit. Shiga toxins are able to cross intestinal epithelial monolayers by an unknown mechanism, after which they presumably are spread systemically through the bloodstream. Endothelial cells appear to be particularly important target cells for Shiga toxins. After binding its glycolipid receptor and entering the host cell, the toxin is transported retrograde in membrane-bound vesicles to the endoplasmic reticulum. The A subunit induces depuration of a specific adenine residue in ribosomal RNA; this leads to cessation of protein synthesis and death of the cell. The altered surface of the intoxicated endothelial cell serves as a nidus for activation of the coagulation cascade, which leads to the formation of microthrombi and causes distal ischemic necrosis, platelet consumption, and red cell fragmentation—the hallmarks of the hemolytic-uremic syndrome.[12]**

to reduce EHEC infections is under development. These include measures to reduce colonization in cattle; vaccine development; and improved food-safety measures.

Diarrhea Due to Enteroaggregative E. coli *and Diffuse-Adhering* E. coli

Enteroaggregative *E. coli* (EAEC) and diffuse-adhering *E. coli* (DAEC) are distinguished by characteristic patterns of adherence to tissue culture cells on in vitro assays. It is likely that these pathotypes contain a heterogeneous mixture of strains that do not entirely share pathogenetic or clinical features.[5,36,37] Our understanding of the epidemiology, pathogenesis, and management of these infections is rudimentary, but several interesting features have been defined.[38]

Epidemiology EAEC organisms are associated with acute and chronic diarrhea in children in developing and developed countries[17,39,40]; they have also been isolated from patients with AIDS.[41,42] In addition, recent studies have found that EAEC is a frequent cause of travelers's diarrhea, rivaling the incidence of ETEC.[43] Interestingly, carriage of EAEC, even in the absence of overt symptoms, is associated with evidence of growth retardation in children.[44] DAEC has been associated with diarrhea in older children in developing countries.[45,46]

Pathogenesis EAEC strains produce a variety of pili and toxins, but further study is needed to clarify the role that these factors play in causing disease. The pathogenetic mechanisms of DAEC remain obscure.

Diagnosis Diarrhea caused by EAEC may contain mucus or blood and may be accompanied by cramps. In some cases, particularly in patients with AIDS, the diarrhea can be protracted. The clinical features of DAEC infection have not been well described. The diagnosis of these infections requires tissue culture assays that are performed only in the research setting.

Treatment Case reports and studies in small series of patients have suggested that AIDS patients who are infected with EAEC may respond to antibiotic treatment.[47]

EXTRAINTESTINAL INFECTIONS

E. coli can infect a variety of extraintestinal sites, including the urinary tract, the meninges (in neonates), the lungs, the peritoneum, the gallbladder, and the biliary tree; *E. coli* infections can also occur in association with intravascular and prosthetic devices [*see Table 1*]. *E. coli* can also be involved in polymicrobial infections such as intra-abdominal abscesses and skin and soft tissue infections. Bacteremia can complicate extraintestinal *E. coli* infections. Although the virulence factors responsible for all of these diseases have not been well studied, it is clear that the strains that cause extraintestinal infections are not a random sample of *E. coli* from the host intestine. On the other hand, these strains lack most of the virulence factors associated with those that cause diarrhea; rather, the strains that cause extraintestinal infections are more likely to possess the genes for hemolysin to produce an antiphagocytic capsule and a variety of fimbriae, and to sequester iron than are strains isolated from the GI tract. The similarity in the repertoire of putative virulence factors in strains isolated from UTIs and other extraintestinal infections has led to the conclusion that extraintestinal pathogenic *E. coli* (ExPEC) should be considered a single pathotype.[48]

E. coli is by far the leading cause of UTIs in otherwise healthy persons, and it is an important cause of UTIs in those patients whose urinary tracts are compromised by anatomic abnormalities, foreign bodies, or host immune defects. The bacteria that cause UTIs are more likely than fecal *E. coli* isolates to possess the genes for a variety of factors under study as potential virulence determinants. Of these factors, P fimbriae and hemolysin are prominent.[49] Interestingly, however, the ubiquitous type 1 fimbriae that are produced by virtually all strains of *E. coli* and related organisms play a critical role in the pathogenesis of *E. coli*–associated UTI. However, there is much more to the pathogenesis of UTI than the production of type 1 fimbriae, because the presence of these organelles does not distinguish uropathogenic *E. coli* from other strains. The genome of a prototype strain of extraintestinal pathogenic *E. coli* confirms that these strains possess many genes that are absent from *E. coli* K-12.[4] More detailed information on the pathogenesis, clinical features, and treatment of UTI is presented elsewhere [*see 7:XXIII Infections of the Urinary Tract*].

The diagnosis of these infections is confirmed by isolating the organism in culture from appropriate clinical specimens. Treatment is guided by susceptibility testing. The rising prevalence of resistance to trimethoprim-sulfamethoxazole in *E. coli* isolates from the community and the alarming rise in the prevalence of strains that produce extended-spectrum β-lactamases are narrowing therapeutic options.[50-52]

Proteus Infections

Named after a character in Homer's *Odyssey* who could change shape, organisms belonging to the genus *Proteus* are noted for their ability to take two forms: (1) typical bacillary swimmer cells, which express a variety of surface fimbriae as well as flagella, and (2) highly elongated swarm cells, which express hundreds of flagella and few other surface structures. Swarm cells provide a challenge to the clinical microbiologist because the organisms frequently swarm over culture plates, which interferes with the isolation of individual colonies. By far, the most commonly isolated *Proteus* species is *P. mirabilis*.

Pathogenesis

Proteus rapidly hydrolyzes urea to form carbon dioxide and ammonium hydroxide. In the urinary tract, this reaction results in an increase in pH. This reaction also alters the solubility of polyvalent ions and leads to the formation of struvite calculi. These stones can then obstruct urinary catheters, leading to bacterial persistence and urosepsis. In a murine model of ascending UTI, a urease-negative mutant of *P. mirabilis* was found to be severely limited in its ability to colonize the urinary tract, and this mutant strain failed to form stones.[53] Studies in animal models have confirmed the ability of *P. mirabilis* to produce several fimbriae that play a role in infection.[54]

EPIDEMIOLOGY AND ETIOLOGY

Although *P. mirabilis* occasionally causes UTI in otherwise healthy persons, it is more commonly isolated from patients with abnormalities of the urinary tract, particularly those with indwelling urethral catheters and those with stones. Notably, *Proteus* has a predilection for causing upper urinary tract infections.[55] Whereas *P. mirabilis* rarely causes infections outside the urinary tract, other members of the genus and closely related organisms such as *Morganella morganii* may be isolated from skin

infections and soft tissue infections, especially skin ulcers in patients with diabetes mellitus.

Diagnosis

The diagnosis of a urinary tract infection caused by *Proteus* organisms can be suspected in patients with compatible symptoms and signs who have complicated urinary tracts, including those patients with indwelling urinary catheters and functional or anatomic abnormalities. Evidence of upper urinary tract involvement (e.g., fever, flank pain, and sepsis), catheter obstruction, or known renal calculi strongly supports the diagnosis, which can be confirmed by culture.

Treatment

Most strains of *P. mirabilis* are susceptible to many antibiotics, but some *Proteus* species are highly resistant. In the treatment of UTIs caused by *Proteus* organisms, the underlying urinary abnormality and the clinical appearance of the patient must be taken into account. Treatment of asymptomatic bacteriuria in patients with urinary calculi or anatomic or functional abnormalities provides no long-term benefit to the patient and merely increases the potential for antimicrobial resistance [*see 7:XXIII Infections of the Urinary Tract*].

Klebsiella Infections

Klebsiella pneumoniae and, to a lesser extent, *K. oxytoca* are responsible for the vast majority of human *Klebsiella* infections. These organisms are found in the environment and in the GI tract.

EPIDEMIOLOGY AND ETIOLOGY

Although *Klebsiella* species occasionally cause UTI in otherwise healthy persons, the majority of *Klebsiella* infections occur in compromised hosts. *K. pneumoniae* can cause community-acquired pneumonia, classically in patients with alcoholism, with dramatic findings such as currant jelly sputum and a bulging fissure sign (Friedländer pneumonia). In practice, pulmonary infections caused by *Klebsiella* are difficult to distinguish on clinical grounds from those caused by other organisms.[56] Most *Klebsiella* infections occur in hospitals, where these bacteria cause UTI, pneumonia, wound infections, biliary infections, and primary bacteremia.[57] *Klebsiella* are often second only to *E. coli* as a cause of nosocomial gram-negative bacteremia.[57,58] These infections can occur as epidemics or sporadically.[59] Particularly problematic are outbreaks of nosocomial infections caused by strains of *Klebsiella* that produce extended-spectrum β-lactamases.[51,52] These organisms are frequently resistant to multiple antibiotics, owing to the presence of plasmids that encode multiple antibi-otic-resistance genes.

Pathogenesis

The primary virulence factor for *Klebsiella* is a luxuriant polysaccharide capsule, which has antiphagocytic properties. *Klebsiella* organisms also produce type 1 fimbriae; like ExPEC organisms, they also produce other fimbriae and have iron-acquisition systems and a reactive lipopolysaccharide.[60]

Diagnosis

The clinical features of community-acquired pneumonia caused by *K. pneumoniae* are not sufficiently distinctive to differentiate patients with infections caused by this organism from those who have infections caused by other agents. Similarly, nosocomial infections and UTIs caused by *Klebsiella* cannot be diagnosed on the basis of clinical features.

In the microbiology laboratory, a presumptive identification of *Klebsiella* infection is often made when a highly mucoid, lactose-fermenting, ampicillin-resistant, gram-negative bacillus is isolated and is confirmed by further testing.

Treatment

Treatment of *Klebsiella* infections requires consultation with a clinical microbiology laboratory or specialists in infectious diseases to ensure selection of an antibiotic to which the organism is susceptible. *Klebisella* isolates that do not produce extended-spectrum β-lactamases are usually resistant to ampicillin but may be sensitive to cephalosporins, trimethoprim-sulfamethoxazole, aminoglycosides, combinations of penicillins and β-lactamase inhibitors, and fluoroquinolones, any of which may be used to treat infections caused by susceptible organisms.

Enterobacter and *Serratia* Infections

Epidemiology and Etiology

Enterobacter and *Serratia* are closely related to *Klebsiella;* like *Klebsiella,* they are principally opportunistic pathogens that cause a variety of nosocomial infections. In addition, *S. marcescens* has been isolated from the blood or other clinical specimens of patients who use injection drugs.[61] Although several species of *Enterobacter*—including *E. cloacae* and *E. aerogenes,* as well as the closely related species *Pantoea agglomerans*—cause infections, *S. marcescens* is the only *Serratia* species that has been isolated from patients with appreciable frequency.

Pathogenesis

Enterobacter and *Serratia* organisms share with *Klebsiella* organisms the ability to produce antiphagocytic capsules. One important clinical difference is that *Enterobacter* species have an inducible chromosomal cephalosporinase. This enzyme renders the organisms resistant not only to first-generation cephalosporins but also to many second- and third-generation cephalosporins after high-level induction of cephalosporinase in the presence of these antibiotics. Such resistance may not be detected in the microbiology laboratory on initial testing and may become apparent only when the organism is again isolated from patients who fail to respond to therapy.

Diagnosis

As with infections caused by *Klebsiella,* infections caused by *Enterobacter* and *Serratia* do not have distinguishing clinical features and are diagnosed by culture of the organism from a normally sterile site or from a nonsterile site in a patient with associated signs or symptoms.

Treatment

Second- and third-generation cephalosporins should be used cautiously in patients with serious *Enterobacter* infections, even if the isolate appears to be susceptible on initial testing.[62] When the organism is susceptible to alternative agents such as extended-spectrum penicillins, carbapenems, or fluoroquinolones, their use may be advisable.

IX INFECTIONS DUE TO THE ENTERIC PATHOGENS CAMPYLOBACTER, SALMONELLA, SHIGELLA, YERSINIA, VIBRIO, AND HELICOBACTER

MARCIA B. GOLDBERG, M.D.

In the United States, diarrhea is the third most common medical complaint, with an annual incidence of 1.5 to 5.0 illnesses per person. Rates of occurrence are highest in children, followed by the elderly. Worldwide, diarrhea is the second most common cause of death for all age groups and the leading cause of death in children.

The most common bacterial causes of diarrhea in the United States are gram-negative bacteria. *Campylobacter* species are the most common infectious organisms (46%), followed by *Salmonella* (28%), *Shigella* (17%), and *Escherichia coli* O157 (5%) [*see Figure 1*].[1]

Campylobacter Infections

EPIDEMIOLOGY

Campylobacter organisms are the most common cause of bacterial gastroenteritis in the United States, with 2.1 to 2.4 million cases estimated to occur each year.[2] This disease is most common in children. The incidence of *Campylobacter* enteritis is as much as 39-fold higher in HIV-infected persons than in the general population[3]; recurrent infection and infection with antibiotic-resistant strains are also more common.[4,5]

Campylobacter infection is acquired by ingestion of contaminated foodstuffs in 80% of cases. Exposure to infected dogs, unpasteurized milk, contaminated unchlorinated water, and infected persons has also been reported to spread the organism. Improper handling of uncooked chicken and consumption of undercooked chicken are the most common food-related causes. The infectious inoculum is only approximately 800 organisms[6]; therefore, secondary infection occurs in as many as two thirds of household contacts. Neonates born to infected mothers are at extremely high risk for infection, which can be life threatening.

C. jejuni is the most common cause of *Campylobacter* enteritis. Other species of *Campylobacter*, particularly *C. coli* and *C. upsaliensis* (for which dogs are the normal host), are common causes of enteritis in AIDS patients. *C. fetus* is the predominant cause of systemic infection. Two thirds of patients with systemic *Campylobacter* infection are males. Many are in their middle 50s; more than 25% are farm workers, butchers, or abattoir workers; and most have a major underlying illness, such as alcoholism, cirrhosis, diabetes, lymphoproliferative disorder, or valvular or atherosclerotic heart disease.

PATHOGENESIS

Campylobacter enteritis is thought to involve bacterial invasion of intestinal epithelial cells,[7] as does *Salmonella* or *Shigella* enteritis. Intestinal lesions are similar to those of granulomatous or idiopathic ulcerative colitis. The pathogenesis of systemic *Campylobacter* infection is poorly understood. Genetic techniques have been developed that will allow molecular characterization of the pathogenesis of *Campylobacter* infection.[8,9] *C. jejuni* infection may be complicated by Guillain-Barré syndrome. In such cases, antibodies to ganglioside GM1 and other peripheral nerve gangliosides are frequently detected. The lipopolysaccharide from *C. je-*

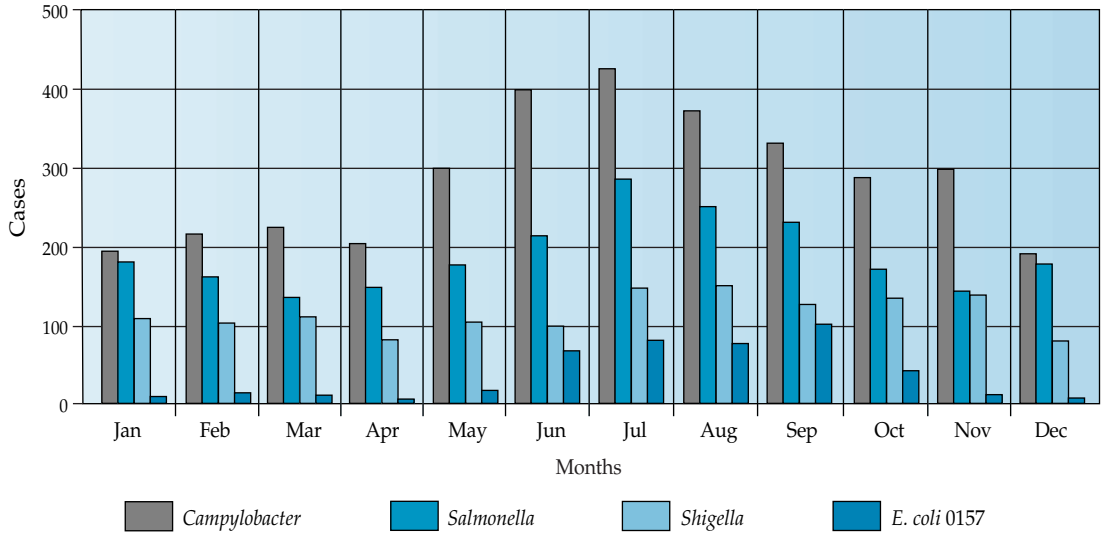

Figure 1 **Cases of gastroenteritis caused by *Campylobacter, Salmonella, Shigella,* and *E. coli* O157 reported to the Collaborating Sites Foodborne Disease Active Surveillance Network (CDC/USDA/FDA), 1996.[1]**

juni isolates displays molecular mimicry with several gangliosides, which suggests that the neurologic syndrome is caused by autoimmune recognition of gangliosides induced by exposure to the *C. jejuni* lipopolysaccharide.

DIAGNOSIS

Clinical Manifestations

The incubation period for *Campylobacter* enteritis is usually 2 to 4 days. Illness typically begins with crampy periumbilical pain and fever, which is followed by diarrhea with profuse, watery, foul-smelling stools. Abdominal pain can range from mild to severe, mimicking acute appendicitis, bowel perforation, or intussusception. Stool is grossly bloody or melanotic in 30% of patients and guaiac positive in 60%.

Patients with *Campylobacter* bacteremia present with symptoms common to many bacteremias: fever, malaise, headache, chills, night sweats, anorexia, and abdominal pain. Lethargy and confusion may occur without focal neurologic findings. A nonproductive cough may be present in the absence of focal pulmonary findings. Endocarditis may occur in 10% of patients. Meningitis is uncommon, although neonates are at extremely high risk.

Physical Examination

Physical findings in both *Campylobacter* enteritis and systemic *Campylobacter* infection are nonspecific.

Laboratory Tests

In *Campylobacter* enteritis, stool examination may reveal the diagnosis in as many as two thirds of cases. In fresh stool, *Campylobacter* organisms are small, motile, comma- or corkscrew-shaped; in Gram stains, they may be gull winged, curved, gram-negative organisms. Leukocytes are present in the stool in about 75% of cases.

Campylobacter organisms do not grow on standard media used in the detection of enteric pathogens but, rather, require specific media and specific environmental conditions.[10] If a stool sample cannot be delivered to a laboratory quickly, storage of the sample in an airtight container at 4° C or inoculation of transport medium (e.g., Cary-Blair) can improve the recovery of organisms.

Diagnosis of systemic *Campylobacter* infection is based on the isolation of the organism in blood cultures. *Campylobacter* organisms may grow slowly, so cultures should be incubated for 2 weeks or longer. In both systemic and intestinal infection, leukocytosis is common.

DIFFERENTIAL DIAGNOSIS

In the setting of acute onset of watery diarrhea, fever, and abdominal pain, *Campylobacter* infection should be considered. The differential diagnosis of diarrheal disease with polymorphonuclear leukocytes in the stool is enteritis caused by *Campylobacter*, *Salmonella*, *Shigella*, or *Yersinia enterocolitica* infection or by idiopathic ulcerative colitis. *Salmonella* and *Yersinia* infections are less likely when there is detectable blood in the stool. Systemic *Campylobacter* infection cannot be easily distinguished from other bacteremias.

TREATMENT

Campylobacter enteritis is usually self-limited, making specific therapy unnecessary. However, it may be prudent to administer antibiotics to patients with moderately severe disease (i.e., those with high fever, bloody diarrhea, or bacteremia or those who pass more than eight stools a day), immunosuppressed patients, pregnant women, or patients with symptoms that worsen or persist more than 7 days after diagnosis. Administration of antibiotics before laboratory confirmation of infection has been shown to reduce the median duration of symptoms from 10 days to 5 days.[11] However, empirical institution of antibiotics for diarrheal syndromes suggestive of enterohemorrhagic *E. coli* may increase the risk of hemolytic-uremic syndrome.[12]

Erythromycin is the treatment of choice for *Campylobacter* enteritis [*see Table 1*]. The newer macrolides, including azithromycin, and fluoroquinolones have also been used successfully [*see Table 1*]. However, resistance to fluoroquinolones is increasing rapidly worldwide; in 1998, approximately 10% of isolates in Minnesota were resistant to fluoroquinolones.[13] Moreover, strains resistant to both fluoroquinolones and macrolides have been isolated in Thailand. Fluid replacement should be administered as needed. On the basis of data for *Shigella* and *Salmonella* enteritis, antimotility agents such as Lomotil (diphenoxylate hydrochloride with atropine sulfate) should probably be avoided.

For systemic *Campylobacter* infection, imipenem or gentamicin, or a combination of the two, is the treatment of choice. Chloramphenicol, other aminoglycosides, and tetracyclines are also effective. Most isolates are resistant to penicillin, cephalosporins, vancomycin, and rifampin.

COMPLICATIONS

Postinfectious arthritis occurs in approximately 1% of patients, Guillain-Barré syndrome (or its variant, Miller Fisher syndrome) occurs in approximately 0.1%,[14] and hemolytic-uremic syndrome occurs rarely. Postinfectious arthritis presents as a sterile monoarticular or migratory polyarticular arthritis—particularly involving the knee—that begins 7 to 10 days after the onset of diarrhea and may persist for months or become chronic; 60% of patients carry the HLA-B27 haplotype, which is associated with an increased prevalence of ankylosing spondylitis and related spondyloarthropathies. In patients with Guillain-Barré syndrome, up to 40% have evidence of recent *Campylobacter* infection,[14] 20% are left with some long-term disability, and 5% die of the syndrome or its complications. Both postinfectious arthritis and Guillain-Barré syndrome are thought to be caused by autoimmune processes.

PROGNOSIS

Recurrence or relapse of *Campylobacter* infection may occur. Severe, persistent, or bacteremia-associated enteritis may occur in AIDS patients.

Salmonella Infections

EPIDEMIOLOGY

Disease caused by *Salmonella* organisms can be divided into two categories: typhoidal and nontyphoidal. *S. typhi* and *S. paratyphi* are the pathogens in typhoidal disease. Nontyphoidal disease results from all other serovars that infect humans. In the United States, nontyphoidal *Salmonella* organisms, most commonly *S. typhimurium* and *S. enteriditis*, are the second most frequently isolated cause of bacterial diarrhea (approximately 1.4 million cases annually).[15]

More than 95% of nontyphoidal *Salmonella* infections are food-borne; the remainder are nosocomial infections or are ac-

quired from pets (reptiles and birds); from infected persons; or from contaminated water, drugs, or solutions. Outbreaks have been linked to eggs, cheese, fresh fruits and vegetables, juice, dry cereal, and ice cream premix.[16] *Salmonella* organisms can be passed transovarially from chicken to egg, and most *S. enteriditis* cases are traced to undercooked eggs.[16] *Salmonella* organisms are commonly carried by farm animals, and antibiotic resistance, particularly of *S. typhimurium*, has been linked to the use of antibiotics in animal feed.[17]

In the United States, *S. typhi* and *S. paratyphi* cause fewer than 1,000 cases of infection annually, more than 70% of which are acquired abroad.[15] Humans are the only host of these pathogens, and spread is person-to-person or via contaminated foodstuffs or water.

The inoculum for *Salmonella* infection is approximately 10^5 to 10^9 organisms but is lower in infants, in persons with pernicious anemia, and in persons taking antacids or H_2 receptor blockers. Additional risk factors are old age, alteration of the endogenous bowel flora (e.g., by recent antimicrobial therapy), HIV infection, therapeutic immunosuppression, alteration of the reticuloendothelial system (e.g., malaria or *Bartonella* infection), sickle-cell disease, splenectomy, diabetes, malignancy, and rheumatologic disorders, including lupus. HIV-infected persons have a 20- to 100-fold increased risk of *Salmonella* infection and a significantly increased risk of severe invasive disease.

Classification of *Salmonella* organisms is confusing because disease may be caused by more than 2,500 serovars, all of which belong to a single species, designated *S. enterica* and *S. choleraesuis*. However, in clinical settings, serovars are commonly referred to as species (e.g., *S. enterica* serovar *enteriditis* is called *S. enteriditis)*, as will be done herein.

PATHOGENESIS

Salmonella organisms are internalized by intestinal M cells, which are specialized epithelial cells that overlie Peyer patches and are enriched in the ileum. Organisms are transported to the lymphoid tissue of the Peyer patches, from which they may enter the systemic circulation. *Salmonella* organisms have specialized mechanisms for survival inside of macrophages. Recruitment of inflammatory cells, including macrophages, into the Peyer patches may lead to their enlargement and necrosis after several weeks of infection. *Salmonella* organisms are also able to induce internalization into and transit across nonspecialized intestinal epithelial cells into deeper tissues.

Salmonella serovars vary in their pathogenesis. *S. anatum*, *S. derby*, and *S. newport* are usually limited to the intestine. *S. choleraesuis* rapidly enters the bloodstream and causes little damage in the intestine. *S. typhi* bacteremia often leads to seeding of the liver and biliary tree.

GASTROENTERITIS

Diagnosis

Clinical manifestations The incubation period for gastroenteritis caused by *Salmonella* organisms typically ranges from 6 to 72 hours. Symptoms of the disorder include nausea, vomiting, fever, diarrhea, and abdominal cramps. Stools are typically loose, of moderate volume, and do not contain blood. In rare cases, the presentation may mimic appendicitis or inflammatory bowel disease. Diarrhea is generally self-limited, lasting 3 to 7 days.

Physical examination Physical findings are nonspecific. Fever with temperatures to 39° C (102° F) for 1 to 2 days, mild abdominal tenderness, and hyperactive bowel sounds may be present. A more prolonged or more hectic fever pattern suggests bacteremia, metastatic foci, or both.

Laboratory tests Microscopic examination of stool reveals leukocytes and, rarely, red blood cells. *Salmonella* organisms are readily cultured from stool on selective media used routinely in clinical microbiology laboratories. Isolation of *Salmonella* organisms from otherwise sterile body fluids is also accomplished using routine media. The mean duration of fecal carriage after resolution of diarrhea for nontyphoidal *Salmonella* organisms is 1 month in adults and 7 weeks in young children.[18]

Differential Diagnosis

The presentation of *Salmonella* gastroenteritis is similar to that of other febrile diarrheal syndromes, including infection caused by *Campylobacter* organisms, infection caused by *Shigella* organisms, infection caused by *Y. enterocolitica*, and inflammatory bowel disease. Frankly bloody diarrhea is more suggestive of *Shigella* or enterohemorrhagic *E. coli* infection than of *Salmonella* infection.

Treatment

Antibiotics are not recommended for patients with uncomplicated gastroenteritis, because the illness is generally self-limited, and antibiotic therapy may prolong intestinal carriage.[19]

Antibiotics should be administered to patients who are severely ill or at risk for extraintestinal spread of infection, including infants; persons older than 50 years; and patients with cardiac valvular or mural abnormalities, patients with prosthetic vascular grafts, or patients who are receiving immunosuppressive therapy. Effective therapeutic agents include fluoroquinolones, trimethoprim-sulfamethoxazole, ampicillin, and third-generation cephalosporins. Because resistance to trimethoprim-sulfamethoxazole or ampicillin is common, treatment with a fluoroquinolone or a third-generation cephalosporin is appropriate when susceptibilities of the isolate are not known. Duration of therapy should be only 48 to 72 hours or until the patient becomes afebrile; longer therapy may increase the likelihood of long-term carriage.

Complications

Infants are at high risk for central nervous system infection. In some patients, *Salmonella* organisms invade the intestinal epithelium and enter the bloodstream, causing septicemia. Septicemia may in turn cause metastatic infection of other organs, including endovascular sites, the hepatobiliary tract, the spleen, bone, and, less commonly, the brain.

CARRIER STATE

The carrier state, defined as carriage of *Salmonella* organisms in the stool for more than 1 year after initial infection, occurs in 0.2% to 0.6% of persons infected with nontyphoidal *Salmonella* and 3% of persons infected with *S. typhi*.[20] The site of chronic infection is the biliary tree. The presence of stones or chronic scarring makes eradication more difficult. Long-term carriage may occur more rarely in the urinary tract, particularly in the setting of obstructive uropathy, tuberculosis, or schistosomiasis.

Table 1 Selected Therapies for Enteric Pathogens

Pathogen	*Drug (Trade Name)*	*Dose*	*Relative Efficacy*	*Cost ($)*	*Comment*
Campylobacter	Erythromycin	12.5 mg/kg p.o. every 6 hr for 7 days	Drug of choice	1.00–1.49/day	*Campylobacter* enteritis strains resistant to erythromycin and related drugs have been isolated in Thailand
	Azithromycin (Zithromax)	500 mg p.o. every day for 3 days	Has been used successfully	10.00–19.99/day	*Campylobacter* enteritis strains resistant to azithromycin and related drugs have been isolated in Thailand
	Ciprofloxacin (Cipro)	500 mg p.o. twice a day for 3 days	Has been used successfully	7.00–7.99/day	*Campylobacter* enteritis strains resistant to ciprofloxacin and related drugs are increasing
Salmonella	Ciprofloxacin (Cipro)	500 mg p.o. twice a day for 10 days	Drug of choice for isolates resistant to ampicillin and trimethoprim-sulfamethoxazole	7.00–7.99/day	Antimicrobial therapy for *Salmonella* enteric fever; must confirm organism susceptibility to nalidixic acid and ciprofloxacin; if nalidixic acid–resistant, use higher doses of ciprofloxacin (10 mg/kg twice a day)
	Ceftriaxone (Rocephin)	1–2 g I.M. or I.V. daily for 10–14 days	Drug of choice for isolates resistant to ampicillin and trimethoprim-sulfamethoxazole	60.00–69.99/day	Antimicrobial therapy for *Salmonella* enteric fever
	Amoxicillin	1 g p.o. every 6 hr for 10–14 days	For susceptible isolates only	0.25–0.49/day	
	Trimethoprim-sulfamethoxazole (Bactrim)	1 double-strength tablet p.o. twice a day for 10–14 days	For susceptible isolates only	0.10–0.24/day	
	Dexamethasone	3 mg/kg I.V. once, then 1 mg/kg I.V. every 6 hr for 48 hr	Adjunct to antimicrobial therapy when disease is accompanied by shock, coma, stupor, obtundation, or delirium	80.00–89.99/day	Glucocorticosteroid therapy for *Salmonella* enteric fever; continuation beyond 48 hr may increase the risk of relapse
	Ampicillin or amoxicillin	2–4 g/day in divided doses for 4–6 wk	Treatment of choice	0.75–0.99/day or 0.25–0.49/day	Antibiotic therapy for *Salmonella* carrier state
	Trimethoprim-sulfamethoxazole (Bactrim)	1 double-strength tablet p.o. twice a day for 4–6 wk	For penicillin-allergic patients or ampicillin-resistant isolates	0.10–0.24/day	
	Ciprofloxacin (Cipro)	500 mg p.o. twice a day for 4–6 wk	For penicillin-allergic patients or ampicillin-resistant isolates	7.00–7.99/day	
Shigella	Trimethoprim-sulfamethoxazole	160/800 mg p.o. twice a day for 3–5 days	Treatment of choice	0.10–0.24/day	Antibiotic therapy for *Shigella* enteritis acquired in the United States
	Norfloxacin (Noroxin)	400 mg p.o. twice a day for 3–5 days	Alternative therapy or for trimethoprim-resistant isolates	4.00–4.99/day	Antibiotic therapy for *Shigella* enteritis acquired in the United States
			Treatment of choice		Antibiotic therapy for *Shigella* enteritis acquired in Southeast Asia, Africa, the Middle East, Japan, South America, Spain, or Canada; trimethoprim resistance is common
	Ciprofloxacin (Cipro)	500 mg p.o. twice a day for 3–5 days	Alternative therapy or for trimethoprim-resistant isolates	7.00–7.99/day	Antibiotic therapy for *Shigella* enteritis acquired in the United States
			Treatment of choice		Antibiotic therapy for *Shigella* enteritis acquired in Southeast Asia, Africa, the Middle East, Japan, South America, Spain, or Canada; trimethoprim resistance is common
	Ofloxacin (Floxin)	300 mg p.o. twice a day for 3–5 days	Alternative therapy or for trimethoprim-resistant isolates	7.00–7.99/day	Antibiotic therapy for *Shigella* enteritis acquired in the United States
			Treatment of choice		Antibiotic therapy for *Shigella* enteritis acquired in Southeast Asia, Africa, the Middle East, Japan, South America, Spain, or Canada; trimethoprim resistance is common

Table 1 (*continued*)

Pathogen	*Drug (Trade Name)*	*Dose*	*Relative Efficacy*	*Cost ($)*	*Comment*
Yersinia	Gentamicin	5 mg/kg/day in divided doses	Suggested therapy	3.00–3.99/day	Antibiotic therapy for *Y. enterocolitica* septicemia; may be used alone or in combination with other antibiotics listed as therapy for *Y. enterocolitica* in this table
	Doxycycline	100 mg I.V. every 12 hr	Suggested therapy	—	
	Trimethoprim-sulfamethoxazole	8–10 mg trimethoprim/kg/day I.V. in divided doses every 6 hr	Suggested therapy	10.00–19.99/day	
	Ciprofloxacin (Cipro)	200–400 mg I.V. every 12 hr	Suggested therapy	60.00–69.99/day	
	Ampicillin	100–200 mg/kg/day I.V. in divided doses	Suggested therapy	7.00–7.99/day	Antibiotic therapy for *Y. pseudotuberculosis* septicemia
	Streptomycin	20–30 mg/kg/day I.M.	Suggested therapy	3.00–3.99/day	
	Tetracycline	20–30 mg/kg/day p.o. or I.V. in divided doses	Suggested therapy	—	
Vibrio	Tetracycline	10–12.5 mg/kg p.o. four times a day for 2 days	Treatment of choice	0.10–0.24/day	Antibiotic therapy for *V. cholerae*; eradicates the organism
		1 g p.o. once	Alternative therapy	—	Antibiotic therapy for *V. cholerae*; controls symptoms but may result in asymptomatic bacteriologic relapse
	Ciprofloxacin (Cipro)	1 g p.o. once	For tetracycline-resistant strains	—	Antibiotic therapy for *V. cholerae*
	Erythromycin	250 mg p.o. four times a day for 3 days	For tetracycline-resistant strains	1.00–1.49/day	
	Trimethoprim-sulfamethoxazole	1 double-strength tablet twice a day for 3 days	For tetracycline-resistant strains	0.10–0.24/day	
Helicobacter	Proton-pump inhibitor (omeprazole [Prilosec] or lansoprazole [Prevacid]) *or* Ranitidine bismuth citrate (Tritec) *plus* Two of the following: Amoxicillin Clarithromycin (Biaxin) Metronidazole (Flagyl)	Omeprazole 20 mg or lansoprazole 30 mg p.o. twice a day for 14 days 400 mg p.o. twice a day for 14 days 1 g p.o. twice a day 500 mg p.o. twice a day 500 mg p.o. twice a day for 14 days	Suggested therapy	100.00–149.99/mo 90.00–99.99/mo 100.00–149.99/mo 0.25–0.49/day 7.00–7.99/day 0.50–0.74/day	Triple-therapy combination[50]; for resistant *H. pylori*, ranitidine bismuth citrate may be slightly better than proton-pump inhibitor; metronidazole may cause nausea, metallic taste, headaches, or disulfiram-like reaction (avoid alcohol)
	Proton-pump inhibitor (omeprazole [Prilosec] or lansoprazole [Prevacid]) *plus* Tetracyline *plus* Bismuth subsalicylate (Pepto-Bismol) *plus* Metronidazole (Flagyl)	Omeprazole 20 mg or lansoprazole 30 mg p.o. twice a day for 14 days 500 mg p.o. four times a day for 14 days 525 mg p.o. four times a day for 14 days 500 mg p.o. three times a day for 14 days	Suggested therapy	100.00–149.99/mo 90.00–99.99/mo 0.10–0.24/day 3.00–3.99/day 0.50–0.74/day	Quadruple-therapy combination[50]; metronidazole may cause nausea, metallic taste, headaches, or disulfiram-like reaction (avoid alcohol)
	Proton-pump inhibitor (omeprazole [Prilosec] or lansoprazole [Prevacid]) *plus* Tetracyline *plus* Bismuth subsalicylate (Pepto-Bismol) *plus* Furazolidone (Furoxone)	Omeprazole 20 mg or lansoprazole 30 mg p.o. twice a day for 14 days 500 mg p.o. four times a day for 14 days 525 mg p.o. four times a day for 14 days 500 mg p.o. three times a day for 14 days	For patients who have failed combination therapies listed above	100.00–149.99/mo 90.00–99.99/mo 0.10–0.24/day 3.00–3.99/day —	Quadruple-salvage-therapy combination[50]; furazolidone, a monoamine oxidase inhibitor, may cause nausea, vomiting, headache, tachycardia, and elevated blood pressure; must consider potential interactions with other medications and foods

Diagnosis

Clinical manifestations The carrier state is generally asymptomatic. If the carrier state is accompanied by obstructive uropathy or gallstones, symptoms associated with that syndrome may be present.

Physical examination The physical examination of a patient in the carrier state is unremarkable.

Laboratory tests The carrier state is documented by culture of *Salmonella* organisms utilizing routine techniques.

Treatment

Ampicillin or amoxicillin [*see Table 1*] will eradicate the *Salmonella* organisms in 80% of persons in the carrier state. Alternative therapy is trimethoprim-sulfamethoxazole or ciprofloxacin [*see Table 1*]. Long-term gallbladder carriage can be effectively eliminated by cholecystectomy accompanied by 10 to 14 days of any of the regimens recommended for treatment of bacteremia. However, this approach should be reserved for individuals in whom eradication is required for public health reasons (e.g., food handlers and health care workers).

BACTEREMIA AND VASCULAR INFECTION

Nontyphoidal *Salmonella* organisms have a propensity to colonize sites of vascular abnormality, such as prosthetic vascular grafts, atherosclerotic plaques, and aneurysms.[21] The presence of high-grade bacteremia (more than 50% of three or more blood cultures are positive) is suggestive of endovascular infection.

Diagnosis

Clinical manifestations Patients with endovascular infection typically have high fevers that persist even after several days of therapy.

Physical examination The physical examination may reveal tenderness at the site of the infection, but it may also yield normal results.

Laboratory tests High-grade bacteremia (i.e., more than 50% of three or more blood cultures are positive) is suggestive of endovascular infection. Echocardiography and other imaging studies should be conducted to search for endovascular lesions.

Treatment

Life-threatening bacteremia, endovascular infection, or focal metastatic infection should be empirically treated with both a fluoroquinolone and a third-generation cephalosporin until antibiotic susceptibilities are known. For documented or suspected endovascular infection, 6 weeks of I.V. therapy with a β-lactam antibiotic, such as ampicillin or a cephalosporin, should be administered. For low-grade bacteremia, 7 to 14 days of I.V. therapy is adequate. Endovascular infection may require surgical intervention. However, in cases in which surgical resection of infected grafts is not feasible, lifelong oral suppressive therapy has been successful.[22]

In patients with AIDS, a first episode of *Salmonella* bacteremia should be treated with 7 to 14 days of I.V. antibiotics, followed by 4 weeks of an oral fluoroquinolone. AIDS patients who experience relapses of *Salmonella* bacteremia should be treated with an oral fluoroquinolone or trimethoprim-sulfamethoxazole for long-term suppression.

ENTERIC FEVER

Diagnosis

Clinical manifestations The incubation period for organisms that cause enteric fever ranges from 5 to 21 days. Initially, diarrhea or constipation may develop, followed by fever and then by headache, malaise, anorexia, myalgias, arthralgia, cough, and sore throat.[23] Approximately 1 week later, systemic toxemia, neuropsychiatric manifestations (psychosis and confusion), coryza, cough, sore throat, chest pain, and nausea and vomiting with or without abdominal pain may occur. Symptoms resolve spontaneously after 2 to 4 weeks.

Physical examination Results of the physical examination vary depending on the phase of the illness. During the toxemic

Table 2 Probability of Positive Cultures from Various Sites during Enteric Fever[24]

Phase of Illness (Time since Initial Exposure)	*Disease Manifestations*	*Cultures*				
		Blood	*Stool*	*Urine*	*Bone Marrow*	*Rose Spots*
Incubation period (0–1 wk)	Diarrhea in 10%–20%; constipation in some	Negative	Transiently positive	Negative	Negative	Negative
Active invasion (1–2 wk)	Fever, headache, malaise, anorexia, myalgia, arthralgia, cough, and sore throat	80%–90% positive	Negative	Negative	Negative	Negative
Established disease (2–4 wk)	Systemic toxemia, neuropsychiatric manifestations (psychosis and confusion), coryza, cough, sore throat, chest pain, nausea, vomiting, and abdominal pain	80%–90% positive	80% positive	25% positive	90% positive	60% positive
Convalescent period (4–5 wk)	—	Negative, except with ongoing disease or relapse	50% positive	10% positive	Decreasingly positive	Decreasingly positive
Late focal complications (> 5 wk)	Cholecystitis, osteomyelitis, soft tissue abscess	Negative, except with ongoing disease or relapse	Decreasingly positive	Decreasingly positive	—	—

Table 3 Vaccination for Enteric Fever

Vaccine	*Dose*	*Relative Efficacy*	*Cost ($)*	*Comment*
Ty21a (Vivotif Berna)	One enteric-coated capsule 1 hr before a meal every day for 4 days	43%–96%; not effective if administered with concomitant antimicrobial or antimalarial therapy	18.92	Live-attenuated vaccine; not recommended for immunosuppressed or children younger than 6 yr; boost every 5 yr; few side effects
Vi capsular polysaccharide [ViCPS] (Typhim Vi)	25 μg in 0.5 ml I.M. once	55% in one study[51]	30.21	Side effects: fever (1%), headache (1.5%–3%), local erythema or induration (7%); not recommended for children younger than 2 yr; boost every 2 yr
Heat-killed whole organism *Salmonella typhi*	0.5 ml I.M. for 2 doses administered more than 4 wk apart	51%–77%	9.39	Side effects: fever (17%–29%), severe headache (10%), pain at injection site (35%–60%), rare severe reactions; boost (0.1 ml) every 3 yr; dose for children 6 mo to 10 yr of age is 0.25 ml

phase of the illness, the patient's condition is acute. In 50% of patients, splenomegaly and hepatomegaly are present. In 30% of patients, rose spots (2 to 4 mm, slightly raised, discrete, irregular, blanching pink macules) appear on the anterior chest in crops of 5 to 15. The spots last 3 to 4 days and fade without a scar.

Laboratory tests The probability of culturing the organism from various sites varies during the course of illness [*see Table 2*].[24] Cultures of bone marrow and punch biopsies of rose spots may be positive when other cultures are negative, particularly during or after antibiotic therapy. Leukopenia, anemia, and moderately elevated liver function test results and muscle enzyme levels are common. Leukocytosis, transient thrombocytopenia, and clotting abnormalities are less common.

Differential Diagnosis

Enteric fever may be confused with other systemic febrile illnesses.

Treatment

Enteric fever can be successfully treated with ampicillin or amoxicillin, third-generation cephalosporins, fluoroquinolones, or trimethoprim-sulfamethoxazole [*see Table 1*]. However, given the prevalence of organisms resistant to ampicillin and third-generation cephalosporins among isolates from the Indian subcontinent, Southeast Asia, and Africa, therapy should consist of a fluoroquinolone or trimethoprim-sulfamethoxazole until antibiotic susceptibilities are known.[25] In cases of severe disease (associated shock, coma, stupor, obtundation, or delirium), dexamethasone [*see Table 1*] has been shown to improve survival,[26] although continuation of steroids beyond 48 hours may increase the rate of relapse.[27]

Several enteric fever vaccines are available [*see Table 3*]. Vaccination is recommended for individuals traveling to developing countries who will have prolonged exposure to contaminated food and drink. Vaccination is an adjunct and not a replacement for careful eating and drinking.

Complications

Nonmetastatic complications, which include pneumonia (5% of cases), intestinal hemorrhage (3% to 20% of cases), intestinal perforation (2% to 3% of cases), acute cholecystitis (2% of cases), and myocarditis (1% to 2% of cases), often occur 2 to 4 weeks after the initial onset of symptoms. Less commonly, endocarditis, pericarditis, orchitis, and splenic or liver abscesses may occur. In the setting of intestinal perforation, repeat blood cultures should be drawn, and antibiotics should be broadened to cover anaerobic and aerobic bowel flora.

Shigella Infections

EPIDEMIOLOGY

Shigella organisms are estimated to cause 450,000 cases of diarrhea annually in the United States,[15] and they are an important cause of diarrhea and death worldwide.[28] *Shigella* includes four species: *S. dysenteriae, S. sonnei, S. boydii,* and *S. flexneri*. In industrialized countries, *S. sonnei* is currently most common, and *S. flexneri* accounts for essentially all other cases. In developing countries, *S. dysenteriae* is also common. Humans are the only natural host of *Shigella* organisms, and they are spread by fecal-oral contact or, in 20% of cases, through contaminated food or water.

The infectious inoculum is as few as 10 to 100 organisms.[29] Consequently, outbreaks spread readily and recurrences are common in day care centers, mental institutions, and other crowded settings. Disease is most common among young children, and secondary infection rates in families are as high as 20%.

PATHOGENESIS

Initially, *Shigella* organisms colonize the proximal small bowel, where secretion of an enterotoxin probably causes the initial symptoms. The organisms then pass into the colon, where they invade and spread through the epithelial layer. *Shigella* organisms induce the release of proinflammatory cytokines. Bacterial spread, in conjunction with the intense acute inflammatory response, leads to the formation of ulcerations and microabscesses in the colonic epithelium. *Shigella* organisms rarely gain access to the bloodstream or infect deeper tissues. The toxin Stx (formerly called Shiga toxin) is present only in *S. dysenteriae* and contributes to the more severe diarrhea that can accompany *S. dysenteriae* infection. Related enterotoxins are produced by members of all *Shigella* species.

DIAGNOSIS

Clinical Manifestations

The incubation period for *Shigella* organisms is typically 3 days, with a range of 1 to 7 days. Initial symptoms usually include fever, abdominal cramps, and watery diarrhea, which are followed by abdominal cramps, tenesmus, rectal urgency, and

small-volume diarrhea. Diarrhea during this later stage is frequent (eight to 10 episodes a day), and stools may be bloody with mucus. If left untreated, disease is generally self-limited, lasting 7 days or less.

Physical Examination

Physical findings are nonspecific. Patients may appear toxic and have a high temperature (up to 41° C [106° F]). Abdominal tenderness, particularly in the left lower quadrant, and hyperactive bowel sounds are common.

Laboratory Tests

Stool cultures are usually positive during the acute illness. Later, *Shigella* organisms may be isolated by direct culture of material from rectal ulcerations. Direct microscopic examination of stool stained with methylene blue (or another stain) is extremely important because the presence of abundant leukocytes in the proper clinical setting is strongly suggestive of shigellosis. In *Salmonella* enteritis, *Campylobacter* enteritis, and idiopathic ulcerative colitis, leukocytes may also be present in the stool. The white blood cell count may be elevated with an increase in the percentage of immature forms, and metabolic abnormalities may be present.

DIFFERENTIAL DIAGNOSIS

In the setting of high fever, tenesmus, rectal urgency, and diarrhea with blood- and mucus-containing stools, *Shigella* infection should be suspected. However, *Shigella* infection can resemble any febrile diarrheal syndrome, including those caused by *Campylobacter*, *Y. enterocolitica*, and *Salmonella* organisms and by inflammatory bowel disease.

TREATMENT

For patients with significant dehydration, particularly young children and the elderly, oral and, if necessary, intravenous rehydration should be administered. Antibiotics are not essential, but administration of an antibiotic to which the organism is susceptible has been shown to shorten the course of clinical illness and the period of fecal excretion.[30,31] Given the ease of person-to-person *Shigella* transmission, many experts recommend that all individuals with documented infection be treated for public health reasons. For *Shigella* infection acquired in the United States with an unknown antibiotic susceptibility pattern, the treatment of choice is trimethoprim-sulfamethoxazole [*see Table 1*] because ampicillin resistance is common. The alternative therapy or therapy for trimethoprim-resistant isolates is norfloxacin, ciprofloxacin, or ofloxacin [*see Table 1*]. For *Shigella* acquired in Southeast Asia, Africa, the Middle East, Japan, South America, Spain, or Canada, the treatment of choice is a fluoroquinolone, because resistance to trimethoprim-sulfamethoxazole is common [*see Table 1*]. Azithromycin has also been used successfully. Cephalosporins have limited efficacy.

COMPLICATIONS

Complications are generally rare but include intestinal obstruction in the setting of severe colonic disease (2.5% of cases), bacteremia (4% of cases), colonic perforation (1.7% of fatal cases), and toxic megacolon (3% of *S. dysenteriae* infections). Proctitis and rectal prolapse (in children) also occur as complications. Metabolic disturbances are relatively common, although severe dehydration is uncommon because stool volume is generally low. Seizures occur in approximately 5% of infected children, generally in the setting of high fever and metabolic abnormalities.[32]

Reactive arthritis may occur 1 to 2 weeks after diarrhea, either alone or accompanied by conjunctivitis and urethritis (Reiter syndrome); 70% of these patients have the HLA-B27 haplotype. Although most commonly caused by enterohemorrhagic *E. coli* infection, hemolytic-uremic syndrome may occur after *Shigella* infection. Hemolytic-uremic syndrome is associated with infection caused by *S. dysenteriae* and is thought to be mediated by Stx.

PROGNOSIS

Prognosis is generally excellent. Settings that predispose to recurrence of disease are those with suboptimal hygiene, such as day care centers or crowded living conditions.

Yersinia Infections

EPIDEMIOLOGY

All three *Yersinia* species, *Y. enterocolitica*, *Y. pseudotuberculosis*, and *Y. pestis*, are pathogenic for humans. *Y. enterocolitica* and *Y. pseudotuberculosis* are widely distributed in nature and cause a variety of zoonoses. In the United States, *Y. enterocolitica* is estimated to cause approximately 100,000 cases of diarrhea annually,[15] predominantly in children. *Y. pseudotuberculosis* is a sporadic cause of purulent mesenteric adenitis.

Transmission of *Y. enterocolitica* is usually by ingestion of contaminated foodstuffs, including meat, milk and other dairy products, mussels, tofu, and oysters. Person-to-person transmission has also been reported, with a significant rate of secondary cases within families.[33] Transfusion of *Y. enterocolitica*–contaminated red blood cells has been a cause of severe transfusion reactions with high mortality.[34] Among the approximately 60 serogroups of *Y. enterocolitica*, three (O:3, O:8, and O:9) cause most human disease. Individuals with underlying cirrhosis or hemochromatosis, particularly if being treated with desferrioxamine, are at increased risk for bacteremia and metastatic disease.

PATHOGENESIS

Y. enterocolitica and *Y. pseudotuberculosis* transit the stomach, invade the mucosa of the terminal ileum at Peyer patches, and colonize mesenteric lymph nodes. *Yersinia* organisms are able to both replicate intracellularly and bind to macrophages and inhibit phagocytosis. The inflammatory response that ensues in the terminal ileum may be clinically mistaken for appendicitis or Crohn ileitis.

DIAGNOSIS

Clinical Manifestations

In older children and adults, *Y. enterocolitica* causes a febrile diarrheal syndrome in which the prominent symptom is colicky abdominal pain, predominantly localized to the right lower quadrant. In younger children, the illness may include vomiting and bloody diarrhea. Exudative pharyngitis has also been reported.[35] Septicemia, which occurs in individuals with iron overload or other chronic diseases, is often complicated by metastatic abscesses formation. *Y. pseudotuberculosis* causes mesenteric adenitis, which mimics acute appendicitis, with fever and right lower quadrant pain.

Physical Examination

On physical examination, patients with *Yersinia* infection are typically found to have fever and right lower quadrant tenderness.

Laboratory Tests

Leukocytosis is common. Microscopic examination of the stool will reveal fecal leukocytes. Whereas isolation of *Yersinia* organisms from normally sterile body fluids is straightforward, isolation from stool is difficult because the organisms appear similar to and grow more slowly than other Enterobacteriacae organisms; selective media for *Yersinia* organisms have not been developed. *Yersinia* serology, which turns positive 1 to 2 weeks after infection, may be useful in the setting of one of the autoimmune syndromes that may complicate infection. *Y. enterocolitica* is carried in the stool for an average of 1 month after the resolution of symptoms.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of diarrheal disease with polymorphonuclear leukocytes in the stool is enteritis caused by infection with *Campylobacter*, *Salmonella*, *Shigella*, or *Y. enterocolitica* or caused by idiopathic ulcerative colitis. Mesenteric adenitis caused by *Yersinia* infection may mimic appendicitis.

TREATMENT

Enteritis and mesenteric adenitis caused by *Y. enterocolitica* or *Y. pseudotuberculosis* are generally self-limited, and no clear role for antibiotic therapy has been established. Although direct proof is lacking, in principle, antiperistaltic agents should be avoided.

Septicemia caused by either *Y. enterocolitica* or *Y. pseudotuberculosis* should be aggressively treated with antibiotics because mortality is high. The suggested agents for treatment of *Y. enterocolitica* septicemia are gentamicin, doxycycline, trimethoprim-sulfamethoxazole, or a fluoroquinolone, alone or in combination [*see Table 1*].[36] *Y. enterocolitica* organisms produce a β-lactamase and are therefore resistant to penicillins and cephalosporins. The suggested agents for treatment of *Y. pseudotuberculosis* septicemia are ampicillin, streptomycin, and tetracycline [*see Table 1*]. For either *Y. enterocolitica* or *Y. pseudotuberculosis*, enteric precautions should be adopted.

COMPLICATIONS

Either reactive polyarthritis or erythema nodosum complicates 1% to 5% of *Y. enterocolitica* infections in adults in the United States and 10% to 30% of such infections in Scandinavia. On occasion, *Y. pseudotuberculosis* infections in adults are also complicated by reactive polyarthritis or erythema nodosum. These disorders may be the presenting complaint. Therefore, in individuals with such complaints, *Yersinia* infection should be considered and serology and cultures should be performed. These complications of *Yersinia* infections rarely occur in young children.

Reactive polyarthritis develops 2 days to 1 month after the onset of gastrointestinal symptoms. It persists for more than a month in two thirds of patients and for more than 4 months in one third of patients. Knees, ankles, toes, fingers, and wrists may be involved. Synovial fluid usually contains fewer than 25,000 white blood cells/ml, with a preponderance of polymorphonuclear leukocytes and negative cultures. The disorder may be particularly severe in individuals with the HLA-B27 haplotype, presenting as full-blown ankylosing spondylitis or as Reiter syndrome.

Erythema nodosum develops 2 to 20 days after the onset of gastrointestinal symptoms. It typically resolves spontaneously within a month and is twice as common in women than in men. Skin lesions are usually on the legs and trunk.

PROGNOSIS

The prognosis for *Y. enterocolitica* enteritis is excellent. In contrast, *Y. enterocolitica* septicemia is fatal in 50% of cases and *Y. pseudotuberculosis* septicemia is fatal in 75% of cases, despite appropriate antimicrobial therapy.

Vibrio Infections

CHOLERA

Epidemiology

The natural reservoir of *V. cholerae* is aquatic invertebrates in brackish or marine environments. Certain strains have become pathogenic for humans and have caused seven pandemics throughout history, the most recent of which began in Asia in 1961. There are 139 serotypes of *V. cholerae*, defined by the O surface antigen. Initially, the seventh pandemic was caused by an O1 strain of biotype El Tor, but in 1992, a new strain emerged from the pandemic strain that carried a new O antigen, which was designated O139. The emergence of the new strain was concurrent with rapid spread of cholera through Latin America and Africa. Currently, the continuing pandemic is caused by two strains, O139 and an O1 strain that differs from the initial O1 strain and likely emerged from the O139 strain.[37]

Spread of cholera is primarily through ingestion of fecally contaminated water and food, especially, but not exclusively, seafood. Only about 50 cases of cholera are estimated to occur in the United States annually,[15] predominantly in persons who acquire it while traveling in endemic areas. The rate of secondary infection in households is very high, suggesting that person-to-person transmission is occurring. Because *V. cholerae* is sensitive to gastric acid, the infectious inoculum in normal hosts is 10^{10} organisms, but in persons taking antacids or who have achlorhydria, the inoculum may be 10^6 organisms or fewer. Natural immunity to cholera is long lasting, with specificity to the O1 antigen. Thus, in endemic areas, disease is most common in children, but nonimmune adults traveling in the region are susceptible. Furthermore, alteration of the O antigen, as seen with the shift from O1 to O139 in 1992, leads to widespread susceptibility in adults.

Pathogenesis

V. cholerae colonize the proximal small intestine and secrete one major and at least two minor enterotoxins. The major toxin, cholera toxin (CTX), binds the ganglioside GM1 on the intestinal epithelium and activates adenylate cyclase, which in turn leads to the accumulation of cyclic adenosine monophosphate (cAMP). Increased levels of cAMP cause chloride secretion and inhibit sodium absorption, resulting in the characteristic profuse isotonic watery diarrhea.

V. cholerae does not invade intestinal tissue, and there is no tissue inflammatory response. Absorptive processes unaffected by cAMP, including glucose-facilitated salt and water absorption, are unaltered, allowing oral rehydration with glucose-electrolyte solutions.

Diagnosis

Clinical manifestations The hallmark of cholera is massive watery diarrhea consisting of thin, gray-brown, mucus-containing fluid (so-called rice-water stools). The diarrhea begins a few days after initial exposure to *V. cholerae* and is soon followed by copious vomiting without retching. Notably absent are fever (which occurs in only 5% of cases), abdominal pain, tenesmus, and strain. Muscle cramps may occur as a result of electrolyte shifts. Dehydration ranges from mild to severe. A rare variant in the presentation is so-called cholera sicca, in which abdominal ileus and distention occur, and diarrhea is absent. If left untreated, symptoms of cholera resolve in 1 to 7 days.

Physical examination Patients appear anxious and restless, with sunken eyes, dry mucous membranes, poor skin turgor, hyperactive bowel sounds, hypotension, and tachycardia. Obtundation may occur with severe dehydration. As much as 1 L/hr of fluid may be excreted in stools.

Laboratory tests Microscopic examination of Gram stains of stool reveals the small (1 to 3 μm long), comma-shaped, gram-negative organisms. *V. cholerae* grow well on a variety of selective media; TCBS (thiosulfate-citrate-bile salt-sucrose) agar is commonly used.

In patients with moderate-to-severe dehydration, packed cell volume, serum specific gravity, and total protein levels are elevated. In patients with severe disease, prerenal azotemia, metabolic acidosis with an elevated anion gap, normal to low serum potassium levels, normal to slightly low serum sodium and chloride levels , and leukocytosis are seen.

Differential Diagnosis

In patients with severe dehydration, cholera resembles little else. In patients with mild to moderate dehydration, the presentation is similar to that of enterotoxigenic *E. coli* (ETEC) or rotavirus.

Treatment

The cornerstone of management is prompt replacement of lost fluid and electrolytes. Replacement fluid and electrolytes should be administered intravenously for patients with severe dehydration, patients with moderate dehydration who do not tolerate oral intake, and patients who are purging large amounts of fluid (10 to 20 ml/kg/hr). Initially, replacement fluid should consist of lactated Ringer solution or a solution containing 5 g NaCl, 4 g $NaHCO_3$, and 1 g KCl for each liter of sterile distilled water. The goal is to return the patient to normal hydration status within 4 hours, which, in severely dehydrated persons, may require administration of fluids at 50 to 100 ml/kg/hr. Once rehydration has been accomplished, as determined by hemodynamic status and urine production, normal hydration status should be maintained by replacement of continuing losses of fluid. For those patients with mild disease, rehydration can be accomplished by oral administration of a glucose-electrolyte solution that consists of 20 g glucose, 3.5 g NaCl, 2.5 g $NaHCO_3$, and 1.5 g KCl for each liter of water.

Antibiotics are an adjunct to rehydration therapy; they can reduce the duration of symptoms and infection, as well as the overall fluid requirements. Tetracycline is the drug of choice [*see Table 1*]. Tetracycline-resistant isolates have been identified in Latin America, Bangladesh, and Tanzania; appropriate therapy for these isolates is ciprofloxacin, erythromycin, or trimethoprim-sulfamethoxazole. The only cholera vaccine (Wyeth Laboratories) commercially available in the United States provides protection in only 30% to 50% of cases and has a high rate of side effects.[38] In general, the vaccine should be administered only if required for entry into a foreign country.

Complications and Prognosis

Acute renal failure has complicated cholera in patients with severe dehydration who did not receive proper rehydration. In patients with severe dehydration who receive no treatment, mortality is about 50%.

OTHER INFECTIONS CAUSED BY *VIBRIO* SPECIES

In the United States, other *Vibrio* species are estimated to cause approximately 8,000 cases of disease annually.[15] These species include *V. parahaemolyticus*, *V. vulnificus*, and nontoxigenic strains of *V. cholerae*.

V. parahaemolyticus

V. parahaemolyticus is a common cause of diarrhea in the Chesapeake Bay area, the Gulf Coast region, and the Pacific Northwest. The organism is ubiquitous in coastal waters and is typically acquired by ingestion of raw or undercooked shellfish. Clinical illness most commonly consists of explosive watery diarrhea, crampy abdominal pain, and low-grade fever. Wound infections and septicemia also occur. The organism can be cultured from stool on selective media such as TCBS and from sterile body fluids in routine blood culture media or on blood agar plates. The illness is self-limited, lasting less than 7 days. Antibiotic treatment has not been shown to shorten the course of the illness, although if administered, tetracycline is probably the best choice because of its documented efficacy against *V. cholerae*.

V. vulnificus

V. vulnificus, an important cause of serious disease, can be isolated from waters of the eastern and western coasts of the United States, as far north as Cape Cod and the northern Pacific coast,[39] particularly during the summer months. In compromised persons, particularly those with chronic liver disease or iron-overload states but also other immunosuppressed persons, *V. vulnificus* can cause an overwhelming sepsis, accompanied by metastatic cutaneous lesions in the form of hemorrhagic bullae or vesicles that evolve into necrotic ulcers. This syndrome with bacteremia is fatal in over 50% of cases. More than 90% of patients have consumed raw oysters within a week of the onset of illness. Therapy consists of adequate debridement and parenteral antibiotics. Tetracycline is probably the drug of choice; either cefotaxime or ciprofloxacin is an alternative. Animal studies suggest that the combination of tetracycline and cefotaxime may be better than either drug alone.[40]

In both immunocompromised and healthy hosts, *V. vulnificus* can cause a second syndrome—a rapidly progressive cellulitis, fasciitis, or myositis that follows infection of a superficial wound, typically after cleaning shellfish. In addition to antimicrobials, incision and drainage with debridement are often necessary.

Non-O1 V. cholerae

Strains of *V. cholerae* (non-O1 *V. cholerae*) that do not produce cholera toxin can cause an acute febrile gastroenteritis. Non-O1 *V. cholerae* are distributed worldwide in saltwater and freshwa-

ter. Exposure is generally by ingestion of raw shellfish, particularly oysters. Diarrhea can range from mild to severe. Usually, no treatment is necessary, but in severe disease, rehydration and tetracycline are recommended.

Helicobacter Infections

EPIDEMIOLOGY

Helicobacter pylori is directly linked to the development of duodenal ulcer, gastric ulcer disease, and gastritis and to the long-term complications of gastric adenocarcinoma and gastric mucosa–associated lymphoid tissue (MALT) lymphoma. The organism is believed to be the cause of peptic ulcer disease in 90% of individuals with duodenal ulcers and in 70% to 90% of individuals with gastric ulcers. Cure of the infection significantly decreases the risk of long-term malignant complications.[41] Whether *H. pylori* also plays a role in peptic ulcer disease in the setting of nonsteroidal anti-inflammatory drug usage is less clear.

H. pylori infection is the most common long-term bacterial infection worldwide, with higher prevalence in developing countries than in industrialized countries. In the United States, the prevalence is 10% for persons 18 to 30 years of age, 30% to 45% for persons 30 to 60 years of age, and 50% for persons older than 60 years.[42,43] The prevalence is severalfold higher in African Americans and Hispanics than in non-Hispanic whites,[44] which is likely a reflection of the impact of socioeconomic status and living conditions on transmission as well as possibly an indication of a minor role of hereditary susceptibility.

Evidence suggests that transmission occurs from person to person by the fecal-oral or oral-oral route.[45] Humans appear to be the major reservoir, although the organism has also been isolated from other primates and domestic cats. A second *Helicobacter species*, *H. heilmanii*, has been observed in the stomachs of humans,[46] but whether it has a role in the pathogenesis of gastric disease is unknown.

PATHOGENESIS

H. pylori organisms colonize the gastric mucus and adhere to gastric epithelial cells. They survive the acidic environment of the stomach by surrounding themselves with pH-buffering ammonia that is produced from hydrolysis of urea by a bacterial urease. *H. pylori* induces autocrine stimulation and proinflammatory cytokine release, causing alterations in acid secretion and acute and chronic inflammation that, in turn, potentiate the disease process and contribute to the development of the malignant complications of infection. The exact mechanisms are not fully understood, although a cluster of genes known as the *cag* pathogenicity island appears to be involved.

DIAGNOSIS

Clinical Manifestations

Acute *H. pylori* infection produces symptoms of gastroenteritis in up to 60% of patients, including nausea, vomiting, epigastric pain, and fever. Symptoms last 3 to 14 days. A period of hypochlorhydria begins a few weeks after clinical symptoms resolve and lasts 2 to 8 months. Hypochlorhydria is associated with gastritis, which causes the symptoms that frequently bring patients to medical attention.

Physical Examination

During the acute gastroenteritis syndrome, physical findings are nonspecific. Epigastric tenderness and fever may be present. Long-term findings are those of gastritis or peptic ulcer disease.

Laboratory Tests

Three of the more useful diagnostic tests in the initial diagnosis of *H. pylori* infection are (1) the carbon-13 (^{13}C) urea breath test (UBT), (2) the stool antigen test (HpSA), and (3) the enzyme-linked immunosorbent assay (ELISA) serology test [*see Table 4*]. The UBT and HpSA are noninvasive. The UBT does not pose a significant radiation exposure risk and is therefore safe for pregnant women and children. Because proton-pump inhibitors reduce the load of *H. pylori*, they should be stopped 2 weeks before either the UBT or the HpSA is performed.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the acute gastroenteritis syndrome caused by *H. pylori* includes other causes of acute small intestinal infection, including toxin-induced gastroenteritis caused by *Clostridium perfringens, Bacillus cereus, Staphylococcus aureus*, ETEC, giardiasis, and viral gastroenteritis.

TREATMENT

Given the potential serious long-term complications of *H. pylori* infection, any individual who has documented infection should be treated. Recommended treatment regimens all consist of combinations of antibiotics and antisecretory agents or a bismuth formulation [*see Table 1*]. For duodenal ulcer disease caused by antibiotic-susceptible *H. pylori*, success rates range from 95% to 99%. Success rates may be lower in patients without duodenal ulcer disease. Success rates have been shown to

Table 4 Sensitivity and Specificity of Tests for *Helicobacter pylori* Infection[52,53]

Test	*Sensitivity (%)*		*Specificity (%)*	
	*Before Treatment**	*After Treatment†*	*Before Treatment**	*After Treatment†*

ELISA	> 90	Not useful	> 90	Not useful

*N = 501.
†N = 133.
ELISA—enzyme-linked immunosorbent assay HpSA—*H. pylori* stool antigen UBT—13C-urea breath test

be reduced by treatment with two agents rather than three or four; shortening of the course of therapy from 14 days to 10 or 7 days; or lowering of the dose of metronidazole from 500 mg to 250 mg. The combination of clarithromycin and metronidazole may be more successful than the combination of clarithromycin and ampicillin, although rigorous comparisons have not yet been performed.

Cure should be confirmed in all treated patients. The optimal tests for confirmation are the UBT and the HpSA [*see Table 4*] because serum antibody levels will remain elevated for at least 9 months. To ensure that any residual organisms have had the chance to multiply to detectable levels, UBT or HpSA should be delayed until at least 4 weeks after the course of therapy is completed, and proton-pump inhibitors should be stopped 2 weeks before the test. H_2 receptor antagonists can be continued until the day of testing because they have no effect on *H. pylori*.

Resistance to clarithromycin currently occurs in 11% of isolates in the United States and is an increasing problem. Resistance to metronidazole has also been reported; however, the combination of 500 mg of metronidazole with ampicillin or clarithromycin and a proton-pump inhibitor is effective even in the setting of metronidazole resistance.

Although information about the antibiotic susceptibility of the infecting strain is always useful, isolation of *H. pylori* is not trivial, requiring endoscopy and biopsy. Therefore, it is reasonable to treat suspected *H. pylori* infection empirically and obtain antibiotic susceptibility tests only if the initial therapy fails. In general, if a 14-day course of combination therapy fails, the possibility of resistance should be considered. Moreover, if the failed course of therapy included metronidazole and clarithromycin, antibiotic susceptibilities should be determined. Particular antibiotic combinations should not be repeated unless in vitro susceptibility is demonstrated.

COMPLICATIONS

H. pylori infection is probably the cause of the majority of MALT lymphomas. More than 90% of individuals with MALT lymphoma have evidence of *H. pylori* infection, and eradication of the infection during the premalignant phase leads to cure of the lymphomatous process.[47,48]

H. pylori gastritis can progress to chronic atrophic gastritis, which is thought to be a precursor for gastric adenocarcinoma. A prospective study of 1,526 patients in Japan who had duodenal ulcers, gastric ulcers, gastric hyperplasia, or nonulcer dyspepsia showed that gastric cancer developed in patients infected with *H. pylori*, but not in uninfected patients.[49] Treatment of *H. pylori* infection may reduce the risk of adenocarcinoma. However, gastric adenocarcinoma will develop in only a minority of patients with *H. pylori* gastritis, and some gastric adenocarcinomas occur in patients without evidence of prior *H. pylori* infection.

PROGNOSIS

In follow-up to a course of combination therapy, infection is again detected in a small but significant percentage of cases. Presence of *H. pylori* organisms usually represents recurrence rather than reinfection because most isolates are identical to the original isolate. If standard combination therapies fail, antibiotic susceptibility testing of the isolate and salvage therapy should be considered [*see Table 1*].

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

X INFECTIONS DUE TO HAEMOPHILUS, MORAXELLA, LEGIONELLA, BORDETELLA, AND PSEUDOMONAS

Shawn J. Skerrett, m.d.

Haemophilus, Moraxella, Legionella, Bordetella, and *Pseudomonas* are gram-negative bacteria that are important respiratory pathogens. All can also cause other types of infections. Vaccines have markedly reduced the incidence of disease from *Haemophilus* and *Bordetella,* but these organisms remain sources of morbidity and potentially life-threatening infection.

Haemophilus influenzae Infections

In 1892, the German bacteriologist Richard Pfeiffer made the sensational claim that he had identified the etiologic agent of influenza.[1] He had repeatedly observed a bacillus in purulent sputum obtained from influenza victims and found that this organism could be cultured on media supplemented with blood. Pfeiffer's blood-loving bacillus was named *Haemophilus influenzae*.[1] Although the causative link with influenza proved false, *H. influenzae* was subsequently recognized as the leading cause of meningitis in young children and an important agent of respiratory infections.

H. influenzae occurs in encapsulated and unencapsulated forms.[2] Encapsulated strains express one of six antigenically distinct capsular polysaccharides, designated *a* through *f*. The type b strain was responsible for most invasive *Haemophilus* infections before the widespread use of conjugate vaccines began in the 1980s. The other capsular groups are rarely implicated as pathogens. Unencapsulated strains do not react with antisera directed at the polysaccharide antigens and thus are nontypeable. These strains are common commensals but can cause mucosal and invasive infections.

epidemiology

H. influenzae is strictly a human parasite: no nonhuman host is known, and *H. influenzae* is not found free in nature. Essentially all persons are colonized by one or more strains of *Haemophilus* by 1 year of age.[2] The primary reservoir for *H. influenzae* is the human upper respiratory tract, although the organism can also be carried on the conjunctivae and in the genital tract. Population studies have found that 40% to 80% of persons harbor unencapsulated strains of *H. influenzae* in the nasopharynx.[2,3] Type b strains were recovered from nasopharyngeal swabs of 2% to 4% of children before the widespread use of the conjugate vaccines, but now such strains are found in less than 1% of children in vaccinated populations. The specific strains colonizing a person's pharynx change over time, and multiple strains can be found concurrently.[2,3] Colonization of the normally sterile tracheobronchial tree with nontypeable strains of *H. influenzae* occurs commonly in people with chronic airway disease, such as cystic fibrosis, bronchiectasis, and chronic obstructive pulmonary disease (COPD), and in asymptomatic smokers.[2,4] In very young infants, nasopharyngeal colonization with *H. influenzae* is associated with an increased risk of otitis media.[2] Persistent colonization of the lower respiratory tract with *H. influenzae* is associated with increased airway inflammation[5] and may contribute to the progression of COPD.[4]

H. influenzae can be transmitted from person to person, leading to secondary cases of infection in households, day care centers, and institutions.[2] The risk of invasive *H. influenzae* infection is age related. The incidence is highest in children younger than 5 years, with a second peak late in life.[6] The distribution and burden of invasive *H. influenzae* infection have been dramatically altered by the use of conjugate vaccines directed against the type b capsular polysaccharide.[7] In unvaccinated populations, the incidence of infection peaks between 6 and 18 months of age, but in vaccinated populations, the risk is highest in the first 6 months of life, before the primary immunization series is completed. In the prevaccine era, there were approximately 20,000 cases a year of invasive *H. influenzae* infection in children younger than 5 years in the United States. Meningitis accounted for 60% of these cases, and 95% of the infections were caused by type b strains.[7] Currently, fewer than 400 cases of invasive *H. influenzae* infection in children younger than 5 years are reported to the Centers for Disease Control and Prevention (CDC) each year, and the minority of these are type b infections.[6] Conjugate vaccine usage has also reduced the overall incidence of invasive *H. influenzae* infection in older children and adults, although an increase in non–serotype b infections has been observed.[8] Most cases of invasive *H. influenzae* in the United States now occur in adults, with pneumonia being the most common type of infection.[6] Certain population groups remain at increased risk, including Native Americans, Alaskan Natives, and African Americans.[7] An increased risk of invasive *H. influenzae* type b infection is also observed in association with complement deficiencies, hypogammaglobulinemia, and splenic dysfunction. The incidence of *H. influenzae* pneumonia is increased in the settings of recent influenza, HIV infection, alcoholism, advanced age, and underlying COPD.

pathogenesis and immunity

All *Haemophilus* organisms are small, pleomorphic, nonmotile, gram-negative coccobacilli. They are facultative anaerobes with fastidious nutritional requirements. Aerobic growth of *H. influenzae* requires X and V factors, both of which are contained in red blood cells. X factor (hematin) is not a single nutrient but, rather, refers to several diffusable pigments that supply protoporphyrins. V factor is nicotinamide adenine dinucleotide, a coenzyme that is released by lysis of red cells. All species of *Haemophilus* grow well on chocolate agar, which contains red cells that have been disrupted by heating.

Unencapsulated strains of *H. influenzae* selectively colonize and locally invade the respiratory tract. *H. influenzae* binds to airway mucins but evades mechanical clearance by inhibiting ciliary beat frequency and damaging ciliated epithelium. The ciliotoxic properties of *H. influenzae* have been attributed to the lipid A, peptidoglycan, and lipoprotein components of the bacterial cell

wall. Most strains of *H. influenzae* also produce a protease that cleaves both serum and secretory IgA, thus inactivating a major component of mucosal host defense.[2,3] *H. influenzae* attaches to respiratory epithelial cells with the aid of several adhesins, including pili, high-molecular-weight hemagglutinins, and other surface proteins.[3] *H. influenzae* preferentially binds to nonciliated cells and to epithelium damaged by recent viral infection or exposure to toxins such as cigarette smoke.[2,3] *H. influenzae* not only can attach to the surface of respiratory epithelium but can enter and survive in epithelial cells and mucosal macrophages and penetrate intercellular junctions to invade the submucosal interstitium.[2,4]

H. influenzae type b is less efficient at colonization than unencapsulated strains, but it has a much greater capacity to invade and survive within the bloodstream.

The magnitude and duration of bacteremia is a critical determinant in the development of *H. influenzae* meningitis, which results mainly from hematogenous seeding rather than direct spread from contiguous infection.[2] The type b capsule facilitates invasion by shielding the organism from complement- and antibody-mediated phagocytosis.[2] The lipo-oligosaccharide in the *H. influenzae* outer membrane is another important factor in the pathophysiology of invasive *H. influenzae* infection: its lipid A component has typical endotoxin activity and contributes to local and systemic inflammatory manifestations of infection, including septic shock.[3]

Antibodies constitute the principal defense against *H. influenzae* type b. These antibodies are directed against the bacteria's capsule, which is composed of repeating units of polyribosyl ribitol phosphate (PRP). Anticapsular antibodies facilitate ingestion of *H. influenzae* by phagocytes and mediate the complement-dependent bactericidal activity of immune serum. Antibodies specific for the PRP component of *H. influenzae* appear by 4 years of age and coincide with the age-related decline in susceptibility to invasive disease.[2] Host resistance to nontypeable strains of *H. influenzae* is less well understood but also involves humoral immunity.[2-4]

CLINICAL SYNDROMES

In the prevaccine era, *H. influenzae* type b was responsible for nearly all invasive *H. influenzae* infections in young children and approximately 50% of invasive infections in adults.[9-11] Meningitis accounted for more than half of the childhood cases of invasive *H. influenzae* type b infection, followed by pneumonia, epiglottitis, primary bacteremia, cellulitis, and musculoskeletal infections.[12] In adults, pneumonia has been the most common manifestation of invasive *H. influenzae* infection, followed by primary bacteremia, epiglottitis, meningitis, obstetric infections, and septic arthritis.[9-11] Widespread use of conjugate vaccines has dramatically reduced the overall incidence of invasive type b infections, but infections caused by nontypeable *H. influenzae* remain important in both children and adults. Unencapsulated strains of *H. influenzae* are principally associated with otitis media, sinusitis, bronchitis, and pneumonia but can also infect other sites.

Meningitis

H. influenzae type b is the leading cause of meningitis in children younger than 5 years in unvaccinated populations but has become rare in immunized communities.[7,12] In adults, *H. influenzae* (predominantly type b) accounts for approximately 4% of cases of community-acquired and nosocomial meningitis.[9,13,14] Adult cases often are associated with contiguous infection of the paranasal sinuses, mastoids, or middle ear or with antecedent head trauma.[13-15] Childhood cases, in contrast, result from bacteremic seeding and often follow an upper respiratory infection.

The clinical manifestations of *H. influenzae* meningitis in both children and adults are typical of acute bacterial meningitis.[9,15] Most patients present with fever, headache, and lethargy. The cerebrospinal fluid is usually cloudy, with a neutrophilic pleocytosis, increased protein concentration, and reduced glucose levels. The diagnosis is made by detecting *H. influenzae* in blood or CSF (see below). The clinical course may be fulminant, leading to death within 24 hours. The overall mortality of *H. influenzae* meningitis in young children is approximately 5%, but 20% to 30% of survivors suffer residual neurologic sequelae. Morbidity is reduced in children treated with dexamethasone.[16] The mortality in adult cases is 10% to 30%.

Epiglottitis

Epiglottitis is a life-threatening infection that is most prevalent in children 2 to 7 years of age but also occurs in older children and adults. *H. influenzae* type b is the most common cause of epiglottitis in all age groups, and the incidence of epiglottitis has declined since the availability of conjugate vaccines.[2,17]

The usual presenting symptoms of epiglottitis are sore throat, odynophagia, dyspnea, and fever; respiratory symptoms are more common in children than adults.[17] The onset of epiglottitis is often abrupt, and the progression can be very rapid. On examination, patients are anxious and may assume an airway-protective posture, sitting erect with the neck extended and the chin protruding forward. Drooling and a muffled voice are useful clues. Stridor, tachypnea, and use of accessory muscles to breathe are common findings in children. The diagnosis can be confirmed by laryngoscopy, with visualization of the cherry-red swollen epiglottis in children or the diffuse supraglottic edema more typical of adult cases. Laryngoscopy must be undertaken with care because the procedure may precipitate acute airway obstruction. A lateral neck x-ray also can be diagnostic, but the supine position should be avoided and patients with suspected epiglottitis should not travel to the radiology suite unless accompanied by a physician prepared to secure an airway. Blood cultures are positive in many cases.

An artificial airway (endotracheal intubation or tracheostomy) should be established emergently in all children with epiglottitis and in adults with evidence of airway compromise. All patients with epiglottitis should be admitted to the hospital for observation and treatment with parenteral antibiotics. Death can result from acute airway obstruction or from septic shock. The mortality is less than 5%.

Pneumonia

H. influenzae is the second or third most common cause of community-acquired pneumonia in adults, identified in 1% to 12% of hospitalized cases.[18] Most of the isolates in these cases are nontypeable strains.[19] In contrast, community-acquired *H. influenzae* pneumonia in children is caused mainly by type b and now is rare in vaccinated populations.[12]

In adults, the risk factors for *H. influenzae* pneumonia include COPD, advanced age, alcoholism, and HIV infection.[9,19,20] *H. influenzae* has also been identified as an important cause of nosocomial pneumonia in the first 5 days of hospitalization, before the indigenous flora of the upper respiratory tract have been replaced.[21]

H. influenzae pneumonia presents as a typical acute pneumonia, with fever, cough productive of purulent sputum, chest pain, and dyspnea.[9,19] Crackles and diminished breath sounds usually

are evident on lung auscultation. The chest x-ray may reveal a bronchopneumonic pattern or focal consolidation, often multilobar. Pleural effusions are common. The diagnosis of *H. influenzae* pneumonia is made most often from the sputum Gram stain and culture, although the organism is frequently missed on sputum smears.[18] Blood cultures are positive in 20% to 30% of cases. Complications of *H. influenzae* pneumonia include empyema, purulent pericarditis, and metastatic infection. The reported mortality of *H. influenzae* pneumonia is 5% to 20%, but it is higher in patients with bacteremia or suppurative complications.

Tracheobronchitis

H. influenzae can cause tracheobronchitis in patients with underlying COPD and, more rarely, in immunocompromised patients.[4,19] The airways of patients with chronic lung disease are often colonized with nontypeable strains of *H. influenzae*, and the acquisition of new strains is associated with acute exacerbations of chronic bronchitis.[4,22] The clinical presentation is characterized by an increase in cough, purulent sputum production, and dyspnea. Fever and leukocytosis may also be present, but the chest film is clear. The sputum Gram stain shows abundant leukocytes, with a predominance of gram-negative coccobacilli.

Otitis Media and Sinusitis

Nontypeable strains of *H. influenzae* are isolated from 15% to 30% of purulent middle-ear effusions in both children and adults.[23] *H. influenzae* is now the leading cause of persistent otitis media in children immunized with the pneumococcal conjugate vaccine.[24]

As with all cases of otitis media, infants typically present with fever and irritability and older children and adults complain primarily of ear pain. The clinical diagnosis is made by otoscopy. A bacteriologic diagnosis requires tympanocentesis, but this procedure is warranted only for evaluation of treatment failures. Nontypeable strains of *H. influenzae* can also be isolated from maxillary aspirates in approximately 25% of children and adults with acute sinusitis.[25] In addition to experiencing common cold symptoms such as rhinorrhea and cough, patients with sinusitis often have unilateral pain, purulent nasal discharge, and reduced transillumination. Confirmatory sinus x-rays and diagnostic aspiration are usually unnecessary.[25] Empirical management includes topical or systemic decongestants, or both, and antibiotics that are effective against *S. pneumoniae, H. influenzae,* and *Moraxella (Branhamella) catarrhalis.*

Extrapulmonary Infections

Cellulitis *H. influenzae* type b is an important cause of cellulitis in unvaccinated children younger than 5 years and is rarely implicated in skin infections of older persons.[9,12,26] The face is the most common site in young children. A raised, warm, tender area of erythema on the cheek or periorbital area is typical, sometimes with a distinctive bluish hue. Underlying sinusitis is common with periorbital and orbital infection. Blood cultures are often positive.

Bone and joint infections In the prevaccine era, *H. influenzae* type b caused approximately 10% of cases of septic arthritis and hematogenous osteomyelitis in infants and young children, but this is now uncommon.[27] Most cases of *H. influenzae* septic arthritis in children are monoarticular, involving large weight-bearing joints. A respiratory source of infection is usually evident. The diagnosis is established by arthrocentesis.

Rare cases of *H. influenzae* pyarthrosis have been described in adults.[9,28] About half of these cases are polyarticular, and most are in patients with alcoholism, immunodeficiency, joint disease, or trauma. Extra-articular sites of infection are apparent in 50% of patients. As in children, most adult cases of *H. influenzae* septic arthritis are caused by type b strains and accompanied by bacteremia.

Conjunctivitis Nontypeable strains of *H. influenzae* have long been appreciated as common causes of purulent conjunctivitis. These infections are contagious, and outbreaks can occur, particularly in day care centers.[2] *H. influenzae* conjunctivitis is easily diagnosed from stains and cultures of conjunctival swabs.

Robert Koch was the first to identify small gram-negative rods in conjunctival exudates collected in Egypt in 1883.[1] This organism was successfully cultured 3 years later by John Weeks, an American ophthalmologist. The Koch-Weeks bacillus, formerly named *Haemophilus aegyptius,* is now known to be a variant of *H. influenzae*. A particularly virulent strain of this organism has been responsible for outbreaks and sporadic cases of Brazilian purpuric fever in young children. This is a fulminant illness in which resolution of an episode of purulent conjunctivitis is followed by high fever, vomiting, abdominal pain, petechiae, purpura, peripheral necrosis, and vascular collapse.[2]

Bacteremia *H. influenzae* b bacteremia without localizing infection can occur in children younger than 5 years and in older persons with defective humoral immunity.[9,12] These patients can deteriorate rapidly, and in rare cases, the bacteremia resembles meningococcemia with purpura fulminans or the Waterhouse-Friderichsen syndrome.[26] Nontypeable strains of *H. influenzae* have also been implicated in neonatal and puerperal sepsis.[9,10,26]

Other infections *H. influenzae* is a rare cause of genitourinary infections, including salpingitis, endometritis, chorioamnionitis, epididymitis, and prostatitis.[10,26] Other rare manifestations of *H. influenzae* infection include appendicitis, chlolecystitis, peritonitis, and endocarditis.[9,26]

MICROBIOLOGIC DIAGNOSIS

The diagnosis of invasive *H. influenzae* infection is generally made from positive cultures of blood, CSF, joint fluid, or other normally sterile sites. CSF and joint fluid Gram stains reveal bacteria in 70% to 80% of cases of meningitis and septic arthritis, respectively. However, the morphology of the organisms is often misleading: plump gram-negative rods, filamentous organisms, gram-negative diplococci, and underdecolorized gram-positive cocci have been described.[9,15,26] Similarly, sputum Gram stains of patients with tracheobronchitis or pneumonia usually show abundant leukocytes and the characteristic gram-negative coccobacilli, but misinterpretations are common.[18] The small gram-negative rods can be overlooked in the pink background on the slide or misinterpreted as gram-positive cocci if the specimen is poorly decolorized.

Type b capsular antigen can be detected by latex agglutination or enzyme-linked immunosorbent assay (ELISA) in CSF, serum, or concentrated urine in up to 90% of invasive infections. Antigen detection is particularly attractive in patients who have already received antibiotic therapy at the time of presentation, but the results rarely influence outcome, because cultures or Gram stains are diagnostic in nearly all antigen-positive cases.[29]

ANTIBIOTIC TREATMENT

The initial antibiotic of choice for meningitis and other invasive *H. influenzae* infections is a third-generation cephalosporin such as ceftriaxone or cefotaxime. These agents are highly active against all isolates of *H. influenzae*, penetrate the CSF, and eradicate nasopharyngeal carriage of *H. influenzae* type b. The pediatric dose of ceftriaxone is 50 mg/kg every 12 hours and that for cefotaxime is 50 mg/kg every 6 hours. For adults, the maximum dose of ceftriaxone is 2 g every 12 hours, and that for cefotaxime is 2 g every 6 hours. The preferred alternative treatment for *H. influenzae* meningitis is chloramphenicol (75 to 100 mg/kg/day in six divided doses). Children with *H. influenzae* meningitis also should receive dexamethasone (0.6 mg/kg/day in four divided doses). Other antibiotics that are highly active against nearly all strains of *H. influenzae* include carbapenems, aztreonam, β-lactam/β-lactamase inhibitor combinations, fluoroquinolones, azithromycin, and tetracycline[30,31] [*see Table 1*]. Ampicillin is highly effective against sensitive strains, but 35% to 40% of North American isolates of *H. influenzae* are resistant to ampicillin. Most ampicillin resistance is mediated by β-lactamase production, but conventional susceptibility testing is recommended for invasive isolates to detect all resistant strains. Intravenous antibiotic therapy is recommended for meningitis and endocarditis and for the initial treatment of other invasive infections. Less severe *H. influenzae* infections can be managed with oral antibiotics. Most *H. influenzae* infections can be cured with 7 to 10 days of therapy, but treatment should continue for 3 to 6 weeks in cases of osteomyelitis or endocarditis.

Table 1 Antibiotics Effective against *Haemophilus influenzae* and *Moraxella catarrhalis*[30,31]

Antibiotic	H. influenzae *Susceptible (%)*	M. catarrhalis *Susceptible (%)*
Ceftriaxone	100	100
Cefpodoxime	100	99
Cefdinir	98	100
Cefuroxime	98–99	99
Ampicillin	68–72	< 10
Amoxicillin-clavulanate	> 99	> 99
Fluoroquinolones	> 99	100
Azithromycin	> 99	100
Clarithromycin	60–90	100
Telithromycin	98	100
Tetracycline	> 98	> 99
Chloramphenicol	> 99	100
Trimethoprim-sulfamethoxazole	79–82	> 97

PREVENTION

Immunization

The introduction of conjugate vaccines in the late 1980s has resulted in a greater than 97% reduction in the incidence of invasive *H. influenzae* type b infections in children younger than 5 years.[7,12] Currently, four conjugate vaccines are licensed in the United States.[32] All are composed of the PRP component of the *H. influenzae* type b capsule in covalent linkage with a carrier protein and elicit protective antibodies directed at PRP. Conjugate vaccines have succeeded the polysaccharide vaccines introduced in the 1970s; those earlier polysaccharide vaccines did not contain a carrier protein and were less effective.[12]

The vaccines are given in a primary series starting at 2 months of age, with the schedule depending on the product. A booster dose is given at 12 to 15 months of age. Immunocompromised children may require additional boosters.[32] Local reactions are experienced by about 25% of persons, but systemic reactions are rare. Adults at high risk for invasive *H. influenzae* infection as a result of sickle cell disease, splenectomy, immunoglobulin or complement deficiency, B cell malignancy, or HIV infection should be considered for vaccination, but specific guidelines have not been developed.

Secondary Prevention

Chemoprophylaxis with rifampin (20 mg/kg/day; maximum, 600 mg a day for 4 days) is more than 95% effective in eliminating nasopharyngeal carriage of *H. influenzae* and is recommended to prevent secondary cases of invasive infection in children at risk. Rifampin prophylaxis should be administered to all adults and children in households with at least one member (other than the index case) who is younger than 4 years and is unimmunized or incompletely immunized.[32] Treatment should also be given to all contacts in households with at least one member younger than 1 year who has completed the primary series but has not yet received a booster dose. Chemoprophylaxis of children and supervisory adults in child care and nursery school settings is recommended if at least two cases of invasive disease have occurred in the attendees within 60 days and if incompletely immunized children are in attendance. Finally, rifampin should be given to victims of invasive disease unless they were treated with ceftriaxone or cefotaxime, which eradicate the carrier state.

Other Haemophilus *Infections*

There are now 15 recognized species of the genus *Haemophilus*. *H. parainfluenzae, H. aphrophilus,* and *H. paraphrophilus* can be found among the flora of the oral cavity and upper respiratory tract. These organisms are primarily commensals, but in rare cases, they cause endocarditis and respiratory tract infection. Endocarditis caused by *Haemophilus* species usually develops on a diseased valve, is typically subacute in onset, and is often complicated by major systemic emboli. Combination antibiotic therapy is generally curative, but valve replacement is frequently necessary. Non-*influenzae* species of *Haemophilus* have antimicrobial susceptibilities that are similar to *H. influenzae,* but they are less likely to be ampicillin resistant.[33]

***Moraxella* (*Branhamella*) *catarrhalis* Infections**

M. catarrhalis was first described by the German microbiologist Seifert in 1882. Originally called *Micrococcus catarrhalis,* the organism was renamed *Neisseria catarrhalis* in 1920, then assigned to the new genus *Branhamella* in 1970, and subsequently reclassified as *Moraxella (Branhamella) catarrhalis*. Although recognized as a cause of tracheobronchitis and pneumonia by early investigators, *M. catarrhalis* was dismissed as a harmless commensal for much of the 20th century, until regaining stature as a potential pathogen over the past 25 years.[34]

EPIDEMIOLOGY

The distribution of *M. catarrhalis* is limited to the human respiratory tract, except for occasional isolates from the conjunctiva and genital tract. Nearly 80% of children harbor *M. catarrhalis* in the nasopharynx by 2 years of age, but colonization declines

with age. Fewer than 6% of healthy adults carry *M. catarrhalis*, although the organism can be isolated from the sputum of 5% to 32% of patients with chronic bronchitis or bronchiectasis.[4,35,36] Colonization is a dynamic process, with individual strains persisting for only a few months. Carriage of *M. catarrhalis* also exhibits seasonal variation, with colonization and infection being more prevalent in the winter months.[36]

M. catarrhalis is the third most common cause of otitis media, sinusitis, and acute exacerbations of chronic bronchitis, after *H. influenzae* and *S. pneumoniae*.[25,35] The majority of lower respiratory tract infections attributed to *M. catarrhalis* in adults occur in patients with underlying COPD.[35]

PATHOGENESIS

M. catarrhalis is a nonmotile, gram-negative diplococcus that is morphologically indistinguishable from *Neisseria* species. *M. catarrhalis* grows well aerobically on blood agar and chocolate agar. The characteristic convex, opaque colonies can be pushed across the agar surface in the manner of a hockey puck. Other species of *Moraxella* are predominantly gram-negative coccobacilli that can be found among the normal flora of humans and other mammals, but they rarely cause disease.

The virulence of *M. catarrhalis* is related to its capacity to colonize the respiratory mucosa. *M. catarrhalis* expresses a number of potential adhesins, but the mechanisms underlying the respiratory tropism of this organism are poorly understood.[4,35] Similarly, the factors that influence the transition from asymptomatic colonization to infection have not been deciphered. In the case of otitis media and sinusitis, it is likely that nasopharyngeal bacteria will gain access to adjacent spaces after mucosal injury. The expression of particular virulence factors also may be important in pathogenesis. For example, strains of *M. catarrhalis* isolated from symptomatic persons are more likely to exhibit resistance to the bactericidal activity of serum complement than strains harbored by asymptomatic carriers. Recovery from *M. catarrhalis* infection is accompanied by strain-specific antibody responses,[35,36] but the key elements of host defense against this organism are unknown.

CLINICAL SYNDROMES

Tracheobronchitis

Acute exacerbations of chronic bronchitis are the most common manifestations of *M. catarrhalis* infection in adults.[4,33,34] As with exacerbations caused by other organisms, dyspnea and cough productive of purulent sputum are the cardinal symptoms; fever also may be present. *M. catarrhalis* can be implicated by the predominance of gram-negative diplococci on Gram stains of purulent sputum, with isolation of *M. catarrhalis* in culture. In approximately 30% of cases involving *M. catarrhalis,* additional pathogens are present in the sputum.

Pneumonia

Most cases of pneumonia caused by *M. catarrhalis* occur in the elderly, particularly those with underlying COPD.[35] The clinical features are those of a mild, acute pneumonia: fever, cough productive of purulent sputum, dyspnea, and chest pain are the common symptoms. Focal evidence of consolidation may be evident on physical examination. The chest x-ray usually reveals patchy alveolar or interstitial opacities that are often multilobar. Pleural effusions are uncommon. The diagnosis is usually made from the sputum Gram stain and culture. Bacteremia, empyema, and other suppurative complications are rare.

Otitis Media and Sinusitis

M. catarrhalis can be isolated from middle-ear effusions in 15% to 20% of cases of acute otitis media in children, usually in pure culture.[35] Polymerase chain reaction detects *M. catarrhalis* DNA in an even higher proportion of middle-ear exudates. Similarly, maxillary aspirates yield *M. catarrhalis* in about 20% of children with acute sinusitis.[25,35] However, less than 10% of episodes of acute sinusitis in adults can be attributed to *M. catarrhalis*.[25]

Other Infection

Nosocomial outbreaks of *M. catarrhalis* infection, predominantly involving the respiratory tract and occurring mainly in patients with underlying cardiopulmonary disease, have been reported in children and adults.[35] The mode of transmission has not been clear. *M. catarrhalis* has also been reported as a rare cause of invasive infections, including meningitis, endocarditis, septic arthritis, and bacteremia.[35] Underlying lung disease and neutropenia have been identified as risk factors for *M. catarrhalis* bacteremia, but invasive infections originating in the upper respiratory tract have occurred in previously healthy individuals. *M. catarrhalis* can also cause conjunctivitis and rare urogenital infections.[35]

ANTIBIOTIC TREATMENT

More than 90% of clinical isolates of *M. catarrhalis* produce β-lactamases that render ampicillin and amoxicillin ineffective.[30,31] Penicillin–β-lactamase–inhibitor combinations, second- and third-generation cephalosporins, fluoroquinolones, macrolides, and tetracyclines are active against nearly all strains of *M. catarrhalis* [*see Table 1*].

Legionellosis

In the summer of 1976, a mysterious outbreak of pneumonia occurred among participants in the American Legion's bicentennial convention in Philadelphia, killing 34 of the 221 people afflicted.[37] The disorder became known as Legionnaires disease. Its cause remained obscure until Joseph McDade and his colleagues at the CDC isolated a novel bacterium from the spleens of guinea pigs that had been injected with lung tissue harvested from victims of the epidemic.[38] The new agent was named *Legionella pneumophila*. Studies with stored sera identified this organism as the cause of Pontiac fever—so named after an outbreak of a nonpneumonic, influenzalike illness that occurred in Pontiac, Michigan, in 1968—as well as other cases of epidemic and sporadic respiratory disease dating back to 1943.[39] *L. pneumophila* was the first of several previously unknown agents to emerge as important human pathogens in the late 20th century. In the years since the Philadelphia outbreak of legionellosis, many other *Legionella* species have been identified and implicated in a growing spectrum of human disease.

The family Legionellaceae now includes more than 40 species of the genus *Legionella,* with over 60 distinct serotypes.[40] Almost all of these organisms have been isolated from the environment, and approximately half of them have been associated with human disease. *L. pneumophila* remains the most important human pathogen in this family, accounting for more than 80% of legionellosis cases diagnosed in the United States.[40,41] Other species of *Legionella* produce a similar spectrum of disease and may be underappreciated as causes of human infection.[40]

EPIDEMIOLOGY

The Legionellaceae are widely distributed in freshwater habitats throughout the world.[39,40] They thrive in warm water en-

riched with iron, often in biofilms with other organisms that supply essential nutrients, such as blue-green algae or macrophytes. Legionellae can also replicate in free-living protozoa, and amebae may be their natural hosts. Man-made aquatic environments that often harbor legionellae include hot-water systems, cooling towers, air conditioners, industrial coolants, whirlpool baths, and humidifiers. The factors that promote the growth of legionellae in water tanks and potable water supplies include a temperature between 30° and 60° C, stagnation, decayed or rusted pipes and fixtures, and infrequent or ineffective decontamination. Water systems harboring legionellae can be disinfected by superheating (> 70° C) and flushing, hyperchlorination, or metallic ionization.[40,41]

Legionellosis is acquired mainly by the inhalation of aerosolized bacteria from an environmental source,[39-41] typically a man-made device. Examples of proven disseminators include showerheads, water faucets, cooling towers, evaporative condensers, respiratory therapy equipment, produce misters, whirlpool baths, and decorative fountains. Only a few cases of legionellosis have been linked to natural aquatic sources such as hot springs. Potting soil also has been identified as a source of infection. Transient contamination of the oropharynx followed by microaspiration may occur occasionally, particularly in patients with nasogastric tubes; stable colonization of the upper respiratory tract by legionellae has not been described. Wounds can be infected by direct inoculation with contaminated water, and oral ingestion has been postulated as a potential source of rare intestinal infections. There is no evidence for person-to-person transmission.

The epidemiologic patterns of legionellosis include common-source epidemics, sporadic cases, and endemic disease in institutions with contaminated water supplies. The infection is more common in the summer months, when seasonal conditions promote the growth of legionellae in the environment, and the use of air conditioners and other cooling devices facilitates the dissemination of airborne bacteria.

Legionella species have been reported to cause from 1% to 15% of community-acquired pneumonias leading to hospitalization,[18] but they consistently rank among the leading causes of severe community-acquired pneumonia leading to respiratory failure.[42] In hospitals with contaminated water supplies, legionellae are important agents of nosocomial pneumonias.

The risk factors for *Legionella* pneumonia include cigarette smoking; alcoholism; recent travel; chronic lung, heart, or kidney disease; diabetes mellitus; cancer; and the use of immunosuppressive medications (especially corticosteroids).[41] Transplant recipients are at particularly high risk and have been the sentinel victims in several nosocomial outbreaks. *Legionella* infections are uncommon but unusually severe in HIV-infected patients.

The epidemiologic features of pneumonic and nonpneumonic legionellosis differ in several respects.[39,43] During epidemics, the attack rate of *Legionella* pneumonia varies from 0.2% to 7%, whereas nonpneumonic legionellosis afflicts over 65% of the people exposed. The incubation period of Legionnaires disease varies from 2 to 12 days, but Pontiac fever usually strikes within 48 hours of exposure. One or more risk factors can be identified in most victims of *Legionella* pneumonia. In contrast, nonpneumonic legionellosis readily affects the normal host. Common sources have resulted in cases of both Legionnaires disease and Pontiac fever, suggesting that bacterial inoculum and host factors are important in determining the clinical course of infection. It is possible that Pontiac fever results primarily from the inhalation of bacterial endotoxin.[43]

PATHOGENESIS AND PATHOLOGY

The Legionellaceae are small, pleomorphic, flagellated gram-negative bacilli that often appear coccobacillary in tissue.[39,40] They are enveloped by a laminated outer membrane with a unique lipid structure that differs from the lipopolysaccharide of other gram-negative bacteria. Legionellae are facultative intracellular parasites: they can replicate independently or in other cells. They are strictly aerobic but grow best in a reduced-oxygen environment. Buffered charcoal–yeast extract agar supplemented with L-cysteine, ferric iron, and α-ketoglutarate is the most suitable artificial medium.

After inhalation into the lungs, *L. pneumophila* enters alveolar macrophages via coiling or conventional phagocytosis and replicates in a specialized vacuole.[40,44] The formation of this protected intracellular compartment is directed by the *dot* (defective organelle trafficking) and *icm* (intracellular multiplication) genes of *L. pneumophila*. These genes encode for a type IV secretion system that modifies the endocytic pathway of the host cell and delays fusion of the phagosome with lysosomes. As nutrients become scarce, the production of cytotoxins by the stressed bacteria leads to rupture of the macrophage, and the cycle begins anew. The secretion of proteases by *L. pneumophila* contributes to tissue injury.[44] Spreading infection leads to the recruitment of blood-borne phagocytes, but *L. pneumophila* is relatively resistant to killing by neutrophils and multiplies within monocytes. Humoral immunity appears to play little role in host defense against this infection, because *L. pneumophila* is resistant to the lytic effects of antibody and complement, and opsonization by specific antibody promotes uptake of the organism by phagocytic cells without stimulating bacterial killing. Ultimately, the infection is probably contained by suppression of intracellular replication by interferon-gamma–mediated activation of macrophages and the destruction of infected cells by cytotoxic lymphocytes.[45]

Impairments in specific host defenses underlie the increased risk of legionellosis in certain groups. For example, the alveolar macrophages of smokers are greater in number and more susceptible to parasitism by *L. pneumophila* than the macrophages of nonsmokers.[46] Smokers' macrophages exhibit greater expression of the CD11b/CD18 integrin complex that mediates uptake of *L. pneumophila,* and they also contain more iron, an essential bacterial nutrient, than the alveolar macrophages of nonsmokers. Toll-like receptors (TLRs) stimulate the immune response to *Legionella,* and single-nucleotide polymorphisms that affect the functions of TLR4 and TLR5 have been associated with susceptibility to Legionnaires disease.[47,48] Conditions associated with impaired cellular immunity, such as T cell malignancies, HIV infection, and the use of immunosuppressive medications, result in deficient macrophage activation and failure to contain intracellular infection.

Pathologically, pneumonic legionellosis is characterized by confluent multilobular or lobar consolidation, with no predilection for particular segments.[49] Involvement is bilateral in approximately half the cases. Small pleural effusions are common, but empyema is unusual. The most common histologic pattern is an acute fibrinopurulent alveolitis, with little or no involvement of the conducting airways. There is a dense intra-alveolar infiltrate of macrophages and polymorphonuclear leukocytes, accompanied by an abundant fibrinous exudate and proteinaceous debris. The alveolar septae are congested, and there may be a minor vasculitic component. The bacteria are found in the alveolar exudate and are located mainly within macrophages.

A second histologic pattern of Legionnaires disease is diffuse alveolar damage. This is characterized by an intra-alveolar, fi-

brinoserous exudate with hyaline membrane formation and evidence of epithelial injury. Few organisms can be identified in this setting, but bacterial invasion of the interstitium may be observed. These features may coexist with the fibrinopurulent pattern and are predominantly found in immunocompromised patients. Fibrosis may occur with resolution of the infection. Bronchiolitis obliterans organizing pneumonia is an unusual complication.

CLINICAL SYNDROMES

Two distinct clinical syndromes of legionellosis have been recognized: the pneumonic form known as Legionnaires disease, and the nonpneumonic, self-limited syndrome called Pontiac fever. The spectrum of infection also includes asymptomatic seroconversion and rare focal infections of extrapulmonary organs.

Legionnaires Disease

The classic picture of Legionnaires disease is that of a chronically ill, middle-aged smoker with rapidly progressive pneumonia associated with nonpurulent sputum, diarrhea, confusion, hyponatremia, and abnormal liver function tests. The clinical features of Legionnaires disease are protean, however, so the disorder cannot reliably be distinguished from other pneumonias on clinical grounds alone[39,50,51] [*see Table 2*].

Legionnaires disease typically begins with a brief prodrome of profound weakness, malaise, myalgias, and headache. High fever and shaking chills accompany the development of a cough that is productive in approximately half the cases. Sputum is generally nonpurulent. Chest pain is common, and progressive dyspnea is the rule. Watery diarrhea, nausea, and vomiting are often reported.

Physical examination usually reveals a distressed, tachypneic patient. High fever is a hallmark of legionellosis, and temperatures exceeding 39° C (102.2° F) are found in most patients, even those who are immunosuppressed.[50] Relative bradycardia (a heart rate less than 100 beats a minute despite a temperature of 40° C [104° F] or higher) may be present. Evidence of consolidation is typically evident on lung auscultation. An encephalopathy ranging from mild confusion to obtundation is common, and focal neurologic deficits have been described.

Routine laboratory tests also typically show an array of abnormalities[39,50,51] [*see Table 2*]. The complete blood count typically demonstrates leukocytosis with a left shift, although a white blood cell count above 15,000/mm^3 is unusual. Hyponatremia and abnormal liver enzymes are reported in approximately half the cases. Hypophosphatemia, azotemia, an elevated creatine kinase level, and an increased serum amylase level may also be found. Urinalysis often reveals proteinuria, hematuria, or both.

The chest x-ray in *Legionella* pneumonia may demonstrate poorly marginated, rounded nodules; patchy alveolar infiltrates; or consolidation in a segmental or lobar distribution.[50,52] The infiltrates are unilobar at presentation in most cases, but radiologic progression to multilobar disease is common. Small pleural effusions are frequently evident, but empyema is unusual. Cavitation is an uncommon finding that is most often seen in immunocompromised patients.

Extrapulmonary manifestations of Legionnaires disease can be striking and may reflect the effects of bacterial toxins, host-derived mediators, or metastatic infection.[41] Neurologic deficits are usually metabolic in origin, but focal bacterial encephalitis has been described. The pathogenesis of the watery diarrhea that often accompanies *Legionella* pneumonia is obscure, but intestinal abscesses and peritonitis have been reported. Acute renal failure may complicate legionellosis, as a result of acute tubular necrosis, rhabdomyolysis, or glomerulonephritis. Pyelonephritis is rare. Overt dissemination of *Legionella* infection from the lungs to other organs occurs most commonly in immunocompromised persons.

Table 2 Manifestations of Legionnaires Disease[80]

Manifestations	*Percentage of Cases*
Symptoms and signs	
Fever	67–100
Chills	42–77
Cough	65–92
Sputum production	41–75
Hemoptysis	0–41
Chest pain	14–52
Dyspnea	14–59
Headache	17–56
Myalgias	20–43
Altered mental status	21–43
Diarrhea	21–47
Nausea, vomiting	9–37
Abdominal pain	5–20
Laboratory abnormalities	
Leukocytosis	53–78
Hyponatremia	17–55
Elevated liver enzymes	14–88
Hypophosphatemia	25–51
Azotemia	15–60
Proteinuria	25–56
Hematuria	0–50

Unusual sites of *Legionella* infection include the skin (cellulitis and wound infection), the heart (myocarditis, pericarditis, and prosthetic valve endocarditis), and the abdomen (pancreatitis, colitis, and appendicitis).[41] Infections at these sites have been reported in the absence of pneumonia. In some instances, the infection appears to have resulted from direct inoculation of tissue or a prosthetic device with contaminated water. Other cases may result from bacteremic seeding from the lungs.

Pontiac Fever

The most common nonpneumonic form of legionellosis is Pontiac fever.[39] This syndrome is characterized by a prodrome of malaise, diffuse myalgias, and headache, followed hours later by fever and chills. A mild, nonproductive cough and sore throat may develop, but respiratory tract symptoms are not prominent. Nausea, vomiting, and diarrhea are common, as are neurologic disturbances such as dizziness, neck pain or stiffness, confusion, irritability, nightmares, and ataxia. The physical examination is unremarkable except for the presence of fever, and laboratory tests reveal only leukocytosis. The chest film is clear. The diagnosis is primarily made serologically and supported by the isolation of *Legionella* from an environmental source. Evidence of infection can be detected by PCR or, in some cases, urinary antigen testing. The acute illness resolves spontaneously in 2 to 5 days, but full recovery may take weeks.

MICROBIOLOGIC DIAGNOSIS

The diagnosis of legionellosis requires the isolation of the organism in culture, detection of microbial antigens or nucleic

Table 3 Diagnostic Tests for Legionellosis[18,53]

Test	*Specimen*	*Sensitivity (%)*	*Specificity (%)*	*Comment*
Culture	Sputum, BALF	11–80	100	All species; requires selective media
Direct fluorescent antibody	Sputum, BALF	22–75	> 90	*Legionella pneumophila* only
Urinary antigen	Urine	48–90	> 95	*L. pneumophila* serogroup 1 only
Serology				
Fourfold change*	Blood	60–80	>90	*L. pneumophila* only
Single titer		10–27	> 85	
PCR	Sputum, BALF, serum, urine	10–100	> 95	All species; not widely available

*Between acute and convalescent samples.
BALF—bronchoalveolar lavage fluid PCR—polymerase chain reaction

acids in body fluids, or demonstration of serologic evidence of infection [*see Table 3*]. However, an early clue to the diagnosis of Legionnaires disease can be obtained from nonspecific stains of sputum, bronchoalveolar lavage fluid, or lung tissue.[18] Although legionellae are poorly seen on routine Gram stain, visualization of these small, pleomorphic gram-negative bacilli is improved if basic fuchsin is used as the counterstain in place of safranin O. The intracellular organisms can also be seen on Gimenez, Dieterle, or Wright-Giemsa stains. *L. micdadei* is unique among the Legionellaceae in appearing acid fast in clinical specimens.

Culture of sputum, bronchoalveolar lavage fluid, or lung tissue is the preferred means of confirming the diagnosis.[18,41] Specialized media are required for the isolation of *Legionella* (see above), so cultures for these pathogens must be specifically requested of the laboratory. All *Legionella* species can be isolated after 3 to 5 days of incubation, and the recovery of organisms from any body fluid or tissue is diagnostic of infection. Sputum submitted from patients with suspected legionellosis should not be discarded even if epithelial cell contamination occurs, because poor-quality specimens may still yield the organism. Experienced microbiology laboratories can recover legionellae from pretreatment sputum in most cases of legionellosis, but not all laboratories are skilled in this regard, and many patients do not produce sputum.

Antigen detection provides an opportunity for more rapid diagnosis.[18,53] The direct fluorescent antibody (DFA) test can identify organisms in sputum, bronchoalveolar lavage fluid, or lung tissue, even after a few days of antibiotic therapy. However, the interpretation of DFA preparations requires considerable expertise, and the sensitivity of this test is limited to specific antigens. The most commonly used monoclonal antibody preparation detects only *L. pneumophila* serogroups 1 through 12, and commercially available pooled antisera are limited to a few species. Urinary antigen detection is currently the most helpful test for rapid diagnosis of legionellosis. Antigens appear in the urine within 3 days of the onset of illness and may persist for months, although most patients stop excreting antigen within 6 weeks. The sensitivity of this test is higher in cases of severe pneumonia than in cases of milder disease.[54] The major limitation of urinary antigen testing is that currently available tests reliably detect only *L. pneumophila* serogroup 1.

DNA amplification techniques are very promising for the rapid diagnosis of legionellosis.[18,53] Preliminary experience suggests that PCR can detect any species of *Legionella* in sputum, throat swabs, and bronchoalveolar lavage fluid with high sensitivity and specificity. *Legionella* DNA has also been detected in the urine and blood of patients with legionellosis. These tests hold great promise but require additional evaluation and refinement to establish their role in clinical practice.

Serologic evidence of infection can be obtained by indirect immunofluorescence, microagglutination, or ELISA.[18] A fourfold increase in titer between acute and convalescent samples is very specific for infection with *L. pneumophila* serogroup 1, but tests for other serogroups and species are more subject to cross-reactivity and have not been standardized. Approximately half of patients with Legionnaires disease will seroconvert within 4 weeks from the onset of illness, and 75% will do so within 9 weeks. A small number of patients take as long as 14 weeks to demonstrate an antibody response, and no serologic response will be detected in up to 25% of cases. The major limitation of seroconversion is the delay in diagnostic information. A single titer of 1:256 or higher

Table 4 Treatment of Legionellosis

Antibiotic Class	*Drug*	*Dosage*	*Comment*
Fluoroquinolones	Levofloxacin	500 mg p.o. or I.V. q. 24 hr for 10 days	May be preferred in immunocompromised patients because the agents are bactericidal
	Gatifloxacin	400 mg p.o. or I.V. q. 24 hr for 10 days	
	Moxifloxacin	400 mg p.o. q. 24 hr for 10 days	
	Ofloxacin	400 mg p.o. or I.V. q. 24 hr for 10 days	
Macrolides	Azithromycin	500 mg p.o. or I.V. q. 24 hr for 5–10 days	Most active of its class against *Legionella*
	Clarithromycin	500 mg p.o. or I.V. q. 24 hr for 10 days	—
	Erythromycin	500 mg p.o. or 1 g I.V. q. 6 hr for 10–14 days	Less well tolerated than other macrolides
Tetracyclines	Doxycycline	100 mg p.o. or I.V. q. 12 hr for 10–14 days	May be less effective than fluoroquinolones or macrolides

suggests acute infection with *L. pneumophila* but is found in less than 30% of patients during the acute phase of illness.

TREATMENT AND PROGNOSIS

There are no controlled trials to guide the treatment of legionellosis, but retrospective observations, anecdotal experience, animal studies, and in vitro testing support the efficacy of fluoroquinolones, macrolides, tetracyclines, and rifampin in the treatment of Legionnaires disease [*see Table 4*].[41,42,55] Fluoroquinolones may be preferred in immunocompromised patients because they are bactericidal (in contrast to macrolides and tetracyclines), exhibit the most activity in experimental models, and may induce a more rapid clinical response than macrolides.[55,56] All of the fluoroquinolones appear to be effective, but ciprofloxacin is less active than other agents in this class. Azithromycin is the most active macrolide against *Legionella*. Both azithromycin and clarithromycin are more effective and better tolerated than erythromycin. Rifampin is highly active against *Legionella,* and anecdotal evidence supports its use in combination with erythromycin in severely ill or immunocompromised patients. Of the tetracyclines, doxycycline and minocycline are the most active agents, but these drugs appear to be less effective than fluoroquinolones or macrolides. Trimethoprim-sulfamethoxazole also may be effective, but clinical experience is limited. All of these agents share the ability to penetrate the intracellular environment of macrophages, where legionellae replicate. β-Lactam antibiotics and aminoglycosides generally are ineffective in legionellosis.

The optimum duration of therapy is unknown. Immunocompromised persons and patients with unusually severe disease may warrant treatment for 2 to 3 weeks, but experience with newer macrolides and fluoroquinolones suggests that shorter courses are adequate.[41,55]

The prognosis of *Legionella* pneumonia is influenced by the status of host defenses and the timely initiation of effective antibiotic treatment.[41,42] With appropriate treatment, the mortality of Legionnaires disease varies from approximately 5% in healthy persons to 25% in immunocompromised patients.

Pertussis (Whooping Cough)

Whooping cough was first described in 16th-century France.[57] The name pertussis was coined by the English physician Thomas Sydenham in 1679, in reference to the intensive cough that is the hallmark of this disease. *Bordetella pertussis,* the causative agent, was first isolated by Bordet and Gengou in 1906. Other members of the genus that are associated with human disease include *B. parapertussis* and *B. bronchiseptica.*[58] *B. parapertussis* lacks pertussis toxin but causes a mild form of whooping cough. *B. bronchiseptica* is a zoonotic pathogen that can cause human respiratory illness; in immunocompromised patients, manifestations of disease may be severe.[58]

EPIDEMIOLOGY

B. pertussis is exclusively a human pathogen: no carrier state, animal host, or natural reservoir is known. The infection is transmitted from person to person by aerosol droplets and is very contagious, spreading quickly among close contacts. Pertussis is endemic year-round, with the peak incidence in summer and fall.[58] Epidemics occur at intervals of 2 to 5 years.[58] The attack rate is highest in infants younger than 1 year and is higher in females than males.[58] In the prevaccine era, pertussis was the leading cause of death in children younger than 14 years in the United States. The introduction of the killed whole cell vaccine in the 1940s led to a marked reduction in the prevalence of pertussis, which fell steadily until reaching its nadir in 1981. Since 1982, there has been a resurgence of reported cases of pertussis in the United States. During this time, the incidence in children younger than 5 years has remained relatively constant, but an increasing proportion of cases has been recognized in adolescents and young adults.[58] More than 60% of the 11,647 cases of pertussis reported to the CDC in 2003 occurred in persons older than 10 years.[6] Most early childhood cases of pertussis now occur in children who either are too young to have received vaccine or have been inadequately vaccinated.[6,58,59] Cases in adolescents and adults probably reflect the waning of immunity 5 to 10 years after vaccination. It is likely that pertussis is markedly underreported in older children and adults, because the characteristic whooping cough is usually absent in these age groups. Mildly ill or asymptomatic adults with unrecognized pertussis serve as important reservoirs for the infection of more susceptible children.

Although effective vaccines have dramatically reduced the importance of pertussis in developed countries, the disease remains a leading cause of morbidity and mortality in unvaccinated populations. An estimated 50 million cases of pertussis occur worldwide each year, leading to 300,000 deaths.[60,61]

Table 5 Virulence Factors of *Bordetella pertussis*[60]

Virulence Factor	*Effects*
Filamentous hemagglutinin	Attachment to ciliated epithelium; uptake by leukocytes via complement receptor 3
Agglutinogens, fimbriae	Attachment to epithelium
Lipopolysaccharide	Endotoxin activity
Tracheal cytotoxin	Ciliostasis, epithelial injury
Adenylate cyclase toxin	Induces increased cyclic adenosine monophosphate; impairs leukocyte function
Dermonecrotic toxin	Vascular smooth muscle contraction, ischemic necrosis
Pertussis toxin	Inhibits G protein–coupled signaling; lymphocytosis, hyperinsulinemia, encephalopathy
Type III secretion system	Delivers proteins into cytoplasm of target cells

PATHOGENESIS

Bordetellae are small, aerobic, gram-negative coccobacilli. They have fastidious growth requirements (see below). Pertussis is primarily a disease of the conducting airways, characterized histologically by generalized inflammation of the bronchi and bronchioles with a mucopurulent luminal exudate.[57] The bacilli grow on the surface of ciliated epithelium, where they thrive through the expression of surface components and secreted toxins that suppress mechanical and cellular host defenses [*see Table 5*].

Pertussis toxin is the most intriguing factor produced by *B. pertussis.* This heterodimeric protein catalyzes adenosine diphosphate (ADP)–ribosylation of guanine nucleotide–binding (G) proteins, thereby inhibiting signal transduction through G-coupled transmembrane receptors.[58,60] How this action is linked to

the pathophysiology of pertussis is not well understood. Pertussis toxin causes lymphocytosis, hyperinsulinemia, and possibly encephalopathy, but its role in the respiratory manifestations of whooping cough remains enigmatic.[58,60] Antibodies directed against pertussis toxin are protective against disease, yet *B. parapertussis,* which does not produce the toxin, can cause a similar (albeit milder) respiratory illness.

Relatively little is known of the essential elements of host defense against pertussis, but cellular and humoral immunity are both involved.[58,60] Protective maternal antibodies are not transferred across the placenta, contributing to the susceptibility of infants. The resolution of whooping cough is accompanied by the disappearance of *B. pertussis* from the airway epithelium.

CLINICAL MANIFESTATIONS

Classic pertussis is a three-stage illness lasting 4 to 8 weeks.[57,58,60] After an incubation period of 6 to 20 days, the clinical manifestations begin with the catarrhal stage. This phase lasts 1 to 2 weeks and resembles the common cold, with rhinorrhea, conjunctivitis, lacrimation, low-grade fever, and mild nonproductive cough. The distinctive paroxysmal stage follows for 2 to 4 weeks and is characterized by violent spasms of coughing. In a typical episode, a single expiration is punctuated by five to 20 explosive coughs in rapid succession, followed by a gasping, forceful inhalation through a narrowed glottis that produces the characteristic whoop. Paroxysms often are accompanied by cyanosis and followed by emesis. Infants have less pronounced whoops but may become apneic during coughing fits. The violent coughing can result in epistaxis, conjunctival hemorrhage, petechiae, rib fractures, pneumothorax, incontinence, hernias, and rectal prolapse. Paroxysms occur 10 to 30 times a day, often begin without warning, and can be triggered by activities such as eating, drinking, sneezing, yawning, or exposure to airborne irritants. The paroxysms are exhausting, and patients avoid oral intake, leading to dehydration and weight loss.

Physical examination during the spasmodic stage often is unremarkable. Eyelid edema may be present, and auscultation of the chest may reveal coarse rales and rhonchi. Fever is unusual in the absence of complications. The blood count at this time is characterized by marked lymphocytosis: the total WBC count often exceeds 30,000/mm^3, of which more than 60% are lymphocytes. Hypoglycemia is occasionally observed. Chest radiographs are usually normal but may demonstrate hyperinflation, atelectasis, or perihilar infiltrates.[57,62] Complications that can develop during the paroxysmal phase include pneumonia, otitis media, seizures, and encephalopathy. Pneumonia, caused either by *B. pertussis* or by a secondary invader, develops in 10% to 15% of young children and is responsible for most deaths.[59] The convalescent third stage of pertussis, during which the frequency and severity of the cough gradually diminish, usually lasts 1 to 3 weeks but may extend for months.

Adults and adolescents with partial immunity have a less severe illness and typically present with a persistent cough of several weeks' duration. The cough is paroxysmal and often productive of purulent or nonpurulent sputum, but whoops are unusual. As in children, violent coughing in adults with pertussis may result in posttussive vomiting, syncope, urinary incontinence, and rib fractures. About half of adult patients report a preceding catarrhal illness. Lymphocytosis is usually absent. Numerous recent studies suggest that 10% to 32% of adolescents and adults with cough lasting longer than 1 to 2 weeks have serologic evidence of pertussis.[58,63] Annual serologic screening programs have found that undiagnosed pertussis is common in adolescents and adults.

A presumptive diagnosis of pertussis can be made in susceptible children with the characteristic whooping cough and lymphocytosis. However, the typical whoop is not uniformly present, and similar illnesses can be caused by *B. parapertussis*, respiratory viruses (particularly adenovirus, parainfluenza, and respiratory syncytial virus), *Mycoplasma pneumoniae,* and *Chlamydia pneumoniae*.[58]

MICROBIOLOGIC DIAGNOSIS

Microbiologic confirmation of pertussis is best made during the catarrhal or early paroxysmal stages, when *B. pertussis* can be detected in the nasopharynx by culture, immunofluorescence, or PCR.[58,60,64] Cultures of nasopharyngeal aspirates have higher yields than those of nasopharyngeal swabs; if the latter are used, calcium alginate and Dacron are the preferred materials. Throat specimens are unsatisfactory because the oropharynx lacks the ciliated epithelium to which *B. pertussis* adheres. The nasopharyngeal sample should be directly streaked on suitably enriched media, such as charcoal-blood agar or Bordet-Gengou agar. If a delay in plating is anticipated, a charcoal-containing transport medium (e.g., Regan-Lowe) should be used.[64] Typical colonies of tiny gram-negative bacilli appear after 3 to 7 days of culture, and identification can be confirmed by agglutination or immunofluorescence. Culture yield is reduced by antibiotic therapy or prior immunization and falls with the duration of illness. Cultures are usually negative during the paroxysmal phase and in adults with persistent cough.

B. pertussis can also be detected in respiratory secretions by DFA staining in 30% to 65% of cases during the catarrhal stage.[58,60,64] Polyclonal antibody preparations have been plagued by variable sensitivity and poor specificity, but a monoclonal reagent has been found to be more satisfactory.[64] Nonetheless, immunofluorescence is mainly used as a screening test for outbreak investigation.

PCR testing of nasopharyngeal specimens has been found to be more sensitive than culture or immunofluorescence for the diagnosis of pertussis, with specificity greater than 85%.[58,60,64] This very promising technique has become increasingly available, but the methods and reagents for the diagnosis of pertussis by PCR have not yet been standardized.

Detection of serum antibody responses to *B. pertussis* by ELISA remains an important if imperfect diagnostic tool. Serologic tests are most useful for the diagnosis of pertussis in unvaccinated children, in whom the sensitivity of paired specimens or a single elevated titer more than 5 weeks after the onset of symptoms is 50% to 90%.[58,64] Multiple antigens are often used in antibody assays to enhance sensitivity, but pertussis toxin is the only antigen unique to *B. pertussis*.[58,64] The interpretation of serologic results in vaccinated persons is more difficult. The meaning of a single elevated antibody titer should be defined in relation to age-matched, population-specific controls.[63,64] Paired specimens have limited utility because the anamnestic response to infection is usually so rapid that no significant rise in antibody concentrations occurs between acute and convalescent sera.[63,64]

TREATMENT

Antibiotic therapy with erythromycin speeds elimination of *B. pertussis* from the nasopharynx and reduces transmission of infection.[58,60] Antibiotic treatment may also ameliorate the severity of disease, even if it is started in the paroxysmal phase, but this

is less clear. The estolate form of erythromycin, 40 mg/kg/day (maximum, 2 g/day) divided in two to four doses, is preferred and should be administered for 7 to 14 days.[65] There is limited evidence that the newer macrolides, clarithromycin (15 to 20 mg/kg/day in two divided doses, to a maximum dosage of 1 g/day for 7 days) and azithromycin dihydrate (15 to 20 mg/kg/day in one dose, to a maximum dosage of 600 mg/day for 5 days), are also effective.[65] Alternative agents that speed elimination of *B. pertussis* include trimethoprim-sulfamethoxazole, tetracycline, and chloramphenicol.[60] Fluoroquinolones are active against *B. pertussis* in vitro, but their efficacy in the treatment of pertussis has not been demonstrated.

The value of antibiotic therapy in adults with persistent cough and suspected pertussis is unknown.

Infants with pertussis should be hospitalized for monitoring, airway suctioning, oxygen supplementation, hydration, and nutritional support. Treatment of severe cases with pertussis immune globulin has shown promise in animal studies and human trials.[66] Systemic corticosteroids may be helpful in infants with life-threatening disease.[60] Inhaled corticosteroids and bronchodilators are of uncertain value in ameliorating symptoms.

PREVENTION

Pertussis can be prevented by quarantine of infected individuals, prophylactic antibiotic treatment of exposed infants, and vaccination. Patients with active pertussis in the catarrhal and early paroxysmal stages should be isolated for 5 to 7 days after starting antibiotics. Prophylactic treatment of household contacts with a full course of erythromycin can reduce the spread of disease and is recommended for young children who have not completed primary immunization. In neonates, however, erythromycin prophylaxis is associated with an increased risk of hypertrophic pyloric stenosis.[67]

Immunization with inactivated whole-cell vaccine was introduced in 1948, and acellular vaccines composed of inactivated pertussis toxin and one or more additional components were licensed in 1991. Current recommendations call for primary immunization with an acellular vaccine, which is combined with diphtheria and tetanus toxoids (DTaP), at ages 2, 4, and 6 months, with boosters at 15 to 18 months and at 4 to 6 years.[68] Pertussis vaccines provide approximately 80% protection from clinical pertussis, and immunized persons who become ill after exposure experience less severe disease.[58,68] Protection declines with time.[58] Historically, boosters have not been given to older children and adults because of the unacceptable toxicity of the whole-cell vaccine; reactions to whole-cell pertussis vaccine (DTP) in children include local pain and swelling, fever, anorexia, irritability, vomiting, hypotonic hyporesponsiveness, seizures, and anaphylaxis. All of these reactions are much less common with the acellular vaccines.[58,68] The acellular vaccine is immunogenic and well tolerated by adolescents and adults.[69,70] The routine use of vaccine in adolescents and adults, who constitute the major reservoir for pertussis, has the potential to reduce the overall burden of pertussis and the transmission of the disease to children; however, recommendations for boosters in these age groups have not been established.

Pseudomonas aeruginosa Infections

P. aeruginosa is an important opportunistic pathogen, with a prominent role in cystic fibrosis. The organism was first isolated from a surgical wound in 1882 by the French pharmacist Carle Gessard.[71] The species designations in both the original name for the organism, *Bacillus pyocyaneus,* and its modern name, *P. aeruginosa,* refer to the blue-green pigments produced by these bacteria, which may serve as clinical markers for infection.[72] More than a dozen species of *Pseudomonas* are now recognized, but only *P. aeruginosa* is an important human pathogen.

EPIDEMIOLOGY

P. aeruginosa is widely distributed in nature, particularly in water, soil, and vegetation. Nutritional versatility, suppression of competitors, and resistance to antibiotics contribute to the diverse habitat of this organism.[72] *P. aeruginosa* is not part of the normal flora of most humans, but it can be cultured from the stool, throat, nose, or moist areas of the skin of up to 20% of healthy persons.[71,72]

P. aeruginosa is mainly an opportunistic and nosocomial pathogen. It has a marked predilection for colonizing damaged epithelium, such as burned skin, bronchiectatic airways, and sites of indwelling appliances such as tracheostomy tubes, endotracheal tubes, urinary catheters, intravascular devices, peritoneal dialysis catheters, and body piercings.[71,73] Patients with cystic fibrosis are especially prone to airway colonization. The risk of colonization at any site increases with exposure to broad-spectrum antibiotics and duration of hospitalization.[72] Colonization is an important antecedent to invasive infection, particularly in neutropenic patients.[71,72] Additional risk factors for invasive disease include cytotoxic chemotherapy, treatment with corticosteroids, and HIV infection.[71,74] Persons with diabetes mellitus are at risk for invasive external otitis.

Outbreaks of *P. aeruginosa* infection can result from common-source exposures. Community outbreaks of folliculitis have been associated with swimming pools, whirlpool baths, and hot tubs. Ocular infections have resulted from contaminated cosmetics and contact lens solution.[71] In hospitals, epidemics of *P. aeruginosa* infection have been linked to contaminated sinks, mops, cleaning solutions, therapy pools, respiratory therapy equipment, endoscopic devices, flowers, vegetables, and water pitchers.[71]

PATHOGENESIS

P. aeruginosa is a motile gram-negative bacillus that is typically thin and either straight or slightly curved. It does not ferment sugars and grows strictly aerobically. *P. aeruginosa* has simple nutritional requirements and tolerates a wide range of environmental conditions. It grows well on most laboratory media and emits a sweet, grapelike odor. Most strains produce one or more diffusable pigments, including pyocyanin, pyoverdin, pyorubin, and pyomelanin.[71]

P. aeruginosa is a formidable pathogen that is well equipped by an exceptionally large genome to colonize and invade epithelial surfaces, undermine host defenses, and induce systemic toxicity. *P. aeruginosa* attaches to tracheobronchial mucus and replicates in a biofilm on the mucosal surface, using quorum sensing to coordinate environmental adaptation and virulence factor production.[74,75] Although *P. aeruginosa* adheres poorly to normal epithelium, it readily attaches to damaged epithelial cells via pili and other adhesins.[74,75] The persistence of some strains of *P. aeruginosa* on epithelial surfaces is aided by the abundant secretion of tenacious mucopolysaccharide, which facilitates adherence to host cells, inhibits ciliary activity, and blocks ingestion by phagocytes. The virulence of *P. aeruginosa* is further aided by a type III secretion system that permits injection of exotoxins S, T, U, and Y directly into host cells, thus promoting cytotoxicity and

inflammation.[74,75] Invasion across epithelial surfaces by *P. aeruginosa* is made possible by proteolytic enzymes that damage epithelial cells, loosen tight junctions, and digest extracellular matrix.[74,75] These enzymes also interfere with host defenses by cleaving immunoglobulins, complement, and cytokines. Secreted toxins such as exotoxin A, leukocidin, hemolysins, and pyocyanin cause additional tissue damage, hemolysis, and cytotoxicity to macrophages, neutrophils, and lymphocytes. Vascular injury by exotoxin A can result in local or distant hemorrhagic necrosis. Damage to epithelial and endothelial barriers permits the entry of bacteria, bacterial products, and endogenous proinflammatory mediators into the systemic circulation, leading to systemic toxicity and shock.

The striking association of *P. aeruginosa* with cystic fibrosis (CF) is an area of special interest.[76] Most patients with CF are initially colonized with an environmental, nonmucoid strain of *P. aeruginosa*. These bacteria eventually undergo a phenotypic shift in the CF airway to express an unusual lipopolysaccharide structure and hypersecrete mucoid exopolysaccharide (alginate).[76] The factors controlling these adaptations and the mechanisms underlying the persistence of *P. aeruginosa* in the CF airway remain incompletely understood. *P. aeruginosa* binds somewhat more avidly to CF epithelium than to normal epithelial cells.[75,76] However, the uptake of *P. aeruginosa* by epithelial cells is defective in CF. The cystic fibrosis transmembrane conductance regulator (CFTR) may serve as a receptor for the internalization of surface bacteria, and shedding of these infected cells may be a normal defense mechanism against *P. aeruginosa* that is defective in CF.[75,76] Also, human β defensin 1, an antibacterial peptide secreted by airway epithelial cells, is inactive in the high salt concentrations that some investigators have found in CF airways.[75,76] Chronic inflammation precipitated by *P. aeruginosa* infection contributes to the airway injury and progressive loss of pulmonary function that characterize CF.

CLINICAL SYNDROMES

Pneumonia

Nosocomial pneumonia *P. aeruginosa* is one of the most common causes of hospital-acquired pneumonia and is implicated in approximately 25% of cases complicating mechanical ventilation.[21,77] Risks for nosocomial *P. aeruginosa* pneumonia include prolonged hospitalization, mechanical ventilation for 7 days or longer, and exposure to broad-spectrum antibiotics.[77] Tracheal colonization with *P. aeruginosa* usually precedes infection.

The clinical features of ventilator-associated pneumonia are nonspecific: fever, purulent tracheal secretions, leukocytosis, and new or changing infiltrates on chest films.[21,77] The radiographic abnormalities are multifocal and bilateral in most cases of *P. aeruginosa* pneumonia and are more severe than those observed with other nosocomial pathogens.[21] Cavitation is evident on plain films or chest tomography in about 25% of cases.[78]

The diagnosis of hospital-acquired pneumonia in critically ill patients is challenging because tracheal colonization with potential pathogens cannot be distinguished easily from infection on clinical grounds.[21,77] The diagnosis of *P. aeruginosa* pneumonia, particularly in intubated patients, is most accurately made from quantitative cultures of bronchoscopic specimens. Yields of colony-forming units (CFU) of 1,000/ml from a protected specimen brush or 10,000/ml from a bronchoalveolar lavage are indicative of infection. Blood cultures are positive in less than 10% of cases.

Hospital-acquired pneumonia caused by *P. aeruginosa* is associated with a worse outcome than infections caused by other pathogens. In well-documented cases of *P. aeruginosa* ventilator-associated pneumonia, the reported crude mortality ranges from 45% to 85% and the attributable mortality is about 40%.[77,79] In fatal cases, death usually results from septic shock or multiple-organ failure.[77] Relapses are relatively common after successful treatment.[77,79]

Community-acquired pneumonia *P. aeruginosa* is a rare cause of community-acquired pneumonia but is disproportionately represented among the most severe cases.[80,81] Most patients with *P. aeruginosa* pneumonia have underlying conditions that place them at particular risk for colonization of the lower airways with *P. aeruginosa* (e.g., cystic fibrosis, bronchiectasis, or tracheostomy); have important defects in host defenses caused by malignancy, aplastic anemia, cytotoxic chemotherapy, or advanced HIV infection; or have been recently hospitalized.[80,81] The few cases of *P. aeruginosa* pneumonia that have been reported in healthy persons have occurred predominantly in smokers.[80]

Community-acquired *P. aeruginosa* pneumonia is typically acute in onset and rapidly progressive.[72,80] Fever, cough, chest pain, and progressive dyspnea are the usual symptoms. The cough is generally productive of purulent sputum that may be streaked with blood. On examination, patients are apprehensive, often confused, and acutely ill, with fever, tachypnea, tachycardia, hypotension, and cyanosis. The chest x-ray typically reveals multifocal, nodular alveolar infiltrates, often bilateral. Small areas of parenchymal cavitation may be evident, but large effusions and empyema are unusual. Routine laboratory findings are nonspecific and may include leukocytosis or leukopenia, elevated transaminase levels, and azotemia. Sputum Gram stains demonstrate gram-negative bacilli in nearly all cases, and sputum cultures grow *P. aeruginosa* in more than 80% of cases.[72,80] Blood cultures often are positive. The clinical course is usually rapidly progressive despite therapy, with most patients experiencing respiratory failure. Mortality exceeds 25%.[80,81]

Pneumonia in HIV disease *P. aeruginosa* infections of the lower respiratory tract are unusually common in patients with advanced HIV disease, and the incidence may be increasing.[74,82] These infections occur in the setting of very low $CD4^+$ T cell counts (median, < 25 cells/mm^3). Additional risk factors in some cases include neutropenia, recent antibiotic therapy, and treatment with corticosteroids. Most infections are community acquired. The clinical course can be fulminant, but a subacute presentation also has been described, characterized by productive cough, fever, and dyspnea for days to weeks. The radiographic features are similar to those of other cases of community-acquired *P. aeruginosa* pneumonia. *P. aeruginosa* is readily identified in purulent sputum in the majority of cases; blood cultures are positive in 10% to 30% of cases.

Most patients with *P. aeruginosa* pneumonia complicating HIV infection respond to antibiotic treatment, but relapses are common.

Cystic Fibrosis

More than 80% of patients with CF develop chronic airway infection with mucoid strains of *P. aeruginosa*. This infection is associated with chronic airway inflammation, progressive loss of pulmonary function, and eventual death from respiratory failure.[74,76] Intensive and prolonged treatment of initial infection with aerosolized tobramycin or colistin may delay chronic infec-

tion and preserve pulmonary function.[76] Once chronic infection with mucoid *P. aeruginosa* is established, it is virtually impossible to eradicate.

Patients with CF experience pulmonary exacerbations that are associated with an increased density of *P. aeruginosa* in sputum. These episodes are characterized symptomatically by increased coughing, more purulent or bloody sputum, chest congestion, and dyspnea. Physical signs include tachypnea, use of accessory muscles for breathing, fever, and weight loss. A decline in airflow is evident on pulmonary function testing, and the chest x-ray may demonstrate new or changing infiltrates.[76]

Treatment of pulmonary exacerbations in CF includes chest physiotherapy, bronchodilators, mucolytics, and combination antibiotic therapy guided by in vitro susceptibility testing of sputum isolates.[76] Intermittent maintenance therapy with inhaled tobramycin (300 mg twice daily during alternate months) can suppress *P. aeruginosa,* improve airflow, and reduce the need for hospitalization.[83] Macrolides such as azithromycin also may improve lung function in CF patients colonized with *P. aeruginosa*, by mechanisms that are unclear.[84]

Bacteremia

P. aeruginosa bacteremia occurs predominantly in hospitalized patients with severe underlying disease.[74,85-87] The most common sources of infection are the lower respiratory tract, the urinary tract, and the skin; intravascular catheters are implicated in 7% to 16% of cases. No primary source of infection can be identified in up to 50% of episodes. The overall mortality of *P. aeruginosa* bacteremia is approximately 20%. An increased risk of death is observed in patients with pneumonia, severe sepsis, fatal underlying disease, and delayed administration of effective antibiotic therapy.

Endocarditis

P. aeruginosa is a rare cause of infective endocarditis. The majority of reported cases have occurred in injection drug users.[74,88] Occasional episodes have complicated cardiac surgery or involved seeding of a prosthetic device. Most cases have been localized to the right side of the heart and have developed on normal valves.

Patients with right-sided infection often present with a prolonged febrile illness and may complain of cough or chest pain associated with radiographic evidence of septic pulmonary emboli.[88] Patients with aortic or mitral valve involvement follow a more acute clinical course that may include evidence of congestive heart failure, myocardial abscess, or systemic embolization.[88] The diagnosis of *P. aeruginosa* endocarditis is made from blood cultures, cardiac auscultation, and echocardiography.

Most right-sided infections can be cured by 6 weeks of high-dose parenteral treatment with an extended-spectrum penicillin and an aminoglycoside. Left-sided infections usually require valve replacement surgery in conjunction with medical therapy.[74,88,89] The overall survival in left-sided infections is approximately 50%.

Urinary Tract Infections

P. aeruginosa is a common cause of urinary tract infection in hospitals and chronic care facilities. These infections usually follow instrumentation, surgery, or catheterization of the urinary tract, often in patients recently treated with antibiotics.[72,74] Symptomatic infections can be treated with single-agent antibiotic therapy. Catheter-associated infections are unlikely to be eradicated unless the catheter is removed.

Ear Infections

Swimmer's ear *P. aeruginosa* is commonly isolated from cases of acute diffuse external otitis (swimmer's ear), which is associated with freshwater swimming in warm, humid climates.[74] This condition is characterized by an inflamed, draining, pruritic, and sometimes painful external auditory canal. Local cleansing followed by topical treatment with an otic solution containing 2% acetic acid or an antibiotic in combination with corticosteroids speeds recovery. Recurrences are common.

Malignant (necrotizing) otitis externa *P. aeruginosa* is the pathogen in nearly all cases of malignant external otitis, a chronic, invasive infection of the external auditory canal that predominantly afflicts elderly persons with diabetes mellitus.[74,90] Rarely, cases have been reported in AIDS patients and immunocompromised children. The infection spreads to the temporal bone and mastoid, often involving the adjacent cranial nerves as they exit the skull. Severe otalgia is the presenting symptom, and most patients have purulent otorrhea with an intact tympanic membrane. Facial nerve paresis is evident in 30% to 40% of cases; other cranial neuropathies are less common. Fever and other systemic signs of infection are usually absent. The erythrocyte sedimentation rate (ESR) is nearly always markedly elevated. Technetium-99m bone scanning is very sensitive but not specific for this condition. CT and magnetic resonance imaging are useful for defining the extent of disease, with MRI being more sensitive for delineating the soft tissue component.[74,90] The diagnosis can be made from the clinical presentation, imaging studies, and cultures of diseased bone or granulation tissue in the external canal.

Local debridement and antibiotic therapy for 4 to 8 weeks are successful in most cases. An oral fluoroquinolone (e.g., ciprofloxacin, 750 mg twice daily) is usually effective. Parenteral therapy with an antipseudomonal β-lactam with or without an aminoglycoside may be required for recalcitrant cases or those caused by resistant strains.[74,90] The ESR, serial gallium-67 scans, or both can be used as markers of disease activity and guides to duration of therapy.

Eye Infections

P. aeruginosa is an important cause of keratitis, particularly in contact lens wearers.[74] This infection develops as a complication of corneal injury, which permits bacterial attachment to the damaged epithelium and subsequent invasion.

The clinical manifestations begin with a small, painful ulcer that spreads with gray discoloration and edema of the cornea, anterior chamber reaction, and mucopurulent exudate. The microbiologic diagnosis can be made by Gram stain and culture of purulent material in the base of the ulcer.

Emergent treatment is with frequent (every 15 to 30 minutes) topical applications of an ophthalmic solution containing high concentrations of an aminoglycoside or fluoroquinolone. *P. aeruginosa* is also occasionally implicated in posttraumatic endophthalmitis and nosocomial conjunctivitis.

Central Nervous System Infections

Meningitis caused by *P. aeruginosa* occurs most often as a complication of neurosurgery.[74] Rare cases result from *P. aeruginosa* bacteremia, particularly in debilitated patients with cancer or severe burns.

Fever and depressed consciousness are the cardinal manifestations. The onset often is insidious in postoperative cases. The

diagnosis is made from culture and Gram stain of the cerebrospinal fluid.

Ceftazidime is the preferred treatment, often given in combination with an intravenous aminoglycoside. Alternative agents that achieve adequate levels in the cerebrospinal fluid include meropenem, aztreonam, and ciprofloxacin. Intrathecal therapy with aminoglycosides may be required for refractory cases or highly resistant organisms.[74]

Bone and Joint Infections

P. aeruginosa is associated with a distinctive spectrum of acute and chronic osteochondral infections that result from hematogenous seeding, direct inoculation, or contiguous spread from adjacent tissues.[74] Hematogenous infections are most commonly seen in injection drug users and typically involve the sternoclavicular joints, symphysis pubis, sacroiliac joints, or cervical vertebrae. Lumbosacral vertebral osteomyelitis may complicate instrumentation of the urinary tract via contamination of the venous plexus shared by the pelvis and the spine. *P. aeruginosa* is also the most common cause of osteochondritis after puncture wounds of the foot. This syndrome is most often seen in children and results from direct inoculation of bacteria colonizing the moist insoles of their sneakers. Chronic osteomyelitis caused by *P. aeruginosa* can develop as a complication of orthopedic surgery, sternotomy, or contiguous infection of pressure sores or ischemic skin ulcers.

The cardinal symptom of acute osteochondral *P. aeruginosa* infection is pain lasting days to weeks. Examination is notable for local tenderness and diminished mobility, frequently with warmth and erythema. Fever and leukocytosis are often present, and the ESR is almost always elevated. The clinical presentation of chronic osteomyelitis is subtler than that of acute infection. Pain, nonunion, and draining ulcers are common, often without systemic manifestations.

Imaging studies are important in the evaluation of *P. aeruginosa* bone and joint infections.[91] Plain x-rays or CT scans can reveal evidence of bony destruction or periosteal reaction but may be negative early in the clinical course. MRI is more sensitive than radiography, particularly for nonosseous changes. Technetium-99m bone scans are invariably positive in osteomyelitis but may be normal when the infection is confined to the joint. Confirmation of *P. aeruginosa* as the pathogen is made from joint aspiration or bone biopsy. Blood cultures are negative in most cases.

Treatment of *P. aeruginosa* osteochondral infections usually requires 4 to 6 weeks of antibiotic therapy. An antipseudomonal β-lactam in combination with an aminoglycoside is generally recommended, but single-agent therapy, particularly with a fluoroquinolone, may be effective.[74,91] Surgical debridement is necessary when bone necrosis is evident, but most infections confined to a joint can be treated with antibiotics alone. In the case of *P. aeruginosa* osteochondritis of the foot in children, 1 week of antibiotic therapy after debridement is sufficient for cure. Chronic infections are difficult to eradicate, and suppressive therapy may be required.

Skin Infections

P. aeruginosa causes a variety of cutaneous infections that can affect normal skin after submersion in contaminated water.

Folliculitis Outbreaks of folliculitis, or swimmer's itch, have been associated with the use of hot tubs, whirlpools, therapy baths, and swimming pools.[74] The presenting feature is a diffuse, pruritic eruption that may be follicular, maculopapular, vesicular, or pustular. The rash develops 8 hours to 5 days after exposure and usually involves skin that had been covered by a swimsuit. Mild headache and other complaints may be present, but fever is unusual. *P. aeruginosa* can be identified from stains and cultures of pustular lesions. Topical drying agents may ease symptoms, but the rash resolves within 7 days without specific therapy.

Hot-foot syndrome Another waterborne infection is *Pseudomonas* hot-foot syndrome, which is characterized by the development of tender, warm, erythematous 1- to 2-cm nodules on a background of plantar or palmar erythema.[92] These lesions appeared in children 10 to 40 hours after being in a contaminated wading pool and resolved without antibiotic treatment within 7 to 14 days.

Green-nail syndrome This syndrome results from discoloration of the nail plate by pyocyanin and occurs in persons who frequently submerge their hands. Local cleansing and debridement, including draining of any associated paronychia, are generally successful.[74,93]

Toe web infection *P. aeruginosa* is a frequent cause of toe web infections. These occur most often in tropical climates and may complicate minor trauma or tinea pedis. The affected toe webs are macerated, thickened, and painfully fissured; a purulent exudate is often present. Examination under a Wood lamp can reveal green-white fluorescence from the elaboration of pyoverdin. Toe web infections often can be managed with local measures, but systemic antibiotics may be needed in severe cases.[74,93]

Burn wound sepsis In years past, *P. aeruginosa* was the most common agent of burn wound sepsis, which was the leading cause of death after thermal injury. With the development of effective topical antimicrobials, wound excision, and other advances in burn wound care, burn wound sepsis has become far less common. Fungi are now the dominant pathogens, but *P. aeruginosa* remains an important consideration. Suspicion of wound sepsis should be aroused by the appearance of dark-brown, black, or violaceous discoloration of the wound. Hemorrhage, purulent drainage, or green pigment also may be present. Blood cultures may be positive, but the diagnosis of invasive infection is made from wound biopsies demonstrating microbial invasion of normal tissue. Treatment of *P. aeruginosa* infection is with systemic antibiotics, topical mafenide acetate cream, and surgical debridement.[94] *P. aeruginosa* can also cause posttraumatic cellulitis, deep abscesses, necrotizing fasciitis, and other locally invasive pyodermas, particularly in immunocompromised persons.[74]

Ecthyma gangrenosum Ecthyma gangrenosum is a distinctive skin infection that results in most cases from *P. aeruginosa* bacteremia, usually in the setting of neutropenia, cancer, burns, AIDS, or other severely debilitating conditions.[74,93] The lesions may be discrete or multiple and begin as painless macules or nodules that may become vesicular or bullous. The lesions undergo central hemorrhagic necrosis and ulceration over a period of 12 to 24 hours, with a surrounding rim of tender erythema. Ecthyma gangrenosum is characterized histologically by bacterial invasion of dermal veins. Blood cultures are usually positive, and *P. aeruginosa* can be demonstrated in biopsies or scrapings from the base of

the ulcer. Treatment requires prompt administration of intravenous antibiotics and management of the underlying condition.

ANTIBIOTIC TREATMENT

The treatment of *P. aeruginosa* infections is particularly challenging because of the remarkable resistance of this organism to most antibiotics and its propensity to develop further resistance during the course of therapy. The intrinsic antimicrobial insensitivity of *P. aeruginosa* arises from several complementary mechanisms.[74,95] First, a relatively impermeable outer membrane limits the access of antibiotics to their binding sites. Second, an active efflux pump can expel agents that penetrate the outer barrier. Third, expression of a chromosomally encoded β-lactamase is induced on exposure to β-lactam antibiotics. Furthermore, mutations in *P. aeruginosa* can result in the rapid selection of resistant organisms during the course of treatment. Fourth, *P. aeruginosa* can acquire plasmids bearing additional resistance genes, such as those encoding for extended-spectrum β-lactamases, carbapenemases, and enzymes that inactivate aminoglycosides.[74,95] Finally, the growth of *P. aeruginosa* in biofilms induces the production of periplasmic glucans that bind and sequester antibiotics.[96]

Antimicrobial agents that are effective against most strains of *P. aeruginosa* include β-lactams, fluoroquinolones, and aminoglycosides [*see 7:XIV Chemotherapy of Infection*]. In the United States, the β-lactams showing the greatest activity against *P. aeruginosa* are meropenem and piperacillin-tazobactam; the most effective fluoroquinolone remains ciprofloxacin, and the most active aminoglycoside is amikacin.[97] Local resistance patterns vary, however, so it is important to determine the antibiotic susceptibilities of individual strains by in vitro testing. Hospital isolates exhibit greater resistance than outpatient isolates, and organisms cultured in intensive care units are the most resistant. Multidrug-resistant strains are increasing in prevalence; these may be susceptible to antibiotic combinations or polymyxins.[74,97]

Treatment of suspected *P. aeruginosa* infection should begin with high doses of an antipseudomonal β-lactam in combination with an aminoglycoside or fluoroquinolone. The use of two agents increases the likelihood of effective initial therapy, which is associated with reduced mortality.[85,87] Whether combination therapy should be continued after sensitivities are known is unclear.[98] On the one hand, the combination of an aminoglycoside with a β-lactam antibiotic results in synergistic killing of *P. aeruginosa* and improves outcome in some animal models of infection.[80,99] Prospective observational studies have found combination therapy with β-lactams and aminoglycosides to be associated with improved survival in neutropenic or bacteremic patients with *P. aeruginosa* infections.[99,100] On the other hand, aminoglycosides are relatively toxic, and other antibiotic combinations are less predictably synergistic against *P. aeruginosa*.[80] Recent retrospective clinical studies have not identified any survival advantage of dual-drug therapy over treatment with a single effective agent.[77,85-87] Combination therapy also has not been shown to suppress the emergence of resistant strains. Despite this uncertainty, it may be prudent to use combination therapy whenever possible because of the high mortality and refractory nature of *P. aeruginosa* infections. An exception is urinary tract infection, which can be treated effectively with a single agent. Most *P. aeruginosa* infections can be cured with 2 to 3 weeks of antibiotic therapy, but longer courses are required for endocarditis and osteomyelitis.

XI INFECTIONS DUE TO BRUCELLA, FRANCISELLA, YERSINIA PESTIS, AND BARTONELLA

W. CONRAD LILES, M.D, PH.D.

Brucellosis, tularemia, (bubonic) plague, and bartonellosis are zoonoses (i.e., infectious diseases that can be transmitted from animals to humans) caused by gram-negative bacilli. The causative agents of these diseases are *Brucella* species, *Francisella tularensis, Yersinia pestis,* and *Bartonella* species, respectively. Infected arthropods, such as ticks or fleas, can serve as vectors for the transmission of tularemia, plague, and bartonellosis. In general, the diagnosis of these zoonoses requires the physician to consider the clinical presentation (which is not always distinctive) in light of the epidemiology of these diseases [*see Table 1*]. Treatment is principally with appropriate empirical antimicrobials [*see Table 2*].

Brucellosis

Brucellosis continues to be a major zoonosis worldwide.[1] The animal reservoirs for the disease include a variety of domesticated animals: cattle, goats, sheep, pigs, and dogs. Human brucellosis (variously known as undulant fever, Malta fever, and Mediterranean fever) is rare in the United States but remains a significant health problem in developing countries. In humans, brucellosis is a disease of protean manifestations, ranging from an indolent febrile syndrome to fulminant endocarditis. Like plague and tularemia, brucellosis is recognized as a potential agent of biological terrorism.[2]

EPIDEMIOLOGY

Virtually all cases of brucellosis arise from direct or indirect exposure to animals.[1,3-5] In animals, brucellosis is a chronic disease that persists lifelong and causes infectious abortion and sterility. *B. abortus* infects predominantly cattle; *B. melitensis,* goats and sheep; and *B. suis,* domestic and wild swine. *B. canis*, the least common cause of human brucellosis, is mostly found in kennel-raised dogs. Infected animals shed large numbers of *Brucella* organisms in their milk, urine, and afterbirth. Hence, brucellosis is considered an occupational hazard for farmers, ranchers, veterinarians, abattoir workers, and laboratory personnel.[3,4,6]

Brucellosis is distributed worldwide, but its incidence varies markedly, depending largely on the degree of its control in domestic animals and the pasteurization of milk. The disease is relatively common in southern Europe, the Middle East, the

Table 1 Diagnosis of Diseases Caused by *Brucella*, *Francisella*, *Yersinia*, and *Bartonella* Species

	Brucella *(Brucellosis)*	Francisella tularensis *(Tularemia)*	Yersinia pestis *(Plague)*	Bartonella *(Oroya Fever, Bacteremia, Cat-Scratch Disease)*
Animal reservoir	Cattle, goats, sheep, swine, dogs	Widespread: mammals, birds, fish, amphibians, arthropods	Rodents (rats, ground squirrels, prairie dogs); other animals possible	Cats, phlebotomine sandflies (Andes Mts.)
Transmission	Direct contact through skin lesions, airborne, ingestion of contaminated dairy products	Direct contact, airborne, arthropod bites	Flea bites, animal bites or scratches, airborne	Oroya fever: sandfly bites Bacteremia: body lice Cat-scratch disease: cat bites or scratches; possibly, cat flea bites
Incubation period (range)	10–14 days (5 days to several months)	3–7 days (1–21 days)	Bubonic: 2–7 days Pneumonic: 2–3 days (1–14 days)	Oroya fever: 3–12 wk Bacteremia: days to months Cat-scratch disease: 3–10 days
Clinical manifestations	Protean: fever and tachycardia, flulike syndrome, liver or spleen enlargement, lymphadenopathy, rashes or skin lesions	Flulike illness, ulcer at site of skin inoculation, regional lymphadenopathy, rash, GI symptoms	Flulike illness, buboes (inguinal/axillary lymphadenopathy) Septicemic: GI symptoms	Oroya fever: flulike illness, lymphadenopathy, hemolytic anemia, thrombocytopenia Bacteremia: fever, malaise, anemia, thrombocytopenia, splenomegaly, cardiac murmur, bacillary angiomatosis (in HIV) Cat-scratch disease: inoculation-site lesion, regional lymphadenopathy, low-grade fever
Laboratory tests	WBCs normal or decreased; RBCs and platelets typically decreased; ESR variable; culture of body fluid and tissue; serology	Screening tests often unremarkable; mild to moderate elevation of AST and ALT; serology (late)	WBCs 15,000–25,000/µl, left shift; fibrin split products ↑; DIC possible; AST, ALT, and bilirubin elevated; culture of body fluid and tissue; direct immunofluorescence	Oroya fever: blood culture Bacteremia: blood culture Cat-scratch disease: diagnosis usually clinical

ALT—alanine aminotransferase AST—aspartate aminotransferase ESR—erythrocyte sedimentation rate RBC—red blood cell WBC—white blood cell

Table 2 Treatment of Diseases Caused by *Brucella*, *Francisella*, *Yersinia*, and *Bartonella* Species

Infection	*Drug*	*Dosage*	*Relative Efficacy*	*Cost*	*Comments*
Brucella *(Brucellosis)*	Doxycycline *plus* Gentamicin *or* Streptomycin	100 mg p.o., b.i.d., for 6 wk 3–5 mg/kg/day I.V. in divided doses for 2–3 wk 1 g I.M. q.d. for 2–3 wk	First choice	\$0.05—0.12/day 120 mg I.V. q. 8 hr: \$5.00–5.99/day 500 mg I.M. b.i.d.: \$3.00–3.99/day	Relapse rate ~ 6%
	Doxycycline *plus* Rifampin	100 mg p.o., b.i.d., for 6 wk 600–900 mg p.o., b.i.d., for 6 wk	Alternative choice	\$0.05–0.12/day 600 mg p.o. once daily: \$60.00–69.99/mo.	Relapse rate ~ 15%
	Ciprofloxacin	500 mg p.o., b.i.d., for 30 days, with rifampin (see above)	Adjunctive therapy	—	Adjunctive therapy
Francisella tularensis *(Tularemia)*	Streptomycin	500 mg–1 g I.M. q. 12 hr for 7–14 days	First choice	500 mg I.M. b.i.d.: \$3.00–3.99/day	—
	Gentamicin	3–5 mg/kg/day I.V. in divided doses q. 8 hr for 7-14 days	Equally effective	120 mg I.V. q. 8 hr: \$5.00–5.99/day	—
	Tetracycline	500 mg p.o., q.i.d., for 21–28 days	Alternative choice	500 mg p.o., q.i.d.: \$0.10—0.24/day	Relapse can occur if therapy < 21 days
	Doxycycline	100 mg p.o., b.i.d., for 21–28 days	Alternative choice	—	Relapse can occur if therapy < 21 days
	Chloramphenicol	1 g I.V., p.o.* q. 6 hr for 21–28 days	Alternative choice	1 g I.V. q. 6 hr: \$150.00–199.99/day	Relapse can occur if therapy < 21 days; consider for treatment if signs or symptoms of meningitis are present
	Ciprofloxacin	500 mg p.o., b.i.d., for 14–21 days	Alternative choice	500 mg p.o., b.i.d.: \$7.00–7.99/day	Limited data
Yersinia pestis *(Bubonic Plague)*	Streptomycin	30 mg/kg/day I.M. in divided doses q.12 hr, for 10 days or at least 3 days after clinical recovery; or for 5 days, followed by gentamicin for 5–10 days (see below)	First choice	500 mg I.M. b.i.d.: \$3.00–3.99/day	Continue antibiotic therapy for 10 days, or at least 3 days after clinical recovery
	Gentamicin	2 mg/kg I.V. loading dose, then 1.7 mg/kg I.V. q. 8 hr	Equally effective	120 mg I.V. q. 8 hr: \$5.00–5.99/day	Continue antibiotic therapy for 10 days, or at least 3 days after clinical recovery
	Tetracycline	500 mg I.V./p.o., q.i.d.	Alternative choice	500 mg p.o., q.i.d.: \$0.10–0.24/day	Continue antibiotic therapy for 10 days, or at least 3 days after clinical recovery
	Doxycycline	100 mg I.V./p.o., b.i.d.	Alternative choice	100 mg p.o., b.i.d.: \$0.05–0.12/day	Continue antibiotic therapy for 10 days, or at least 3 days after clinical recovery
	Chloramphenicol	500 mg–1 g I.V./p.o.* q.i.d.	Alternative choice	1 g I.V. q. 6 hr: \$150.00–199.99/day	Continue antibiotic therapy for 10 days, or at least 3 days after clinical recovery
	Tetracycline	500 mg p.o., q.i.d.	Chemoprophylaxis	\$0.10–0.24/day	Chemoprophylaxis for contacts of patients with pneumonic plague
	Doxycycline	100 mg p.o., b.i.d.	Chemoprophylaxis	\$0.05–0.12/day	Chemoprophylaxis for contacts of patients with pneumonic plague
	Streptomycin	20 mg/kg/day I.M. in two divided doses	Chemoprophylaxis	500 mg I.M., b.i.d.: \$3.00–3.99/day	Chemoprophylaxis for contacts younger than 8 yr of age of patients with pneumonic plague
	Trimethoprim-sulfamethoxazole	40 mg/kg p.o., b.i.d.	Chemoprophylaxis	800/160 mg p.o., b.i.d.: \$0.10–0.24/day	Chemoprophylaxis for contacts younger than 8 yr of age of patients with pneumonic plague

Table 2 (*continued*)

Table 2 Treatment of Diseases Caused by *Brucella*, *Francisella*, *Yersinia*, and *Bartonella* Species

Infection	*Drug*	*Dosage*	*Relative Efficacy*	*Cost*	*Comments*
Bartonella (*Bartonellosis*)	OROYA FEVER				
	Chloramphenicol	500 mg p.o.*/I.V. q.i.d. for ≥ 1 wk	First choice	1 g I.V. q. 6 hr: $150.00–199.99/day	—
	Tetracycline	500 mg p.o./I.V. q.i.d. for ≥ 2 wk	Alternative choice	$0.10–0.24/day	—
	Doxycycline	100 mg p.o./I.V. q.i.d. for ≥ 2 wk	Alternative choice	$0.05–0.12/day	—
	Ampicillin	500 mg p.o./I.V. q.i.d. for ≥ 2 wk	Alternative choice	500 mg p.o., q.i.d.: $0.75–0.99/day	—
	URBAN TRENCH FEVER WITH BACTEREMIA				
	Erythromycin	500 mg p.o., q.i.d., for 14 days	—	—	Azithromycin and clarithromycin are probably equally effective
	Doxycycline	100 mg p.o., b.i.d., for 14 days	—	$0.05—0.12/day	—
	URBAN TRENCH FEVER WITH ENDOCARDITIS				
	Gentamicin	2 mg/kg I.V. loading dose, then 1.7 mg/kg I.V. q. 8 hr	—	120 mg I.V. q. 8 hr: $5.00–5.99/day	In conjunction with valve replacement
	Ciprofloxacin *plus* Rifampin	Ciprofloxacin, 500 mg p.o., b.i.d., plus rifampin, 600 mg p.o., q.d, for ≥ 4–6 mo	—	—	Limited data; monitor for surgical valve replacement; levofloxacin can be substituted for ciprofloxacin
	Ciprofloxacin *plus* a macrolide	Ciprofloxacin, 500 mg p.o., b.i.d., plus an oral macrolide (erythromycin, clarithromycin, or azithromycin) for ≥ 4–6 mo	—	—	Limited data; monitor for surgical valve replacement; levofloxacin can be substituted for ciprofloxacin
	CAT-SCRATCH DISEASE				
	Azithromycin	500 mg p.o. once, then 250 mg p.o., q.d., for 4 days	—	250 mg p.o., q.d.: $6.00–6.99/day	Azithromycin is only agent shown to be effective in placebo-controlled, double-blind clinical trial; alternative choices include rifampin, gentamicin, trimethoprim-sulfamethoxazole, doxycycline, ciprofloxacin, and levofloxacin
	BACILLARY ANGIOMATOSIS				
	Erythromycin	500 mg p.o., q.i.d., for 2 mo (4 mo for osteomyelitis or peliosis hepatis)	First choice	250 mg (base) p.o., q.i.d.: $1.00–1.49/day	—
	Doxycycline	100 mg p.o., b.i.d., for 2 mo (4 mo for osteomyelitis or peliosis hepatis)	First choice	$0.05–0.12/day	—
	Clarithromycin	500 mg p.o., b.i.d., for 2 mo (4 mo for osteomyelitis or peliosis hepatis)	Alternative choice	500 mg p.o., b.i.d.: $7.00–7.99/day	—
	Azithromycin	250 mg p.o., q.d., for 2 mo (4 mo for osteomyelitis or peliosis hepatis)	Alternative choice	250 mg p.o., q.d.: $6.00–6.99/day	—
	Ciprofloxacin	500–750 mg p.o., b.i.d., for 2 mo (4 mo for osteomyelitis or peliosis hepatis)	Alternative choice	500 mg p.o., b.i.d.: $7.00–7.99/day	—
	Doxycycline *plus* Rifampin	Doxycycline: 100 mg I.V./po., b.i.d., plus rifampin, 300 mg p.o., b.i.d., for 2 mo (4 mo for osteomyelitis or peliosis hepatis)	Alternative choice	$0.05–0.12/day	For severe or relapsed cases

*Note: Chloramphenicol is not distributed as an oral drug in the United States.

Indian subcontinent, parts of Africa, Mexico, and Central and South America.[1,3-5]

In the United States, the incidence of brucellosis has declined to less than 100 cases annually, coincident with public health programs and the virtual elimination of *B. abortus* infection in cattle. Currently, most cases of brucellosis acquired in the United States are caused by *B. melitensis* and can be linked to ingestion of unpasteurized goat-milk products from foreign countries, such as Mexico, and exposure to *Brucella* cultures in microbiology laboratory personnel.[4,6-8] Transmission of brucellosis by bone marrow transplantation was recently reported.[9]

ETIOLOGY

Brucellosis is transmitted to humans by direct contact with infected animals or their body fluids (inoculation occurs through cuts or abraded skin); via inhalation of aerosolized

organisms; or by ingestion of unpasteurized dairy products. Because of the low density of organisms in muscle, consumption of meat products has rarely been implicated in infection.[1,3-5]

PATHOGENESIS

Brucella organisms are small, nonmotile, non–spore-forming, gram-negative coccobacilli. The organisms are relatively hardy and can survive in dairy products or refrigerated meats for weeks to months. Although they grow aerobically, some species require supplemental carbon dioxide for primary isolation. In culture, *Brucella* strains are relatively slow growing; isolation from clinical specimens can require incubation for 30 days or more.[1,4]

Infection can occur via the gastrointestinal tract, broken skin, oral mucosa, conjunctiva, or respiratory tract. Once inoculated, bacteria travel to regional lymph nodes and multiply. They then enter the bloodstream and localize in cells of the reticuloendothelial system (particularly the liver, spleen, bone marrow, and lymph nodes) and kidney. At tissue sites of infection, noncaseating granulomas characteristically develop. Bacteremia can lead to metastatic infection at various sites, including bone, joints, meninges, and cardiac valves.[1,3-5]

DIAGNOSIS

Clinical Manifestations

The incubation period for brucellosis is usually 10 to 14 days, but it ranges from 5 days to several months. Onset of illness can be abrupt or insidious. The presentation is nonspecific; fever, chills, headache, myalgias, anorexia, malaise, and fatigue are common. Fever and tachycardia are present in approximately 90% of cases, hepatomegaly in 25% to 30%, splenomegaly in about 40%, and lymphadenopathy (most commonly cervical) in 10% to 40%. Cutaneous manifestations, which occur in approximately 5% of patients, include a variety of nonspecific maculopapular rashes, erythema nodosum, petechiae, and purpura. Other symptoms and signs will depend on specific organ involvement in individual cases.

Brucellosis can follow an acute, subacute, or chronic course. Untreated disease may persist for months to years and may cause a syndrome of relapsing fevers. Because the symptoms and signs of brucellosis may be nonspecific, it is important to obtain a detailed history that includes occupation, travel, exposure to animals, or ingestion of high-risk foods, such as unpasteurized dairy products[1,3-5] [*see Table 1*].

Laboratory Tests

The leukocyte count is typically normal or decreased. Anemia and thrombocytopenia are relatively common. The erythrocyte sedimentation rate is variable and rarely helpful.

Definitive diagnosis of brucellosis depends on isolation of the organism from blood, bone marrow, urine, cerebrospinal fluid, or other body fluids or tissues. The sensitivity of a single blood culture ranges from 15% to 70%, depending on the method used and the length of incubation. Because *Brucella* organisms grow slowly, cultures should be maintained for at least 4 weeks to increase recovery. The use of lysis centrifugation culture systems has been reported to hasten recovery. Culture of bone marrow is reportedly more sensitive than conventional blood culture.

Presumptive diagnosis of brucellosis can be made by serologic studies showing specific brucella IgG antibodies or the presence of IgM antibody to *Brucella*.[3-5,10] It should be noted that the standard brucella serum agglutination test does not detect antibodies to *B. canis*. In suspected *B. canis* infection, serologic tests specific for that species should be ordered. Molecular diagnosis using polymerase chain reaction has been developed but is currently not available for routine clinical use.[11]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of brucellosis includes enteric fever, malaria, infectious mononucleosis (Epstein-Barr virus [EBV] infection), atypical mononucleosis (cytomegalovirus infection), Q fever, miliary tuberculosis, subacute bacterial endocarditis, HIV infection, and visceral leishmaniasis (kala-azar).[4]

TREATMENT

Brucellosis requires prolonged treatment with a tetracycline, typically supplemented with a second antibiotic: an aminoglycoside, rifampin, or perhaps a fluoroquinolone[1,3-5] [*see Table 2*]. Significant resistance to trimethoprim-sulfamethoxazole has limited the use of this agent.[5] Recent studies from Spain and the Middle East suggest that the best initial regimen is doxycycline (100 mg p.o., b.i.d.) for 6 weeks, plus either gentamicin (3 to 5 mg/kg a day I.V. in divided doses) or streptomycin (1 g/day I.M.) for the first 2 to 3 weeks. Relapse occurs in approximately 6% of patients treated with this regimen.[12] Doxycycline can also be combined with 6 weeks of rifampin (600 to 900 mg p.o., b.i.d.), although relapse has been reported in approximately 15% of patients treated with this regimen.[13] Fluoroquinolones have demonstrated good activity against *Brucella* in vitro, but clinical results have been disappointing; therefore, those agents should be regarded as adjunctive rather than primary therapy.[13] Although corticosteroid therapy has been recommended for management of brucellosis involving the central nervous system, no controlled studies have demonstrated its efficacy. No satisfactory vaccines for human brucellosis are currently available.[1]

COMPLICATIONS

Brucellosis can cause complications in almost any organ system. Endocarditis occurs in less than 2% of cases but accounts for the majority of brucellosis-related deaths. Infected aneurysms of the brain, aorta, and other vessels can occur. Direct invasion of the central nervous system occurs in only about 5% of cases. Meningitis is the most frequent CNS complication. Bone and joint involvement is relatively common, with a reported occurrence of 20% to 60%. Sacroiliitis and spondylitis are the most common musculoskeletal complications.[14] The GI tract is involved in as many as 70% of patients. Inflammation of Peyer patches can cause ileitis or colitis. Brucellosis can cause granulomatous hepatitis, pyogenic hepatic abscesses, or cholecystitis. Although renal involvement in brucellosis is unusual, orchitis has been reported in 20% of men with brucellosis. Respiratory tract involvement in brucellosis ranges from flulike symptoms to pneumonia with or without pleural effusions. A variety of ocular complications have been reported, including uveitis and endophthalmitis.

PROGNOSIS

A relapse rate of 5% to 25% can be expected in patients treated for brucellosis, depending on the antibiotic regimen employed (see above). Relapse is especially common in spondylitis.[14] Mortality is highest in cases of endocarditis. Cardiac valve replace-

ment surgery, in addition to prolonged antimicrobial therapy, is often required for successful resolution of endocarditis.[15]

Tularemia

Infection by *Francisella tularensis* causes clinical tularemia. This disease is a zoonosis of substantial complexity whose natural hosts or vectors include more than 100 species of wild mammals; several species of birds, fish, and amphibians; and more than 50 species of blood-sucking arthropods (including ticks, fleas, and deerflies). Tularemia has been recognized widely throughout the Northern Hemisphere, where it was formerly known by a variety of names, such as rabbit fever, deerfly fever, market men's disease, wild-hare disease, Ohara disease (Japan), and water-rat trappers' disease (Russia). *F. tularensis* could potentially be used in biological warfare or terrorism.[16]

EPIDEMIOLOGY

Tularemia is most commonly found in the temperate zones of the Northern Hemisphere. Five subspecies of *F. tularensis* have been recognized on the basis of biologic properties and geographic location. Type A biovar (*F. tularensis* biovar *tularensis*), the most virulent, is found only in North America, where it causes 70% to 90% of all cases of tularemia. This biovar is transmitted by infected rabbits and ticks, and untreated infection can be fatal. The less virulent type B biovar (*F. tularensis* biovar *palearctica*) is present in temperate zones worldwide. It is transmitted by rodents or aquatic animals and can cause mild or subclinical disease. *F. tularensis* biovar *palearctica mediasiatica* and *F. tularensis* biovar *palearctica japonica* are found in central Asia and Japan, respectively. *F. tularensis* biovar *novicida* rarely causes disease in humans or animals.

In the United States, human tularemia has been reported from every state except Hawaii.[17,18] In 1993, the last year in which tularemia was designated a notifiable disease by the Centers for Disease Control and Prevention (CDC), 132 cases were reported in the United States[19] [*see Figure 1*]. The disease clusters in the lower midwestern states, especially Arkansas, Oklahoma, and Missouri.[17,20]

The most important reservoirs of *F. tularensis* are rabbits, hares, and hard ticks.[18] The three major North American tick vectors of tularemia are *Dermacentor variabilis* (dog tick), which is widely distributed throughout North America; *Amblyomma americanum* (Lone star tick) in the southeastern and south central United States; and *D. andersoni* in the western United States. Infected *Ixodes* ticks can also transmit tularemia.[18,21,22] Aside from hard ticks, other reported arthropod vectors for transmission of tularemia to humans include deerflies, horseflies, and mosquitoes.[17,20,21]

Hunters, trappers, game wardens, veterinarians, meat handlers, laboratory workers, and pet owners are considered populations at increased risk for tularemia. However, as many as 40% of patients with tularemia relate no history of contact with a potential animal reservoir or arthropod vector.

ETIOLOGY

Humans generally acquire tularemia by direct contact with infected wild mammals or via bites from infected arthropods. Domestic animals, such as pet cats and dogs that have preyed on infected wild animals, can serve as sources of tularemia transmission to humans via bites, scratches, or licks.[23,24] Transmission has also resulted from inhalation of aerosolized organisms or ingestion of contaminated meat or water.[17,18,25] No documented human-to-human transmission of tularemia has been reported.[17,18,25,26]

The etiology of human tularemia shows some seasonal variation. During the summer, most cases occur as a result of arthropod bites. During the fall and winter, hunters and trap-

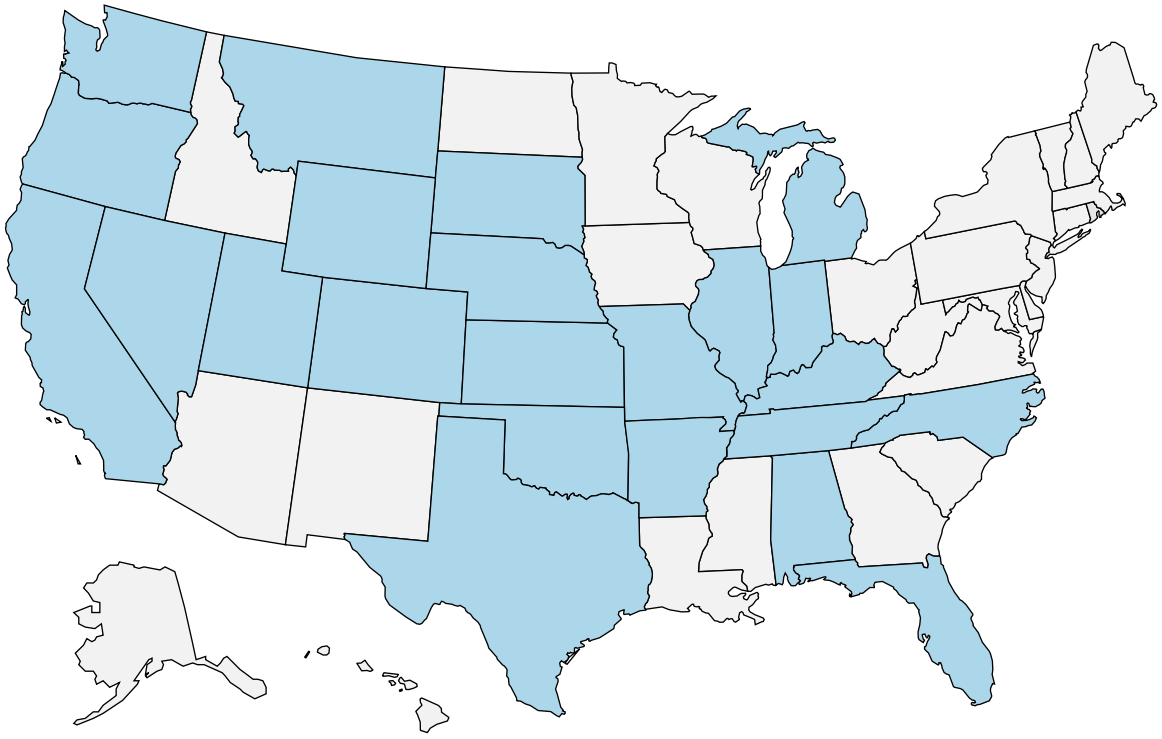

Figure 1 **States in blue are those reporting cases of tularemia in 1993.**

pers may acquire tularemia while skinning and dressing wild game.

PATHOGENESIS

F. tularensis is a small, pleomorphic, nonmotile, intracellular, gram-negative coccobacillus that grows fastidiously as an obligate aerobe. In culture, it requires cysteine-enriched blood agar for growth. In the environment, it can remain viable at low temperatures for 3 to 4 months in mud, water, or decayed animal carcasses.

F. tularensis is highly infectious. As few as 10 to 50 organisms can cause clinical tularemia after inhalation or intradermal injection, and 10^8 organisms can cause disease if ingested. The skin and mucous membranes are the most common portals of entry for *F. tularensis.* After inoculation, the organism multiplies locally to produce an erythematous, tender papule within 2 to 5 days, which subsequently becomes an ulcer with a black base (chancriform lesion). Bacteria then usually spread to regional lymph nodes, causing lymphadenopathy. Sepsis syndrome can occur with bacteremia or in cases of widely disseminated disease.

Histopathologically, tularemia is characteristically associated with mononuclear cell infiltration and granuloma formation. Those features can resemble the pathology of tuberculosis.

DIAGNOSIS

Clinical Manifestations

The usual incubation period of tularemia is 3 to 7 days (range, 1 to 21 days). Classically, tularemia presents as a severe illness with a sudden onset of fever, chills, headache, malaise, fatigue, and generalized myalgias and arthralgias. However, the severity of illness, especially in tick-borne disease, is highly variable, ranging from mild, afebrile, self-limited disease to rare cases of septic shock. Typically, an ulcer with surrounding inflammation develops at the site of inoculation. The inoculation ulcer may persist for weeks to months in untreated cases.

Most patients (70% to 90%) acquire infection by inoculation of the skin. Regional lymphadenopathy often develops in the inguinal/femoral nodes in adults and the cervical nodes in children. A generalized rash, usually maculopapular but occasionally pustular, is seen in approximately 20% of patients. Erythema nodosum has been reported infrequently.

The clinical manifestations of tularemia have been categorized into six recognized syndromes: (1) ulceroglandular, (2) glandular, (3) oculoglandular, (4) oropharyngeal, (5) pleuropulmonary, and (6) typhoidal.

Ulceroglandular tularemia and glandular tularemia are the most common forms of clinical tularemia, accounting for 75% to 85% of cases. Both result from inoculation of the skin. Ulceroglandular disease is characterized by an ulcerated lesion at the site of inoculation and regional lymphadenopathy. The glandular and ulceroglandular syndromes are similar except that the skin lesion is absent in glandular tularemia.

Oculoglandular tularemia is caused by accidental inoculation of the eye with contaminated fingers. Conjunctival inflammation is extremely painful, and numerous ulcers and a yellow exudate are often apparent. Conjunctival involvement is typically associated with preauricular lymphadenopathy (Parinaud complex).

Oropharyngeal tularemia can follow oral inoculation. This syndrome is characterized by an exudative or membranous pharyngitis and cervical lymphadenopathy. A subcategory of oropharyngeal tularemia that can develop after massive ingestion of *F. tularensis* is gastrointestinal tularemia. It is characterized by fever, intestinal ulceration, mesenteric lymphadenopathy, diarrhea, abdominal pain, nausea, vomiting, and gastrointestinal bleeding.

Pleuropulmonary tularemia can be a primary infection, following inhalation of aerosolized organisms, or a secondary manifestation resulting from hematogenous spread of infection to the lungs. The latter occurs in about 10% to 15% of cases of ulceroglandular tularemia. Mediastinal lymphadenopathy may evolve during the course of pleuropulmonary tularemia.

Typhoidal tularemia is the most difficult presentation to diagnose and is associated with the highest mortality.[17,18,25-27] Neither skin lesions nor lymphadenopathy are present; fever and malaise may be the only clinical manifestations. Secondary pleuropulmonary involvement occurs in approximately 50% of cases of typhoidal tularemia.

Laboratory Tests

Laboratory screening tests are often unremarkable in cases of tularemia. The leukocyte count may be slightly elevated or normal. Serum levels of hepatic aminotransferases tend to be mildly to moderately elevated. With pleuropulmonary involvement, chest films show parenchymal infiltrates (typically patchy, in one or multiple lobes), and pleural effusions are common.[17,18,25,26]

Definitive laboratory diagnosis of tularemia is generally based on detection of antibodies to *F. tularensis.* Serum agglutinins are usually detectable by day 10 to 14 of illness and peak approximately 2 to 6 weeks later. Early, appropriate antimicrobial therapy may blunt the rise in antibody titer. A fourfold increase in titer between acute-phase and convalescent-phase specimens is considered diagnostic, but a single specimen with a titer of 1:160 or greater is highly suggestive. A specific enzyme-linked immunosorbent assay (ELISA) for *F. tularensis* antibodies is now available and may eventually replace the serum agglutinins assay. PCR technology has been employed for molecular diagnosis but is not widely available for clinical use.[28-30]

Airborne transmission of *F. tularensis* is possible, so attempts to isolate and culture the organism should be avoided in most clinical laboratories. Biosafety level 2 is recommended for clinical laboratory work with material where contamination with *F. tularensis* is suspected. Biosafety level 3 is required for culture of the organism in large quantities.[31]

DIFFERENTIAL DIAGNOSIS

The skin lesion of ulceroglandular tularemia may resemble that seen in sporotrichosis, ecthyma from *Staphylococcus aureus* or *Streptococcus pyogenes*, skin infection with atypical mycobacteria (e.g., *Mycobacterium marinum*), syphilis, anthrax, rat-bite fever, or rickettsial disease. The lymphadenopathy of tularemia may be similar to that of plague, lymphogranuloma venereum, cat-scratch disease, or necrotizing lymphadenitis. Oropharyngeal tularemia can mimic the exudative pharyngitis caused by *S. pyogenes, Arcanobacterium haemolyticus, Corynebacterium diphtheriae,* and EBV. Pleuropulmonary tularemia is often similar to any of the atypical pneumonias, including those caused by respiratory viruses, *Mycoplasma pneumoniae, Legionella pneumophila, Chlamydia pneumoniae, C. psittaci, Coxiella burnetii, Histoplasma capsulatum,* and *Coccidioides immitis*.[26] Typhoidal tularemia may be confused with enteric fever (typhoid or paratyphoid fever), rickettsial infections, brucellosis, EBV, primary toxoplasmosis, miliary tuberculosis, sarcoidosis, or lymphoma.

TREATMENT

Because of the lack of rapid diagnostic laboratory tests for tularemia, initial treatment is often empirical and based on clinical suspicion. Although streptomycin (500 mg to 1 g I.M. every 12 hours) is the conventional drug of choice, evidence indicates that gentamicin (3 to 5 mg/kg daily I.V. in divided doses every 8 hours) is equally effective. With either agent, treatment should be given for 10 to 14 days in cases of severe clinical illness.[32] Tetracycline (or chloramphenicol) can be used, but relapse may occur if the duration of therapy is less than 21 days.[33] Ciprofloxacin was recently reported to be effective for treatment, but clinical experience is limited.[34-36]

Only partial immunity develops after infection with *F. tularensis*, and cases of reinfection have been documented. Chemoprophylaxis is not recommended for persons potentially exposed to tularemia. A live attenuated tularemia vaccine has been developed. It may be useful for the partial protection of laboratory workers but is not commercially available.[37,38]

COMPLICATIONS

Tularemia can be complicated by bacteremia, meningitis (usually marked by a lymphocytic pleocytosis in the CSF), rhabdomyolysis, acute renal failure, endocarditis, osteomyelitis, pericarditis, and septic shock.

PROGNOSIS

Typhoidal and ulceroglandular tularemia have the worst prognosis, with approximately 5% mortality reported in untreated cases. Prognosis is excellent for patients treated with appropriate antibiotics, with significant clinical improvement generally occurring within 48 hours of starting therapy.[17,18,25]

Plague

Yersinia infections primarily affect rodents, pigs, and birds; humans are accidental hosts. Nevertheless, *Yersinia pestis* (formerly *Pasteurella pestis*) has made its mark in human history as the causative agent of plague—also known as bubonic plague, black plague, and the Black Death. Plague was initially described in biblical times; in the Middle Ages, epidemic bubonic plague killed an estimated one fourth of Europe's population.[39] This disease of antiquity has persisted to the present. Although human plague is now relatively infrequent worldwide, aerosolized *Y. pestis* is well recognized for its potential use as a biological weapon.[40]

EPIDEMIOLOGY

Plague currently exists in widely scattered foci in Asia, Africa, and the Americas. In the 1990s, countries with the greatest number of cases included Tanzania, Madagascar, Democratic Republic of Congo, Vietnam, Peru, India, Myanmar, Zimbabwe, Mozambique, Uganda, and China [*see Figure 2*]. In the United States, about 10 cases of plague are reported annually, primarily from the Four Corners area, where Utah, Colorado, New Mexico, and Arizona meet. In that region, plague is endemic in prairie dog colonies.[41,42]

ETIOLOGY

Plague is a zoonotic infection that affects predominately urban and sylvatic rodents (e.g., rats and ground squirrels, respectively). It is transmitted to its natural animal reservoirs by flea bites or ingestion of contaminated animal tissues. Humans represent accidental hosts who usually acquire infection via bites from infected fleas.[39] Bites or scratches from an infected animal can also transmit plague to humans. In endemic areas, risk factors for acquiring plague include direct contact with

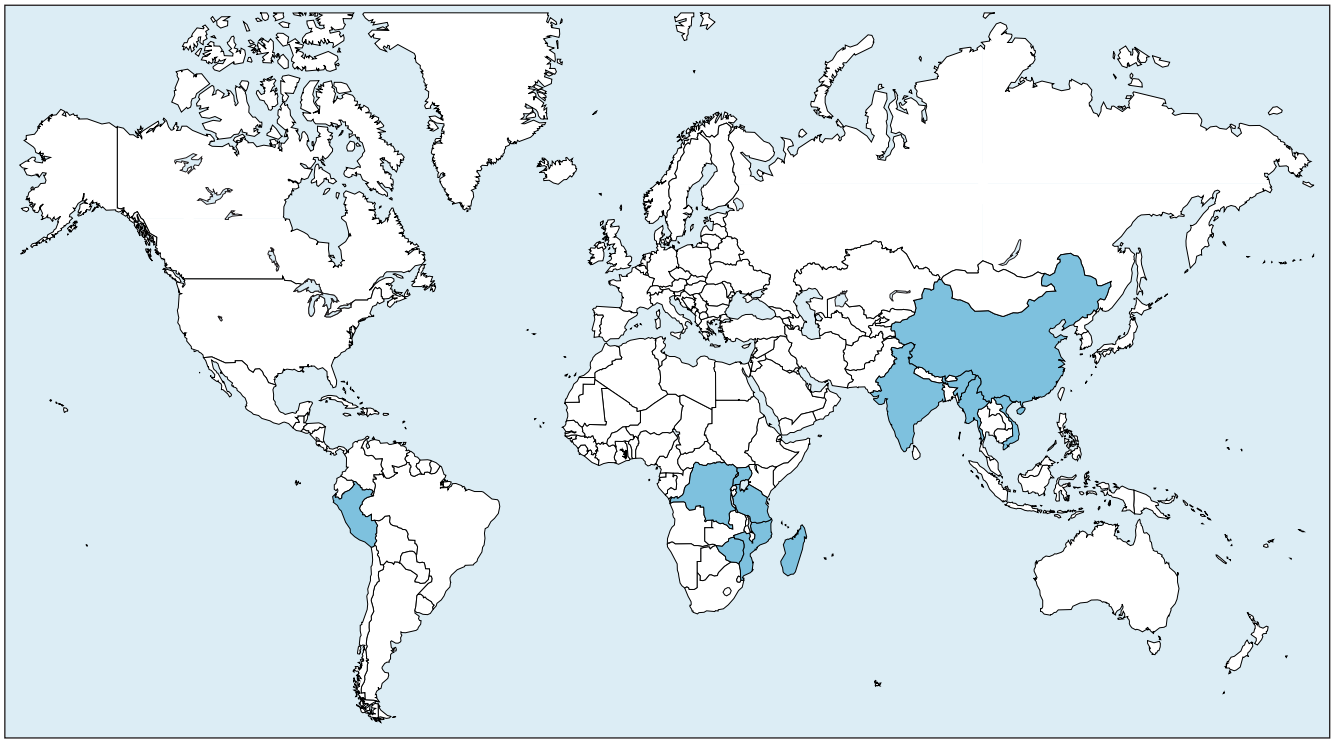

Figure 2 **Shaded countries reported more than 100 cases of plague from 1990–1995.**

rodents or carnivores that prey on them (e.g., cats, dogs), the presence of wild rodents near the place of residence, and pet dogs or cats with fleas.[43]

Plague may also result from inhalation of aerosolized bacilli. Airborne transmission can occur via the cough of an infected patient with pulmonary involvement or from close contact with an infected animal or cadaver.

PATHOGENESIS

Y. pestis is a pleomorphic, non–spore-forming, gram-negative, bipolar-staining coccobacillary member of the family Enterobacteriaceae. It is a nonmotile, facultative anaerobe that is able to grow aerobically on routine microbiologic media. The organism can survive at room temperature in dried blood or the environment for weeks to months.

Y. pestis is one of the most virulent bacteria known. It is usually inoculated through the skin or mucous membranes, where it invades cutaneous lymphatics. Monocytes and macrophages, which can phagocytize *Y. pestis* without killing it, may play a role in spread of infection from the inoculation site. Plague can involve almost any tissue or organ and cause massive destruction if left untreated. Initially, infected lymph nodes are tender and edematous. Later, hemorrhagic necrosis develops in affected nodes, and bacteria enter the bloodstream, where they disseminate to other sites (e.g., liver, spleen, lungs, and central nervous system). Infarcts and hemorrhagic, necrotic nodules are characteristic histopathologic findings at affected tissue sites.[39]

DIAGNOSIS

Clinical Manifestations

The usual incubation periods for bubonic plague and pneumonic plague are 2 to 7 days and 2 to 3 days, respectively (range, 1 to 14 days). Plague generally presents as an acute illness characterized by the abrupt onset of fever, chills, headache, gastrointestinal symptoms, and local pain, followed within hours by the development of a painful, swollen mass of lymph nodes (buboes) in the groin or axilla. Skin overlying buboes is usually red-purple in color. Buboes are initially tense and hard but rapidly become fluctuant. Spontaneous rupture and drainage can occur. Buboes do not develop in patients with septicemic plague; instead, these patients have gastrointestinal signs and symptoms: nausea, vomiting, diarrhea, and abdominal pain. Severe pharyngitis, severe diarrhea, and cough with or without hemoptysis may also be early clinical manifestations of plague[39,44] [*see Table 1*].

Laboratory Tests

The leukocyte count is typically elevated in the range of 15,000 to 25,000 cells/μl, with a shift to the left; leukemoid reactions (> 50,000 cells/μl) can occur. The platelet count may be normal or mildly depressed or may be very low if disseminated intravascular coagulation (DIC) is present. The level of fibrin split products is frequently elevated, even in patients without frank DIC. Serum levels of hepatic aminotransferases and bilirubin are often increased.

Definitive diagnosis of plague is usually based on isolation of *Y. pestis* from cultures of blood, other body fluids, or tissues. Aspiration of buboes may readily yield material for diagnosis. The organism can be easily grown on blood and MacConkey agar, as well as in infusion broth. A direct immunofluorescence test has been developed for rapid identification of *Y. pestis* in clinical specimens, and a passive hemagglutination test is available for presumptive diagnosis based on serology. Both of those tests are available from the CDC Division of Vector-Borne Infectious Diseases, Fort Collins, Colorado (970-221-6400).

DIFFERENTIAL DIAGNOSIS

Clinical suspicion based on knowledge of plague epidemiology is essential for timely diagnosis and institution of appropriate antimicrobial therapy. Plague should be suspected in febrile individuals who have been exposed to rodents or other mammals in regions of the world where plague is endemic. Illness may resemble that caused by a number of other serious infectious diseases, especially tularemia. Other causes of acute, painful lymphadenitis include staphylococcal, streptococcal, and *Pasteurella* infection. Plague pneumonia can be confused with other causes of atypical pneumonia or the hantavirus pulmonary syndrome. The combination of plague-associated abdominal symptoms and DIC can resemble an acute surgical abdomen or *Capnocytophaga canimorsus* sepsis.[44]

TREATMENT

Streptomycin (30 mg/kg I.M. in divided doses every 12 hours) remains the drug of choice for the treatment of plague. Timely administration of streptomycin reduces mortality to approximately 5%. Gentamicin, which is more widely available than streptomycin, also appears to be effective. To prevent relapses, antibiotic treatment should be continued for 10 days or for at least 3 days after defervescence and clinical recovery. Most patients improve rapidly and defervesce within 72 hours of initiation of antimicrobial therapy, although buboes can persist for weeks. Some authorities advocate switching from streptomycin to a different antibiotic for completion of therapy after 5 days of treatment in order to minimize the risk of ototoxicity and nephrotoxicity.

Tetracycline or doxycycline can also be used for plague. Chloramphenicol is the preferred agent for the treatment of plague meningitis, pleuritis, endophthalmitis, and myocarditis because of superior penetration into those tissues. Penicillins, cephalosporins, and macrolides are suboptimal agents for treatment of plague. Trimethoprim-sulfamethoxazole and fluoroquinolones appear to be active against plague in vitro and in animal models, but clinical experience with these agents for the treatment of plague is limited[39,44,45] [*see Table 2*].

All cases of suspected or documented plague should be reported to the state and city or county health departments, the CDC, and the World Health Organization. Plague patients with cough or other signs or symptoms of pneumonia should be placed in strict respiratory isolation for at least 48 hours after initiation of appropriate antibiotic therapy.

Contacts of patients with pneumonic plague or suspected septicemic plague with pulmonary involvement should receive chemoprophylaxis with either tetracycline (500 mg p.o., q.i.d.) or doxycycline (100 mg p.o., b.i.d.). Streptomycin (20 mg/kg/day I.M. in two divided doses) or trimethoprim-sulfamethoxazole (40 mg/kg p.o., b.i.d.) can be used for children younger than 8 years.

Plague vaccine (Cutter Laboratories) is a killed, formalin/phenol-fixed whole-bacteria vaccine that provides only partial protection against infection. Vaccinated individuals who are exposed to plague should still receive chemoprophylaxis.[46]

COMPLICATIONS

Septic shock, DIC, acute respiratory distress syndrome (ARDS), and meningitis are recognized complications of plague, especially in cases in which antimicrobial therapy is inadequate or delayed. Plague meningitis, a rare complication that typically occurs more than 1 week after inadequate antimicrobial therapy, is characterized by fever, headache, menigismus, and neutrophilic pleocytosis of the cerebrospinal fluid.

PROGNOSIS

Reported mortality of untreated plague ranges from 40% to 90%. Mortality is greatest in pneumonic plague. The overall mortality for cases of plague in the United States during the past 20 years has been approximately 15%.[42]

Bartonella Infections

Bartonella (formerly *Rochalimaea*) organisms are small, gram-negative bacilli that are extremely fastidious. They require specialized culture methods for isolation and specific staining techniques for detection in clinical specimens.[47-49] Infections by these organisms can occur in both immunocompromised and immunocompetent individuals.[47,49] Four *Bartonella* species have been documented to be pathogenic in humans: *B. bacilliformis, B. quintana, B. henselae,* and *B. elizabethae*.[47,49] The spectrum of diseases caused by *Bartonella* can be divided into five categories: (1) Oroya fever (classic bartonellosis), (2) trench fever, (3) bacteremia and endocarditis, (4) cat-scratch disease, and (5) bacillary angiomatosis.

OROYA FEVER (CLASSIC BARTONELLOSIS)

Oroya fever (chronic bartonellosis; Carrión disease) is caused by infection with *B. bacilliformis* transmitted to humans by the bite of infected phlebotomine sandflies. The disease is geographically restricted to valleys of the Andes Mountains at elevations between 800 m (2,624 ft) and 2,500 m (8,200 ft) above sea level, which are found in Peru, Ecuador, and Colombia.

Diagnosis

Oroya fever, caused by primary bacteremia, develops 3 to 12 weeks after inoculation. The onset of illness can be either insidious or abrupt. Clinical manifestations include fever, chills, headache, myalgias and arthralgias, abdominal pain, generalized lymphadenopathy, progressive hemolytic anemia, and thrombocytopenia.[47,49,50]

Definitive diagnosis of acute bartonellosis is based on the isolation of *B. bacilliformis* from blood cultures. The organism can be grown on Colombia agar with 5% defibrinated human blood or semisolid nutrient agar with 10% rabbit hemoglobin aerobically at 28º C. Colonies usually appear in 7 to 10 days. The presence of intraerythrocytic bacilli in a Giemsa-stained thin blood smear provides rapid confirmation of acute bartonellosis. Serologic tests have been developed in research laboratories but are not widely available.[47,49]

Treatment

Standard treatment consists of chloramphenicol (2 g/day p.o. or I.V.) for at least 1 week. Alternative agents include tetracycline (or doxycycline) or ampicillin.[51] Without treatment, mortality is high. Survivors are temporarily at risk for secondary salmonellosis or toxoplasmosis. Asymptomatic bacteremia is estimated to persist in approximately 15% of survivors.

In untreated cases, resolution of primary infection may be followed weeks to months later by the onset of verruca peruana. This manifestation of chronic bartonellosis consists of recurrent crops of nodular skin lesions, which may ulcerate and bleed. Mucosal and visceral lesions may also occur. Histopathologic examination of active lesions demonstrates neovascular proliferation and occasional bacilli in the interstitium.[47,49]

TRENCH FEVER

Trench fever is caused by infection with *B. quintana,* which is transmitted to humans via feces of infected human body lice (*Pediculus humanus*).[52] Epidemics of the disease occurred in troops engaged in trench warfare in World War I and in World War II troops deployed in crowded and unsanitary conditions.

Diagnosis

The incubation period of classic trench fever was 3 to 38 days, and illness was typically characterized by the abrupt onset of fever, associated with headache, dizziness, conjunctival injection, myalgias, arthralgias, hepatosplenomegaly, a transient maculopapular rash, leukocytosis, and albuminuria. The duration of acute illness was generally 3 to 5 days, and relapses were not uncommon. Less commonly, unremitting fever would persist for 2 to 6 weeks.[47,49]

Treatment

Much of the clinical experience with trench fever predates the antibiotic era. It is not known whether one regimen is superior to another.

BACTEREMIA AND ENDOCARDITIS

Recently, a syndrome termed urban trench fever was recognized in urban homeless persons (usually with a history of alcoholism and malnutrition) and in HIV-infected individuals.[47,49,53,54] In the urban homeless population, the syndrome is caused by *B. quintana* bacteremia and is often associated with apparently culture-negative endocarditis.[47,49,53-56] In the HIV-infected population, the bacteremia can be caused by either *B. quintana* or *B. henselae,* and concomitant bacillary angiomatosis (see below) is often present.[47,49,57,58] As with classic trench fever, the human body louse is the vector for transmission of *B. quintana* (the animal reservoir remains unknown); cats transmit *B. henselae.* Clinical manifestations of urban trench fever include fever, malaise, anemia, thrombocytopenia, splenomegaly, and cardiac murmurs.[47,49,53-56]

Diagnosis

Diagnosis is based on the isolation of *B. henselae* or *B. quintana* from blood, which is best accomplished using lysis-centrifugation blood culture. Growth of those organisms is slow, and incubation for more than 30 days may be required. Acridine orange staining can be used to enhance detection of *Bartonella* organisms in culture. An antibody titer of 1:1,600 or higher against either *B. henselae* or *B. quintana* also strongly suggests bartonellosis as the cause of endocarditis in a patient with valvular vegetations.[47,49]

Treatment

For bacteremia without endocarditis, a 14-day regimen of either a macrolide or a tetracycline (e.g., doxycyline, 100 mg p.o., b.i.d.) is recommended. No definitive treatment regimen has been established for endocarditis. Surgical valve replacement

plus aminoglycoside therapy has been used. An alternative approach has been to give prolonged (4 to 6 months or more) combination therapy with a fluoroquinolone plus either rifampin or a macrolide. Patients treated with that regimen should be followed carefully for clinical deterioration that would necessitate valve replacement[47,49,54-56] [*see Table 2*].

CAT-SCRATCH DISEASE

Although *Afipia felis* was first identified as the causative agent of cat-scratch disease , it is now clear that *B. henselae* causes the overwhelming majority of cases.[47,49,59] The domestic cat serves as the major reservoir of *B. henselae*, which is transmitted to humans by a scratch or bite—usually from a kitten or feral cat—or possibly via infected cat fleas.[47,49] The incubation period is generally 3 to 10 days.

Typically, a primary cutaneous papule or pustule develops at the site of inoculation. Regional lymphadenopathy follows in approximately 90% of cases and persists for 10 to 120 days. Lymphadenopathy is most common at axillary, cervical, and submandibular sites. Less commonly, epitrochlear, inguinal, femoral, or supraclavicular nodes may be involved. Approximately 10% of involved nodes suppurate spontaneously. Low-grade fever occurs in approximately 50% of patients and lasts for several days. Less frequent symptoms and signs include malaise, fatigue, headache, and rash.[47,49]

Relatively common presentations of atypical cat-scratch disease are Parinaud oculoglandular syndrome—a self-limited syndrome of granulomatous conjunctivitis and preauricular lymphadenitis—and encephalitis, which occurs primarily in children.[47,49,60,61] About one half of patients with cat-scratch disease encephalitis experience seizures. Although full recovery from cat-scratch disease encephalitis may require weeks to months, the overall prognosis is good, with few patients experiencing permanent neurologic sequelae.[47,49,61] Other atypical manifestations of cat-scratch disease include self-limited granulomatous hepatitis or splenitis, atypical pneumonitis, osteitis, and neuroretinitis.[47,49,62-66]

Most cases of cat-scratch disease are diagnosed presumptively, on the basis of the clinical presentation and a history of exposure to cats. The differential diagnosis of typical cat-scratch disease includes tularemia, mycobacterial infection, plague, brucellosis, mononucleosis, syphilis, lymphogranuloma venereum, sporotrichosis, histoplasmosis, toxoplasmosis, and lymphoma.

Serologic confirmation of cat-scratch disease is usually not required. When clinically warranted, either immunofluorescence antibody testing or ELISA, available through commercial clinical diagnostic laboratories, can be used to detect antibodies against *B. henselae.* Those serologic studies have essentially supplanted the cat-scratch disease skin test in clinical practice. In biopsy specimens obtained from lymph nodes, skin, or conjunctiva, cat-scratch disease can be confirmed by the detection of small, pleomorphic bacilli in sections prepared with a Warthin-Starry or Brown-Hopps stain.[47-49] PCR technology has been used to detect *B. henselae* in clinical specimens but is currently not widely available for routine clinical diagnosis.[47-49,67]

In immunocompetent patients, both typical and atypical CSD generally resolve spontaneously without antimicrobial therapy. Most *B. henselae* isolates are susceptible in vitro to a wide variety of antimicrobials, including β-lactams, tetracyclines, macrolides, aminoglycosides, fluoroquinolones, vancomycin, and rifampin. However, clinical response does not correlate well with susceptibility testing for *B. henselae*.[47,49,68] Although a variety of agents have been reported to be effective in anecdotal reports and case series (including rifampin, gentamicin, trimethoprim-sulfamethoxazole, doxycycline, ciprofloxacin, and ofloxacin), only azithromycin (500 mg p.o. for 1 day, then 250 mg p.o. daily for 4 days) has been shown to accelerate resolution of typical cat-scratch disease lymphadenopathy in a placebo-controlled, double-blind clinical trial.[69]

BACILLARY ANGIOMATOSIS

Bacillary angiomatosis (epithelioid angiomatosis, bacillary epithelioid angiomatosis) is a form of neovascular proliferation associated with infection by either *B. henselae* or *B. quintana.* It was first described as a disease of the skin and regional lymph nodes of HIV-infected persons. Subsequently, bacillary angiomatosis was documented in a large variety of tissues, including liver, spleen, bone, brain, respiratory tract, gastrointestinal tract, and uterine cervix. It has also been found, albeit rarely, in other immunocompromised hosts and in apparently immunocompetent patients. In HIV-infected persons, it is a relatively late opportunistic infection, usually occurring after the $CD4^+$ lymphocyte count has declined to less than 100 cells/μl.[47,49,57,58]

Cutaneous disease is the most frequently recognized manifestation of bacillary angiomatosis. Lesions generally appear in crops and can have verrucous, papular, or pedunculated features. They often have an erythematous base and vascular appearance but may occasionally be dry, scaly, hyperkeratotic, or plaquelike. Painful subcutaneous nodules and osseous lesions can develop. Regional lymphadenopathy is common, but involved nodes rarely suppurate or drain.[47,49]

Peliosis hepatis, consisting of venous lakes in the hepatic parenchyma, is a relatively common manifestation of bacillary angiomatosis. Splenitis can also occur. Hepatosplenomegaly is often present, and an increased serum alkaline phosphatase level is a common laboratory finding. Peliotic spaces in the liver and spleen appear as hypodense lesions on abdominal computed tomography. Thrombocytopenia and pancytopenia may develop, as well as concomitant bacteremia or endocarditis, in patients with bacillary peliosis.[47,49,57,58]

The lesions of bacillary angiomatosis may be indistinguishable clinically from Kaposi sarcoma, and biopsy is usually necessary to distinguish between the two disorders and guide management. Both hematoxylin-eosin staining, which differentiates bacillary angiomatosis from Kaposi sarcoma, and Warthin-Starry staining, which detects *Bartonella* bacilli, should be performed on biopsy specimens. Lesions of bacillary angiomatosis are characterized by lobular proliferation of endothelial-lined capillaries; the endothelial cells are protuberant, unlike the spindle-shaped endothelial cells in Kaposi sarcoma. Recovery of *Bartonella* organisms by culture from lesions of bacillary angiomatosis is difficult.[47-49]

The recommended first-line therapy for bacillary angiomatosis in HIV-infected patients is either erythromycin (500 mg p.o., q.i.d.) or doxycycline (100 mg p.o., b.i.d.). Alternative agents include clarithromycin (500 mg p.o., b.i.d.), azithromycin (250 mg p.o. daily), and ciprofloxacin (500 to 750 mg p.o., b.i.d.). For severe cases, consideration should be given to combination therapy with doxycycline (100 mg p.o. or I.V., b.i.d.) plus rifampin (300 mg p.o., b.i.d.). Bacillary angiomatosis usually responds rapidly to either erythromycin or doxycycline therapy. A Jarisch-Herxheimer reaction may occur with the initiation of antimicrobial therapy. Patients who have only cutaneous lesions

should receive at least 2 months of treatment; in those with osteomyelitis or peliosis hepatis, therapy should be continued for a minimum of 4 months. Relapses can occur after discontinuance of therapy. HIV-infected patients who experience relapses should be treated lifelong with either a tetracycline or a macrolide.[47,49]

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XII MYCOPLASMA INFECTIONS

R. Doug Hardy, m.d.

Mycoplasmas are the smallest known free-living organisms. Their size—150 to 350 nm—is closer to that of viruses than of bacteria. Unlike viruses, however, mycoplasmas are able to grow in cell-free media and possess both RNA and DNA. Notably, they lack a cell wall and are bound by a cell membrane. The absence of a rigid cell wall explains many of the biologic properties of mycoplasmas, including resistance to β-lactam antibiotics and marked pleomorphism among individual cells.

Mycoplasmas are prokaryotes of the class Mollicutes. The entire genomes of many *Mycoplasma* species have been sequenced and have been found to be among the smallest of prokaryotic genomes. The characterization of *M. genitalium,* which has only 580,070 base pairs and 468 predicted proteins, has helped define the minimal set of genes necessary for cellular life.[1,2] The absence of genes related to the synthesis of amino acids, fatty acid metabolism, and cholesterol necessitates a parasitic or saprophytic dependence on the host for exogenous nutrients, such as nucleic acid precursors, amino acids, fatty acids, and sterols.

At least 13 *Mycoplasma* species, two *Acholeplasma* species, and one *Ureaplasma* species have been isolated from humans with varying frequency; most of these species are thought to be normal inhabitants of oral and urogenital mucous membranes.[3] Only three species, *M. pneumoniae, M. hominis,* and *U. urealyticum,* have been shown conclusively to be pathogenic in humans. *M. pneumoniae* is the species that has been most clearly demonstrated to cause disease in humans. The respiratory tract is its primary site of involvement. *M. hominis* and *U. urealyticum* are associated with a variety of genitourinary tract disorders and neonatal infections. Evidence also implicates a fourth species, *M. genitalium,* as a cause of disease in humans. Rarely, other *Mycoplasma* species may cause disease in immunocompromised persons.

Mycoplasma pneumoniae

EPIDEMIOLOGY

M. pneumoniae is a major cause of community-acquired respiratory illness in children and adults, both in terms of clinical severity and numbers affected. *M. pneumoniae* is often grouped with *Chlamydophila pneumoniae* and *Legionella* species as being among the most important bacterial causes of so-called atypical community-acquired pneumonia. However, it is now known that atypical pneumonia caused by these pathogens cannot be reliably differentiated from pneumonia caused by typical community-acquired pathogens, such as *Streptococcus pneumoniae,* on the basis of clinical manifestations, general laboratory tests, or radiographic findings.[4,5] Hence, many experts believe that the term atypical is inappropriate and misleading. It is important to note, however, that the etiologic diagnosis of infection by these pathogens requires advanced methods of detection—methods that go beyond Gram stain or routine culture. *Mycoplasma* pneumonia has also been referred to as Eaton agent pneumonia, primary atypical pneumonia, and walking pneumonia.

M. pneumoniae was first isolated in the early 1940s by Eaton from a patient with primary atypical pneumonia; it was proved to be a cause of clinical disease in humans in the 1960s.[5,6] *M. pneumoniae* is the only *Mycoplasma* species that has clearly been established to be a cause of human respiratory tract disease, although *M. genitalium* has been isolated from the respiratory tract of patients with mixed infections involving *M. pneumoniae,* an organism with which *M. genitalium* can be confused.[7] *M. pneumoniae* is known to cause many acute respiratory syndromes in humans, including pharyngitis, tracheobronchitis, reactive airway disease (wheezing), and community-acquired pneumonia. It is likely that the incidence of upper respiratory tract illness is 10 to 20 times that of pneumonia. Infection is spread from one person to another by respiratory droplets expectorated during coughing; infection results in clinically apparent disease in the majority of cases.[5] The incubation period for *M. pneumoniae* is 2 to 4 weeks; hence, the course of infection in a specific population (e.g., within a family or an institution) may last several weeks [*see Figure 1*].[8] Intrafamily attack rates may be as high as 84% in children and 41% in adults. Outbreaks of *M. pneumoniae*–related illness often occur in institutional settings such as military bases, boarding

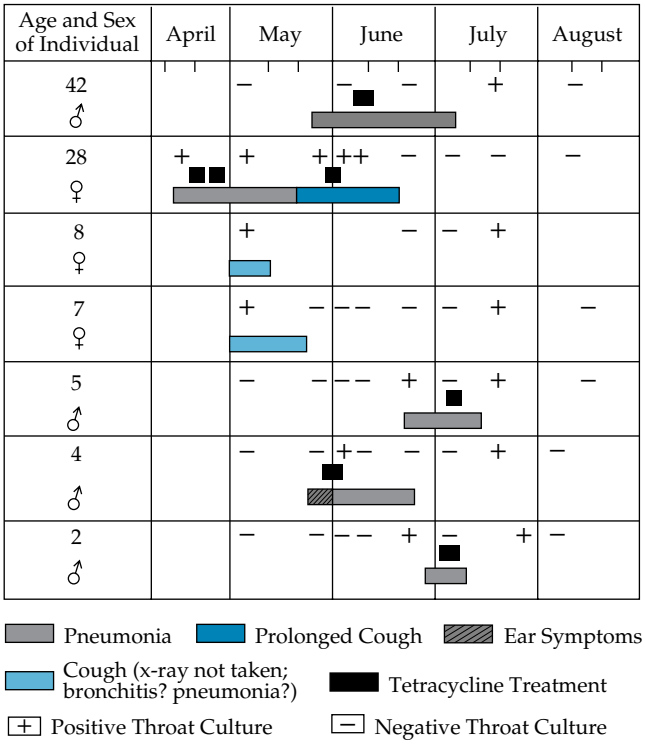

Figure 1 **During a 5-month period, a *Mycoplasma pneumoniae* infection spread through seven members of a family. Positive throat cultures were obtained in all seven individuals, but clinically documented pneumonia was observed in only five. Pneumonia was treated with tetracycline. In the other two infected individuals, coughs developed during the period in which their throat cultures were positive, suggesting the possibility of *Mycoplasma*-induced bronchitis or pneumonia; however, radiologic confirmation of the diagnosis was not obtained. A prolonged cough followed the episode of pneumonia in one patient, and ear symptoms were observed in another. Positive throat cultures were obtained in six of seven patients after cessation of therapy and disappearance of symptoms.**

schools, and summer camps. Infections tend to be endemic, with sporadic epidemics every 4 to 7 years, without seasonal preponderance.[5]

The importance of *M. pneumoniae* as a cause of community-acquired pneumonia has become more evident with the development of advanced techniques for identifying this pathogen. For community-acquired pneumonia in adults, *M. pneumoniae* is the most frequently detected atypical organism. Analysis of 13 studies of community-acquired pneumonia published since 1995 (which included 6,207 ambulatory and hospitalized adults) showed that the overall prevalence of *M. pneumoniae* was 22.7%; by comparison, the prevalence of *C. pneumoniae* was 11.7%, and that of *Legionella* species was 4.6%.[9] It must be acknowledged that these studies represent varying populations and used varying methods to establish the etiologies of community-acquired pneumonia.[9]

In community-acquired pneumonia, *M. pneumoniae* often occurs as part of a mixed infection. In a 1-year prospective study of 346 consecutive adults admitted with community-acquired pneumonia, 64% of those with *M. pneumoniae* infections were coinfected with other agents—most often with *S. pneumoniae*, followed by *C. pneumoniae* and *Legionella* species.[10] In a study of *C. pneumoniae* community-acquired pneumonia in adults, 35.5% had a mixed infection; *M. pneumoniae* was the second most common copathogen, after *S. pneumoniae*.[11] Review of epidemiologic studies revealed the presence of at least one other pathogen in 33% to 64% of *M. pneumoniae* pneumonia.[9,11] *S. pneumoniae* with *M. pneumoniae* or *C. pneumoniae* appears to be the most common combinations of agents in mixed pneumonia, and these combinations have been given the most attention in clinical investigations.[9,12,13] Further study is required to define the clinical significance of *M. pneumoniae* coinfections, to determine whether infection with *M. pneumoniae* predisposes patients to invasion by other respiratory pathogens, and to establish whether the etiologic agents of mixed infections have an additive or synergistic clinical impact.

PATHOGENESIS, PATHOLOGY, AND IMMUNOLOGY

Classically, mycoplasmas act as extracellular parasites. The pathogenicity of *M. pneumoniae* depends on its extracellular attachment and the initiation of injury to the membrane of the host cell.[14] *M. pneumoniae* penetrates mucociliary secretions by means of gliding motility and adheres firmly to the surface of respiratory epithelial cells.[15] *M. pneumoniae* attaches to ciliated respiratory epithelial cells at the base of the cilia by means of a complex terminal organelle at one end of the elongated organism. This cytodherence is mediated by interactive adhesins and accessory proteins clustered at the tip organelle; it is not limited to epithelial cells or to human-derived tissues.[16,17] Multiple unlinked, incomplete copies of the genes that encode these adhesins constitute approximately 5% of the *Mycoplasma* genome; it has been proposed that recombination between gene copies generates antigenically variant proteins that avoid host immune recognition.[17] One or more sialated glycoproteins act as one type of receptor on the surface of the epithelium.[18,19]

M. pneumoniae causes physiologic and cytolytic injury to the host cells (e.g., ciliated respiratory epithelium), in part by the production of hydrogen peroxide.[20,21] Inhibition of host catalase by *M. pneumoniae*–derived hydrogen peroxide and superoxide anion, followed by oxidation of host membrane lipids and proteins, may then result in cumulative local cytotoxic effects.[22,23] Other mechanisms of physiologic and cytolytic injury are also under investigation. Lung biopsies from patients with *M. pneumoniae* community-acquired pneumonia reveal an inflammatory process involving the trachea, bronchioles, and peribronchial tissue with a monocytic infiltrate coinciding with a luminal exudate of polymorphonuclear leukocytes.[24,25]

Although *M. pneumoniae* is classically thought of as an extracellular organism, it (as well as some other mycoplasmas, including *M. penetrans, M. fermentans* var. *incognitos*, and *M. gallisepticum*) can live and replicate intracellularly in human cells.[26-29] Residence of *M. pneumoniae* in an intracellular reservoir, perhaps protected from the host's immunologic response and from antibiotics, might explain the organism's apparent ability to establish chronic infection, such as occurs in asthmatic patients.[30,31]

Mycoplasmas have been shown to activate natural killer cells, macrophages, and complement; to stimulate the proliferation of B cells and T cells; and to induce expression of major histocompatibility complex class I and II molecules.[32] Because mycoplasmas lack a cell wall, they also lack cell wall–derived stimulators of the innate immune system, such as lipopolysaccharide, lipoteichoic acid, and murein (peptidoglycan) fragments. However, lipoproteins from various *Mycoplasma* species appear to have potent inflammatory properties. Three lipoproteins/lipopeptides of *M. fermentans* origin—macrophage-activating lipopeptide–2 (MALP-2), P48, and M161Ag (identical to MALP-404)—have been shown to have the ability to modulate the host immune system through a Toll-like receptor 2 (TLR2) and TLR6 pathway and through β_2 integrin.[33-35] MALP-2 is a 2-kd lipopeptide from the cell membrane of *M. fermentans* that has been shown to induce cytokines and chemokines in human monocytes.[36] In *M. pneumoniae,* the genes for more than 30 different lipoproteins have been detected.[1] Activation of TLR2 on macrophages by *M. pneumoniae*–derived lipoproteins with resultant production of tumor necrosis factor–α and nitric oxide has been reported.[37]

Studies in mice with severe combined immunodeficiency support the hypotheses that innate immunity provides most of the defense against *Mycoplasma* infection in the lungs, that humoral immunity provides protection against dissemination of *Mycoplasma* infection, and that cellular immunity may play a role in exacerbating mycoplasmal lung disease.[38] Also supportive are the findings that patients with T cell deficiencies do not have more severe pneumonia from *M. pneumoniae* and that patients with humoral immunodeficiencies do not have more severe lung disease from *M. pneumoniae* than immunocompetent patients in the early stages of infection but do have more disseminated disease (e.g., arthritis, meningitis, and osteomyelitis).[39-41]

M. pneumoniae infection in humans provokes a specific immune response that results in the production of secretory IgA and circulating IgG antibodies. Naturally acquired humoral immunity is associated with partial protection against reinfection; in particular, the immunity that follows more severe *M. pneumoniae* infections (e.g., pneumonia) is more protective and longer lasting than that which follows mild infection.[42] Bona fide second attacks of *M. pneumoniae* pneumonia have been reported occasionally, however, both in immunocompetent and in immunodeficient patients. The ability of *M. pneumoniae* and other mycoplasmas to trigger autoimmune responses is an area of active research.[43]

The role of cytokines and chemokines in *M. pneumoniae* infection has been investigated in vitro, in animal models, and in humans.[44-47] Evidence indicates that various cytokines (including inflammatory, anti-inflammatory, T helper type 1, and T helper type 2 cytokines) as well as chemokines have pivotal roles in modulating *M. pneumoniae* disease. However, a concerted theory

on the pathogenic and relative importance of these various modulators is lacking.

DIAGNOSIS

Acute Clinical Manifestations

M. pneumoniae infections have an incubation period of 2 to 4 weeks in naturally occurring cases, but the incubation period is shorter in experimental infection.[5] Approximately 20% of *M. pneumoniae* infections are asymptomatic.[48] Clinically apparent acute *M. pneumoniae* infections generally manifest as pharyngitis, tracheobronchitis, reactive airway disease (wheezing), or a nonspecific upper respiratory tract syndrome. Pneumonia, however, is the best-described clinical manifestation of *M. pneumoniae* infection and occurs in 3% to 13% of infected persons.[48]

The onset of pneumonia is usually gradual (occurring over several days) but may be more abrupt.[49] Although *Mycoplasma* pneumonia may begin with a sore throat, the most common presenting symptom is cough. The cough is typically nonproductive, but some patients produce purulent sputum; in rare instances, the sputum is blood streaked.[48] Headache, malaise, chills, and a temperature of 37.8° to 40.0° C (100° to 104° F) are present in the majority of patients. In a smaller percentage, nasal symptoms occur. Symptoms and signs of pneumonia are not useful for differentiating *M. pneumoniae* pneumonia from other types of community-acquired pneumonia.[4,48,50,51]

Symptoms related to the ears or tympanic membrane findings on physical examination may be noted in approximately 6% of patients with *M. pneumoniae* pneumonia; 1% may have bullous myringitis. Because direct cultures rarely if ever grow *M. pneumoniae,* there is little evidence to support the old belief that this organism is an important cause of otitis media, with or without bullous myringitis.[52]

Wheezes or rales are present in approximately 80% of patients with *Mycoplasma* pneumonia; bronchial breath sounds are noted less frequently. In many patients, however, pneumonia can be diagnosed only on chest x-ray. Pleural rubs are rare, as are pleural effusions of sufficient magnitude to be detected on physical examination.[48]

Symptoms usually resolve within 2 to 3 weeks after the onset of illness. In about 20% of patients, symptoms and radiologic abnormalities persist for at least a month. Although *M. pneumoniae* pneumonia is generally self-limited, appropriate antimicrobial therapy can significantly shorten the duration of clinical illness.[53] In some patients, long-term recurrent wheezing may follow the resolution of acute pneumonia.[54,55] Relapse and recurrence of pneumonia are infrequently reported.

Pulmonary complications of *M. pneumoniae* pneumonia may occur and, on rare occasions, result in death. Fulminant disease may be more common in young, previously healthy adults. Multilobar involvement, lung abscess, massive pleural effusion, acute respiratory distress syndrome, and diffuse interstitial fibrosis have been described. At particular risk for these complications are patients with Down syndrome, sickle cell disease, and other immunodeficient states.[56-59] *M. pneumoniae* does not seem to play an important role in lower respiratory tract infections in either children or adults with HIV infection.[60]

Chronic Infection and Wheezing

In many patients, *M. pneumoniae* can be cultured from the respiratory tract for up to several months after clinical and radiologic resolution of acute pneumonia.[7] There have been no controlled studies of such chronic infections using methods more sensitive than culture, such as polymerase chain reaction (PCR). *M. pneumoniae* apparently can be a long-term respiratory tract pathogen associated with recurrent wheezing, and it may contribute to the severity of chronic asthma.[54,55]

Extrapulmonary Manifestations

A variety of extrapulmonary manifestations may develop during the course of acute *M. pneumoniae* respiratory tract infection. The most important of these are neurologic, dermatologic, cardiac, rheumatologic, and hematologic in nature.[3,56,61] Overall, these manifestations are uncommon, given the frequency of *Mycoplasma* infection. The mechanisms of these complications appear to include disseminated infection (especially in patients with humoral immunodeficiencies); autoimmune phenomena; and, possibly, toxin production.[62] Notably, respiratory disease is absent in many patients with extrapulmonary *M. pneumoniae* disease.[63]

Neurologic disease is reportedly the most common nonpulmonary manifestation of *M. pneumoniae* infection.[63-67] A wide spectrum of neurologic manifestations has been reported. The most common ones are meningoencephalitis, encephalitis, polyradiculopathy (including Guillain-Barré syndrome), and aseptic meningitis; less common neurologic manifestations include cranial neuropathy, acute psychosis, cerebellar ataxia, acute demyelinating encephalomyelitis, cerebrovascular thromboembolic events, and transverse myelitis. In a prospective 5-year study of acute encephalitis in children, *M. pneumoniae* was determined to be the likely cause in 11 of 159 patients (6.9%). Findings on clinical examination, cerebrospinal fluid analysis, electroencephalography, and neuroimaging in patients with *M. pneumoniae* encephalitis are indistinguishable from those in patients with viral encephalitis. Long-term sequelae, such as seizure disorders, hemiparesis, expressive dysphasia, dysarthria, and truncal ataxia, have been described in 48% to 64% of patients after *M. pneumoniae* encephalitis. Preliminary evidence indicates that direct invasion of the central nervous system by *M. pneumoniae* may be the pathogenic mechanism in encephalitis cases in which prodromal symptoms are of short duration (< 5 days), whereas immunologic phenomena may be responsible for cases with a more prolonged prodrome.[63,65-67] The roles of antimicrobial therapy and immune-modulating therapy in the treatment of *M. pneumoniae* neurologic disease are unknown.

Skin eruptions described with *M. pneumoniae* infection include erythematous (macular or maculopapular), vesicular, bullous, petechial, and urticarial rashes; in one study, 17% of patients with *M. pneumoniae* pneumonia had an exanthem.[68] Erythema multiforme major (Stevens-Johnson syndrome) is the most clinically significant skin eruption associated with *M. pneumoniae* infection; it appears to occur more commonly with *M. pneumoniae* than with other infectious agents.[69]

Hematologic manifestations of *Mycoplasma* infection include hemolytic anemia, aplastic anemia, disseminated intravascular coagulation, hypercoagulopathy, and perhaps thrombotic thrombocytopenic purpura.[70-73] Cold agglutinin–induced hemolytic anemia is an uncommon manifestation of *Mycoplasma* pneumonia. Although up to 83% of patients with *M. pneumoniae* infection may have reticulocytosis and a positive direct Coombs test, clinically significant hemolysis is rare.[70] When anemia does occur, it begins suddenly in the second or third week of illness, and the agglutinin titer is high (> 1:512). The process is usually self-limited, lasting a few weeks.

Myocardial disease, pericardial disease, rhabdomyolysis, arthralgias, and arthritis (septic and reactive) have been attributed to *M. pneumoniae*.[3,74-76] Septic arthritis has been described most commonly in hypogammaglobulinemic patients.[41] In addition, hepatitis and pancreatitis have been reported.

General Laboratory Tests and Radiologic Studies

As with clinical findings, general laboratory tests and chest radiography have not been found to be useful for differentiating *Mycoplasma* pneumonia from other types of community-acquired pneumonia.[4,48,50,77] The frequent occurrence of community-acquired pneumonia of mixed etiology may be partly responsible for this finding.[11,78] Measurement of cold agglutinin titers is no longer recommended for the diagnosis of *Mycoplasma* pneumonia, because they are nonspecific and because assays specific for *M. pneumoniae* are now available.

The radiologic abnormalities of *Mycoplasma* pneumonia are varied. The most common pattern on chest radiography is that of peribronchial pneumonia with thickened bronchial markings; streaks of interstitial infiltration; and areas of subsegmental atelectasis, often involving a single lower lobe. Other frequent patterns include platelike atelectasis, nodular infiltration, and hilar adenopathy.[48] Segmental or lobar consolidation is not uncommon. Clinically evident pleural effusions are uncommon in *Mycoplasma* pneumonia, but lateral decubitus views reveal that up to 20% of patients have pleural effusions.

Specific Laboratory Testing

Laboratory diagnosis of an acute *M. pneumoniae* infection can be established (1) by the isolation of *M. pneumoniae* from respiratory tract secretions (oropharyngeal, nasopharyngeal, or pulmonary) with PCR or culture (which requires special media) or (2) by the use of specific serologic tests, such as complement fixation, indirect immunofluorescence, and enzyme immunoassays (EIAs) for specific IgM and IgG antibodies in paired (acute and convalescent) serum samples [*see Table 1*]. Of these methods, EIAs are the most widely used and the most adaptable to the clinical laboratory setting.[79] Serum samples for *M. pneumoniae* serology taken only during the acute phase of illness may not be indicative of infection, because antibodies to *M. pneumoniae* may not develop for 2 weeks or more; therefore, it is important to test both acute and convalescent serum samples for accurate diagnosis. IgM antibodies against *M. pneumoniae* may not be produced during reinfection in older patients (i.e., persons older than 40 years with preexisting anti–*M. pneumoniae* IgG antibodies).[80] In addition, specific IgM can persist for up to a year after acute *M. pneumoniae* infection and so may indicate recent infection rather than acute infection.[79]

M. pneumoniae culture is not recommended for routine diagnosis, because the organism may take weeks to grow and is often difficult to isolate from clinical specimens, so sensitivity is low. PCR allows a rapid and specific diagnosis to be made early in the course of clinical illness. The combination of respiratory tract PCR testing and EIA has been recommended as the most sensitive and rapid approach to the diagnosis of *M. pneumoniae* infection.[81] In children, PCR assays of nasopharyngeal or oropharyngeal samples appear equally effective for the diagnosis of serologically confirmed *M. pneumoniae* pneumonia; however, testing of specimens from both sites is optimal.[82]

TREATMENT

Because the clinical manifestations of *Mycoplasma* pneumonia are not distinctive and laboratory diagnosis is often made retrospectively, treatment is usually empirical, as it is with community-acquired pneumonia in general. The possibility of *M. pneumoniae* infection deserves particular consideration in a patient with community-acquired pneumonia who has failed to respond to treatment with a penicillin or a cephalosporin, because β-lactam antibiotics are ineffective against mycoplasmas. Clinical trials ranging from observational reports to randomized, double-blind, placebo-controlled studies have demonstrated that appropriate antimicrobial therapy significantly decreases the duration of fever, cough, malaise, hospitalization, and radiologic abnormalities in *Mycoplasma* pneumonia.[53] In one study of military trainees with serologically confirmed *M. pneumoniae* pneumonia, treatment with oral erythromycin for 7 days reduced mean duration of fever from 4.2 days to 2.4 days; the duration of hospitalization was reduced from 14.1 days to 7.0 days; and the period in which radiologic abnormalities were present was reduced from 14.8 days to 7.2 days.[83]

Treatment options for acute *M. pneumoniae* infection include macrolides, ketolides, tetracyclines, and most fluoroquinolones (ciprofloxacin and ofloxacin are not recommended because of their high minimum inhibitory concentrations and poor performance in animal studies) [*see Table 2*]. Antimicrobial resistance has not been clinically important in *M. pneumoniae* infections in North America. The optimal antibiotic choice, dosage, and duration are not clear; however, 14 days of therapy is generally recommended.

Even after therapy with appropriate antibiotics, *M. pneumoniae* can still be cultured from respiratory tract secretions.[8,84] The persistence of *M. pneumoniae* in the nasopharynx of children after clarithromycin therapy (given for an acute exacerbation of wheezing accompanying *M. pneumoniae* infection) has been associated with recurrent wheezing.[85] In animal models of *Mycoplasma* pneumonia, treatment with antimycoplasmal agents such as ketolides, quinolones, clarithromycin, and azithromycin also has not eradicated this organism from the respiratory tract.[55] The efficacy of combination antimicrobial therapy for the eradication of *M. pneumoniae* has not been investigated.

Table 1 Accuracy of Diagnostic Tests for *Mycoplasma pneumoniae* Infection[109,110]

Test	*Sensitivity (%)*	*Specificity (%)*	*Comment*
Culture*	≤ 60	100	Not recommended for clinical diagnosis
Polymerase chain reaction (PCR)*	65–90	90–100	Combination of PCR and enzyme immunoassays (EIAs) is optimal for diagnosis
Serologic studies	55–100	55–100	EIAs for *M. pneumoniae* IgM and IgG in paired (acute and convalescent) serum samples is the recommended serologic method

*Using respiratory tract secretions.

Table 2 Antimicrobial Treatment of *Mycoplasma* Infections

Pathogen	*Infection*	*Representative Drugs**
Mycoplasma pneumoniae	Respiratory tract infection	Macrolides: azithromycin, clarithromycin, erythromycin Ketolides: telithromycin Tetracyclines: doxycycline Fluoroquinolones†: levofloxacin, gatifloxacin, moxifloxacin, gemifloxacin
Ureaplasma urealyticum	Nongonococcal urethritis	Doxycycline‡ Azithromycin Alternatives: erythromycin base, levofloxacin
M. genitalium	Nongonococcal urethritis, pelvic inflammatory disease	Azithromycin
M. hominis	Pelvic inflammatory disease; persistent postabortion or postpartum fever; acute pyelonephritis	Doxycycline Clindamycin

*The optimal antibiotic choice for *Mycoplasma* infection is not clear, and a variety of dosages and treatment durations are used; however, the typical duration of *M. pneumoniae* treatment is 14 days.
†Ciprofloxacin and ofloxacin are not recommended.
‡*U. urealyticum* strains that are resistant to tetracyclines are usually sensitive to macrolides or quinolones.

In both animal and human studies, antimycoplasmal therapy significantly alleviated chronic respiratory disease caused by *M. pneumoniae*.[86,87] A randomized, double-blind, placebo-controlled trial in patients with stable chronic asthma showed that 6 weeks of treatment with clarithromycin produced significant improvement on respiratory function testing in those patients who tested positive for *M. pneumoniae* by PCR but not in those who tested negative; control subjects who received placebo also showed no improvement.[87] Additional clinical studies are needed to strengthen this observation.

Mycoplasma hominis, Mycoplasma genitalium, *and* Ureaplasma urealyticum

Because mycoplasmas and ureaplasmas often colonize the lower genitourinary tract of healthy adults (especially those who are sexually active), positive cultures for these organisms do not necessarily constitute proof of infection. Despite this difficulty, there is evidence that *M. hominis, M. genitalium,* and *U. urealyticum* can cause several clinical syndromes.[3,88] The significance of isolating these organisms in a variety of other syndromes is investigational or unknown.

NONGONOCOCCAL URETHRITIS

About 40% of men who experience an initial episode of nongonococcal urethritis have infection caused by *C. trachomatis* [*see 7:XIII Diseases Due to Chlamydia*].[89] In many cases of *Chlamydia*-negative nongonococcal urethritis (negative culture and negative serology), *U. urealyticum* may be the causative agent, as judged by (1) the presence of larger numbers of *U. urealyticum* organisms in *Chlamydia*-negative cases than in *Chlamydia*-positive cases; (2) the production of urethritis in human volunteers and nonhuman primates by intraurethral inoculation of *U. urealyticum* clinical isolates; and (3) the differential response to sulfisoxazole therapy (in one study, all 13 patients with *Chlamydia*-positive, *Ureaplasma*-negative nongonococcal urethritis showed a response, compared with only 14 of 30 *Chlamydia*-negative, *Ureaplasma*-positive patients).[89] *C. trachomatis* is susceptible to sulfonamides, but *U. urealyticum* is not. Such evidence suggests that *U. urealyticum* is the cause of at least some initial episodes of *Chlamydia*-negative nongonococcal urethritis in men—perhaps as many as 15% to 25% of these episodes.[90] Other studies have implicated *U. urealyticum* as a cause of acute urethral syndrome in some women; this organism may also cause chronic voiding symptoms in women, which may be mistaken for interstitial cystitis.[91] It is possible that factors such as serotype, strain-specific virulence determinants, or host factors will explain why positive cultures for *U. urealyticum* are not better correlated with evidence of clinical infection. Alternatively, disease may develop only upon initial exposure to ureaplasmas. *U. urealyticum* also has been implicated in urethroprostatitis and epididymitis.[3]

M. genitalium also appears to cause acute and possibly chronic nongonococcal urethritis.[88,92] One group of investigators found *M. genitalium* DNA in *C. trachomatis*–negative samples from 22% of heterosexual men with nongonococcal urethritis but from only 4% of asymptomatic control subjects.[93] Other studies have confirmed the disproportionate detection rates of *M. genitalium* in patients with nongonococcal urethritis. *M. genitalium* does not have a known role in prostatitis or epididymitis.[88] *M. hominis* does not appear to have a primary etiologic role in nongonococcal urethritis.

Treatment

Doxycycline (100 mg orally two times daily for 7 days) or azithromycin (1 g orally as a single dose) is the recommended treatment for nongonococcal urethritis. Erythromycin base (500 mg orally four times daily for 7 days) or levofloxacin (500 mg once daily for 7 days) are alternatives. These treatment regimens apply to cases associated with *U. urealyticum* as well as *M. genitalium*.[94] Tetracycline resistance has increased in recent decades and has been reported in as many as one third of clinical *U. urealyticum* isolates.[95] Resistant strains are known to cause persistent urethritis that often does not respond to treatment with tetracyclines; however, they are usually sensitive to macrolides or quinolones.[96] Sexual contacts of an index case should be treated at the same time as the index case. Other causes of treatment failure include poor compliance with medications, reinfection, disease caused by *Trichomonas vaginalis* or herpes simplex virus, prostatitis, and noninfectious etiologies.

For *M. genitalium,* the treatment of choice seems to be azithromycin. Treatment failures have been reported with other macrolides and with quinolones.[88,92]

UPPER URINARY TRACT INFECTION

M. hominis causes approximately 5% of acute pyelonephritis cases, judging from culture and serologic data.[97] However, the same association cannot be made for *U. urealyticum*.[3] Treatment of acute pyelonephritis from *M. hominis* is the same as that for pelvic inflammatory disease (PID) from this organism (see below).

U. urealyticum has a limited role in the production of urinary calculi. The frequency with which *U. urealyticum* reaches the kidney, the predisposing factors that allow this to occur, and the relative frequency of renal calculi induced by this organism as compared with other organisms is not known.[3]

PELVIC INFLAMMATORY DISEASE

M. hominis may cause some episodes of PID. In most of these cases, the organism occurs as part of a polymicrobial infection, but isolation of *M. hominis* from laparoscopic cultures of fallopian tubes in women with acute salpingitis has been reported, and the organism may be responsible for a few cases of PID on its own.[98] The prevalence of *M. hominis* involvement in PID may vary with global geographic location. It remains unclear how large a role *M. hominis* plays in the development of acute salpingitis and its sequelae. Some data also exist for an association of *M. genitalium* with PID.[88] In contrast, *U. urealyticum* is not considered to be a cause of PID.[3]

Treatment

M. hominis is resistant to the macrolides. Doxycycline is generally the drug of choice for *M. hominis* infections, although resistance has been reported.[99] Clindamycin is also generally active against *M. hominis*. Quinolones and ketolides have been found to be active in vitro against *M. hominis*; however, clinical experience is lacking.[96,100]

POSTABORTION AND POSTPARTUM FEVER

Positive blood cultures and concurrent seroconversion have implicated *M. hominis* as the primary pathogen in approximately 10% of women who have fever after abortion.[3] *M. hominis* is also responsible for 5% to 10% of fevers that arise more than 24 hours after vaginal delivery.[101] Women with vaginal colonization by *M. hominis* who have low or absent antibody titers against *Mycoplasma* may be predisposed to postpartum fever, which is probably associated with endometritis. These infections are usually self-limited; if symptoms persist, however, specific antimicrobial therapy should be given as for *M. hominis* PID (see above).

OTHER CONDITIONS ASSOCIATED WITH MYCOPLASMAS

M. hominis rarely causes brain abscess, wound infection, poststernotomy mediastinitis,[102] neonatal meningitis, and other nongenitourinary infections.[103,104] These infections are more common in immunocompromised or hypogammaglobulinemic persons. *U. urealyticum* and *M. hominis* can cause septic arthritis in immunodeficient patients,[3] and *U. urealyticum* likely causes neonatal pneumonitis and contributes to neonatal chronic lung disease (including bronchopulmonary dysplasia).[105] It is unclear whether *U. urealyticum* and *M. hominis* can cause male and female infertility,[106] spontaneous abortion,[107] premature labor and low birth weight,[108] and chorioamnionitis.[105]

The author participates in the speakers' bureau for Sanofi-Aventis.

Antimicrobial drugs discussed in this chapter have not been approved by the FDA for use in chronic respiratory Mycoplasma hominis *infection,* M. genitalium *infection, or* M. hominis *infection; azithromycin and levofloxacin have not been approved for use in* Ureaplasma *infection. The use of polymerase chain reaction for the diagnosis of* Mycoplasma *infection is investigational and is not approved by the FDA.*

XIII DISEASES DUE TO CHLAMYDIA

WALTER E. STAMM, M.D.

The chlamydiae are obligate intracellular bacteria that produce a wide variety of infections in many mammalian and avian species.[1] Three species of *Chlamydia* infect humans: *C. trachomatis*, *C. psittaci*, and *C. pneumoniae* [*see Table 1*]. *C. trachomatis* is exclusively a human pathogen and is transmitted from person to person via sexual contact, perinatal transmission, or close contact in households. *C. trachomatis* causes trachoma in arid developing parts of the world and is a major cause of sexually transmitted and perinatal infections worldwide. In the United States, *C. trachomatis* infection is the most common reportable infectious disease.[2] *C. psittaci*, in contrast, is more widely distributed in nature, producing genital, conjunctival, intestinal, or respiratory infections in many avian and mammalian species.[3] Humans are occasionally infected by avian strains after contact with infected birds, incurring a pneumonitis or a systemic infection termed psittacosis.

C. pneumoniae, the third chlamydial species that infects humans, was identified and characterized in the 1980s.[4] It is a fastidious organism that produces upper respiratory tract infection and pneumonitis in both children and adults.[5] Recent studies have also linked *C. pneumoniae* infection to atherosclerotic cardiovascular disease and perhaps to other illnesses, such as asthma and sarcoidosis.[6] Transmission is believed to occur via aerosol droplets; no animal reservoir has been identified.

All chlamydiae share a unique life cycle characteristic of the genus [*see Figure 1*].[7] The organism is transmitted in an extracellular nonreplicating form known as the elementary body. The elementary body adheres to and is phagocytosed into a host epithelial cell. Once inside the epithelial cell, the elementary body transforms into the intracellular replicative form of the organism, the reticulate body. Reticulate bodies divide by binary fission within membrane-bound vacuoles called inclusions. After approximately 36 hours, reticulate bodies condense into elementary bodies, the inclusion ruptures, and the elementary bodies disperse to infect adjacent epithelial cells or to be transmitted to other hosts. A unique feature of the chlamydial inclusion is its ability to resist lysosomal fusion; the mechanism of resistance is as yet unknown. The intracellular milieu also provides the organism with nutrients and serves as a refuge from host immune defense mechanisms.

Although chlamydiae were initially thought to be large viruses, they in fact possess both DNA and RNA, have a cell wall and ribosomes similar to those of gram-negative bacteria, and are inhibited by a variety of antimicrobials (see below).[7] *C. trachomatis*, *C. psittaci,* and *C. pneumoniae* all share a genus-specific lipopolysaccharide antigen. The commonly available complement fixation test for *Chlamydia* measures antibodies against this antigen. The three species can be differentiated serologically with the microimmunofluorescence test, which is directed against epitopes in the major outer membrane protein (MOMP).

Characteristically, chlamydial species produce chronic, persistent, and often asymptomatic infections of the epithelial lining of the eye, respiratory tract, and urogenital tract. Infection of epithelial cells induces secretion of cytokines and initiation of an innate immune response. Induction and persistence of a chronic inflammatory response may eventually result in fibrosis, scarring, and other chronic sequelae of infection.[8]

In cell cultures, chlamydia species are susceptible to many antimicrobials, including tetracycline, doxycycline, erythromycin, azithromycin, rifampin, clindamycin, ofloxacin, and levofloxacin. Although antibiotic-resistant strains of *Chlamydia* have been described, clinical antimicrobial resistance has yet to become a frequent problem in treating chlamydial infections.[9]

Diseases Due to *C. trachomatis*

Unlike *C. pneumoniae,* which appears to have only a single serotype, and *C. psittaci,* whose number of serotypes is unknown, *C. trachomatis* has at least 18 distinct serotypes (serovars).[10] These serotypes confer tissue tropism and disease specificity: serovars A, B, Ba, and C are associated with trachoma, whereas serovars D through K are associated with sexually transmitted and perinatally acquired infections. Serovars L1, L2, and L3 are more invasive than the other serovars, spread to lymphatic tissue, and grow readily in macrophages; they produce the clinical syndromes of lymphogranuloma venereum and hemorrhagic proctocolitis. In addition to these more commonly reported syndromes, *C. trachomatis* has been reported as an infrequent cause of other infections, including endocarditis, peritonitis, pleuritis, and periappendicitis.[11]

LABORATORY DIAGNOSIS

Laboratory testing for *C. trachomatis* has evolved considerably over the past decade. Four types of confirmatory procedures are now available: (1) direct microscopic examination of swabs or tissue scrapings utilizing fluorescent antibody staining (DFA); (2) cell culture isolation of the organism; (3) detection of chlamydial antigens or genes in specimens by immunologic means or nucleic acid amplification testing; and (4) serologic testing for antibodies to *C. trachomatis* [*see Table 2*].

Except in cases of inclusion conjunctivitis, DFA has largely been abandoned for diagnosis of chlamydial infection. Even in inclusion conjunctivitis, nucleic acid amplification testing of conjunctival smears is probably a better choice because of its higher sensitivity. Cell culture techniques for isolation of *Chlamydia* are not widely available and have numerous drawbacks: culture has exacting requirements for specimen transport and is technically demanding and expensive; moreover, its sensitivity is only 60% to 80% of that of newer diagnostic tests.[12] For those reasons, nonculture alternatives utilizing antigen or gene detection are the diagnostic methods of choice in most cases. The least expensive and most widely used of the nonculture tests are enzyme-linked immunoassays that detect chlamydial antigens on urethral or endocervical swabs. These tests, however, have limited sensitivity and specificity and cannot be used to test vaginal swabs or urine for *Chlamydia*.

The newer nucleic acid amplification tests, such as polymerase chain reaction (PCR), ligase chain reaction (LCR), and transcription-mediated amplification (TMA), are the most sensitive and specific of the currently available tests.[13] Uniquely, these tests have high accuracy even when used on specimens that contain only small numbers of organisms (e.g., first-void urine or vaginal swabs). The ability to use such specimens is of particular

Table 1 Comparative Features of *Chlamydia* species

Species	*C. trachomatis*	*C. psittaci*	*C. pneumoniae*
Natural hosts	Humans	Birds, mammals	Humans
Mode of transmission	Sexual; close personal contact; maternal/infant	Zoonotic	Respiratory droplets
Typical diseases	STDs, LGV, trachoma	Pneumonia, psittacosis	Upper respiratory infections, pneumonia, atherosclerotic vascular disease
Risk groups	STDs: sexually active adolescents and young adults Trachoma: young children in arid, unhygienic, crowded conditions	Bird fanciers, pet-shop workers, veterinarians, animal and poultry workers	Young children, older adults
Number of serotypes	18	Unknown	1

LGV—lymphogranuloma venereum STDs—sexually transmitted diseases

importance because their ease of collection facilitates patient compliance and community-based screening programs.

Serologic tests are of little value in the diagnosis of most chlamydial ocular or genital infections.[14] They are useful only in invasive syndromes such as pelvic inflammatory disease, epididymitis, lymphogranuloma venereum, and infant pneumonia, which are associated with significant increases in both microimmunofluorescence and complement-fixing antibodies.

SEXUALLY TRANSMITTED DISEASES

C. trachomatis is the most common bacterial cause of sexually transmitted disease (STD) in the United States, being responsible for an estimated four million cases a year.[2] The spectrum of illness attributable to these infections parallels that of gonococcal infection. In men, the most common syndromes are nongonococcal urethritis and acute epididymitis. In women, mucopurulent cervicitis, urethritis, bartholinitis, acute salpingitis, and perihepatitis are the syndromes most commonly seen. Inclusion conjunctivitis, proctitis, and Reiter syndrome affect both sexes.

Sexually transmitted *C. trachomatis* infection has a widespread distribution and a high incidence and prevalence in adolescents and young adults in the United States and Europe.[15] The age of peak incidence is the late teens and early 20s. Prevalence has been reported at 3% to 8% in general medical clinics and urban high schools, over 10% in asymptomatic military personnel undergoing routine physical examination, and as high as 15% to 20% in men and women attending STD clinics.[16,17] The highest prevalences of infection have been observed in persons who are single, have multiple sexual partners, are not using barrier contraception, report genital symptoms, have an infected sexual partner, or are attending a high-risk clinic such as an STD clinic. As many as 90% of infections in many settings may be asymptomatic and are thus discoverable only by screening. Recurrent chlamydial infections—often from untreated sexual partners—are common in high-risk groups.[18]

C. trachomatis initially infects the columnar epithelium of the genital tract and induces an inflammatory response that may persist for months or years. Serious sequelae, such as scarring of the fallopian tubes and damage to the upper genital tract, occur most often with repeated or persistent infections.[19] The mechanism through which repeated infection induces inflammation and subsequent complications is not clear. The *C. trachomatis* 60 kd heat shock protein has been implicated in these deleterious inflammatory responses and may induce antibodies that cross-react with human heat-shock protein. Other chlamydial proteins also may be important in this process.[20] Host genetic susceptibility may also play a role: persons with particular HLA haplotypes appear to be more susceptible to scarring with either genital or ocular infection.[21]

Nongonococcal Urethritis

Diagnosis Nongonococcal urethritis (NGU), the most common chlamydial urogenital infection in men, typically presents with burning pain on urination, urethral discharge, or urethral itching. A discharge from the urethra may be apparent on observation or may be visible only after stripping the urethra. The discharge is generally clear or mucoid, but it may be mucopurulent or purulent.[22] However, up to half of the men with *C. trachomatis* infection of the urethra will have no clinical manifestations of urethritis. Many of these patients will nevertheless have an increased number of leukocytes on Gram stain of a urethral smear. A presumptive diagnosis of NGU can be made on the basis of a leukocytic urethral exudate (≥ 4 polymorphonuclear leukocytes [PMNs] per 1,000× oil-immersion field) in the absence of concurrent gonococcal infection by Gram stain or culture [*see Table 2*]. About 40% of such cases of presumptive NGU are caused by *Chlamydia*; the remainder are caused by *Ureaplasma urealyticum, Mycoplasma genitalium,* and other microbes.[23] The specific diagnosis of chlamydial infection can be confirmed by a nucleic acid amplification assay such as PCR or LCR, an antigen detection test, or culture.

Treatment Men with presumed or confirmed NGU should be treated with oral doxycycline, 100 mg twice a day for 7 days, or azithromycin, 1 g orally as a single dose. The two regimens appear equally effective.[24] The azithromycin regimen offers the advantage of single-dose therapy but is considerably more expensive. Female partners of men with NGU should be examined and treated for presumed concomitant chlamydial infection.

Epididymitis

In 1% to 2% of men with chlamydial urethritis, the infection ascends in the genital tract to cause acute epididymitis. *C. trachomatis* is the major cause of acute epididymitis in heterosexual men younger than 35 years; other causes include *Neisseria gonorrhoeae* and, less commonly, urinary pathogens such as *Escherichia coli* or *Pseudomonas aeruginosa*.[25] Urinary pathogens are a more common cause of epididymitis in homosexual men who practice rectal intercourse and in men older than 35 years who have had urologic instrumentation or surgery.

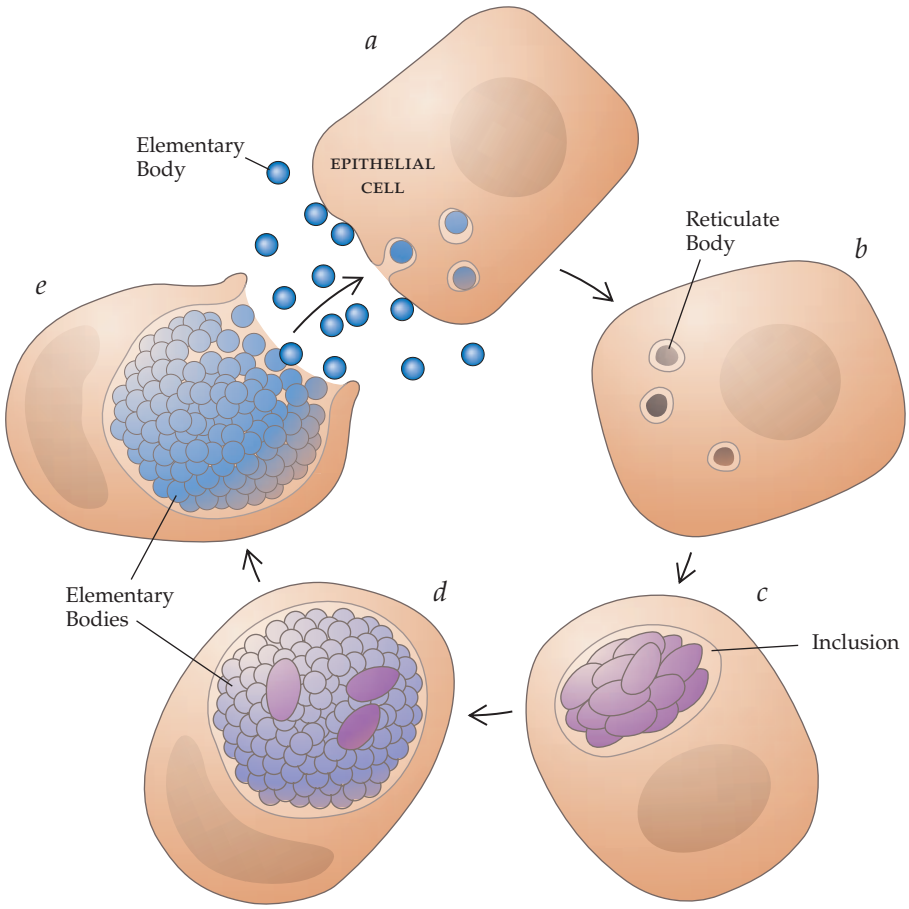

Figure 1 **Life cycle of *Chlamydia*. (*a*) Chlamydiae are transmitted in an extracellular nonreplicating form known as the elementary body. The elementary body adheres to and is phagocytosed into a host epithelial cell. (*b*) Once inside the epithelial cell, the elementary body transforms into the intracellular replicative form of the organism, the reticulate body. (*c*) Reticulate bodies divide by binary fission within membrane-bound vacuoles called inclusions. (*d*) The reticulate bodies then reorganize into elementary bodies; multiplication stops. (*e*) After 35 to 40 hours, the inclusion ruptures, and elementary bodies are released to infect adjacent epithelial cells or to be transmitted to other hosts.**

Diagnosis Epididymitis caused by *C. trachomatis* typically presents as unilateral scrotal pain, fever, and epididymal tenderness and swelling. Testicular torsion should be excluded by a radionuclide scan or Doppler flow study if the diagnosis is in doubt.

Treatment In some patients, epididymitis may be mild enough to be treated on an outpatient basis with oral antibiotics. In other cases, hospitalization is required for management of pain and initiation of parenteral antibiotics. Initial empirical therapy with ofloxacin, 300 mg orally or intravenously twice daily, is recommended until the etiologic agent is identified [*see Table 2*].[26]

Mucopurulent Cervicitis

Endocervical infection with *C. trachomatis* is considered the female counterpart of male urethritis.[27]

Diagnosis *C. trachomatis* cervical infection is often clinically silent, although a careful speculum examination will reveal mucopurulent cervicitis in some cases. When clinical manifestations are present, they are nonspecific—for example, vaginal discharge, vaginal bleeding, lower abdominal pain, or dysuria. On examination, findings include a yellow or green mucopurulent discharge from the endocervical os, the presence of cervical ectropion, edema in the area of ectropion, and easily induced mucosal bleeding.[27] A Gram stain of the endocervical exudate typically shows large numbers of PMNs. Women with suspected mucopurulent cervicitis should be evaluated for both chlamydial and gonococcal infection [*see Table 2*].

Treatment Chlamydial mucopurulent cervicitis is best treated with a single dose of 1 g of azithromycin. This regimen is effective and safe. Although more expensive than doxycycline, azithromycin is cost-effective because adolescents often fail to complete a 7-day course of doxycycline.[28] Unlike doxycycline, azithromycin appears to be safe during pregnancy and is used by many practitioners for treatment of chlamydial mucopurulent cervicitis or cervical infection in pregnant women.[29] Sexual partners of women found to have chlamydial cervical infection or mucopurulent cervicitis should be examined and empirically treated for chlamydial infection.

Table 2 Clinical Characteristics of Common *C. trachomatis* Infections in Adults

	Infection	Symptoms and Signs	Presumptive Diagnosis	Definitive Diagnosis	Treatment
Men	Nongonococcal urethritis	Urethral discharge, dysuria	Urethral leukocytosis; no gonococci seen	Urine or urethral NAAT	Azithromycin, 1 g p.o. (single dose) *or* Doxycyline, 100 mg p.o. b.i.d., for 7 days
	Epididymitis	Unilateral epididymal tenderness, swelling; pain; fever; presence of NGU	Urethral leukocytosis; pyuria on urinalysis	Urine or urethral NAAT; urine culture	Outpatient: Ofloxacin, 300 mg b.i.d. for 10 days *or* Ceftriaxone, 1 g I.M., plus doxycycline, 100 mg p.o., b.i.d., for 7 days
	Proctitis	Rectal pain, discharge, bleeding; history of receptive anal intercourse	≥ 1PMNs/OIF on rectal Gram stain; no gonococci seen	Rectal culture or DFA (NAAT untested)	Doxycycline, 100 mg p.o., b.i.d., for 7 days
	Conjunctivitis	Ocular pain, redness, discharge; simultaneous genital infection	Gram stain of conjunctival swab negative for bacterial pathogens; PMNs on smear	DFA or NAAT on conjunctival swab	Azithromycin, 1 g p.o. (single dose) *or* Doxycyline, 100 mg p.o., b.i.d., for 7 days
Women	Cervicitis	Mucopurulent cervical discharge; cervical bleeding; cervical edema	≥ 20 PMNs/OIF on cervical Gram stain	Urine or cervical NAAT	Azithromycin 1 g p.o. (single dose) *or* Doxycycline, 100 mg p.o., b.i.d., for 7 days
	Urethritis	Dysuria, frequency; no hematuria	Pyuria on UA; negative urine Gram stain and culture	Urine, cervical, or urethral NAAT	Azithromycin, 1 g, p.o. (single dose) *or* Doxycycline, 100 mg p.o., b.i.d., for 7 days
	Salpingitis	Lower abdominal pain, adnexal pain, cervical motion tenderness	Evidence of mucopurulent cervicitis	Urine or cervical NAAT	Outpatient: Ofloxacin, 400 mg b.i.d., p.o., plus metronidazole, 500 mg p.o., b.i.d., for 14 days *or* Ceftriaxone, 250 g I.M. plus doxycycline, 100 mg p.o., b.i.d., for 14 days
	Conjunctivitis	Ocular pain, redness, discharge; simultaneous genital infection	Gram stain of conjunctival swab negative for bacterial pathogens; PMNs on smear	DFA or NAAT on conjunctival swab	Azithromycin, 1 g p.o. (single dose) *or* Doxycycline, 100 mg p.o., b.i.d., for 7 days

DFA—direct fluorescent antibody NAAT—nucleic acid amplification test NGU—nongonococcal urethritis OIF—oil-immersion field PMN—polymorphonuclear neutrophil UA—urinalysis

Acute Urethral Syndrome in Women

In women presenting with dysuria, frequency, and pyuria, *C. trachomatis* is the pathogen that is most commonly identified if urine cultures fail to find *E. coli*, *Staphylococcus saprophyticus*, or other uropathogens.[30] Chlamydial infection should be considered to be the cause of so-called dysuria-pyuria syndrome when the urine culture does not demonstrate expected urinary bacterial pathogens, symptoms have been present for more than 7 days, the patient has a new sexual partner, or concomitant mucopurulent cervicitis is present on examination.[30,31]

Pelvic Inflammatory Disease

C. trachomatis is thought to account for about half of all cases of pelvic inflammatory disease (PID) in the United States.[32] Ascending intraluminal spread of *C. trachomatis* from the lower genital tract can produce endometritis, endosalpingitis, and pelvic peritonitis. On examination, evidence of mucopurulent cervicitis is generally found in women who have laparoscopically verified salpingitis due to *C. trachomatis*.

Diagnosis Chlamydial salpingitis often produces fewer clinical symptoms and signs than gonococcal or anaerobic salpingitis.[33] However, patients often present with lower abdominal pain, adnexal tenderness, vaginal discharge or bleeding, and uterine tenderness. They may or may not have fever.

Treatment Empirical treatment of PID must provide antimicrobial coverage for the major pathogens, including *C. trachomatis*, *N. gonorrhoeae*, and vaginal anaerobes [*see Table 2*]. Screening of high-risk young women for chlamydial cervical infection followed by treatment has been shown to prevent subsequent PID in a prospective cohort study.[34] Thus, chlamydial screening of all sexually active adolescent girls and women younger than 25 years with new sexual partners is strongly recommended.[35]

Complications Infertility and ectopic pregnancy are important sequelae of chlamydial tubal infection. Antecedent *C. trachomatis* PID has been linked to infertility from fallopian tube scarring. In more recent studies, demonstration of persistent, slowly replicating *C. trachomatis* in tubal tissue suggests that these patients may have chronic infection.

Perihepatitis, or Fitzhugh-Curtis syndrome, develops in a subset of women with chlamydial salpingitis. These patients present with right upper quadrant pain, fever, and often adnexal tenderness. The diagnosis can be established with an endocervical nucleic acid amplification test for chlamydia or by demonstration of high titers of antibody to *C. trachomatis*.

Acute Proctitis

Men who practice receptive anal intercourse may develop acute proctitis from *C. trachomatis* strains of serovars D through K or, rarely, L1 through L3.[36] Since 1998, chlamydial proctitis has been resurgent in homosexual and bisexual men in the United States.[37] These infections occasionally develop in heterosexual women. The severity of disease ranges from asymptomatic (which generally occurs in patients infected with serovars D through K) to severe (generally, serovars L1 through L3).

Diagnosis Patients with severe infection typically present with rectal pain, a rectal mucosal discharge, tenesmus, and rectal bleeding. Characteristically, a rectal Gram stain shows one or more PMNs per 1000× oil-immersion field and anoscopy demonstrates a mucopurulent discharge and easily induced mucosal bleeding.[36] The specific diagnosis can be made by rectal culture for *Chlamydia* or by a chlamydial DFA. The sensitivity and specificity of the newer nucleic acid amplification tests for rectal specimens has not been extensively studied, and these tests are not approved for this purpose.

Treatment Treatment regimens for chlamydial proctitis have not been extensively studied. Nevertheless, a 7-day regimen of doxycycline (100 mg b.i.d.) is recommended for cases caused by serovars D through K, and a 21-day course is recommended for cases caused by serovars L1 through L3 [*see Table 2*].

Reiter Syndrome

An unusual complication of chlamydial urethritis, Reiter syndrome (more recently termed reactive arthritis) consists of conjunctivitis, urethritis (or cervicitis in women), oligoarthritis, and characteristic lesions of the skin and mucous membranes [*see 15:III Seronegative Spondyloarthropathies*]. Although the pathogenesis of Reiter syndrome is obscure, more than 80% of affected patients have the HLA B27 haplotype, so a genetic predisposition is clearly involved.[38] Recent studies have found chlamydial antigens and genes in the involved joints, suggesting that viable *Chlamydia* organisms migrate from the urethra to the synovial tissue in these cases.

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is a sexually transmitted infection caused by *C. trachomatis* strains of the L1, L2, and L3 serovars. Typically, the disease begins with a transient primary genital lesion, followed by multilocular suppurative regional lymphadenopathy and, sometimes, hemorrhagic proctitis with associated regional lymphadenitis.[39] The acute phase of the disease is generally associated with fever, leukocytosis, and in some cases proctitis. Possible late complications include genital elephantiasis, rectal strictures, and fistulas of the penis, urethra, and rectum.

Epidemiology LGV occurs primarily in the second and third decades of life and is approximately four times more common in men than in women. Worldwide, the incidence is declining, but the disease is still endemic in parts of Asia, Africa, South America, and the Caribbean. The disease is rare in the United States, with only 186 cases reported in 1995. In the United States, many cases involve travelers or military personnel returning from endemic areas; most microbiologically confirmed cases have been in homosexual or bisexual men.[40]

Clinical manifestations The initial lesion of LGV in heterosexual persons is often a papule, vesicle, or ulcer on the penis or, in women, on the labia. This lesion typically heals without scarring. LGV strains of *C. trachomatis* have occasionally been recovered from these genital ulcers, as well as from the urethra of men or the endocervix of women who present with inguinal adenopathy. It is thus not entirely clear whether the most important primary site of infection is the skin lesion, the urethra, or the endocervix. Alternatively, primary anal or rectal infection may develop in men or women after receptive rectal intercourse.[41] Initial inoculation of the oral mucosa can also occur, leading to primary oral or pharyngeal lesions that may go unnoticed until adenopathy develops.

From the initial site of primary infection (urogenital, anal, rectal, or oral), the organism spreads to adjacent regional lymphatics. Typically, penile, vulvar, or anal infections spread to the inguinal and femoral lymph nodes. Rectal infection produces hypogastric and deep iliac lymphadenitis, whereas upper vaginal or cervical infection may result in obturator and iliac lymphadenitis. Heterosexual men with urogenital infection commonly display the so-called inguinal syndrome, which consists of painful inguinal lymphadenopathy developing approximately 2 to 6 weeks after the presumed exposure. Adenopathy generally is unilateral, with palpable enlargement of the iliac and femoral nodes on the same side as the enlarged inguinal nodes. Although the nodes may be discrete at first, they increasingly become matted, fluctuant, and suppurative. The overlying skin becomes fixed and inflamed and eventually develops multiple draining fistulas. Enlargement of lymph nodes both above and below the inguinal ligament may produce the so-called sign of the groove. On biopsy, the infected nodes have small abscesses surrounded by histiocytes. Spontaneous healing may occur after several months, but scarring and granulomatous masses often persist.

In the United States, LGV proctitis has increasingly been recognized in homosexual men. These patients present with rectal pain and mucopurulent bloody rectal discharge.[42] They often complain of tenesmus and such systemic signs and symptoms as fever, malaise, and weakness. Sigmoidoscopy reveals ulcerative proctocolitis with a purulent exudate and mucosal bleeding.

During the active development of regional lymphadenopathy, many patients experience extensive constitutional symptoms, including fever, chills, headache, meningismus, myalgia, and arthralgias. Complications may include arthritis, aseptic meningitis, encephalitis, hepatitis, and arthritis. If left untreated, rectal infections may eventually progress to perirectal abscesses, anal fistula, and fistulas involving the rectum, the vagina, the bladder, and the pelvic musculature. Rectal strictures are a late complication, as is elephantiasis due to associated lymphatic obstruction.[26]

Laboratory tests LGV is most readily diagnosed serologically. Both the LGV complement fixation test and the microimmunofluorescence test become strongly positive soon after the onset of lymphadenopathy. Alternatively, demonstration of *C. trachomatis* by culture or nucleic acid amplification tests from urethral or cervical specimens or from pus aspirated from buboes can confirm the diagnosis.

Differential diagnosis LGV must be differentiated from other sexually transmitted conditions that produce genital ulcers

and associated adenopathy. These include genital herpes simplex virus (HSV) infection, syphilis, chancroid, and granuloma inguinale. The clinical presentation, epidemiologic circumstances, and specific laboratory testing can usually differentiate these conditions unambiguously.

Treatment Doxycycline, 100 mg orally twice daily for 21 days, is generally recommended for treatment of LGV, despite the absence of trials demonstrating its efficacy. Alternative agents include erythromycin and sulfonamides.

PERINATAL INFECTIONS

Depending on the population tested, 5% to 25% of pregnant women have *C. trachomatis* infection of the cervix. A high proportion of infants born to these infected women will acquire *C. trachomatis* infection during passage through the birth canal.[35] If not identified and treated, the infection may persist for months or years.[43]

Clinically apparent neonatal inclusion conjunctivitis develops in approximately 50% to 60% of infants with perinatally acquired *C. trachomatis* infection.[44] In addition, *C. trachomatis* can often be isolated from the rectum, vagina, and nasopharynx of these infants.[45] Approximately 10% of perinatally infected infants experience a distinctive afebrile pneumonitis-like syndrome.[46]

Neonatal chlamydial conjunctivitis typically develops 5 to 14 days after birth and generally presents as a mucopurulent ocular discharge. Other causes of neonatal conjunctivitis—such as *N. gonorrhoeae*, *Haemophilus influenzae*, *Streptococcus pneumoniae,* and HSV—should also be considered. The diagnosis can be readily confirmed by DFA of a conjunctival smear or by PCR or LCR testing of the discharge. Because infants tend to be infected at multiple sites, systemic therapy is indicated, generally with erythromycin, 50 mg/kg/day orally in four divided doses for 10 to 14 days.

To prevent neonatal infection, all pregnant women should be screened for *C. trachomatis* infection in the third trimester, preferably with a nucleic acid amplification test. Those women found to be infected should be treated with a single 1 g oral dose of azithromycin; amoxicillin, 500 mg orally three times a day for 7 days; or erythromycin base, 500 mg orally four times a day for 7 days.[47]

ADULT INCLUSION CONJUNCTIVITIS

Inclusion conjunctivitis caused by *C. trachomatis* is occasionally seen in adults.

Diagnosis

Adult chlamydial conjunctivitis usually arises from inadvertent inoculation of the conjunctiva in patients with sexually acquired chlamydial infection. These patients typically present with an acute unilateral follicular conjunctivitis. Associated preauricular adenopathy may be evident. Such cases must be distinguished from acute conjunctivitis due to other organisms, such as adenovirus, HSV, or bacterial pathogens. If not treated, the disease may persist for weeks to months, but it typically resolves without scarring or visual impairment. Approaches to diagnosis are the same as those used for neonatal conjunctivitis (see above).

Treatment

Systemic treatment is indicated to cure both the ocular and the genital infection. Treatment regimens are the same as for genital infection (see above). Sexual partners should be evaluated and treated to prevent reinfection.

TRACHOMA

C. trachomatis—specifically, serovars A, B, Ba, and C—is the source of trachoma, the major preventable cause of blindness throughout the world.

Epidemiology

Trachoma remains prevalent in arid portions of the developing world, especially North Africa and the Middle East. Trachoma was formerly endemic in Native Americans of the southwestern United States, but it has largely been eliminated from that population. Transmission of *C. trachomatis* in endemic areas is believed to occur via eye to hand to eye contact, as well as via contaminated towels and other fomites.[48] Flies and other insects also may play a role in transmission. Most infections take place in early childhood, particularly in areas marked by crowding, poor standards of cleanliness, and the lack of clean water. The overall incidence of trachoma, as well as its severity, has been reduced dramatically over the past 35 years, primarily because of improved sanitary conditions and greater availability of clean water.

Pathogenesis

Severe, chronic, blinding trachoma is generally associated with repeated reinfection or persistent infection by trachoma-causing strains of *C. trachomatis*.[49] The immune response to the *C. trachomatis* 60 kd heat shock protein appears to be strongly linked to the conjunctival scarring and pannus formation that causes blindness in trachoma. Host genetic factors are likely also to be important, because specific HLA types are more commonly found in persons with progressive trachoma.[50]

Diagnosis

Clinical manifestations Initially, trachoma presents as a conjunctivitis characterized by multiple lymphoid follicles. Infection generally begins in children between 1 and 4 years of age. Reinfection is common, as is asymptomatic infection.[51] With repeated episodes, the cornea becomes involved, with inflammatory infiltrates and pannus formation (superficial vascularization). Conjunctival scarring eventually develops and causes the eyelids to turn inward and abrade the eyeball.[52] Eventually, corneal epithelial ulceration occurs. Destruction of the lacrimal glands and ducts produces a dry eye.

Laboratory tests Trachoma can be diagnosed on clinical grounds in a patient from an endemic area with follicular conjunctivitis. The diagnosis can be confirmed with culture, DFA, or nucleic acid amplification testing of secretions.

Treatment

Antimicrobial treatment should be provided in the early phases of trachoma, when its impact is potentially greatest. Oral tetracycline (in older children and adults) or erythromycin for 4 to 8 weeks has been recommended. Azithromycin (20 mg/kg orally in a single dose) can be used but may be prohibitively expensive in the developing world. Topical antimicrobials can be used, but their effectiveness is uncertain.

Public health measures to control endemic trachoma have focused on improving hygienic conditions and making clean water available. More recently, mass treatment of villages with single-

dose azithromycin or topical antimicrobials has been utilized. Personal cleanliness and a reduction in flies in a village may also be important.

Disease Due to *C. psittaci*

PSITTACOSIS

C. psittaci infects a wide variety of avian species, including parrots, parakeets, pigeons, finches, chickens, pheasants, and turkeys. Humans become infected through exposure to infected birds. Human infection is subacute, characterized by pneumonitis and a variety of systemic manifestations.[53]

Epidemiology

Parrots, parakeets, and budgerigars (so-called psittacine birds) are the most common sources of human psittacosis. However, human cases have also been attributed to pigeons, ducks, turkeys, chickens, and a variety of other bird species. Psittacosis is an occupational disease of pet-shop employees, pigeon fanciers, taxidermists, veterinarians, poultry workers, and others who work around birds. The actual incidence is unknown: 50 to 100 cases are reported each year in the United States,[54] but it is likely that many cases, especially milder ones, go undiagnosed and thus unreported.

Pathogenesis

C. psittaci can be isolated from the nasal secretions, excreta, tissues, and feathers of infected birds. The birds may be ill, but many show only minor evidence of infection; complete absence of symptoms is uncommon, however.

C. psittaci enters humans via the upper respiratory tract and spreads throughout the body via the bloodstream, localizing primarily in pulmonary alveolar macrophages and the endothelial cells of the liver and spleen.[55] A lymphocytic inflammatory response ensues in the lungs and at other sites of infection. Little is known of the pathogenesis of psittacosis at the cellular or molecular level.

Diagnosis

Clinical manifestations Psittacosis may vary in severity from a mild flulike illness to a fatal disease.[56] The incubation period is typically 7 to 14 days. Often, the illness begins abruptly, with shaking chills and fever. In other cases, onset is more gradual. Among the most common symptoms are a severe headache and a nonproductive cough. Systemic illness characterized by fever, malaise, myalgias, and chills is also common. Features that may help differentiate psittacosis from other pneumonic processes include the absence of signs of consolidation, absence of a pleural effusion, a relative bradycardia, absence of neutrophilia, splenomegaly, abnormal liver function tests, and a rash resembling the rose spots of typhoid fever (Horder spots). The course may be relatively benign and short-lived or severe and prolonged, with complications such as myocarditis, pericarditis, meningitis, or encephalitis.[57]

A history of a recent exposure to birds is most helpful. Other diseases that must be considered include influenza, other viral pneumonias, *M. pneumoniae*, Q fever, Legionnaires disease, and other bacterial or fungal pneumonias. With patients in whom pneumonia is not prominent, other systemic febrile illnesses such as brucellosis, leptospirosis, mononucleosis, hepatitis, or typhoid fever must be considered.

Laboratory tests In psittacosis, the white blood cell count is most commonly normal or decreased and the erythrocyte sedimentation rate is not elevated. Liver function tests may be abnormal. Changes on chest x-ray are typically nonspecific, with patchy infiltrates that may be lobar, wedge shaped, segmental, or nodular. The diagnosis of psittacosis is best confirmed by serologic studies, because *C. psittaci* is difficult to isolate from blood or infected secretions. In addition, the organism is hazardous to work with in the laboratory, and most clinical laboratories do not offer culture diagnosis. A fourfold rise in titer of complement-fixing antibody in acute and convalescent sera from a patient with a compatible clinical syndrome confirms the diagnosis.

Treatment

Tetracycline generally produces a rapid and dramatic response when initiated during the early phase of psittacosis.[58] Generally, 2 g daily given in four divided doses is sufficient. Treatment should be continued for at least 14 days after defervescence to prevent relapse of infection. An alternative to tetracycline is erythromycin. Although as many as 20% of patients died in the preantibiotic era, fewer than 5% of patients do not respond to therapy currently.

Diseases Due to *C. pneumoniae*

C. pneumoniae is a recently described species that, as its name indicates, is associated primarily with respiratory tract infections. Initially, *C. pneumoniae* strains were thought to be variants of *C. psittaci,* but subsequent studies have demonstrated that *C. pneumoniae* is a distinct species, on the basis of differences in small subunit ribosomal RNA sequence, morphology, and antigenic properties.[59] The organisms are fastidious and cannot be easily isolated from respiratory or other clinical specimens. *C. pneumoniae* from clinical specimens grows most effectively in HL cells and Hep 2 cells.[60]

EPIDEMIOLOGY

Because of the difficulty in isolating the organism, most epidemiologic studies have depended on microimmunofluorescence serologic studies. Such studies have indicated that *C. pneumoniae* infection is extremely prevalent, with approximately 40% to 50% of adults demonstrating seropositivity in almost all countries examined worldwide. Infections are uncommon until late childhood; the peak period of incidence appears to be between 10 and 20 years of age.[61] New infections or reinfections are acquired throughout life, however, with the seroprevalence continuing to increase throughout adult life. Serologic studies suggest that infections are more common in men than in women. Transmission is thought to occur from person to person via the respiratory route, much like *Mycoplasma* or respiratory viral infections. Most transmission occurs in schools or households. Well-described outbreaks of *C. pneumoniae* infection have also occurred in settings such as military barracks or school dormitories.[62]

PATHOGENESIS

Little is yet known about the molecular pathogenesis of *C. pneumoniae* infection. However, the organism is thought to initially infect the upper respiratory tract epithelium. In many individuals, long-lived, asymptomatic infection persists at these sites. Recent studies have demonstrated that after infection of

respiratory tract epithelial cells and inflammatory cells, *C. pneumoniae* is likely transmitted throughout the body via macrophages in the bloodstream.[63] There is clear evidence that replication of the organism occurs in vascular endothelium and synovial membranes. As with *C. trachomatis*, the outer membrane protein of *C. pneumoniae* may induce host immune responses that cross-react with human proteins, resulting in autoimmune inflammatory damage to tissues.

DIAGNOSIS

Clinical Manifestations

C. pneumoniae, like other chlamydial species, can produce asymptomatic infection of the respiratory tract and endovascular tissues. *C. pneumoniae* was originally discovered as a cause of upper and lower respiratory tract infection, and the organism may produce a pneumonic illness somewhat like that produced by *Mycoplasma,* although few studies have utilized culture to confirm the presence of *C. pneumoniae* in infected tissues. Characteristically, patients with *C. pneumoniae* pneumonia have prominent antecedent upper respiratory infections and a mild illness with fever, nonproductive cough, and small segmental infiltrates on chest x-ray. Pleuritis and pleural effusion are uncommon. It is likely that *C. pneumoniae* also causes other respiratory infections, including bronchitis, pharyngitis, sinusitis, and otitis media, but this is less extensively studied.

In addition to respiratory diseases, *C. pneumoniae* has recently been associated in serologic studies with a wide range of other conditions, including myocarditis, pericarditis, aseptic meningitis, erythema nodosum, sarcoidosis, asthma, chronic fatigue syndrome, multiple sclerosis, and Alzheimer disease. At present, the validity of these associations remains uncertain; their significance must be demonstrated in further studies.

There is more convincing evidence linking *C. pneumoniae* infection with atherosclerotic vascular disease. More than 30 epidemiologic studies have clearly demonstrated a strong association between serologic evidence for *C. pneumoniae* infection and atherosclerotic disease of the coronary and other arteries.[64] These associations remain after adjustment for potential confounding variables. In addition, *C. pneumoniae* has been identified in atherosclerotic plaques by a variety of techniques, including electron microscopy, DNA hybridization, immunocytochemistry, and PCR.[65] The organism has also been cultured from atherosclerotic plaques, demonstrating the presence of viable *C. pneumoniae* in the vessel wall.[66] Studies in cell-culture systems and in animal models support the hypothesis that *C. pneumoniae* can infect vascular endothelial cells, including smooth muscle cells and macrophages. Animal models also support the contention that *C. pneumoniae* infection of the upper respiratory tract is followed by widespread dissemination of the organism to atheromatous lesions in vessels.[67] In animals, antimicrobial treatment appears to slow the progression of atherosclerotic lesions associated with *C. pneumoniae* infection. Human trials are now ongoing to ascertain whether treatment with antimicrobials can reduce the risk of atherosclerotic heart disease and other vascular diseases associated with *C. pneumoniae* infection.

Laboratory Tests

Confirmation of *C. pneumoniae* respiratory infection is difficult because cell culture techniques are not widely available and in any case are not very sensitive. PCR and DNA probes have been utilized in research laboratories but are not available through most clinical laboratories. Microimmunofluorescence studies showing an increase in antibody to *C. pneumoniae* between acute and convalescent sera provide a specific diagnosis, but this technique is available in only a small number of laboratories. Complement-fixing antibody can also be measured, but that does not distinguish *C. pneumoniae* infection from *C. psittaci* or *C. trachomatis* infection. Accurate diagnosis of *C. pneumoniae* infection likely will await development and implementation of a more accurate and convenient PCR technology.

TREATMENT

There have been no controlled trials to ascertain the best antimicrobial regimen for *C. pneumoniae* respiratory infections. In vitro, *C. pneumoniae* is inhibited by erythromycin, tetracycline, doxycycline, azithromycin, clarithromycin, and some fluoroquinolones, such as levofloxacin. Most experts recommend tetracycline (2 g daily in four divided doses) or doxycycline (100 mg b.i.d.) as initial therapy. Treatment should be given for at least 2 to 3 weeks. Many cases can be managed in the outpatient setting, although severe disease (especially in the elderly) may occasionally require hospitalization and ventilatory support.

The impact of antimicrobial therapy on either treatment or prevention of atherosclerotic cardiovascular disease is unknown. Antibiotics are not currently recommended for this indication.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XIV ANTIMICROBIAL THERAPY

Timothy H. Dellit, m.d.
Harvey B. Simon, m.d., f.a.c.p.
Thomas M. Hooton, m.d., f.a.c.p.

Overview of Antimicrobial Therapy

The essential feature of effective antimicrobial agents is the ability to inhibit the growth of microorganisms at concentrations tolerated by the host. Antimicrobial agents generally target anatomic structures or biosynthetic pathways unique to microorganisms.

The appropriate choice of an antimicrobial for an infection depends on five considerations: (1) the infecting organism and its antimicrobial susceptibilities; (2) the type of infection (e.g., abscess, bacteremia, meningitis, or urinary tract infection); (3) host factors (e.g., neutropenia, immune deficiencies, concurrent illnesses, age, drug allergies, and renal function); (4) factors associated with antimicrobial agents (e.g., dosage, routes of administration, drug interactions, serum levels and tissue penetration, potential toxicities, and cost); and (5) public health considerations. The widespread use of antibiotics has led to selection for highly resistant organisms that subsequently pose a risk for the patient and the community.

identification of the infecting organism

Prompt identification of the causative organism is essential for the selection of appropriate antimicrobial drugs. A Gram stain of infected body fluids can provide early clues to the etiologic agent. Other relatively simple laboratory procedures, such as immunodiagnostic tests, may provide rapid identification of infecting organisms. If it is not possible to perform a Gram stain, initial decisions are based on the clinical features and the usual bacteriology of the illness, pending results of appropriate cultures. Culture results must be interpreted with full recognition of the indigenous flora on various mucosal surfaces and on the skin. Culture identification of the infecting organism and knowledge of the local antibiograms can offer clues to the likely antimicrobial susceptibilities [*see Table 1*]. However, even within a single institution's antibiogram, patterns of susceptibilities are influenced by patient characteristics (e.g., previous antimicrobial exposure) and location within the hospital (e.g., intensive care unit or general ward). National trends in antimicrobial resistance are tracked by the Centers for Disease Control and Prevention (CDC) (http://www.cdc.gov/drugresistance/community).

determination of bacterial susceptibility to specific drugs

Determination of the in vitro susceptibility of isolated bacteria is usually performed to ensure that the empirical antimicrobial regimen is optimal. Timely availability of susceptibility data allows tailoring, when appropriate, of the antimicrobial regimen. However, the susceptibility of certain species (e.g., group A streptococci) to the drug of choice (e.g., penicillin G) has been so uniform that routine in vitro testing is unnecessary. Moreover, in vitro susceptibility data may not accurately predict the therapeutic outcome. For example, *Enterobacter* infections treated with third-generation cephalosporins, such as ceftazidime, may lead to induction of AmpC β-lactamases and clinical failure despite initial in vitro susceptibility.[1] Similarly, *Klebsiella* species and *Escherichia coli* may harbor extended-spectrum β-lactamases (ESBLs) and still appear susceptible to cephalosporins in vitro unless the clinical microbiology laboratory actively screens for their presence. Cephalosporin treatment of such an apparently susceptible organism with an unrecognized ESBL, however, is associated with a high rate of failure.[2]

Disk diffusion is the classic method of testing antimicrobial susceptibility. When necessary, organisms can be tested by tube dilution techniques to determine the minimal inhibitory concentration (MIC) and the minimal bactericidal concentration (MBC) of various antibiotics. Newer techniques include the gradient diffusion method and various nucleic acid–based tests that can detect genes conferring antimicrobial resistance in bacteria.[3]

the site of infection and ancillary therapy

The efficacy of antimicrobial therapy depends on drug delivery to the site of infection. Transport across the blood-brain barrier varies considerably among antibiotics.[4] Intracellular parasites, such as rickettsiae and mycobacteria, require therapy with agents that can reach the intracellular milieu of the organism. Necrotic lesions, such as sequestra in bone or large abscesses, hinder penetration by antimicrobial agents. Drainage, debridement, or both, combined with antimicrobials, are necessary. Antimicrobial therapy for infection in or around a foreign body or prosthesis often is ineffective unless these materials are removed or replaced. Infections behind obstructing lesions, such as pneumonia that occurs behind a blocked bronchus or cholecystitis caused by biliary obstruction, will not respond to antibiotics until the obstruction is relieved.

factors affecting dosage and route of administration

Many antimicrobial agents are absorbed sufficiently well via the oral route to provide effective serum levels in patients with normal gastrointestinal function.[5] For some antimicrobials (e.g., fluoroquinolones, metronidazole, and linezolid), the pharmacokinetics of the oral agents are almost the same as those of the parenteral formulations, and oral therapy, when appropriate, is much less expensive. The enteral absorption of some antimicrobial agents is impeded by food and some medications (e.g., antacids); these antibiotics, such as tetracyclines, should be administered at least 1 hour before meals or several hours after meals. Certain antibiotics, such as neomycin, are essentially nonabsorbable and are used primarily for their effects on bowel flora. Intramuscular administration is used in a small number of conditions (e.g., benzathine penicillin for syphilis or ceftriaxone for gonorrhea), but most antimicrobial agents cannot be given intramuscularly because of local pain or necrosis at the injection site. Intravenous administration must be used in the treatment of major and life-threatening infections such as septic shock, meningitis, and endocarditis. Patients who are clinically stable after initial intravenous treatment may be ready for discharge from the hospital and may be able to receive parenteral antibiotics on an outpatient basis. Newer antimicrobial agents with long half-lives can be administered with improved intravenous catheters and delivery devices in simplified regimens. Alternatively, the enhanced bioavailability of some antimicrobial agents has allowed many patients to complete a course of oral antimicrobial therapy after they are discharged. Such pharmacologic advances have led to substantial economic benefits, enhanced patient comfort, and good therapeutic results with few complications.[6]

Concurrent Illnesses

Patients with immunosuppressive illnesses are vulnerable to opportunistic pathogens. These patients may require broader antimicrobial coverage and combination therapy for ordinary pathogens. The same is true to a lesser extent for patients with chronic debilitating illness. Patients with renal insufficiency or liver disease may be unusually susceptible to direct drug toxicity [*see* Direct Drug Toxicity, *below*].

Many antimicrobial agents (e.g., penicillins, cephalosporins, aminoglycosides, vancomycin, and fluoroquinolones) are excreted primarily by the kidneys. Guidelines for dosage adjustment in patients who have severe renal failure and are undergoing dialysis or peritoneal dialysis are provided elsewhere [*see 10:IX Pharmacologic Approach to Renal Insufficiency, Appendix A*]. Antibiotics with nonrenal metabolism may be preferable in azotemic patients, provided that the infecting organism is susceptible. A number of antibiotics, including nafcillin, piperacillin, doxycycline, metronidazole, and rifampin, are excreted by the liver.

Pregnancy

The administration of antimicrobial agents during pregnancy and in the postpartum period poses several problems. Foremost is the question of safety, both for the mother and for the fetus or neonate. Although most antibiotics cross the placenta and enter maternal milk, the concentrations to which the fetus or neonate is exposed vary widely. Because the immature liver may lack the enzymes required to metabolize certain drugs, pharmacokinetics and toxicities in the fetus are often very different from those in older children and adults. Teratogenicity is a major concern when any drug is administered during pregnancy. Finally, it may be necessary to alter the dosage schedules of drugs that appear to be safe to use during pregnancy. Increases in maternal blood volume, glomerular filtration rate (GFR), and hepatic metabolic activity often reduce the maternal serum levels of antimicrobials by 10% to 50%, especially late in pregnancy and in the early postpartum period. In some women, delayed gastric emptying may reduce the absorption of antibiotics that have been administered orally during pregnancy.

Even though 25% to 40% of women receive antibiotics during pregnancy, data regarding safety and efficacy in this setting are often scarce. Some general recommendations have been proposed, but they are intended only as a guide [*see Table 2*]; in all cases, therapy must be individualized, and both the indications for antibiotics and the possible risks to mother and fetus must be considered. Individual decisions are also required for lactating mothers. Although most antimicrobial agents appear safe for

Table 1 Antimicrobial Susceptibilities of Clinical Isolates at a Representative Hospital

Table 2 Antibiotics in Pregnancy

*Drug**	*Major Toxic Potential*		*Excreted in Mother's Milk*
	Maternal	*Fetal*	
Class B: Presumed safe based on animal studies			
Azithromycin	GI intolerance	None known	Yes (in animals)
Aztreonam	Allergies	None known	Trace
Cephalosporins	Allergies	None known	Trace
Clindamycin	Allergies, colitis	None known	Trace
Ertapenem	Allergies	None known	Trace
Erythromycin base	Allergies, GI intolerance	None known	Yes
Ethambutol	Optic neuritis	None known	Unknown
Penicillins	Allergies	None known	Trace
Meropenem	Allergies	None known	Trace
Metronidazole (avoid in first trimester)	Hypersensitivity, alcohol intolerance, neuropathy	None known (teratogenic in animals but appears safe in human experience)	Yes
Nitrofurantoin	Pulmonary toxicity, hepatotoxicity	None known	Yes
Quinupristin-dalfopristin	Hepatotoxicity, arthralgias	None known	Unknown
Class C: Uncertain safety; no human studies and animal studies show an adverse effect			
Clarithromycin	GI intolerance	Teratogenic in animals at high doses	Yes (in animals)
Chloramphenicol (avoid at term)	Blood dyscrasias	Gray syndrome	Yes
Fluoroquinolones	GI intolerance	Arthropathies in immature animals	Trace
Imipenem	Allergies, nephrotoxicity	None known	Trace
Isoniazid	Allergies, hepatotoxicity	Neuropathy, seizures	Yes
Linezolid	GI intolerance, marrow suppression	None known	Unknown
Rifampin	Hypersensitivity, hepatotoxicity	None known	Yes
Sulfonamides and trimethoprim-sulfamethoxazole (avoid at term)	Allergies, crystalluria	Kernicterus (at term), hemolysis (G6PD deficiency)	Yes
Vancomycin	Nephrotoxicity	None known	Yes
Class D: Unsafe; evidence of risk that may in certain circumstances be justified			
Aminoglycosides	Nephrotoxicity and ototoxicity	Ototoxicity	Yes
Erythromycin estolate	Hepatotoxicity	None known	Yes
Tetracyclines	Hepatotoxicity, renal failure	Tooth discoloration and dysplasia, impaired bone growth	Yes

*Antibiotics are listed according to FDA pregnancy class. No antibiotics are designated class A with safety established in human studies.
G6PD—glucose-6-phosphate dehydrogenase GI—gastrointestinal

breast-fed infants, chloramphenicol, fluoroquinolones, and tetracyclines should be avoided.[7]

Advanced Age

Physiologic changes that occur with age can alter the pharmacokinetics of antimicrobial agents. For example, decreased gastric acidity and intestinal motility can impair drug absorption; increased body fat and decreased serum albumin levels can alter drug distribution; and decreased hepatic blood flow and enzymatic action can delay drug metabolism. Although these factors have not consistently affected antibiotic levels in the elderly, the decrease in GFR that occurs with age can lead to the accumulation of drugs excreted by the kidney. The high therapeutic index of the penicillins and cephalosporins obviates major changes in dosage schedules in elderly patients who have normal serum creatinine levels. However, in the case of aminoglycosides and vancomycin, decreased dosage schedules are often required. Ideally, drug levels should be measured and renal function should be monitored when these agents are given. The dosage of amantadine and rimantadine should also be reduced in elderly patients.

COMPLICATIONS OF ANTIMICROBIAL THERAPY

There are three general types of complications with antimicrobial agents: hypersensitivity reactions (which are not dose related), direct drug toxicity (which usually is dose related and manifests itself in a single organ or, occasionally, in several organs), and microbial superinfection. In rare situations, antimicrobial therapy can lead to a worse clinical outcome. For example, antibiotic therapy has been associated with the development of hemolytic-uremic syndrome in children with gastroenteritis caused by *E. coli* 0157:H7.[8]

Hypersensitivity Reactions

A history of allergies should be taken before antimicrobial therapy is initiated in any patient.[9] More information is available regarding allergies to the penicillins than allergies to other agents, but skin eruptions, drug fever, and even anaphylaxis may be produced by many antibiotics. Allergic reactions occur in 1% to 10% of patients who receive penicillin. Fatal anaphylactic reactions are much less frequent [*see* Allergic Reactions to β-Lactam Antibiotics, *below*].

Direct Drug Toxicity

Although antimicrobial agents can damage virtually all human organ systems, the potential for toxicity varies widely from drug to drug.[10] The principal antibiotics that are directly toxic to the kidney are aminoglycosides and polymyxins. Patients with preexisting renal insufficiency are at increased risk for toxic reactions to various antibiotics, including nephrotoxicity, coagulopathies and other hematologic toxicities, seizures, and ototoxicity and other neurotoxicities.

Hematologic toxicity Chloramphenicol can produce bone marrow suppression, which is usually mild and reversible, but rarely presents as an irreversible fatal aplastic anemia. Chloramphenicol, sulfonamides, nitrofurantoin, and primaquine can cause hemolytic anemia in patients who have deficiencies of erythrocyte glucose-6-phosphate dehydrogenase (G6PD). Hemolytic anemia, thrombocytopenia, and leukopenia that involve an immune mechanism can be caused by penicillins, cephalosporins, tetracyclines, and rifampin, but these reactions are uncommon. Macrolides and trimethoprim-sulfamethoxazole have been associated with agranulocytosis. Trimethoprim can produce anemia, leukopenia, and thrombocytopenia from folate deficiency, which is reversible with folinic acid. Linezolid can also produce myelosuppression, which appears to be reversible with discontinuance of the drug. Patients receiving linezolid for more than 2 weeks are at greatest risk, and the complete blood count with differential should be monitored weekly in such patients. Neutropenia can occur during therapy with penicillins, cephalosporins, or vancomycin. It may be severe but is self-limited, with recovery occurring 1 to 7 days after the antibiotic is withdrawn. Penicillins inhibit platelet aggregation by adenosine diphosphate, which may account for the bleeding that occurs in some patients receiving these antibiotics in high doses. Various cephalosporins may produce coagulopathies by prolonging the prothrombin time. The methylthiotetrazole side chain present in cephalosporins such as cefotetan appears to be responsible.

Ototoxicity Antibiotics may produce a wide range of toxic effects on the central and peripheral nervous systems. Ototoxicity, either vestibular or auditory, can be produced by any of the aminoglycosides; neuromuscular blockade is much less common. Minocycline has occasionally been reported to produce significant vestibular reactions. Vancomycin can cause auditory neurotoxicity. Intravenous administration of penicillin and other β-lactams may produce seizures, especially when administered in very high doses or when given to azotemic patients or to patients with underlying epilepsy.

Neurotoxicity Peripheral neuropathy can occur as a complication of therapy with nitrofurantoin, particularly when renal failure is present. The neuropathy that occurs with isoniazid can be prevented by the daily administration of 50 mg of pyridoxine. Tetracycline may in rare instances produce reversible benign intracranial hypertension with headache and papilledema. Nalidixic acid may also produce intracranial hypertension and seizures in children. Metronidazole can sometimes cause ataxia, encephalopathy, seizures, or peripheral neuropathies. Ofloxacin has been reported to cause seizures, and mania has been attributed to clarithromycin. Optic neuritis, usually manifested by decreased visual acuity and decreased perception of the color green, may occur as a side effect of ethambutol.

Nephrotoxicity The principal antimicrobials that produce adverse effects on the liver are those used in the treatment of tuberculosis: isoniazid, rifampin, aminosalicylic acid, and pyrazinamide. Trovafloxacin was restricted for use in seriously ill patients because of hepatotoxicity, but other fluoroquinolones have not been implicated. The tetracyclines can occasionally cause fatty liver with hepatotoxicity; this is most likely to occur in patients receiving 2 g or more daily by the intravenous route. Patients receiving high-dose β-lactam antibiotics may develop hepatitis or cholestasis, presumably as a result of hypersensitivity reactions. Nitrofurantoin may cause chronic active hepatitis in some patients. Erythromycins and sulfonamides have been associated with acute hepatitis.

GI complications GI reactions to antibiotics result either from direct irritation by the drug, the occurrence of which is usually dose related, or from bacterial overgrowth.[11] Irritative GI side effects are usually produced when antibiotics are administered orally rather than parenterally. The predominant site of irritation varies from drug to drug; for example, erythromycin more commonly produces gastric irritation with epigastric distress and nausea, whereas tetracyclines may produce diarrhea and upper GI symptoms. Some qualitative and quantitative changes in the intestinal flora occur after antibiotic administration. These intestinal changes may contribute to flatulence and other lower GI symptoms, including antibiotic-associated diarrhea, which are quite common when broad-spectrum antibiotics are administered orally. An important subset of antibiotic-associated diarrhea involves the selective overgrowth of *Clostridium difficile* and resultant pseudomembranous colitis [*see 7:V Anaerobic Infections and 4:III Diarrheal Diseases*].

Other toxicities Antibiotics may cause various other toxicities. Erythromycin and other macrolides can cause prolongation of the QTc interval and polymorphic ventricular tachycardia. In rare instances, this toxicity occurs in the absence of predisposing factors, but it is more likely to occur in patients with significant heart disease and in patients taking terfenadine, astemizole, or cisapride. Several fluoroquinolones, particularly grepafloxacin, sparfloxacin, and gatifloxacin, can have similar effects on cardiac conduction.[12] All fluoroquinolones can cause tendinitis. Trimethoprim-sulfamethoxazole can cause hyperkalemia, particularly in azotemic patients. Sulfonamides, fluoroquinolones, and tetracyclines can produce photosensitivity.[13]

Microbial Superinfection

Antimicrobial therapy reduces the number of susceptible organisms from the normal flora of the skin, oropharynx, genitourinary tract, and gastrointestinal tract and exerts selective pressures that favor survival of drug-resistant organisms. Such resistant organisms can occasionally establish a superinfection (i.e., a new infection caused by a different pathogen from the one being treated) either at the site of the original infection or at remote sites.

PUBLIC HEALTH CONSIDERATIONS

Antimicrobial Resistance

The extensive use of antimicrobial agents, especially in intensive care units[14] and other health care facilities, strongly favors the selection of resistant microbial species, particularly bacterial strains harboring plasmids that confer transmissible resistance.[15-17] The widespread use of antibiotics in animal husbandry and agri-

culture compounds the problem; roughly 50% of the 25,000 tons of antibiotics that are sold annually in the United States are used in agriculture and aquaculture.[18] Infections from highly resistant strains of *Enterococcus, Streptococcus pneumoniae, Staphylococcus, Neisseria gonorrhoeae, Salmonella, Serratia, Klebsiella, Acinetobacter, Enterobacter, Pseudomonas,* and *Mycobacterium* have become important problems. Infections from resistant strains can spread rapidly—first within an institution, then throughout a community, and eventually even globally.[19] Although antimicrobial resistance is a worldwide problem, control depends on local measures, beginning with the judicious prescription of antibiotics by individual practitioners in combination with sound infection control practices. Through the Campaign to Prevent Antimicrobial Resistance in Healthcare Settings (http://www.cdc.gov/drugresistance/healthcare), the CDC offers resources for infection control. There is national concern that the relatively small number of new antimicrobial agents in development will not keep pace with the emergence of drug resistance.

Specific Antimicrobial Agents

The simultaneous use of multiple antibiotics in a shotgun fashion should be avoided because of the problems of drug toxicity and hypersensitivity reactions, microbial superinfections, and antagonisms between certain agents. Most bacterial infections can be treated satisfactorily with a single antimicrobial agent. There are a limited number of situations, however, in which the simultaneous administration of different antimicrobial agents is warranted: (1) when synergism occurs between two antimicrobials against a specific infecting agent; (2) to prevent the emergence of resistance to one or more drugs; (3) for treatment of polymicrobial infections for which one antibiotic is not sufficient; and (4) for initial empirical treatment of life-threatening infections before isolation of the etiologic agent.

Although the choice of antimicrobial drugs must always be individualized, there are useful guidelines that can be followed [*see Table 3*].[20,21]

β-LACTAM ANTIBIOTICS

Penicillins

The penicillins are bactericidal antibiotics that impair synthesis of the bacterial cell wall peptidoglycan by attaching to penicillin-binding proteins located in the cell membrane. These enzymes are responsible for linking individual elements of the bacterial cell wall together. Penicillins and other β-lactam antibiotics have different affinities for the various penicillin-binding proteins.[22]

The penicillins may be classified into subgroups on the basis of their structure, β-lactamase susceptibility, and spectrum of action. Dosages of these agents vary according to the type and severity of infection. The penicillins are generally well tolerated. Hypersensitivity and GI reactions are the most common side effects, though granulocytopenia, hemolytic anemia, bleeding, interstitial nephritis, hepatitis, and seizures may occur. The adverse effects of penicillin are generally shared by all its derivatives. However, broad-spectrum penicillins are more likely to cause pseudomembranous colitis, and penicillins with α-carboxyl substitutions, such as ticarcillin, are more likely to impair platelet function. Patients allergic to one penicillin compound are likely to be allergic to other penicillins.

Penicillin G and penicillin V Penicillin G, the first antibiotic to be used for systemic infections, is still the drug of choice for various infections. Resistance to penicillin has not been observed in group A streptococci and *Treponema pallidum*, and penicillin G is highly effective in subacute bacterial endocarditis caused by susceptible bacteria. Penicillin V (phenoxymethyl penicillin) has the same spectrum of activity as penicillin G but is more acid-stable and is thus better absorbed from the GI tract. The narrow spectra of penicillin G and V, however, limit their use to a small number of indications, and resistance to these agents is increasing, particularly with *S. pneumoniae* strains. Although all forms of penicillin introduced since the release of penicillin G are prescribed by weight, penicillin G is still prescribed for parenteral administration by unitage. For interconversion, 1 mg of penicillin G equals approximately 1,600 units. Procaine penicillin G and benzathine penicillin G are slowly absorbed, allowing dosing every 12 to 24 hours and weekly, respectively, for treatment of highly susceptible pathogens.

Penicillinase-resistant penicillins Penicillinase-resistant penicillins were developed for their activity against β-lactamase–producing *S. aureus*. Nafcillin and oxacillin are usually administered parenterally. Oxacillin is also available in an oral formulation, but cloxacillin and, especially, dicloxacillin are preferred for oral administration because of superior GI absorption. The emergence of methicillin-resistant *S. aureus* (MRSA) continues to be a major public health issue.

Penicillinase-susceptible broad-spectrum penicillins Ampicillin has a broader spectrum of activity than penicillin G. Its spectrum encompasses not only most pneumococci, meningococci, gonococci, and various streptococci but also some gram-negative bacilli. Like penicillin G, however, ampicillin is readily cleaved by β-lactamase and is useless in the treatment of infections caused by *S. aureus* or other organisms producing this enzyme. Plasmids conferring ampicillin resistance have appeared in *S. typhi*, *Haemophilus influenzae,* and *N. gonorrhoeae*. Increasing resistance has appeared in strains of *E. coli, S. pneumoniae, N. gonorrhea,* and nontyphoidal *Salmonella*.

Amoxicillin has a spectrum of activity that is identical to that of ampicillin, but amoxicillin is more efficiently absorbed from the GI tract, and effective concentrations are present in the circulation for twice as long.

Extended-spectrum carboxypenicillins The change from an amino to a carboxyl substituent on the side chain converts ampicillin to carbenicillin. Carbenicillin has an extended spectrum of activity against gram-negative bacilli, including *Pseudomonas, Proteus* species other than *P. mirabilis*, and some strains of *Enterobacte*r. β-Lactamase–producing *S. aureus* is resistant to carboxypenicillins. The indanyl carbenicillin ester is acid stable and is suitable for oral administration in the treatment of urinary tract infections caused by susceptible gram-negative bacilli, including *Pseudomonas,* but serum levels are too low for use in other infections. Ticarcillin is the other carboxypenicillin; it is administered intravenously to treat serious infections caused by susceptible organisms. Ticarcillin has an extended spectrum of activity against gram-negative bacilli, including *P. aeruginosa*, but it is ineffective against *Klebsiella*. Because of the widespread use of these antibiotics, however, many strains of *P. aeruginosa* are now resistant to the carboxypenicillins.[23]

Extended-spectrum ureidopenicillins Like the carboxypenicillins, the ureidopenicillins (i.e., azlocillin, mezlocillin, and

Table 3 Antimicrobial Drugs of Choice for Various Infections in Adults[20]

	Causative Organism	Drug of Choice*	Alternative Drugs*
Gram-Positive Cocci	*Staphylococcus aureus*		
	Methicillin-susceptible	Penicillinase-resistant penicillin[1]	A cephalosporin,[2,3] clindamycin, vancomycin, amoxicillin-clavulanate, ampicillin-sulbactam, ticarcillin-clavulanate, piperacillin-tazobactam, a carbapenem,[4] a fluoroquinolone[5]
	Methicillin-resistant[6]	Vancomycin, with or without rifampin or gentamicin	Linezolid; quinupristin-dalfopristin; daptomycin; clindamycin[7]; trimethoprim-sulfamethoxazole (TMP-SMX), minocycline,[8] or a fluoroquinolone[5] with or without rifampin
	Coagulase-negative staphylococci[9]	Vancomycin, with or without rifampin or gentamicin	Linezolid; quinupristin-dalfopristin; daptomycin; a fluoroquinolone[5] with or without rifampin
	Anaerobic streptococcus (*Peptostreptococcus*)	Penicillin G[10]	Clindamycin, a cephalosporin,[2,3] vancomycin
	Streptococcus bovis	Penicillin G[10]	A cephalosporin,[2,3] vancomycin
	Groups A, C, and G streptococci	Penicillin G[10] or penicillin V	A cephalosporin,[2,3] a macrolide,[11] clindamycin, vancomycin
	Group B streptococcus	Penicillin G,[10] ampicillin, or amoxicillin	A cephalosporin,[2,3] macrolide,[11] vancomycin
	S. pneumoniae		
	Penicillin susceptible	Penicillin G[10] or penicillin V, ampicillin, or amoxicillin	A cephalosporin,[2,3] a macrolide,[11] a fluoroquinolone,[5] a carbapenem,[4] vancomycin
	Non–penicillin susceptible	Vancomycin, ceftriaxone or cefotaxime, a fluoroquinolone,[5] a carbapenem[4]	Linezolid, quinupristin-dalfopristin
	Viridans streptococci	Penicillin G,[10] with or without gentamicin	A cephalosporin,[2,3] vancomycin
	Enterococcus		
	Penicillin-susceptible endocarditis or other serious infection	Penicillin G[10] or ampicillin + gentamicin[12] or streptomycin	Vancomycin with gentamicin[12] or streptomycin
	Uncomplicated urinary tract infection	Ampicillin or amoxicillin	Nitrofurantoin, a fluoroquinolone,[5] fosfomycin
	Vancomycin-resistant	Linezolid or quinupristin-dalfopristin	Chloramphenicol, doxycycline[8]
Gram-Positive Bacilli	*Bacillus anthracis*	Penicillin G[10]	Ciprofloxacin,[5] a tetracycline,[8] erythromycin
	B. cereus, B. subtilis	Vancomycin	Clindamycin, a carbapenem[4]
	Clostridium difficile	Metronidazole[13]	Vancomycin (oral)
	C. perfringens	Penicillin G[10] or clindamycin	Metronidazole,[13] a carbapenem,[4] chloramphenicol
	C. tetani	Metronidazole[13]	Penicillin G,[10] a tetracycline[8]
	Corynebacterium diphtheriae	Erythromycin	Penicillin G[10]
	Corynebacterium, JK group	Vancomycin	Penicillin G[10] with gentamicin, erythromycin
	Erysipelothrix rhusiopathiae	Penicillin G[10]	A cephalosporin,[2,3] a fluoroquinolone[5]
	Listeria monocytogenes	Ampicillin, with or without gentamicin	TMP-SMX
	Propionibacterium	Penicillin G[10]	Clindamycin
	Rhodococcus equi	Imipenem,[4] aminoglycosides, erythromycin, or vancomycin, with or without rifampin	Ciprofloxacin,[5] TMP-SMX, tetracycline,[8] clindamycin
Gram-Negative Cocci	*Moraxella catarrhalis*	Second- or third-generation cephalosporin[2,3] or a fluoroquinolone[5]	TMP-SMX, amoxicillin-clavulanate, a macrolide, a tetracycline[8]
	Neisseria gonorrhoeae	Ceftriaxone, cefpodoxime, or a fluoroquinolone[5]	Spectinomycin
	N. meningitidis		
	Meningitis, bacteremia	Penicillin G[10]	Ceftriaxone, cefotaxime, TMP-SMX, a fluoroquinolone,[5] chloramphenicol
	Carrier state	Rifampin	Minocycline,[8] ciprofloxacin[5]
Enteric Gram-Negative Bacilli	*Bacteroides fragilis*	Metronidazole	Clindamycin, cefoxitin, cefotetan, cefmetazole, a carbapenem,[4] ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, piperacillin-tazobactam, chloramphenicol
	Campylobacter jejuni	Erythromycin or azithromycin	A fluoroquinolone,[5] a tetracycline,[8] gentamicin
	Citrobacter	A carbapenem[4]	A fluoroquinolone,[5] amikacin, TMP-SMX, a third- or fourth-generation cephalosporin[2,3]
	Enterobacter	A carbapenem[4]	A third- or fourth-generation cephalosporin,[2,3] a fluoroquinolone,[5] ticarcillin-clavulanate, piperacillin-tazobactam, aztreonam, gentamicin
	Escherichia coli		
	Serious infection	A third- or fourth-generation cephalosporin[2,3]	A carbapenem,[4] ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, piperacillin-tazobactam, a fluoroquinolone,[5] an aminoglycoside, aztreonam
	Uncomplicated cystitis	TMP-SMX or a fluoroquinolone[5]	Ampicillin or amoxicillin
	Helicobacter pylori	Omeprazole + amoxicillin + clarithromycin; or tetracycline[8] + metronidazole + bismuth subsalicylate	Tetracycline[8] + clarithromycin + bismuth subsalicylate; amoxicillin + metronidazole[13] + bismuth subsalicylate; amoxicillin + clarithromycin

Note: all superscript numbers refer to footnotes that follow table.

Table 3 (*continued*)

	Causative Organism	Drug of Choice*	Alternative Drugs*
Enteric Gram-Negative Bacilli (continued)	*Klebsiella*	A third- or fourth-generation cephalosporin[2,3]	A carbapenem,[4] ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, piperacillin-tazobactam, a fluoroquinolone,[5] TMP-SMX, an aminoglycoside, aztreonam
	Proteus mirabilis	Ampicillin or amoxicillin	A cephalosporin,[2,3] a fluoroquinolone,[5] TMP-SMX, a carboxypenicillin or ureidopenicillin,[14] a carbapenem,[4] an aminoglycoside, aztreonam
	Non-*mirabilis*, including *P. vulgaris*, *Morganella morganii*, and *Providencia rettgeri*	A third- or fourth-generation cephalosporin[2,3]	A carbapenem,[4] ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, piperacillin-tazobactam, a fluoroquinolone,[5] an aminoglycoside, aztreonam
	Providencia stuartii	A third- or fourth-generation cephalosporin[2,3]	A carbapenem,[4] ticarcillin-clavulanate, piperacillin-tazobactam, a fluoroquinolone,[5] TMP-SMX, an aminoglycoside, aztreonam
	Salmonella typhi	Ceftriaxone or a fluoroquinolone[5]	Chloramphenicol, TMP-SMX, ampicillin
	Other *Salmonella* species	Ceftriaxone or cefotaxime or a fluoroquinolone[5]	Amoxicillin, TMP-SMX, chloramphenicol
	Serratia	A carbapenem[4]	A third- or fourth-generation cephalosporin,[2,3] ticarcillin-clavulanate, piperacillin-tazobactam, a fluoroquinolone,[5] TMP-SMX, an aminoglycoside, aztreonam
	Shigella	A fluoroquinolone[5]	TMP-SMX, ampicillin, ceftriaxone, azithromycin
	Yersinia enterocolitica	TMP-SMX	A fluoroquinolone,[5] cefotaxime, ceftriaxone, an aminoglycoside
Other Gram-Negative Bacilli	*Acinetobacter*	Imipenem or meropenem[4]	An aminoglycoside, sulbactam (available as ampicillin-sulbactam)
	Aeromonas hydrophila	TMP-SMX	A fluoroquinolone,[5] an aminoglycoside, a carbapenem[4]
	Bartonella henselae (cat-scratch disease)	Azithromycin	Ciprofloxacin,[5] TMP-SMX, gentamicin, rifampin, erythromycin
	B. henselae (bacillary angiomatosis)	Erythromycin	Doxycycline,[8] azithromycin
	Bordetella pertussis (whooping cough)	Erythromycin	Azithromycin or clarithromycin, TMP-SMX
	Brucella	A tetracycline,[8] with rifampin	A tetracycline[8] with gentamicin or streptomycin; chloramphenicol, with or without streptomycin; TMP-SMX with or without gentamicin; ciprofloxacin[5] with rifampin
	Burkholderia cepacia	TMP-SMX	Imipenem or meropenem,[4] ceftazidime, chloramphenicol
	B. pseudomallei (melioidosis)	Imipenem or meropenem[4]	Ceftazidime, amoxicillin-clavulanate, chloramphenicol + doxycycline[8] + TMP-SMX
	Calymmatobacterium granulomatis (granuloma inguinale)	TMP-SMX	A tetracycline[8] or fluoroquinolone[5] with or without gentamicin
	Capnocytophaga canimorsus	Penicillin G[10]	Cefotaxime or ceftriaxone, a carbapenem,[4] a fluoroquinolone,[5] clindamycin
	Eikenella corrodens	Ampicillin	A macrolide, a tetracycline,[8] amoxicillin-clavulanate, ampicillin-sulbactam, ceftriaxone
	Francisella tularensis (tularemia)	Streptomycin	Gentamicin, a tetracycline,[8] chloramphenicol, ciprofloxacin[5]
	Fusobacterium	Penicillin G[10]	Metronidazole, clindamycin, cefoxitin, chloramphenicol
	Gardnerella vaginalis (bacterial vaginosis)	Metronidazole (oral)[13]	Intravaginal metronidazole, intravaginal or oral clindamycin
	Haemophilus ducreyi (chancroid)	Azithromycin or ceftriaxone	Ciprofloxacin[5] or erythromycin
	H. influenzae Bronchitis, otitis media	TMP-SMX	Ampicillin or amoxicillin, amoxicillin-clavulanate, a macrolide, a fluoroquinolone,[5] cefuroxime, cefotaxime, ceftriaxone
	Meningitis, epiglottitis, life-threatening infections	Cefotaxime or ceftriaxone	Chloramphenicol, meropenem
	Legionella species	Fluoroquinolone[5] or azithromycin, with or without rifampin	Erythromycin, doxycycline,[8] TMP-SMX
	Leptotricia buccalis	Penicillin G[10]	A tetracycline,[8] clindamycin, erythromycin
	Pasteurella multocida	Penicillin G[10]	A tetracycline,[8] a cephalosporin,[2,3] amoxicillin-clavulanate, ampicillin-sulbactam
	Pseudomonas aeruginosa Urinary tract infections	Ciprofloxacin[5]	Levofloxacin,[5] a carboxypenicillin or ureidopenicillin,[14] ceftazidime, cefepime, imipenem or meropenem,[4] an aminoglycoside, aztreonam
	Other infections	Ceftazidime, cefepime, imipenem or meropenem,[4] a carboxypenicillin or ureidopenicillin[14] with or without tobramycin or gentamicin	Ciprofloxacin[5], amikacin
	Stenotrophomonas maltophila	TMP-SMX	Minocycline,[8] ticarcillin-clavulanate, a fluoroquinolone[5]
	Streptobacillus moniliformis (rat-bite fever)	Penicillin G[10]	A tetracycline,[8] streptomycin
	Vibrio cholerae	A tetracycline[8]	A fluoroquinolone,[5] TMP-SMX
	V. vulnificus	A tetracycline[8]	Cefotaxime
	Yersinia pestis (plague)	Streptomycin with or without a tetracycline[8]	A tetracycline,[8] chloramphenicol, gentamicin, TMP-SMX

Note: all superscript numbers refer to footnotes that follow table.

(*continued*)

Table 3 (*continued*)

	Causative Organism	*Drug of Choice**	*Alternative Drugs**
Acid-Fast Bacilli	*Mycobacterium avium* complex	Clarithromycin or azithromycin with ethambutol, with or without rifabutin	Amikacin, ciprofloxacin[5]
	Mycobacterium fortuitum/chelonae complex	Amikacin with clarithromycin	Cefoxitin, rifampin, a sulfonamide, doxycycline,[8] ethambutol, linezolid
	Mycobacterium kansasii	Isoniazid with rifampin, with or without ethambutol or streptomycin	Clarithromycin or azithromycin, ethionamide, cycloserine
	Mycobacterium leprae	Dapsone with rifampin, with or without clofazimine	Minocycline,[8] ofloxacin or sparfloxacin, clarithromycin
	Mycobacterium marinum	Minocycline[8]	TMP-SMX, rifampin, clarithromycin, doxycycline,[8] ethambutol
	Mycobacterium tuberculosis	Isoniazid with rifampin, pyrazinamide, and ethambutol	Streptomycin, a fluoroquinolone,[5] cycloserine, ethionamide, para-aminosalicylic acid, capreomycin, kanamycin, amikacin
Actino-mycetes	*Actinomyces israelii*	Penicillin G[10]	A tetracycline,[8] erythromycin, clindamycin
	Nocardia	TMP-SMX	Minocycline,[8] sulfisoxazole, imipenem or meropenem,[4] amikacin, cycloserine, linezolid
Chlamydia	*Chlamydia psittaci* (psittacosis)	A tetracycline[8]	Chloramphenicol
	C. trachomatis		
	Inclusion conjunctivitis	Erythromycin	A sulfonamide (topical plus oral)
	Lymphogranuloma venereum	A tetracycline[8]	Erythromycin
	Pneumonia	Erythromycin	A sulfonamide
	Trachoma	Azithromycin	A tetracycline[8] (topical plus oral), a sulfonamide (topical plus oral)
	Urethritis or pelvic inflammatory disease	Doxycycline[8] or azithromycin	Erythromycin, ofloxacin, amoxicillin
	C. pneumoniae	A macrolide or tetracycline[8]	A fluoroquinolone[5]
Ehrlichia	*Ehrlichia chaffeensis*	Doxycycline[8]	Chloramphenicol
	E. ewingii	Doxycycline[8]	—
	E. phagocytophila	Doxycycline[8]	Rifampin
Myco-plasma	*Mycoplasma pneumoniae*	A macrolide or tetracycline[8]	A fluoroquinolone[5]
	Ureaplasma urealyticum	Erythromycin	A tetracycline,[8] clarithromycin, azithromycin, ofloxacin
Rickettsia	Various rickettsial organisms Rocky Mountain spotted fever, epidemic and endemic (murine) typhus, rickettsial pox, Q fever, scrub typhus	Doxycycline[8]	Chloramphenicol, a fluoroquinolone,[5] rifampin
Spirochetes	*Borrelia burgdorferi* (Lyme disease)	Doxycycline,[8] amoxicillin, ceftriaxone	Penicillin G,[10] azithromycin, clarithromycin
	B. recurrentis (relapsing fever)	A tetracycline[8]	Penicillin G[10]
	Leptospira	Penicillin G[10]	A tetracycline[8]
	Treponema pallidum (syphilis)	Penicillin G[10]	A tetracycline,[8] ceftriaxone

*These are general recommendations; susceptibility data should be used to guide therapy. Empirical therapy should be based on knowledge of local susceptibility patterns when possible.

Note: all superscript numbers in table refer to footnotes below.

1. For severe infections, I.V. nafcillin or oxacillin is preferred. For mild infections, oral cloxacillin or dicloxacillin may be used. High doses of penicillin G, ampicillin, amoxicillin, carbenicillin, or ticarcillin do not overcome the clinical resistance of penicillinase-producing staphylococci to these drugs. The combinations of ampicillin with sulbactam, amoxicillin with clavulanate, ticarcillin with clavulanate, and piperacillin with tazobactam have activity against β-lactamase–producing *S. aureus*.

2. Cephalosporins are sometimes used as alternatives to penicillin in patients with suspected penicillin allergy but should not be used in patients with severe hypersensitivity reactions such as anaphylaxis or urticaria.

3. For treatment of staphylococcal or nonenterococcal streptococcal infections, a first-generation cephalosporin such as cefazolin (I.V.) or cephalexin (p.o.) may be used. Cefoxitin, cefotetan, and cefmetazole have increased anaerobic activity, including against *B. fragilis*. Ceftazidime and cefepime are active against *P. aeruginosa*. (See text for further details.)

4. Imipenem tends to be more active against gram-positive cocci, whereas meropenem is more active against gram-negative bacilli. Ertapenem has decreased activity against *Acinetobacter*, *Pseudomona*s, and *E. faecalis*. None of the carbapenems are active against methicillin-resistant *S. aureus*, *E. faecium*, or *Stenotrophomonas*.

5. Levofloxacin, gatifloxacin, gemifloxacin, and moxifloxacin have increased activity against *S. pneumoniae*, including penicillin-resistant strains. They also have good activity against *S. aureus*, but resistance among methicillin-resistant strains is common. Ciprofloxacin is most active against *Pseudomonas*. For *M. tuberculosis*, levofloxacin, ofloxacin, ciprofloxacin, gatifloxacin, or moxifloxacin could be used. Fluoroquinolones are not recommended for children or pregnant women. (See text for further details.)

6. These strains are also resistant to other β-lactams, including cephalosporins and carbapenems.

7. Isolate should be examined for inducible resistance to clindamycin before this agent is used.

8. Tetracycline should not be used in pregnant women or children younger than 9 years.

9. In vitro susceptibility testing with cephalosporins or penicillins may be misleading because of heteroresistance and because these antibiotics may be bacteriostatic only. For serious infections, vancomycin is preferred.

10. Crystalline penicillin G is administered parenterally for serious infections. For less severe infections caused by pneumococci, group A streptococci, or T. *pallidum*, procaine penicillin is administered I.M. once or twice daily. For mild infections caused by streptococci and pneumococci, oral penicillin V is preferable to oral penicillin G. Benzathine penicillin G is given I.M. (once monthly for the prophylaxis of rheumatic fever, a single injection for the treatment of group A streptococcal pharyngitis) when patient's compliance with oral medication is questionable and for treatment of syphilis, in one to three doses at weekly intervals, depending on the stage of the disease. Penicillin-resistance is increasing in *S. pneumoniae* strains.

11. Macrolide resistance is increasing among strains of *S. pneumoniae* and group A streptococci.

12. Various aminoglycosides have been used in synergistic combination with penicillin or vancomycin. Because of the appearance of enterococcal strains resistant to the synergistic action with streptomycin (but not gentamicin), gentamicin is preferred for use in the combination.

13. Antibiotics may be administered orally for antibiotic-associated pseudomembranous enterocolitis. Vancomycin and metronidazole are equally effective, but metronidazole is much less expensive.

14. The carboxypenicillins are carbenicillin and ticarcillin; the ureidopenicillins are mezlocillin, azlocillin, and piperacillin. When one of these drugs is used for a severe infection, an aminoglycoside is often recommended, as well.

piperacillin) are ampicillin derivatives. They are active against most organisms that are susceptible to ampicillin, including many pneumococci, most streptococci, *N. meningitidis,* and most *E. coli* and *P. mirabilis* strains. They have extended activity against *P. aeruginosa,* although the prevalence of resistance is rising. β-Lactamase–producing staphylococci and *H. influenzae* are resistant to the ureidopenicillins.

The carboxypenicillins and ureidopenicillins also differ from ampicillin in their increased effectiveness against many anaerobes, including about 50% of *Bacteroides fragilis* strains. However, the major role of these drugs depends on their spectrum of activity against resistant gram-negative bacilli, which is somewhat broader for the ureidopenicillins than it is for the carboxypenicillins. Despite these in vitro differences, clinical studies have not demonstrated that the ureidopenicillins are superior to the carboxypenicillins in treating organisms susceptible to both groups. The newer cephalosporins and carbapenems, however, appear preferable for treating infections caused by resistant *Klebsiella* and *Serratia* strains. Because of the concern about emerging resistance, these drugs should generally be used with an aminoglycoside to treat seriously ill patients, especially patients with neutropenia.

The serum levels, tissue distribution, half-life, and recommended dosage ranges of piperacillin, mezlocillin, and azlocillin are similar to those of ticarcillin. Unlike ticarcillin and carbenicillin, which are solely excreted by the kidneys, the ureidopenicillins are excreted in the bile and the urine and do not accumulate in patients with renal failure. The toxicities of these drugs are similar, except that the ureidopenicillins are less likely to impair platelet function or cause hypokalemia.

Penicillin–β-lactamase inhibitor combinations The major mechanism of resistance to the penicillins is bacterial production of β-lactamase enzymes that hydrolyze the β-lactam ring, rendering the molecule inactive. Clavulanate, sulbactam, and tazobactam are β-lactam compounds that have little intrinsic antibacterial activity except for sulbactam in *A. baumannii* infections.[24] They do, however, bind irreversibly to the β-lactamase enzymes that are produced by many bacteria, thus inactivating these enzymes and rendering the organisms susceptible to β-lactamase–susceptible penicillins.

Clavulanate is combined with amoxicillin in an oral formulation. Ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam are parenteral formulations. The combinations are active against ampicillin-susceptible organisms and various ampicillin-resistant organisms, including β-lactamase–producing strains of *Moraxella catarrhalis, H. influenzae, E. coli, K. pneumoniae,* some *Proteus* species, and *S. aureus* (except methicillin-resistant strains). The combinations are also active against many anaerobes, including *B. fragilis*. However, *P. aeruginosa* and many strains of *Serratia* and *Enterobacter* are resistant to amoxicillin-clavulanate and ampicillin-sulbactam. These agents are not active against bacteria resistant to the penicillin derivative when the resistance is not mediated by β-lactamase production. For example, penicillin-resistant strains of *S. pneumoniae* have altered penicillin-binding proteins and are not affected by the addition of a β-lactamase inhibitor.

Amoxicillin-clavulanate therapy has been used successfully to treat upper and lower respiratory tract infections, urinary tract infections, and human and animal bites. Twice-daily administration is effective. The ampicillin-sulbactam combination has been used successfully to treat gynecologic and intra-abdominal infections, as well as infections of the upper and lower respiratory tracts, urinary tract, skin and soft tissues, and bones and joints. Ticarcillin-clavulanate has been successful in the treatment of pulmonary, urinary tract, bone, soft tissue, and bloodstream infections. Piperacillin-tazobactam is very similar to ticarcillin-clavulanate in its very broad spectrum of activity, pharmacokinetics, toxicities, and expense. The recommended dosage of 3 g of piperacillin and 375 mg of tazobactam every 6 hours for adults with normal renal function is lower than the recommended dosage for piperacillin alone (18 g/day) and may not be sufficient for some serious infections caused by *P. aeruginosa*. An increased dose of 4 g of piperacillin and 500 mg of tazobactam is approved for nosocomial pneumonia when there is concern for infection from *Pseudomonas* species.

Cephalosporins

The cephalosporins and closely related cephamycins (e.g., cefoxitin and cefotetan) comprise a large family of β-lactam antibiotics. Like the penicillins, the cephalosporins are bactericidal antibiotics that inhibit bacterial cell wall synthesis and have a low intrinsic toxicity. The adverse effects of the cephalosporins are mainly hypersensitivity reactions, local pain (with intramuscular use), and thrombophlebitis (with intravenous use). Less common toxicities include GI symptoms, elevated liver enzyme levels, and renal impairment. Third-generation and fourth-generation cephalosporins may cause seizures, including nonconvulsive status epilepticus, in patients with renal failure.[25] Pseudomembranous colitis may also develop. Because the cephalosporins share immunologic cross-reactivity, patients who are allergic to one cephalosporin are likely to be allergic to others. There is also a possibility of cross-reactivity in penicillin-allergic patients.[26]

The cephalosporins are grouped into generations on the basis of their antibacterial spectrum[27] [*see Table 4*]. In general, activity against gram-positive cocci diminishes from the first generation to the third generation, whereas the spectrum of activity against gram-negative organisms increases. The single fourth-generation agent, cefepime, has an extended spectrum of activity against both gram-positive and gram-negative organisms. Agents in each group exhibit pharmacologic differences in serum levels and half-lives, leading to substantial variation in dosing. Most cephalosporins are excreted primarily by the kidneys and require dose reduction in the presence of renal failure, with the notable exceptions of ceftriaxone and cefoperazone [*see 10:IX Pharmacologic Approach to Renal Insufficiency, Appendix A*]. Cephalosporins cross the placenta and penetrate the pericardium and joints. The third- and fourth-generation cephalosporins have good cerebrospinal fluid penetration and are effective in treating meningitis, whereas none of the first-generation drugs and only one of the second-generation agents (cefuroxime) are effective in treating meningitis.

First-generation cephalosporins The first-generation cephalosporins are active against many gram-positive bacteria, including penicillin-susceptible pneumococci, penicillinase-producing *S. aureus,* and most streptococci. However, they are ineffective against MRSA, coagulase-negative staphylococci, penicillin-resistant pneumococci, enterococci, and *Listeria*. Although the first-generation cephalosporins are active against many strains of *E. coli, K. pneumoniae,* and *P. mirabilis,* they are ineffective against many other gram-negative species because these organisms produce β-lactamases.

Table 4 Properties of Cephalosporin Antibiotics

	Specific Agent	Trade Names	Comments*
First Generation	Oral		
	Cefadroxil	Duricef, Ultracef	Longer half-life
	Cephalexin	Keflex	Most experience with this agent
	Cephradine	Anspor, Velosef	Properties are similar to those of cephalexin
	Parenteral		
	Cefazolin	Ancef, Kefzol	Longer half-life; well tolerated when given I.M.
	Cephapirin	Cefadyl	Properties are similar to those of other first-generation cephalosporins
	Cephradine	Anspor, Velosef	Properties are similar to those of other first-generation cephalosporins
Second Generation	Oral		
	Cefaclor	Ceclor	Moderately active against *Haemophilus influenzae*
	Cefuroxime axetil	Ceftin	Active against *H. influenzae*
	Cefprozil	Cefzil	Active against *H. influenzae*
	Cefditoren pivoxil	Spectracef	Active against *H. influenzae*
	Loracarbef	Lorabid	A carbacephem with properties and spectrum similar to cefuroxime
	Parenteral		
	Cefamandole	Mandol	Active against *H. influenzae*; may cause bleeding
	Cefmetazole	Zefazone	Spectrum and half-life similar to cefoxitin; may cause bleeding
	Cefonicid	Monocid	Spectrum similar to that of cefamandole
	Ceforanide	Precef	Spectrum similar to that of cefamandole
	Cefotetan	Cefotan	Spectrum similar to that of cefoxitin; longer half-life than cefoxitin; may cause bleeding
	Cefoxitin	Mefoxin	Active against anaerobes, including *Bacteroides fragilis*
	Cefuroxime	Zinacef, Kefurox	Active against *H. influenzae*; only second-generation drug approved for meningitis (selected pathogens)
Third and Fourth Generation	Oral		
	Cefixime	Suprax	More active against gram-negative bacilli, gonococci, *Moraxella catarrhalis*, and *H. influenzae* than other oral cephalosporins but much less active against *Staphylococcus aureus*; not active against *Pseudomonas*; currently not available in the United States
	Cefdinir	Omnicef	Similar to cefpodoxime
	Cefpodoxime	Vantin	Similar to cefixime but more active against *S. aureus*
	Ceftibuten	Cedax	Similar to cefixime except poor activity against pneumococci and staphylococci
	Parenteral		
	Cefepime	Maxipime	Fourth-generation cephalosporin active against most gram-positive cocci (except enterococci and methicillin-resistant staphylococci), *Neisseria*, *Haemophilus*, enteric gram-negative bacilli, and *Pseudomonas*
	Cefoperazone	Cefobid	Increased activity against *P. aeruginosa* but less against Enterobacteriaceae; may cause bleeding
	Cefotaxime	Claforan	More active against gram-positive cocci
	Ceftazidime	Fortaz, Tazidime, Tazicef	More active against *Pseudomonas*
	Ceftizoxime	Cefizox	Properties are similar to those of cefotaxime
	Ceftriaxone	Rocephin	Longer half-life; less active against *Pseudomonas*, *B. fragilis*

Note: Detailed information about the various cephalosporins is covered in the text.
*Agents are being compared with other members of the same generation of cephalosporins.

Second-generation cephalosporins The second-generation cephalosporins consist of two groups: the true cephalosporins (such as cefuroxime) and the cephamycins (such as cefoxitin, cefotetan, and cefmetazole). Because they are not as vulnerable to the β-lactamases that are produced by many of the gram-negative bacteria, the second-generation cephalosporins have enhanced activity against gram-negative bacilli, including many strains *of E. coli, Klebsiella, Serratia,* and *Proteus* that are resistant to the first-generation cephalosporins. However, second-generation cephalosporins are not effective against *Pseudomonas* or *Enterobacter* species. The second-generation cephalosporins retain some activity against gram-positive organisms that are susceptible to first-generation cephalosporins. The cephamycins have enhanced anaerobic activity, including activity against *B. fragilis,* and are effective in intra-abdominal and pelvic infections; however, these agents have largely been supplanted by combination therapy with pencillin and a β-lactamase inhibitor and by the carbapenems.

Third- and fourth-generation cephalosporins The third-generation cephalosporins differ from other cephalosporins in some important respects. Their enhanced ability to resist hydrolysis by the β-lactamases of many gram-negative bacilli gives them an expanded antibacterial spectrum. Pharmacologically, these drugs also have an important advantage: unlike older cephalosporins, they achieve therapeutic levels in the cerebrospinal fluid and can be used to treat meningitis. These advantages, however, come at an increased cost, in that there is an emerging resistance to these agents and that their effect on the normal flora causes increased colonization with vancomycin-resistant *Enterococcus* (VRE).

Although third-generation agents are less active than the older cephalosporins against many gram-positive cocci,[28] they are active against most penicillin-nonsusceptible pneumococci. Like other cephalosporins, the third-generation agents are inactive against enterococci, MRSA, and *Listeria*; however, they have enhanced potency against many gram-negative bacilli, including *E.*

coli, Klebsiella, Proteus, Serratia, and *Citrobacter* organisms. They are also very active against penicillinase-producing and non–penicillinase-producing strains of *H. influenzae* and gonococci. The third-generation cephalosporins are active against most *Salmonella* species and have been clinically effective in the treatment of typhoid fever and other *Salmonella* infections. Resistant strains are now beginning to emerge in the United States, however.[29] Although most *Enterobacter* species initially appear susceptible to third-generation cephalosporins, they may rapidly develop resistance during therapy as a result of inducible cephalosporinases.[1] Hence, it may be prudent to avoid using a cephalosporin as the sole therapy for these organisms. Similarly, *Klebsiella* species may appear susceptible by disk-diffusion testing but may harbor an ESBL, which renders therapy with a third-generation cephalosporin ineffective.[2] Increased zone size around the combined ceftazidime-clavulanate disk relative to the zone size of ceftazidime alone is indicative of the presence of ESBLs.

Although third-generation cephalosporins exhibit activity against *B. fragilis* and other anaerobes, the cephamycins cefoxitin, cefotetan, and cefmetazole are more active. Ceftazidime has the greatest activity against *P. aeruginosa*. Cefoperazone also demonstrates good activity, but the other third-generation cephalosporins have been disappointing. Other nosocomial gram-negative pathogens that are resistant to these drugs include *Acinetobacter* and *Stenotrophomonas*.

Cefepime is a fourth-generation cephalosporin with broad antimicrobial activity against both aerobic gram-positive bacteria (e.g., penicillin-nonsusceptible *S. pneumoniae*) and methicillin-susceptible *S. aureus*; it is also effective against gram-negative bacteria, including *H. influenzae, Neisseria,* and Enterobacteriaceae. Its activity against *Pseudomonas* is similar to that of ceftazidime. Compared to the third-generation cephalosporins, cefepime is a weaker inducer of AmpC β-lactamase and is more stable in the presence of this enzyme.[30] The clinical significance of this finding remains to be determined.

Carbapenems

Imipenem and meropenem were the first carbapenems available for clinical use in the United States; the third, ertapenem, received Food and Drug Administration approval in 2002. Like other β-lactam antibiotics, they are bactericidal and act by inhibiting bacterial cell wall synthesis.[31] Three properties account for the extraordinarily broad antibacterial spectrum of the carbapenems: the ability to penetrate the cell membrane of gram-negative bacteria; high affinity for critical penicillin-binding proteins; and resistance to hydrolysis by β-lactamases.

Imipenem is extensively hydrolyzed in the renal tubule, which results in low urinary levels of the drug and the production of a nephrotoxic metabolite. Cilastatin prevents this degradation by inhibiting the brush-border enzyme dehydropeptidase-1; cilastatin and imipenem are administered simultaneously in equal doses. Meropenem and ertapenem are not susceptible to degradation by dehydropeptidase and can therefore be administered without cilastatin. Ertapenem has a longer half-life than the other carbapenems, allowing for a single daily dose; imipenem, on the other hand, requires dosing every 6 hours, and meropenem, every 8 hours.[32] The carbapenems are primarily excreted in the urine; the dosage should be reduced in azotemic patients.

The carbapenems have broader antibacterial spectra than any other β-lactam antibiotics; they are effective against most clinically important gram-positive and gram-negative bacteria, including anaerobes. Whereas imipenem tends to be more active against gram-positive cocci, meropenem appears to be more active against gram-negative bacilli. However, neither drug is active against methicillin-resistant staphylococci, *E. faecium,* or *Stenotrophomonas*. Ertapenem has a similarly broad spectrum of coverage; however, compared to the other carbapenems, ertapenem has decreased activity against *Pseudomonas, Acinetobacter,* and *E. faecalis*.

Carbapenems are extraordinarily active against gram-negative bacteria. Virtually all Enterobacteriaceae are susceptible. *Haemophilus* and *Neisseria* species are also susceptible to carbapenems but at drug concentrations somewhat higher than those of third-generation cephalosporins. *Acinetobacter,* which is resistant to most other β-lactam antibiotics, is usually susceptible to imipenem and meropenem, although resistance appears to be increasing. All three carbapenems retain activity against most bacterial strains expressing the inducible AmpC β-lactamase enzyme (e.g., *Serratia, Citrobacter,* and *Enterobacter*), as well as organisms containing ESBL; in fact, carbapenems are the drugs of choice for infections caused by such organisms. Gram-negative anaerobes, including *B. fragilis,* are susceptible. *P. aeruginosa* is generally susceptible to imipenem and meropenem, but resistance has emerged with increased carbapenem use.

The safety of carbapenems seems comparable to that of other β-lactam antibiotics. Nausea and vomiting, local pain at injection sites, and hypersensitivity are the most common reactions. Seizures, although unusual, are a potential concern with imipenem. They have been observed in 0.9% of patients who have received the drug; risk factors for seizures include excessive dosage, preexisting CNS lesions, epilepsy, and renal insufficiency. Meropenem is less likely to provoke seizures. Transient elevations of liver enzymes and leukopenia can occur in patients who are given carbapenems. Antibiotic-associated pseudomembranous colitis has occurred.

Because the structure of the carbapenems resembles that of the penicillins and cephalosporins, there is potential for cross-reactivity in patients allergic to other β-lactam antibiotics. Clinical experience in this situation is limited, but it appears prudent to avoid carbapenems in patients who experience anaphylactic reactions to β-lactam drugs and to use carbapenems with caution in patients who have milder allergies to penicillins or cephalosporins.[33]

Carbapenems have been used successfully in patients with pneumonia, intra-abdominal infections, complicated skin and soft tissue infections, complicated urinary tract infections, endocarditis, bacteremia, osteomyelitis, and febrile neutropenia. The broad spectrum and apparent low toxicity of carbapenems are impressive, but they should be used with restraint and selectivity.

Monobactams

The monobactams are monocyclic β-lactam antibiotics that lack the thiazolidine ring found in penicillins and the dihydrothiazine ring found in cephalosporins.[31] Aztreonam is currently the only available monobactam. The antibacterial activity of aztreonam depends on its ability to penetrate the outer membrane of gram-negative bacilli, as well as on its high affinity for penicillin-binding protein–3 and its resistance to hydrolysis by the β-lactamases of gram-negative bacilli.

The antibacterial activity of aztreonam is restricted to aerobic or facultative aerobic gram-negative bacteria. Most strains of *H. influenzae,* gonococci, and meningococci are susceptible to aztreonam, as are most enteric gram-negative bacilli, including *E. coli,*

Klebsiella, Proteus, and *Enterobacter*. Most strains of *P. aeruginosa* are also susceptible, but somewhat higher concentrations of aztreonam are required to kill these bacteria. *Acinetobacter, S. maltophila,* and *B. cepacia* are generally resistant to aztreonam, as are all gram-positive bacteria and anaerobes.

Excellent serum levels are achieved after intramuscular or intravenous administration, and the drug is widely distributed in body tissues and fluids, including the CSF. The serum half-life of aztreonam is about 90 minutes, and glomerular filtration is the major means by which the drug is eliminated. The dosage of aztreonam must be reduced in azotemic patients. The drug is efficiently removed by hemodialysis but not by peritoneal dialysis.

Aztreonam is well tolerated. Its toxicities resemble those of other β-lactam antibiotics; these toxicities include occasional instances of local reactions at the site of injection, rash, diarrhea, nausea, and vomiting. Neither nephrotoxicity nor ototoxicity has been reported. Aztreonam does not cross-react with serum antibodies of penicillin-allergic and cephalosporin-allergic patients, and the drug has been well tolerated in penicillin-allergic patients.

Aztreonam has been used successfully in the treatment of a wide variety of infections caused by gram-negative bacteria, including pneumonias, skin and soft tissue infections, bone and joint infections, urinary tract infections, and bacteremias. Although aztreonam achieves therapeutic concentrations in the CSF, experience in the treatment of meningitis has been very limited.

Because aztreonam combines the spectrum of activity of the aminoglycosides with the low toxicity of the β-lactam antibiotics, it is an attractive alternative for many gram-negative infections. Synergy can be demonstrated between aztreonam and aminoglycosides for some gram-negative bacilli; however, it is not synergistic with other β-lactam agents. More clinical experience is needed to determine the circumstances in which aztreonam should be substituted for or used as a supplement to aminoglycosides.

ALLERGIC REACTIONS TO β-LACTAM ANTIBIOTICS

Hypersensitivity is the most common adverse reaction to β-lactam antibiotics [*see 2:IV Cutaneous Adverse Drug Reactions and 6: XIV Drug Allergies*]. Most often, it is a delayed reaction characterized by maculopapular eruptions, fever, or both. Eosinophilia may also be present. Much less common but much more serious is immediate hypersensitivity, mediated by IgE. Manifestations may include early-onset urticaria, laryngeal edema, or anaphylaxis. Immune complexes can produce serum sickness in some patients. Hypersensitivity to β-lactam antibiotics can also cause hemolytic anemia or allergic interstitial nephritis.

Establishing Drug Allergy

As many as 10% of all patients report a history of penicillin allergy, but only 10% to 20% of those reporting allergy are actually at risk for immediate hypersensitivity reactions.[34] A careful history is the best way to establish true drug allergy. A patient's recollection of rash, urticaria, arthralgias, wheezing, or anaphylaxis confirms the diagnosis of hypersensitivity, whereas treatment failure, diarrhea, vaginitis or other superinfections, or vague symptoms do not. Skin tests have a limited role in predicting true penicillin allergy, but they can help exclude IgE-mediated (anaphylactic) hypersensitivity.[35,36] To document severe allergy, both benzyl penicilloylpolylysine (a major-determinant antigen) and the so-called minor-determinant antigens should be injected; only the former is available commercially, but both are available to most experienced allergists. A wheal-and-flare reaction signifies IgE-mediated allergies; negative reactions to both major and minor determinants make anaphylaxis unlikely, but small test doses of penicillin should be administered for additional safety. Facilities and equipment necessary for the treatment of anaphylaxis should always be on hand when skin testing is performed. Patients with positive skin-test responses have a 41% to 67% chance of exhibiting significant penicillin allergy if they are rechallenged with the drug. The risk to patients with negative skin-test responses is only 1% to 4%, and no life-threatening reactions have been reported.

Desensitization Technique

Patients with penicillin allergy, whether documented by history or by skin testing, should receive other antibiotics for infections. In rare cases in which there is no acceptable alternative to a penicillin (e.g., syphilis in a pregnant woman), desensitization can be attempted. Desensitization is carried out with the equipment and medications for the treatment of anaphylaxis at the bedside: a laryngoscope, oxygen, an endotracheal tube, epinephrine (1:1,000 weight in volume), sodium bicarbonate solution, and a running intravenous infusion. Penicillin doses are administered in graded increases in the forearm at a site low enough for a tourniquet to be applied proximally should a reaction occur. The initial dose of 1 unit of penicillin is applied by scratch test. If there is no wheal-and-flare reaction within 15 minutes, a dose of 2 units is injected intradermally. If no local or systemic reactions occur after another 15 minutes, a dose of 5 units is injected intradermally. If no reactions occur, successive doses that approximately double each previous dose are injected intradermally at 15-minute intervals. When the amount injected becomes large, the penicillin dose is administered subcutaneously. When a dose of 100,000 units has been injected without reaction, penicillin can be given intravenously. If an immediate local or systemic reaction occurs, it can be controlled. Use of an alternative drug is then advisable. Oral desensitization regimens are also available. Neither corticosteroids nor antihistamines will prevent anaphylaxis in an individual who is highly sensitive to penicillin.

Penicillin Allergy and Hypersensitivity to Other Drugs

Patients who are allergic to one penicillin should be considered allergic to all penicillins. However, this generalization may not be true for some children in whom a rash has developed after taking ampicillin or amoxicillin, particularly in the setting of infectious mononucleosis. Patients who are allergic to penicillin have an 8% likelihood of having an allergic reaction to a cephalosporin antibiotic[26]; cephalosporins are best avoided in patients who have IgE-mediated (anaphylactic) hypersensitivity to penicillin. Although there is much less experience with carbapenems (e.g., imipenem, meropenem, and ertapenem), the same guidelines apply for the use of these drugs in patients who are allergic to other β-lactams. However, monobactams (e.g., aztreonam) have not provoked cross-reactive hypersensitivity reactions. There are no reliable skin tests for cephalosporin, carbapenem, or monobactam allergies.

AMINOGLYCOSIDES

The aminoglycosides are bactericidal drugs that inhibit protein synthesis by binding irreversibly to the 30S ribosomal subunit of susceptible bacteria.[37] They exhibit concentration-dependent activity, as well as a postantibiotic effect. Because oxygen is

required to transport aminoglycosides across the outer bacterial membrane, these agents are ineffective against anaerobes and may function poorly in the acidic, anaerobic milieu of abscesses. Although various aminoglycosides display activity against a wide range of microorganisms, they are used chiefly to treat infections caused by aerobic gram-negative bacilli, including *Pseudomonas*. Aminoglycosides are also used in combination with cell wall–active antibiotics (e.g., penicillins and vancomycin) for the synergistic treatment of deep tissue infections caused by enterococci and coagulase-negative staphylococci. In addition, streptomycin is still used to treat tuberculosis, tularemia, and plague.[38]

The aminoglycosides are not absorbed from the GI tract and must be administered intravenously or intramuscularly. The drugs penetrate pleural, ascitic, and synovial fluids in the presence of inflammation, but they diffuse poorly into other body fluids, such as the CSF, respiratory tract secretions, and the aqueous humor.[39] The aminoglycosides are excreted by glomerular filtration, and their dosages must be reduced in the presence of azotemia. Blood levels may be monitored to ensure proper dosing. Peak levels may be lower than anticipated in febrile patients, patients with an expanded extracellular volume, and patients with major burns. The major toxicities of the aminoglycosides include renal damage and ototoxicity, which may be vestibular or auditory.[40] Other adverse reactions include rash, nausea and vomiting, and neuromuscular blockade, which is rare but may occur in patients with myasthenia gravis or in those receiving succinylcholine or similar drugs. Endotoxinlike reactions to gentamicin have been reported.

Specific Aminoglycosides

Gentamicin, netilmicin, and tobramycin have similar spectra of activity, except tobramycin is more active against *P. aeruginosa*. Amikacin is used principally for gentamicin-resistant gram-negative bacilli. Streptomycin is occasionally used in the multidrug treatment of tuberculosis and in synergistic therapy of gentamicin-resistant enterococci.[38] Spectinomycin is used only in the treatment of gonorrhea in patients who are allergic to cephalosporins and fluoroquinolones.[41]

Once-Daily Aminoglycoside Dosing

In patients with normal renal function, aminoglycosides are conventionally administered in divided doses at 8- to 12-hour intervals. To decrease toxicity and cost, once-daily dosing regimens have been widely adopted.[42] In most protocols, the total doses are equivalent in the single-dose and divided-dose regimens. Meta-analyses of such trials concluded that in patients with normal renal function, once-daily dosing is as effective as divided dosing and has a lower risk of toxicity.[43] Although most trials evaluated immunocompetent adults, similar trends were noted for children and for patients with febrile neutropenia. Once-daily dosing has not been studied adequately in pregnant women or in patients with renal dysfunction, burns, ascites, or endocarditis.

The Changing Role of Aminoglycosides

The aminoglycosides are extremely active antibiotics that are clinically effective against many serious infections caused by gram-negative bacilli, and these agents are inexpensive. These assets, however, must be weighed against the potential of aminoglycosides to produce renal and otovestibular toxicity. New efforts to improve the toxic-to-therapeutic ratio of aminoglycosides include once-daily dosage schedules and reevaluations of the recommended therapeutic ranges. To determine the future role of aminoglycosides, the cost-effectiveness of these agents needs to be compared directly with that of the new β-lactams and the fluoroquinolones.

POLYMYXINS

Polymyxins are cationic polypeptides that disrupt the bacterial cell membrane through a detergentlike mechanism. With the development of less toxic agents, such as extended-spectrum penicillins and cephalosporins, parenteral polymyxin use was largely abandoned, except for the treatment of multidrug-resistant pulmonary infections in patients with cystic fibrosis. More recently, however, the emergence of multidrug-resistant gram-negative bacteria, such as *P. aeruginosa* and *Acinetobacter baumannii*, and the lack of new antimicrobial agents has led to the revived use of the polymyxins, particularly colistin (polymyxin E) and polymyxin B.[44] Colistin is bactericidal against gram-negative bacilli, including strains of *Acinetobacter*, *P. aeruginosa*, *Klebsiella*, *Enterobacter*, *E. coli*, *Citrobacter*, *Morganella*, *H. influenzae*, and some strains of *Stenotrophomonas maltophilia*. It is not active against *P. mallei*, *B. cepacia*, *Proteus*, *Providencia*, or *Serratia*. Colistin sulfate is available as an oral formulation for treatment of bowel decontamination; colistimethate sodium can be administered intravenously, intramuscularly, or by nebulization. The recommended intravenous dose is 2.5 to 5 mg/kg/day divided into two to four equal doses; however, dosing must be reduced if renal insufficiency is present. In the largest study of colistin toxicity, which examined 317 courses of therapy, rates of renal insufficiency and neurotoxicity were 20.2% and 7.3%, respectively.[45] Respiratory insufficiency and apnea were seen in 2.1% of patients.

Polymyxin B has been used extensively in topical otic and ophthalmic solutions, but it has more limited parenteral experience than colistin. Originally, colistimethate sodium was thought to be less toxic than polymyxin B; however, if the drugs are administered at comparable doses, their toxicities may be similar.

Given the concern for potential toxicity, the use of colistin and polymyxin B should be viewed as a treatment of last resort in patientswho have serious infections caused by multidrug-resistant gram-negative pathogens for which no other therapeutic options exist.

TETRACYCLINES

Tetracyclines inhibit bacterial protein synthesis by reversibly binding to the 30S ribosomal subunit. Originally, they were widely used because of their broad spectrum of activity against both gram-positive and gram-negative bacteria; they are used less extensively now because of the availability of the more effective bactericidal penicillins, cephalosporins, and fluoroquinolones. The emergence of resistance among gram-negative bacilli, group A streptococci, and pneumococci and the increased risk of superinfection caused by drug-resistant organisms have also tended to limit their use.

Tetracyclines are the drugs of choice in the treatment of rickettsial diseases, such as Rocky Mountain spotted fever, ehrlichiosis, and Q fever; they also have activity against *Francisella, Brucella,* and spirochetes.[46] Tetracyclines are useful in the treatment of pneumonia caused by *Mycoplasma pneumoniae* or *Chlamydia pneumoniae*[47]; urogenital infections caused by *C. trachomatis*; and other chlamydial diseases, such as psittacosis, trachoma, and lymphogranuloma venereum. They may also be used in the

treatment of urinary tract infections caused by susceptible organisms. In the penicillin-allergic patient, doxycycline is an alternative therapy for syphilis, leptospirosis, and cat and dog bites infected by *Pasteurella*. As antimicrobial resistance continues to emerge, a new use has been found for minocycline in the treatment of MRSA. Doxycycline is active against some strains of VRE.[48]

Doxycycline has emerged as the favored tetracycline. It is available in oral and intravenous formulations, has a long half-life that allows administration in one or two daily doses of 100 mg, and does not accumulate in the presence of renal failure. Minocycline is similarly available in oral and intravenous dosing of 100 mg twice daily, whereas the parent tetracycline requires dosing of 250 to 500 mg four times daily. Concomitant ingestion of milk and antacids impairs the absorption of all tetracyclines. The tetracyclines should not be given to children younger than 9 years or to pregnant women, because permanent discoloration of teeth may result. Other potential side effects include phototoxicity, hepatotoxicity, esophageal ulceration, and, rarely, pseudotumor cerebri. In addition, minocycline has been associated with vestibular reactions and skin and mucous membrane discoloration.

GLYCYLCYCLINES

Tigecycline received approval by the Food and Drug Administration in 2005 as the first member of the glycylcycline family. Tigecycline is a semisynthetic derivative of minocycline. Its mechanism of action is similar to that of minocycline in that tigecycline inhibits protein synthesis by binding to the 30S ribosomal subunit.[49] Modification of position 9 in the tetracycline ring, however, allows tigecycline to overcome the two major forms of tetracycline resistance—namely, ribosomal protection and drug efflux. Tigecycline has a broad spectrum of bacteriostatic activity against gram-positive, gram-negative, atypical, and anaerobic bacteria. It is active against multidrug-resistant bacteria, such as penicillin-resistant *S. pneumoniae*, MRSA, VRE, *E. coli* containing ESBL, and *K. pneumoniae*. It is also active against some strains of *Acinetobacter*; however, it is not active against *Pseudomonas* or *Proteus*. Tigecycline is currently indicated in the treatment of complicated intra-abdominal infections and complicated skin and soft tissue infections.

Tigecycline is available only as an intravenous formulation; it is administered at a loading dose of 100 mg, followed by 50 mg every 12 hours. Excretion is primarily through the biliary system. Side effects are similar to those of the tetracyclines, with GI disturbances such as nausea and emesis being the most common.

MACROLIDES

The macrolides are composed of 14, 15, or 16 carbon atoms joined together in a complex circular molecule that is linked to various side chains.[50] In the United States, erythromycin, clarithromycin, azithromycin, and dirithromycin are available. Macrolides inhibit bacterial protein synthesis by reversibly binding to the 50S ribosomal subunit of susceptible microorganisms.

Erythromycin

Erythromycin is active against such gram-positive bacteria as penicillin-susceptible *S. pneumoniae, C. diphtheriae,* and, historically, group A streptococci. In the late 1980s, macrolide-resistant group A streptococci began to emerge worldwide. Resistance in Finland reached 19% overall and 42% in one region; however, these levels decreased to 6% to 8% after a reduction in the use of macrolides in outpatient therapy.[51] Similarly, a clonal outbreak of erythromycin-resistant group A streptococci was recognized in Pittsburgh in 1998.[52] Currently, 5% of group A streptococci are macrolide resistant in the United States.[53] Most pneumococci that are not susceptible to penicillin are also resistant to erythromycin. Erythromycin remains active against *M. pneumoniae, C. trachomatis,* and some gram-negative bacilli, including *Legionella pneumophila, Campylobacter,* and *Bordetella pertussis*. *Neisseria* and *T. pallidum* are also susceptible to erythromycin.

Erythromycin is excreted to a large extent in the bile and only to a minor degree in the urine. The dosage need not be altered in the presence of renal insufficiency. Erythromycin penetrates pleural and peritoneal fluids and crosses the placenta; this allows it to be used to treat syphilis in pregnant women who are allergic to penicillin.

Because erythromycin is active against *Legionella, Mycoplasma,* and *Chlamydia* species, it is an effective treatment for patients with atypical pneumonia [*see 7:XX Pneumonia and Other Pulmonary Infections*]. Erythromycin is also effective for *Campylobacter* gastroenteritis, for the treatment of diphtheria, and for chemoprophylaxis in pertussis carriers. In patients who cannot tolerate penicillins and cephalosporins, erythromycin is an effective alternative for the treatment of streptococcal pharyngitis, though resistance is emerging, and treatment of syphilis. Other uses of erythromycin include granuloma inguinale and chancroid, prophylaxis for elective bowel surgery (for which it is administered orally with neomycin), and acne (for which it is administered topically or orally).

Erythromycin is administered orally at a dosage of 250 mg to 1 g four times daily. Therapeutic serum levels can be achieved with any of the oral erythromycin preparations. Intravenous preparations of erythromycin are available for the treatment of severe infections, but prolonged therapy is difficult because of the frequent occurrence of thrombophlebitis at infusion sites. GI intolerance is the most common side effect. Other adverse reactions shared by the macrolides include rash, stomatitis, pseudomembranous colitis, pancreatitis, and ototoxicity. Because of the occasional occurrence of cholestatic hepatitis after administration of the estolate form, erythromycin base or stearate is preferred for adults.

Clarithromycin

Clarithromycin is a semisynthetic 14-member macrolide that is available only in oral formulation. It is acid stable and is well absorbed from the GI tract irrespective of food ingestion.[50] Like erythromycin, clarithromycin achieves wide tissue penetration. Because of its longer half-life, however, clarithromycin may be administered once or twice a day, rather than four times a day, in 250 to 500 mg doses. In addition, clarithromycin produces fewer GI side effects than erythromycin; some people report a metallic taste. Clarithromycin and other macrolides can produce ventricular arrhythmias when administered with cisapride, astemizole, or disopyramide.

Clarithromycin is highly active against organisms that are sensitive to erythromycin, including streptococci, pneumococci, staphylococci, *Legionella, Campylobacter, Mycoplasma,* and *C. pneumoniae*. Clarithromycin also exhibits excellent activity against *M. catarrhalis* and *H. influenzae*; it is therefore an attractive agent for the treatment of respiratory tract infections, including sinusitis, pharyngitis, bronchitis, and pneumonia caused by susceptible organisms. Clarithromycin has been used successfully in patients who have Legionnaires disease, but azithromycin is the

most active macrolide against *Legionella,* the etiologic agent of this community-acquired pneumonia [*see* Azithromycin, *below*]. The drug has assumed an important role in the multidrug regimens used to treat disseminated *M. avium* complex infections and is active against other nontuberculous mycobacteria, such as *M. chelonae* and *M. fortuitum*. It is also used as a component of some *H. pylori* regimens.

Azithromycin

Azithromycin, a 15-member macrolide, is active against the same broad range of organisms as those that clarithromycin inhibits.[50] An intravenous preparation is available. Like the other macrolides, azithromycin is well absorbed from the GI tract. However, azithromycin differs from clarithromycin in that the bioavailability of azithromycin is decreased by food. As a result, azithromycin should be taken 1 hour before or 2 hours after meals. Azithromycin clears rapidly from serum and moves promptly into interstitial and intracellular tissue compartments. Tissue levels are extraordinarily prolonged, with an average terminal half-life of 68 hours. Therefore, tissue levels of azithromycin can be expected to remain in the therapeutic range from 4 to 7 days after a 5-day treatment course. These unique pharmacokinetics support the current program of administering azithromycin once daily for 5 days. Plasma and tissue levels are considerably lower, however, than those for clarithromycin. Like clarithromycin, azithromycin appears to be well tolerated and to have fewer GI side effects than erythromycin.

Azithromycin has been effective in the treatment of pharyngitis, sinusitis, bronchitis and pneumonia, and skin and soft tissue infections. Azithromycin has also assumed an important role in the treatment of Legionnaires disease and other atypical and community-acquired pneumonias [*see 7:XX Pneumonia and Other Pulmonary Infections*]. In addition to these indications, azithromycin has been used successfully as a single 1 g dose for urethritis and cervicitis caused by *C. trachomatis*. This provides a significant advantage because no other single-dose regimen now exists for these infections. Another important use for azithromycin is in the prophylaxis and treatment of *M. avium* complex infections in patients with AIDS.

Dirithromycin

Dirithromycin is an oral macrolide antibiotic with an antibacterial spectrum similar to that of erythromycin. It can be administered once daily but has no other advantages over erythromycin. The drugs produce similar GI side effects, and dirithromycin is substantially more expensive.

KETOLIDES

Ketolides, which are derived from erythromycin, inhibit bacterial protein synthesis by binding to the 50S ribosomal subunit, which is similar to the action of macrolides.[54] Telithromycin, the first member of the ketolide class of antimicrobial agents, received FDA approval in 2004. Telithromycin is predominantly active against respiratory pathogens, such as *S. pneumoniae* (including penicillin-resistant and macrolide-resistant strains), *H. influenzae, M. catarrhalis, M. pneumoniae, C. pneumoniae,* and *Legionella*; it also has activity against *S. pyogenes* and methicillin-susceptible *S. aureus*. However, telithromycin is inactive against Enterobacteriaceae. Telithromycin has been effective in the management of acute exacerbations of chronic bronchitis, acute bacterial sinusitis, and community-acquired pneumonia. Because telithromycin maintains activity against macrolide-resistant *S. pneumoniae*, it has potential as a fluoroquinolone-sparing agent in situations in which macrolide resistance is a concern.

Telithromycin is well absorbed from the GI tract, and its bioavailability is not affected by food ingestion. Because of its long half-life, the standard dose is 800 mg once a day for 5 to 7 days. Telithromycin is well tolerated; its most adverse side effects are diarrhea, nausea, and headache.

CLINDAMYCIN

Clindamycin inhibits bacterial protein synthesis by binding to the bacterial 50S ribosomal subunit at a site that overlaps with chloramphenicol and macrolides; the use of clindamycin with these drugs results in antagonism.[55] Clindamycin is rapidly absorbed and penetrates most tissues well, with the exception of CSF and brain. It may be administered orally (150 to 450 mg four times a day) or intravenously (600 to 900 mg every 8 hours), depending on the severity of infection. Because clindamycin is excreted primarily by the liver, no dose adjustment is necessary in patients with renal insufficiency; however, in patients with moderate to severe hepatic disease, clindamycin should be administered in half the usual dose. Clindamycin is active against most anaerobes, although resistance is seen in 10% to 20% of infections with *B. fragilis,* peptostreptococci, and clostridia other than *C. perfringens*. Clindamycin also has activity against most aerobic gram-positive bacteria, including *S. aureus, S. pneumoniae,* and group A and other streptococci except *Enterococcus*. It is also active against *B. anthracis,*[56] but clinical experience is very limited.

Clindamycin is indicated in the treatment of serious infections caused by susceptible anaerobes, particularly those originating in the GI and female genital tracts.[57] Clindamycin has also been very effective in the treatment of aspiration pneumonia and lung abscess. Because of its ability to rapidly reduce toxin production, clindamycin may be very helpful in the management of streptococcal toxic-shock syndrome and necrotizing infections caused by *C. perfringens* and *S. pyogenes,* possibly in conjunction with penicillin. Clindamycin has also been used to treat protozoan infections, such as toxoplasmosis and babesiosis.[47] Because clindamycin does not readily penetrate the CNS, even when there is marked meningeal inflammation, it should not be used to treat meningitis. For acne therapy, clindamycin should be used only topically.

Nausea, vomiting, and diarrhea are the most common side effects associated with clindamycin, but hypersensitivity reactions, neutropenia, and thrombocytopenia may also occur infrequently. Although *C. difficile* colitis has been reported with most antimicrobials, the incidence with clindamycin may approach 10% and should limit its indiscriminate use.

METRONIDAZOLE

Metronidazole was originally noted for its effectiveness against certain protozoa such as *Trichomonas, Giardia,* and *Entamoeba* and was later recognized for its anaerobic activity. Metronidazole undergoes a reductive process within the bacterial cell, a process culminating in the damage of bacterial DNA by the activated metabolites.[55]

Metronidazole is bactericidal against almost all anaerobic gram-negative bacilli and against most *Clostridium* species. Although true anaerobic streptococci are generally susceptible to metronidazole, microaerophilic streptococci and *Actinomyces* and *Propionibacterium* species are often resistant. It has supplanted penicillin as the drug of choice for *B. fragilis* and *C. tetani*. Although metronidazole and oral vancomycin are equally effective

in treating *C. difficile* colitis, metronidazole has become the preferred agent because of its lower cost and because of concern for the emergence of VRE. Metronidazole is also effective both orally and vaginally in the treatment of bacterial vaginosis.

When metronidazole is administered orally, it is well absorbed and is widely distributed in body tissues, including those of the CNS. For serious anaerobic infections, the drug is administered intravenously with a loading dose of 15 mg/kg, followed by 7.5 mg/kg every 6 hours until the patient is well enough to take an oral dosage. This is roughly equivalent to 500 mg every 6 to 8 hours. The dosage need not be reduced in azotemic patients, but it should be reduced in patients with hepatic insufficiency.

Side effects of metronidazole include dry mouth associated with a metallic taste and nausea. Concurrent use of alcohol may cause a reaction similar to that produced when alcohol is drunk after disulfiram ingestion. Neurologic symptoms, including peripheral neuropathy and encephalopathic reactions, and neutropenia are uncommon. Pancreatitis has been reported. Metronidazole is mutagenic for bacteria. Metronidazole is carcinogenic for rats and mice; carcinogenicity in humans has not been demonstrated but remains a concern.

Metronidazole is effective in the treatment of a variety of infections caused by anaerobes, including CNS infections, bone and joint infections, abdominal and pelvic sepsis, and endocarditis. Failures have been reported in the treatment of pleuropulmonary infection, which may reflect the polymicrobial nature of these infections.

CHLORAMPHENICOL

Although chloramphenicol remains a useful antibiotic, its role has decreased as less toxic alternatives have become available.[48,55] Because of the rare occurrence of aplastic anemia, clinical use of chloramphenicol should be limited to serious infections for which alternative antibiotics may be less effective. Such infections include those caused by VRE, *B. fragilis,* and *Salmonella,* as well as meningitis caused by *H. influenzae, N. meningitidis,* or *S. pneumoniae* in patients who are allergic to penicillin and cephalosporins. However, other agents are usually preferable to chloramphenicol for such infections. For example, the newer cephalosporins and fluoroquinolones should be considered for salmonellosis; second-generation and third-generation cephalosporins should be considered for ampicillin-resistant strains of *H. influenzae*; linezolid and quinupristin-dalfopristin should be considered for VRE; and combinations of a penicillin and a β-lactamase inhibitor, carbapenems, cefmetazole, cefoxitin, cefotetan, clindamycin, or metronidazole can be used to treat infections caused by *B. fragilis*.

Chloramphenicol may be administered orally or intravenously. Chloramphenicol diffuses rapidly into most tissues, CSF, ascitic fluid, and aqueous humor. The drug is lipid soluble and achieves levels in the brain up to nine times higher than in the serum. Chloramphenicol is inactivated in the liver by conjugation with glucuronic acid; blood levels may increase in patients with marked cirrhosis and jaundice.

One of the more serious and potentially fatal side effects of chloramphenicol is aplastic anemia, which can occur weeks to months after the completion of therapy. A separate dose-related suppression of the bone marrow with neutropenia, anemia, and thrombocytopenia is common during treatment and is usually reversible. Another potentially fatal adverse reaction is the gray-baby syndrome in neonates, which is caused by a diminished ability to conjugate chloramphenicol and to excrete the active form in the urine. Other adverse effects include rash, stomatitis, GI intolerance, and neurotoxic reactions.

In view of the risk of aplastic anemia and neonatal toxicity, the following guidelines should be employed in the use of chloramphenicol: (1) it should be used in the treatment of only those infections for which it is clearly indicated and for which less toxic alternatives are not feasible; (2) repeated courses should be avoided; (3) the complete blood count should be checked two or three times weekly; and (4) the patient should be observed closely for evidence of sore throat, which may be a marker of granulocytopenia.

VANCOMYCIN

Vancomycin is a glycopeptide that impairs cell wall synthesis of gram-positive bacteria. Its spectrum of activity includes staphylococci, streptococci, pneumococci, enterococci, clostridia, *Corynebacterium* species, and other gram-positive bacteria.[57] It is generally bactericidal but is bacteriostatic against some strains of enterococci, coagulase-negative staphylococci, and corynebacteria.

Vancomycin is poorly absorbed when administered orally. The oral route is employed only for the treatment of staphylococcal enterocolitis and *C. difficile* colitis at a dosage of 125 to 250 mg every 6 hours. In adults with severe staphylococcal infection or viridans streptococcal or enterococcal endocarditis who have normal renal function and who are highly allergic to penicillin, vancomycin is administered intravenously at a dosage of 500 mg every 6 hours or 1 g every 12 hours. To avoid hypotension and histaminelike reactions, the drug should always be infused slowly over a period of 1 hour. Pretreatment with antihistamines can help avert the so-called red-man syndrome; in rare cases, desensitization may be necessary. Other adverse effects may include thrombophlebitis at the infusion site, chills and fever, ototoxicity, and possibly nephrotoxicity.

Vancomycin is the drug of choice in the treatment of infections caused by MRSA. Concomitant administration of an aminoglycoside is often necessary when vancomycin is used in the treatment of enterococcal endocarditis. Vancomycin can be very useful in therapy for prosthetic valve endocarditis caused by coagulase-negative staphylococci; it is frequently administered in combination with rifampin and gentamicin in this setting.

Vancomycin does not penetrate normal meninges but does enter the CSF when the meninges are inflamed. Most of the drug is eliminated through the kidneys; in the presence of renal failure, the dose must be reduced. Although serum vancomycin levels are often monitored, measurements are not necessary in routine cases. However, determination of serum levels is an important guide to dosage when the drug must be administered in the presence of impaired renal function; in this setting, peak serum levels of 20 to 40 mg/ml and trough levels of 10 mg/ml or less are considered ideal. Particular attention to ototoxicity and nephrotoxicity is required when vancomycin is administered with an aminoglycoside.

The epidemiology of vancomycin use provides a cautionary tale for this drug and for other antimicrobials.[58] Although vancomycin is a valuable and effective drug, it is often used inappropriately. This has resulted in substantial financial costs and the emergence of vancomycin-resistant organisms, including enterococci[59] and staphylococci[60,61]; infections with these organisms are very difficult to treat [*see 7:I Infections Due to Gram-Positive Cocci*].

STREPTOGRAMINS

Quinupristin and dalfopristin are two structurally distinct

streptogramins that bind to separate sites on the bacterial 50S ribosomal subunit and act synergistically to inhibit protein synthesis.[62] The drugs are marketed together in a 30-to-70 ratio as Synercid. Although quinupristin-dalfopristin is active against a variety of gram-positive bacteria, including *S. pneumoniae* and group A streptococci, its major use is in the treatment of serious infections caused by vancomycin-resistant *E. faecium*. *E. faecalis,* however, is intrinsically resistant to quinupristin-dalfopristin as a result of drug efflux. Quinupristin-dalfopristin may also be useful in occasional vancomycin-intolerant patients with severe infections caused by MRSA or coagulase-negative staphylococci. The combination has activity against *S. aureus* that is intermediately resistant to vancomycin and against vancomycin-resistant *S. aureus*. Although quinupristin-dalfopristin was first marketed in 1999, resistance is already emerging.

The usual dose of quinupristin-dalfopristin is 7.5 mg/kg given intravenously over 1 hour every 8 hours. Because quinupristin-dalfopristin is associated with a high incidence of phlebitis, a central line should be used for intravenous delivery. Other adverse effects include arthralgias and myalgias, which may be severe, and elevated bilirubin levels. The drug is metabolized by the liver, so no dose reduction is required in azotemic patients. Careful attention to drug interactions is important because quinupristin-dalfopristin inhibits the metabolism of drugs such as cyclosporine through the hepatic cytochrome P450 CYP3A4 enzyme.

OXAZOLIDINONES

In 2000, linezolid became the first member of the oxazolidinone class to be approved for clinical use in the United States. Linezolid is a synthetic antibiotic that inhibits protein synthesis by binding to a site on the bacterial 23S ribosomal RNA of the 50S subunit, thus preventing the formation of the 70S initiation complex that is required for ribosomal function.[62,63] It has a unique mechanism of action, and no cross-resistance with other antimicrobials has been reported.

Linezolid is active against nearly all aerobic gram-positive cocci at concentrations of 4 mg/ml or less, including penicillin-resistant pneumococci, MRSA, and VRE; however, resistant strains have been isolated.[64] The drug is bacteriostatic against staphylococci and enterococci, but it is bactericidal against most streptococci. Linezolid is also active against *L. monocytogenes, M. catarrhalis, H. influenzae, N. gonorrhoeae, B. pertussis, P. multocida,* and *Nocardia* species. *C. difficile, C. perfringens,* and *Bacteroides* species are susceptible, but enteric gram-negative bacilli and *Pseudomonas* species are not.

Intravenous and oral preparations of linezolid are available; the usual dosage is 600 mg every 12 hours regardless of the choice of route. The oral form is absorbed rapidly and completely and has 100% bioavailability that is not affected by meals. Linezolid is widely distributed in well-perfused tissues. Nonrenal mechanisms account for 65% of the drug's clearance. Patients with mild to moderate renal or hepatic insufficiency do not require dose reduction. Linezolid is removed by hemodialysis.

Linezolid is fairly well tolerated. Nausea, vomiting, and headaches are the most common side effects, but reversible bone marrow suppression, including thrombocytopenia, leukopenia, and anemia, can also occur, and patients require careful monitoring during prolonged treatment courses as a precaution against these complications. Because linezolid is a reversible inhibitor of monoamine oxidase, patients taking linezolid may experience an exaggerated hypertensive response to sympathomimetic agents such as pseudoephedrine. In addition to avoiding decongestants, patients taking linezolid should avoid foods or beverages with high tyramine content; these include aged cheeses, air-dried meats, tap beer, red wine, soy sauce, and sauerkraut. Concomitant use of adrenergic or serotoninergic antidepressants should be avoided.[65]

Linezolid has been used successfully in the treatment of multidrug-resistant gram-positive bacterial infections, including VRE and MRSA,[62,66] but clinical experience with deep-seated infections such as endocarditis and osteomyelitis is limited. Although resistance is uncommon, it can develop during therapy. As a result, it may be wise to reserve this unique antibiotic for serious infections caused by MRSA, VRE, or coagulase-negative staphylococci that do not respond to vancomycin. It also has a role in decreasing hospital stay for some patients with resistant gram-positive infections,[67] although these patients require close outpatient monitoring.

DAPTOMYCIN

Daptomycin is a cyclic lipopeptide naturally produced by *Streptomyces roseosporus*. It has a unique mechanism of action: it binds to bacterial membranes and causes a rapid depolarization of membrane potential, which leads to the inhibition of protein, DNA, and RNA synthesis, resulting in bacterial death.[68] It is active against most gram-positive aerobic bacteria, including VRE, MRSA**,** glycopeptide intermediately susceptible *S. aureus,* coagulase-negative staphylococci, and penicillin-resistant *S. pneumoniae*. It also has activity against *S. pyogenes, S. agalactiae, S. dysgalactiae,* and *C. jeikeium*. It is currently approved only for complicated skin and soft tissue infections.[69] Daptomycin achieves suboptimal levels in the lungs and should not be used for pulmonary infections.

Daptomycin is bactericidal, and synergy with gentamicin has been demonstrated against staphylococci and enterococci. Although there is limited experience with this new drug, no mechanism of resistance has been identified. In addition, there appears to be no cross-resistance with other antibiotic classes.

Daptomycin is available only in intravenous formulation. The main adverse event seen in early studies of daptomycin administered every 12 hours was a reversible myopathy that affected skeletal muscles. The current once-daily intravenous dose of 4 mg/kg appears to improve the efficacy-toxicity ratio by decreasing the incidence of myopathy. Because daptomycin is primarily excreted by the kidney, the dose should be 4 mg/kg every 48 hours in patients who have a creatinine clearance rate of less than 30 ml/min, including patients on hemodialysis or continuous ambulatory peritoneal dialysis. The role of daptomycin in therapeutics is currently limited, given its narrow indications and the availability of alternative agents, including vancomycin and linezolid.

SULFONAMIDES AND TRIMETHOPRIM

Sulfonamides

Sulfonamides were the first class of antimicrobial agents to be discovered. They inhibit dihydropteroate synthetase in the bacterial folic acid pathway. Although their clinical role has diminished, they are still useful in certain situations. Because of their efficacy and low cost, sulfonamides can be useful in treating uncomplicated urinary tract infections caused by *E. coli,* although resistance is high. Sulfonamides are also useful for *Nocardia* and *Toxoplasma* infections. Topical sulfonamides are still used in a

few situations. Sulfacetamide eyedrops are sometimes employed to treat superficial ocular infections. Topical silver-sulfadiazine cream is administered to burn surfaces to suppress bacterial growth and to prevent subsequent invasive infection. Both the silver ion and the sulfadiazine components of the compound probably contribute to the antibacterial activity.

Trimethoprim

Trimethoprim inhibits dihydrofolate reductase in the bacterial folic acid pathway. Trimethoprim is well absorbed from the GI tract and is widely distributed in most tissues, including the prostate. Most of the drug is excreted unchanged in the urine. Its antibacterial spectrum encompasses many aerobic gram-negative bacilli, but it is not active against *P. aeruginosa*. Trimethoprim is generally well tolerated. Side effects include skin rash (less common than with sulfonamides) and megaloblastic marrow changes. Trimethoprim inhibits renal potassium excretion, and reversible hyperkalemia has been observed in AIDS patients receiving high-dose trimethoprim-sulfamethoxazole.

Trimethoprim is approved only for the treatment of uncomplicated urinary tract infections, for which it has been shown to be as effective as trimethoprim-sulfamethoxazole in 3- and 7-day regimens. The oral dosage is 100 mg twice daily. As a result of the widespread use of trimethoprim in many parts of the world, resistance in uropathogenic *E. coli* has emerged; this has impaired its usefulness in the treatment of urinary tract infections.

TRIMETHOPRIM-SULFAMETHOXAZOLE

Use of the trimethoprim-sulfamethoxazole combination extended the list of clinical situations in which sulfonamides appear to be of value[46]: urinary tract infections, prostatitis, acute otitis media, sinusitis or bronchitis caused by susceptible strains of *H. influenzae* and *S. pneumoniae,* and certain infections caused by MRSA. Trimethoprim-sulfamethoxazole can be used to prevent or treat traveler's diarrhea. It is the drug of choice for the prevention[70] and treatment of *P. jirovecii* pneumonia and nocardiosis. With widespread use, trimethoprim-sulfamethoxazole–resistant strains of *E. coli* are appearing. In areas where the prevalence of *E. coli* resistance is at least 20%, an alternative agent such as a fluoroquinolone should be considered for urinary tract infections.[71,72]

The trimethoprim-sulfamethoxazole synergistic combination is available in oral or intravenous preparations in a 1-to-5 ratio (80 or 160 mg of trimethoprim and 400 or 800 mg of sulfamethoxazole). Both drugs are excreted primarily by the kidneys. The oral dosage of trimethoprim-sulfamethoxazole for the treatment of most infections, including urinary tract infection, in an adult is two single-strength tablets (or one double-strength tablet) every 12 hours. For serious systemic infections, the intravenous dosage is 8 to 10 mg/kg (based on the trimethoprim component) in two to four equal doses every 6 to 12 hours. For *Pneumocystis* pneumonia, the dosage is 15 to 20 mg/kg (based on the trimethoprim component) in equally divided doses every 6 hours. Reduction in dosage is necessary if renal function is impaired.

Adverse reactions to trimethoprim-sulfamethoxazole are similar to those caused by sulfonamides alone and include hypersensitivity reactions, photosensitivity, and nausea and vomiting. Hepatitis, pancreatitis, aseptic meningitis, and megaloblastic anemia occur infrequently. Although hypersensitivity reactions are more common in HIV-infected patients, desensitization protocols have enabled many of these patients with prior reactions to tolerate this medication.[73]

FLUOROQUINOLONES

Since the introduction of ciprofloxacin more than a decade ago, this class of antimicrobial agents has continued to evolve and now includes agents that differ from each other significantly with regard to activity as well as pharmacokinetic and pharmacodynamic properties [*see Table 5*]. The first-generation fluoroquinolones (e.g., ciprofloxacin and ofloxacin) are primarily active against gram-negative and a few gram-positive organisms. The second-generation fluoroquinolone levofloxacin has improved activity against gram-positive bacteria and atypical bacteria but is less potent against certain gram-negative bacteria, such as *P. aeruginosa*. The newer fluoroquinolones (i.e., gatifloxacin, gemifloxacin, and moxifloxacin) have enhanced coverage of gram-positive, atypical, and anaerobic organisms, compared with that of the first-generation and second-generation fluoroquinolones.[74] In particular, these new agents appear to be more active against *S. pneumoniae* and may have decreased potential for the development of resistance.[75]

The fluoroquinolones are bactericidal compounds that inhibit DNA synthesis and introduce double-strand DNA breaks by targeting DNA gyrase and topoisomerase IV.[76] In gram-negative bacteria such as *E. coli, Pseudomonas,* and *N. gonorrhoeae,* the primary target is DNA gyrase and the secondary target is topoisomerase IV. In gram-positive bacteria such as *S. aureus* and *S. pneumoniae,* the primary and secondary targets are reversed. These differences in primary and secondary targets are particularly evident in the earlier fluoroquinolones (e.g., ciprofloxacin and levofloxacin). The newer fluoroquinolones (e.g., gatifloxacin, gemifloxacin, and moxifloxacin) bind equivalently to the two targets. This may imply that concurrent mutations in the two target enzymes would be required for resistance to develop, although this is controversial.

Fluoroquinolones demonstrate concentration-dependent killing. The ratios of the peak concentration to MIC and of the area

Table 5 Selected Properties of Fluoroquinolone Antibiotics

Generic Name	*Trade Name*	*Comments**
Ciprofloxacin	Cipro	Once-daily (p.o.) or twice-daily dosing (p.o., I.V.); most active fluoroquinolone against *Pseudomonas aeruginosa*
Gatifloxacin	Tequin	Once-daily dosing (p.o., I.V.); enhanced activity against *Streptococcus pneumoniae*, atypicals, anaerobes
Gemifloxacin	Factive	Once-daily dosing (p.o.); enhanced activity against *S. pneumoniae*, atypicals, anaerobes
Levofloxacin	Levaquin	Once-daily dosing (p.o., I.V.); moderately active against *S. pneumoniae* and *P. aeruginosa*
Lomefloxacin	Maxaquin	Once-daily dosing (p.o.); less active against *S. pneumoniae*, streptococci, atypicals; phototoxicity
Moxifloxacin	Avelox	Once-daily dosing (p.o., I.V.); enhanced activity against *S. pneumoniae*, atypicals, anaerobes; hepatic elimination
Ofloxacin	Floxin	Twice-daily dosing (p.o., I.V.); same spectrum as levofloxacin

*See text for details. Only properties that distinguish among the fluoroquinolones are listed here.

under the curve to MIC appear to best correlate with clinical efficacy. On the basis of these ratios, ciprofloxacin is the most active fluoroquinolone against *Pseudomonas*, and moxifloxacin demonstrates the most favorable parameters for *S. pneumoniae*. Because the newer fluoroquinolones bind equally to DNA gyrase and topoisomerase IV and because they have enhanced pharmacokinetic and pharmacodynamic parameters for *S. pneumoniae,* it has been argued that they are the preferred fluoroquinolones for community-acquired pneumonia; it is argued that because of their specific properties, the newer fluoroquinolones would prevent the emergence of resistance and maintain the antimicrobial activity of the class.[75,77] When antimicrobial resistance does develop, there tends to be cross-resistance to other fluoroquinolones. Such resistance is usually mediated chromosomally, but plasmid-mediated resistance raises the possibility of transferable resistance.

The fluoroquinolones are broad-spectrum antimicrobials.[78] Most enteric gram-negative bacilli, including *E. coli, Proteus, Klebsiella,* and *Enterobacter,* are highly susceptible. *Pseudomonas* susceptibility has decreased in recent years as fluoroquinolone use has increased. Common GI pathogens such as *Salmonella, Shigella,* and *Campylobacter* species have typically been susceptible, although *Campylobacter* resistance is increasing. Other gram-negative organisms that are killed by low concentrations of the fluoroquinolones are *H. influenzae, P. multocida, M. catarrhalis,* and *Y. enterocolitica*. *Acinetobacter* and *Serratia* are somewhat less susceptible. *B. cepacia* and *S. maltophilia* are fluoroquinolone resistant. Fluoroquinolone-resistant strains of *N. gonorrhoeae* have emerged in the Far East, Hawaii, and mainland United States.[79] Ciprofloxacin is the drug of choice for *B. anthracis,* though other fluoroquinolones are also active in vitro.[56] Among gram-positive cocci, methicillin-susceptible strains of *S. aureus* and coagulase-negative staphylococci are usually susceptible to fluoroquinolones, but resistance has developed, particularly in MRSA, when fluoroquinolones have been used as monotherapy. Activity against enterococci is marginal. Ciprofloxacin and ofloxacin are only moderately active against *S. pneumoniae*. Subsequent generations of fluoroquinolones have increased pneumococcal activity, even against non–penicillin-susceptible pneumococci. Intracellular pathogens such as *Chlamydia, Mycoplasma, Legionella,* and *M. tuberculosis* are susceptible to fluoroquinolones. Gatifloxacin, gemifloxacin, and moxifloxacin are active against anaerobes, though *C. difficile* is resistant.

The fluoroquinolones are rapidly absorbed from the GI tract and have a nearly 100% bioavailability. Penetration into body fluids and tissues is generally excellent, and therapeutic concentrations are readily achieved in bile, stool, urine, prostate, respiratory tract, bone, and muscle. The fluoroquinolones appear to penetrate the CSF in the presence of meningeal inflammation,[80] but experience in treating meningitis is scant. Although serum protein binding is modest, the fluoroquinolones have long serum half-lives, which range from 3 to 4 hours for ciprofloxacin to 12 hours for moxifloxacin. Most fluoroquinolones are eliminated by glomerular filtration and tubular secretion, and their dosages should be reduced in the presence of moderately severe renal failure. Moxifloxacin, however, is excreted chiefly by the liver and achieves low urine levels. As a result, moxifloxacin should not be used in the treatment of urinary tract infections.

The fluoroquinolones appear to be very well tolerated, with mild GI side effects (nausea, vomiting, or anorexia), CNS side effects (light-headedness, dizziness, somnolence, or insomnia), or rash occurring in fewer than 10% of treated patients.[78] Gemifloxacin use for more than 7 days may be associated with an increased risk of rash, particularly in women younger than 40 years. Sparfloxacin contains a halide at position 8 and is associated with significantly more photosensitivity reactions than the other fluoroquinolones. Sparfloxacin and grepafloxacin were withdrawn because they were shown to prolong the QTc interval, but this adverse event has also been reported with levofloxacin, gatifloxacin, and moxifloxacin. Risk factors include underlying cardiac disease, advanced age, hypokalemia, hypomagnesemia, and the concomitant use of other agents that may prolong the QTc interval, such as antiarrhythmics, macrolides, and certain antihistamines. Tendinitis and tendon rupture occur very rarely. Less common side effects include allergic interstitial nephritis, pseudomembranous colitis, and neutropenia. Hepatic toxicity, including fulminant liver failure, has led to the withdrawal of trovafloxacin. Because fluoroquinolones have caused arthropathy in young animals, these drugs should be avoided in children and in women who are pregnant or nursing.

The fluoroquinolones have been useful clinically in a variety of infections, including urinary tract, genital, prostatic, GI, respiratory tract, soft tissue, and bone infections.[78] The fluoroquinolones are effective in preventing gram-negative bacteremia when administered prophylactically to neutropenic patients, but they do not reduce gram-positive bacteremias, febrile episodes, or infection-related mortality. Oral ciprofloxacin in combination with amoxicillin-clavulanate has been used successfully in patients at low risk of complications who have fever and neutropenia after chemotherapy.[81] Use of fluoroquinolones in uncomplicated urinary tract infections has increased in response to the concern about rising resistance to trimethoprim-sulfamethoxazole among uropathogens.[71] Fluoroquinolones should be considered as first-line therapy for pyelonephritis and complicated urinary tract infections. The fluoroquinolones, administered in various regimens ranging from a single dose to 5 days of therapy, are effective in preventing and treating traveler's diarrhea and shigellosis. They have been highly effective in the treatment of typhoid fever. However, prolongation of the carrier state limits their role in nontyphoidal *Salmonella* enteritis, and the development of resistance limits their role in *Campylobacter* enteritis. The fluoroquinolones may be useful in the empirical treatment of severe community-acquired gastroenteritis, particularly if treatment is started early. The role of fluoroquinolones in the intensive care unit, particularly as monotherapy, is limited by the widespread resistance to these agents that has developed among many gram-negative bacteria responsible for nosocomial infections (e.g., *Acinetobacter* and *Pseudomonas*).

Because of their extraordinarily broad antimicrobial activity, their favorable pharmacokinetics, and their low toxicity, the fluoroquinolones are extremely valuable drugs. Like all antimicrobial agents, however, fluoroquinolones should be used judiciously, especially in view of the emerging resistance that accompanies the increased use of these drugs.[82,83]

NITROFURANTOIN

Nitrofurantoin has been commercially available for over 50 years and continues to have an important therapeutic role. It is readily absorbed from the GI tract and rapidly excreted by the kidneys. Therapeutic utility results from the high urinary concentrations achieved. Because antimicrobial levels are not attained in the blood, this drug should be employed only in the treatment of uncomplicated mild to moderate cystitis or for the prevention of cystitis.[84] The spectrum of antibacterial activity in-

cludes *E. coli*, enterococci (including VRE), and some strains of *Klebsiella* and *Enterobacter*. *Proteus* and *Pseudomonas* species are usually resistant. Nitrofurantoin is administered orally at a dosage of 50 mg four times daily or 100 mg twice daily. It should not be administered when there is significant impairment of renal function. Nausea and vomiting are common side effects, but their incidence is decreased by use of the microcrystalline formulation and by taking the drug with food. Less frequent adverse reactions include rash, hypersensitivity pneumonitis, peripheral neuropathy, hepatitis, and hemolytic anemia in association with G6PD deficiency.

FOSFOMYCIN

Fosfomycin is a broad-spectrum antibiotic that inhibits cell wall synthesis and is active against *E. coli* and many other common urinary tract pathogens.[85] However, it has poor in vitro activity against *S. saprophyticus*. Although fosfomycin has been used parenterally in Europe for many years, the drug is approved in the United States only for the single-dose oral treatment of uncomplicated urinary tract infections in women. A 3 g sachet dose is generally effective and well tolerated, with diarrhea being the most common side effect.

RIFAMYCINS

Since its development in the 1960s, rifampin has emerged as a major antituberculosis drug. Rifampin is also active against a variety of bacteria, including coagulase-negative staphylococci and *S. aureus,* but resistance develops rapidly as a result of a single point mutation in bacterial DNA–dependent RNA polymerase when used as monotherapy.[86] When rifampin is combined with a second drug, however, resistance is less likely. It may be combined with vancomycin to treat serious infections with coagulase-negative staphylococci, such as prosthetic valve endocarditis. The combination of rifampin and a fluoroquinolone has been effective in the oral treatment of *Staphylococcus*-infected orthopedic prostheses,[87] *S. aureus* right-sided endocarditis in injection drug users,[88] and osteomyelitis in the diabetic foot.[89] It is also effective in eradicating nasopharyngeal carriage of *N. meningitidis*. More study is needed to determine the optimal role for rifampin in antimicrobial therapy.

Rifaximin, a poorly absorbed (< 0.4%) rifamycin, was approved by the FDA in 2004 for the treatment of traveler's diarrhea caused by noninvasive *E. coli*[90]; in this setting, rifaximin has been demonstrated to have an efficacy similar to that of ciprofloxacin.[91] Because of its poor bioavailability, rifaximin should not be used when there is concern for invasive disease, as evidenced by fever or bloody stools. Rifaximin is well tolerated at oral dosages of either 200 mg three times daily or 400 mg twice daily for 3 days; both dosings achieve very high stool concentrations. Rifaximin is currently being evaluated for its efficacy in the management of small bowel overgrowth syndromes and hepatic encephalopathy.

TOPICAL ANTIMICROBIAL AGENTS

Topical antimicrobial agents have been used for prophylaxis against cutaneous infections, for the treatment of minor wounds and infections, and for the eradication of *S. aureus* nasal carriage. These agents provide high drug concentrations to the desired site with minimal toxicity.[92]

Mupirocin inhibits protein synthesis by preventing the incorporation of isoleucine into the growing protein by binding to isoleucyl transfer-RNA synthetase. It is predominantly active against aerobic gram-positive cocci, including *S. aureus, S. epidermidis,* and β-hemolytic streptococci. Intranasal mupirocin is highly effective for the short-term elimination of *S. aureus*[93]; it has been shown to decrease *S. aureus* infections in dialysis patients,[94] as well as *S. aureus* infections in postsurgery wounds in colonized patients.[95] Although targeted populations may benefit from mupirocin, frequent recolonization and the development of resistance warrant caution against widespread use.

Bacitracin is active against a variety of gram-positive and gram-negative organisms; neomycin and polymyxin target gram-negative organisms, and polymyxin is bactericidal for *P. aeruginosa*.[92] Silver sulfadiazine is most commonly used for the prevention of wound infections in burn patients because of its broad gram-positive and gram-negative activity, including activity against *S. aureus* and *P. aeruginosa.*

Antimicrobial Chemoprophylaxis

The term antimicrobial chemoprophylaxis refers to the use of antimicrobial agents in the prevention of infection either before or very shortly after the introduction of pathogenic organisms—for example, after the occurrence of a compound fracture but before the appearance of clinical infection. Prophylaxis is most effective when a specific drug is selected for its activity against a particular organism, such as postexposure anthrax prophylaxis with ciprofloxacin, doxycycline, or amoxicillin.[56] When prophylaxis is aimed at preventing infection by all possible organisms through the use of broad-spectrum antimicrobials, it merely increases the selection pressure for the emergence of resistant organisms in any infection that may follow. Thus, prophylaxis is ineffective in the prevention of complicating bacterial or mycotic infections in patients with viral respiratory tract infections. Most uses of prophylaxis fall into three general categories: prevention of infection after exposure to a specific pathogen, prevention of specific types of infection in highly susceptible individuals, and prevention of postoperative infectious complications. In many instances, prophylactic use of antimicrobial agents is widely practiced, but convincing data validating the efficacy of this approach are not available.[96]

ANTIMICROBIAL PROPHYLAXIS FOR SURGICAL PROCEDURES

The use of antimicrobial prophylaxis in surgical patients involves a risk-to-benefit appraisal that varies depending on the nature of the operative procedure. To help prevent wound infections in patients undergoing elective surgery, antibiotics should be administered within 2 hours before the incision is made.[97] If prophylactic antibiotics are to be effective, administration should be timed so that therapeutic levels are attained at surgery; in addition, a low-spectrum antimicrobial should be used to inhibit the emergence of resistant organisms. Antibiotics should usually be stopped 24 hours after the procedure. The indications for prophylaxis with different operations have been reviewed, but in many instances, the available data are insufficient to make recommendations.[98] For clean elective surgical procedures such as mastectomy and thyroidectomy in which no tissue (other than the skin) carrying indigenous flora is penetrated, the risks of routine antibiotic prophylaxis outweigh the possible benefits.

When cardiovascular prostheses are employed, vancomycin or a first-generation cephalosporin (e.g., cefazolin) should be administered within 2 hours before surgery and continued for 3 to 5 days. Similar regimens may be employed for major vascular surgery. Because of the grave consequences of infection in a

prosthetic joint, vancomycin or a first-generation cephalosporin is used prophylactically when a total hip replacement is performed. In the repair of open fractures, which are commonly contaminated, prophylactic treatment with a cephalosporin for 5 to 7 days is warranted. Controlled clinical studies have indicated that the administration of oral antibiotics (e.g., enteric-coated erythromycin plus neomycin, or tetracycline plus neomycin) just before colon surgery significantly reduces the incidence of infectious complications. The erythromycin-neomycin combination, 1 g of each administered orally at 1:00 P.M., 2:00 P.M., and 11:00 P.M. on the day before surgery, has been found to reduce the number of aerobic and anaerobic organisms remaining in the colon at the time of surgery. Although the additive benefit of parenteral antimicrobial drugs in colorectal surgery has not been clearly established, a survey showed that most surgeons do combine parenteral cefoxitin or cefotetan with the previously established oral regimens.[99]

XV SEPTIC ARTHRITIS

Brian F. Mandell, m.d., ph.d

Bacterial infections account for less than 20% of all cases of acute monoarticular and oligoarticular arthritis. Crystal-induced arthritis is approximately four times more common. Because septic arthritis represents a potential threat to life and limb, the possibility of infection dictates the sequence and pace of the diagnostic evaluation. This chapter reviews the clinical presentation, diagnosis, microbiology, and treatment of joint infections. Lyme disease, which can manifest as monoarticular or oligoarticular arthritis of the large joints, is discussed elsewhere [*see 7:VII Leptospirosis, Relapsing Fever, Rat-Bite Fever, and Lyme Disease*].

Epidemiology

Case series of patients with septic arthritis include increasing numbers of immunosuppressed and elderly patients with significant comorbidity [*see* Clinical Subgroups at Risk for Septic Arthritis, *below*]. Large retrospective studies from Europe indicate a consistent male-to-female ratio of approximately 1:1, a mean age of approximately 55 years, and polyarticular involvement in up to 15% of cases.[1-3] These data are comparable to those reported from the United States,[4,5] although some clinicians' experiences may include younger patients with disseminated gonococcal infection (DGI) or HIV infection or older patients with prosthetic joints.[6] Patients with damaged joints are at increased risk. Infection complicates 0.05% to 0.48% of arthroscopies[7]; a higher risk is associated with reconstructive or repeat procedures. In rare cases, infection complicates arthrocentesis, intra-articular injection therapy, or direct traumatic penetration of the joint.

Pathogenesis

Presumably, most bacteria reach the joint via the bloodstream and the vascular synovial membrane (and, in children, the epiphyseal plate). Joint invasion may be facilitated by the absence of a developed basement membrane in the normal synovium. Previously damaged joints seem to be at increased risk for infection,[1,6] which may be attributable to unique properties of *Staphylococcus,* the neovascularization of inflamed synovial membranes, or the increased expression of adhesion molecules on activated synovial endothelial cells. Some specific *Staphylococcus, Streptococcus,* and *Neisseriae* strains exhibit tropism to joints.[8] In rare instances, joints are directly infected by traumatic inoculation; this circumstance may be more common in infections involving small finger joints.

Synovial reaction and biochemical changes to cartilage, attributable to mediators released from inflammatory cells and bacteria, occur within hours after experimental joint infection.[9] Experimental models of bacterial arthritis have shown that even if antibiotic therapy is begun within 24 hours of infection, proteoglycans are already at least transiently depleted from cartilage. Loss of cartilage and erosion of subchondral bone may begin within days of infection and evolve into destruction of the joint. Polymorphonuclear neutrophils (PMNs), reacting to chemotactic factors, adhere to endothelial adhesion molecules and infiltrate the synovium, where they participate in the subsequent recruitment of mononuclear cells.

Some studies suggest that the degree of damage is determined by several factors, including the type of infecting organism and the accumulation of PMNs and their release of proteolytic enzymes and perhaps oxygen by-products into the joint space. *N. gonorrhoeae* induces only limited PMN activation in vitro, which may partially explain why minimal joint destruction is observed with this infection, even in studies of rabbits in which the bacteria is directly inoculated into knee joints. Preliminary animal studies suggest that potent anti-inflammatory therapy with corticosteroids, in conjunction with appropriate antimicrobial therapy, may reduce this cartilage destruction.[10,11] These observations have not yet been translated into clinical practice. Consistent with animal data, several studies reported that a delay in the initiation of treatment was a major determinant of poorer functional outcome.[1]

Diagnosis of Septic Arthritis

HISTORY

A thorough history remains a key element in the diagnosis of septic arthritis. Pertinent features include acute onset of joint pain or a significant change in the pattern of chronic joint pain; a history of penetrating joint trauma; a history of prodromal extra-articular symptoms suggestive of bacteremia; any comorbid immunosuppression, including diabetes mellitus, intravenous drug use, or prior intravenous catheterization; the presence of sexually transmitted diseases (STDs); and geographic location (e.g., in the case of Lyme disease). A complaint of sudden onset of articular or periarticular pain should never be ignored, especially if the pain is present both when the joint is at rest and when it is in motion. Because joint infections occur infrequently, patients and physicians may easily but incorrectly attribute the pain to trauma or overuse syndromes, particularly in the case of shoulder pain, or to crystal-induced arthritis if lower extremity or wrist synovitis is present.

Surprisingly, fever is not uniformly present in adults[1-4,12] or children[13] with septic arthritis. Fever may be present in fewer than 60% of patients with nongonococcal septic arthritis. Rigors may be present in fewer than 10% of patients.[12] High spiking fevers (> 39° C [102.2° F]) and rigors can also occur in patients with crystal-induced arthritis.[14] Thus, systemic features are neither sensitive enough nor specific enough to warrant making or excluding the diagnosis of septic arthritis without examination of the synovial fluid.

PHYSICAL EXAMINATION

Detailed physical examination is warranted in all cases of possible septic arthritis, as in any patient with a possible systemic infection or inflammatory disorder. The pattern of joint involvement and the presence of tendinitis or enthesitis should be noted, as should any inflammation of the eyes, skin, or mucosae. The latter finding suggests the possibility of a reactive arthritis. Pain with passive motion of a joint or palpation of the

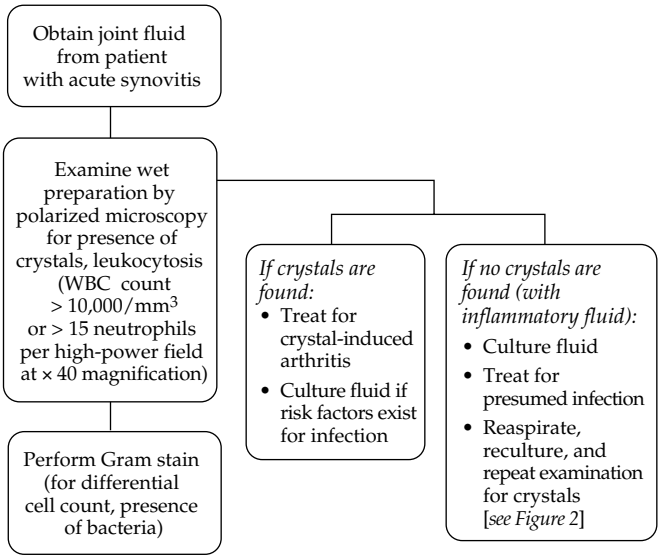

Figure 1 **Algorithm for rapid evaluation of patients with acute monoarticular arthritis on the basis of synovial fluid analysis.**

joint capsule, in the absence of trauma, suggests synovitis. Mild to moderate swelling of an infected hip or shoulder, however, is usually not detectable by examination. Septic bursitis, most commonly affecting the prepatella or olecranon bursae,[15] must be distinguished from arthritis by clinical examination. Unnecessary arthrocentesis can be avoided by appropriate recognition of a periarticular bursitis that needs to be drained. Septic olecranon and prepatellar bursitis, which are the most common sites for septic bursitis, are often associated with a peculiar periarticular, often pitting, edema. A complete joint examination should be undertaken, with specific attention paid to the sternoclavicular, sacroiliac, and midfoot joints. In the absence of risk factors for osteomyelitis or stress fractures, exquisite tenderness of the midfoot should raise particular suspicion for gouty arthritis. Infection of fibrocartilagenous joints seems to be more common in intravenous drug users and in patients with indwelling lines. Psoriatic arthritis may produce dactylitis or mimic a septic joint; thus, even trivial psoriatic skin involvement should be noted. Potential portals of infection (e.g., prior I.V. access sites) should be sought out meticulously.

LABORATORY TESTS

Synovial fluid leukocyte count, polarized microscopy, Gram stain, and culture are the most important initial laboratory investigations in the evaluation of suspected septic arthritis. Acutely or painfully swollen joints should be aspirated [*see Figures 1 and 2*] and the synovial fluid analyzed. Synovial fluid analysis is the diagnostic test of choice to distinguish between crystal-induced arthritis and infection-induced arthritis [*see* Differential Diagnosis of Acute Arthritis, *below*]. Testing for peripheral blood leukocytosis[12,14] and neutrophilia, synovial fluid glucose measurement, mucin clot testing, and assessment for elevations in acute-phase reactants are of insufficient sensitivity and specificity to confirm or exclude the diagnosis of septic arthritis. Synovial fluid leukocytosis and neutrophilia are invariably present in septic arthritis, but their presence does not allow one to distinguish between infection-induced and crystal-induced arthritis [*see 15:IX Crystal-Induced Joint Disease*].[16] Most infected joint fluids have a striking degree of leukocytosis. Although in approximately 25% of cases fluid from infected joints may have a white blood cell (WBC) count of less than 20,000/mm^3, on differential counts, more than 85% of cells are almost always neutrophils.[3,16] Infected bursal fluid may have only a few thousand WBCs. A rapid approximation of the WBC count can be obtained by microscopic examination of a drop of

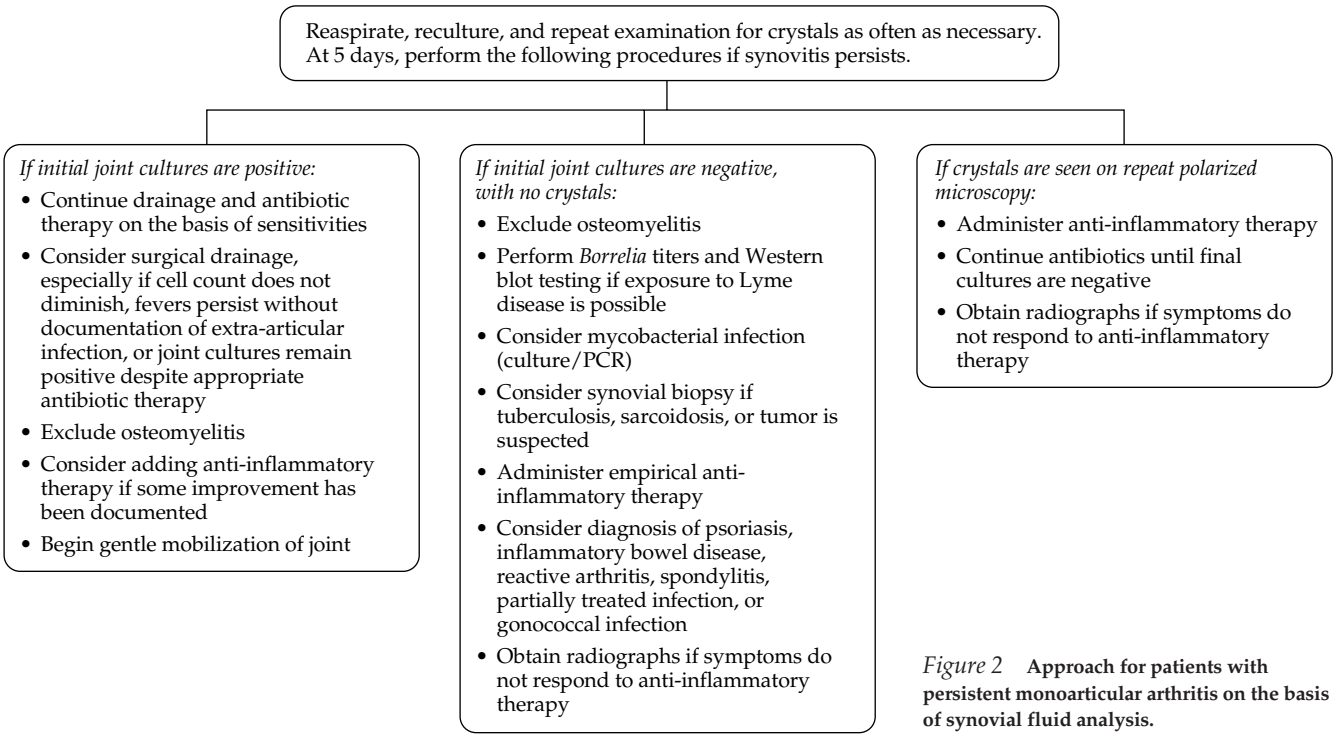

Figure 2 **Approach for patients with persistent monoarticular arthritis on the basis of synovial fluid analysis.**

Table 1 Likely Causes of Septic Arthritis on the Basis of Gram Stain and Patient Demographics

Findings on Gram Stain	*Patient Characteristics*	*Organism(s) of Concern*
No bacteria	Healthy and young	Gonococci, staphylococci
No bacteria	Presence of rheumatoid arthritis	Staphylococci
No bacteria	Significant immunosuppression, intravenous drug use, or recent hospitalization with possible gram-negative infection	Staphylococci, streptococci, *Pseudomonas* (fungal infection much less likely)
No bacteria	Intermittent synovitis of large joint, in an area endemic for Lyme disease	*Borrelia*
No bacteria or gram-negative bacilli	Recent cat or dog bite	*Pasteurella multocida*
Gram-positive bacilli	No specific features	Staphylococci, streptococci
Gram-negative diplococci	No specific features	Gonococci; consider meningococcemia
Gram-negative bacilli	No specific features	Treat for possible *Pseudomonas* infection
Gram-negative bacilli	Presence of systemic lupus erythematosus or sickle cell anemia	Include coverage for *Salmonella*, as well as for *Pseudomonas*
No bacteria	Patient has a prosthetic joint	*Staphylococcus epidermidis, S. aureas* (possibly methicillin-resistant strains)
No bacteria	Exposure to freshwater or saltwater, especially with any injury; chronic joint swelling	*Mycobacterium marinum*

synovial fluid (magnification: × 40), with each WBC estimated to represent 500 WBCs/mm^3.

Gram stain and culture of synovial fluid should be performed in all cases of suspected septic arthritis [*see Table 1*]. A Gram stain will permit evaluation of the percentage of PMNs, but it is not sensitive (< 60%) for the presence of bacteria.[2,3,16] Gonococci are observed even less frequently. Antibiotic-containing culture plates should not be utilized, and samples must be delivered promptly to the laboratory. In the absence of prior antibiotic therapy, synovial fluid culture remains the gold standard for the diagnosis of nongonococcal joint infection. Synovial biopsy may have a slightly greater yield of positive cultures, but it is infrequently performed. There is insufficient evidence to recommend routine biopsy.

Blood cultures should be obtained, as should cultures of any other potential extra-articular source of infection. If gonococcal infection is suspected, workup should include rectal, cervical, urethral, and pharyngeal cultures—any of which may be positive, even in the absence of local symptoms.[17] Cultures and Gram stain of any suspicious skin lesions should be obtained, although these are usually sterile in cases of DGI.

A wet preparation of synovial fluid should be examined by polarized microscopy for the presence of crystals. In rare cases, crystal arthropathy and septic arthritis may coexist; thus, the presence of crystals does not rule out septic arthritis.[5,18] Crystals can be found in synovial fluids from asymptomatic patients with a history of gout. If crystals are observed, patients are generally treated for crystalline arthritis alone [*see 15:IX Crystal-Induced Joint Disease*], unless there is real suspicion of coexistent infection. Hence, synovial fluid cultures should be obtained even when crystals are observed, especially if there is any suspicion of current or remote infection or if the use of therapeutic intra-articular corticosteroid injections is anticipated. Some clinicians order a bacterial culture for all inflammatory synovial fluids, even if crystals are observed. Local laboratory policy may dictate synovial fluid culture technique, but several studies suggest that the diagnostic yield may be improved with direct inoculation of fluid into blood culture vials or isolator tubes.

A potential advance in diagnostic testing has been the development of polymerase chain reaction (PCR) techniques for detection of bacterial DNA within synovial fluid and tissue.[19] PCR has been used to diagnose the presence of *Chlamydia* and *Yersinia* organisms and the presence of *Borrelia burgdorferi, N. gonorrhoeae,* and *Ureaplasma urealyticum* DNA in synovial fluids. Caution must be used, however, when interpreting the results of PCR analyses. Contamination with even minute amounts of DNA can cause false positive results. The test also does not distinguish between the presence of live and dead organisms. Once PCR becomes better standardized and clinical experience is accumulated, PCR may be useful in diagnosing gonococcal, mycobacterial, and partially treated bacterial infections, which are not rapidly diagnosed by routine culture methods. The serum uric acid level should absolutely not be used to diagnose or exclude gouty arthritis; the level may be low, normal, or high at the time of a gout attack. Autoimmune serologies (e.g., antinuclear antibody and rheumatoid factor) are of no value in the initial management of patients with acute monoarticular arthritis. The erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) level may be helpful in monitoring response to treatment in some patients, particularly those with polyarticular or axial joint infections (in whom it can be difficult to assess reduction in local inflammation by physical examination). Although these approaches have not been tested in this specific setting, CRP has been shown to be of value in monitoring patients with bacterial endocarditis.[20] The ESR may be normal in patients with septic arthritis, but it is usually elevated.[1,2,12]

DIAGNOSTIC IMAGING

In the absence of trauma, radiographs are of limited utility in the early diagnosis of acute synovitis. Radiographs are useful when there is clinical suspicion of chronic osteomyelitis, osteonecrosis, or pathologic or insufficiency fracture. Sequential radiographs are useful in evaluating a patient for the development of osteomyelitis. Ultrasound imaging is occasionally useful in documenting hip effusions in children or effusions in other joints in children or adults, especially joints having abnormal anatomy caused by prior mechanical or inflammatory trauma. Patients with suspected sternoclavicular or sacroiliac joint infections should have a computed tomography or magnetic resonance imaging scan performed to evaluate for mediastinal or pelvic extension. Because of its superior soft tissue imaging properties, MRI is useful for the evaluation of periarticular abscesses and soft tissue infections (e.g., psoas abscess mimicking septic arthritis of the hip and subdeltoid bursitis communicat-

ing with the shoulder joint). MRI can detect abnormal marrow signal secondary to osteomyelitis or avascular necrosis but may not help in distinguishing between septic and noninfectious inflammatory synovitis.[21]

Radionuclide scans and other imaging procedures are occasionally useful in localizing and defining the extent of infection. Radionuclide bone scans are sensitive early indicators of changes in periarticular bone metabolism. In a study comparing the use of a technetium-99 (^{99m}Tc) scan with the clinical gold standard of synovial fluid culture in patients with septic arthritis, ^{99m}Tc scanning had a sensitivity of 100%.[22] Radionuclide scans are not specific enough to establish a diagnosis. Scanning with ^{99m}Tc is helpful in differentiating bone from adjacent soft tissue inflammation.[23] Gallium-67 (^{67}Ga) localizes to areas of inflammation and increased bone metabolism. In cases of septic arthritis related to intravenous drug use, ^{67}Ga scans showed positive results several days before ^{99m}Tc scans did. The ^{67}Ga scan has been largely replaced by the indium-111 (^{111}In) leukocyte scan. Although less sensitive than ^{99m}Tc, ^{111}In is thought to be more specific for joint infection than either ^{99m}Tc or ^{67}Ga, because leukocytes do not normally migrate to areas of increased bone metabolism associated with aseptic processes. No radionuclide scan will reliably distinguish between infection-induced and crystal-induced arthritis.

In the vast majority of patients with septic arthritis, especially those from whom synovial fluid can be obtained, radionuclide imaging studies are unnecessary.

Differential Diagnosis of Acute Arthritis

In the patient with acute monoarticular or oligoarticular arthritis, the clinician must promptly distinguish between crystal-induced arthritis and infection-induced arthritis, because the initial treatments of these two conditions are strikingly different. The diagnostic test of choice is synovial fluid analysis. Acutely inflamed or swollen, painful joints, in the absence of obvious trauma, should be aspirated. A single drop of fluid (even the small amount in the hub of the needle of an apparently unsuccessful arthrocentesis) may be sufficient to establish a diagnosis of crystal-induced arthritis. Wet preparation can provide an initial cell count estimate and a polarized microscopic evaluation for crystals. The fluid sample should then be air-dried and a Gram stain performed to both screen for bacteria and calculate the percentage of PMNs. The inability to demonstrate eosinophils by use of this stain technique is rarely of importance. Reactive and enteropathic arthritis are diagnoses that should generally be made only after infection has been excluded by culture of synovial fluid.

Specific Infectious Agents

Causative pathogens are documented by culture in approximately two thirds of presumed septic arthritis cases in most series, and identification rates as high as 93% have been reported. A portal of entry can be identified in half of the patients with septic arthritis; approximately 25% of cases are iatrogenic. In most series, 75% of cases have a possible extra-articular source of infection (e.g., cutaneous, respiratory, or genitourinary).

Determining the causative organism has implications for initial and adjuvant therapies, especially if the organism is resistant to particular therapeutic agents.

Traditionally, bacterial arthritis is divided into nongonococcal and gonococcal types. The distinction is clinically useful because gonococcal infections have a better prognosis than nongonococcal infections. Viral arthritis, which tends to have a self-limited course (except in some cases induced by parvovirus and hepatitis B or C), will not be discussed in this chapter.

NEISSERIA GONORRHOEAE

In some practice settings, DGI is a relatively common cause of septic arthritis and tenosynovitis in healthy, sexually active patients. In a review of 41 cases of gonococcal arthritis, 83% of patients were female, and the mean age was 23 years.[17] Knee synovitis was present in 54% of the patients, followed in frequency by hand and wrist synovitis. Involvement of the hip, but not the spine, is common. Dermatitis (usually sparse peripheral necrotic pustules) and migratory polyarthralgias/polyarthritis were present in 39% and 66% of the patients, respectively. Along with tenosynovitis, these findings constitute the classic triad of DGI. Genitourinary involvement was noted in 63% of the patients but is often asymptomatic in women. Absence of pelvic inflammatory disease does not exclude a diagnosis of DGI. Rectal and pharyngeal colonization are commonly asymptomatic; these sites, as well as blood, should be routinely cultured in all patients suspected of having DGI. Female genital infection may have occurred long before systemic dissemination. The frequency of positive cultures in one study of DGI was as follows: urogenital, 86%; synovial fluid, 44%; rectal, 39%; blood, 13%; and pharyngeal, 7%.[17]

Arthritis and vasculitic skin lesions may reflect local metastatic infection or a sterile inflammation induced by immune complexes. This dual pathophysiology may partially account for both the low frequency of positive joint cultures and the favorable joint outcome. Data compiled by the Centers for Disease Control and Prevention indicate that up to 30% of gonococcal isolates obtained in STD clinics in the United States in 1997 were resistant to penicillin or tetracycline.[24] Resistant strains are capable of systemic dissemination. There have been only rare reports of resistance to ceftriaxone; therefore, initial therapy should include parenteral therapy with ceftriaxone or ciprofloxacin. Fluoroquinolone resistance is now rarely documented.[24] Appropriate regimens, once the infection has been identified, include ceftriaxone (1 to 2 g intramuscularly or intravenously once daily), imipenem (0.5 g intravenously every 6 hours), or cefotaxime (1 g intravenously every 8 hours until 24 to 48 hours after resolution of symptoms). If DGI is clinically suspected but no organism is cultured, empirical therapy with a broad-spectrum cephalosporin is generally continued for approximately 1 week until the lack of any response is documented. Subsequent outpatient therapy should be continued with ciprofloxacin (500 mg orally b.i.d.) or ampicillin (500 to 1,000 mg orally q.i.d.), if the identified pathogen shows sensitivity to these agents. Recognized infection should always prompt an evaluation for other STDs, including syphilis and HIV. Empirical treatment for *Chlamydia trachomatis* infection (doxycycline, 100 mg orally b.i.d. for 7 days, or azithromycin, 1 g orally in a single dose) should also be given because this infection is frequently asymptomatic and can result in infertility if untreated; both partners should be treated whenever possible. Dosages may need to be modified in the presence of severe renal insufficiency. Once the diagnosis is confirmed and clinical response exhibited, addition of an NSAID is a reasonable adjunctive therapy because, as noted above, the synovitis may be induced by immune complexes as well as direct infection.

A dermatitis-arthritis syndrome, similar to DGI, can also be associated with *Haemophilus influenzae, N. meningitidis,* and *Streptobacillus moniliformis* infections, as well as with endovascular infections. Disseminated *Neisseria* infections, which may be recurrent, have been associated with the presence of terminal complement deficiencies.

STAPHYLOCOCCUS

Gram-positive bacteria remain the most common cause of septic arthritis, accounting for 70% to 80% of cases. *S. aureus* accounts for more than half of the cases of culture-positive septic arthritis in studies at university hospitals and for even higher percentages of certain patient subgroups: 70% to 80% of patients with polyarticular septic arthritis; more than 80% of infected patients with rheumatoid arthritis (RA)[25]; and 82% of infected hemodialysis patients.[26] Staphylococcal arthritis was particularly frequent in a series of patients with endocarditis related to intravenous drug abuse.[27] The predominance of *S. aureus* in septic arthritis has remained unchanged over the past 40 years,[1] and there is now an increasing prevalence of methicillin-resistant *S. aureus* (MRSA) and *S. epidermidis* in patients with prosthetic joints. *S. aureus* should always be considered when selecting antibiotics in the initial treatment of presumed septic arthritis.

Gram stain cannot be relied on to differentiate between *Staphylococcus* and *Streptococcus,* because in biologic smears, *Staphylococcus* may not exhibit the clusters seen when grown in vitro. Bacteremia should be assumed in cases of staphylococcal arthritis, although it cannot always be documented. Endovascular infection with possible metastatic seeding to other areas should be considered in patients with persistent fever, leukocytosis, thrombocytosis, or an elevated ESR or CRP level.

Suspected staphylococcal joint infection should be treated initially with vancomycin (1 g intravenously every 12 hours, if renal function is normal) until methicillin resistance can be excluded. An appropriate penicillin or a cephalosporin can often be substituted for completion of a 4- to 6-week treatment course once the sensitivity to these agents is identified.

STREPTOCOCCUS

Non–group A, β-hemolytic streptococci are the second most common cause of septic arthritis, accounting for 10% to 21% of culture-positive cases.[1-3] The number of reported group B (and to a lesser extent, groups C and G) streptococcal infections has been increasing.[28] Group B streptococcal infection may be particularly virulent in diabetic patients; it involves axial joints (sacroiliac, sternoclavicular, and manubriosternal) and may be associated with poor functional outcome. Other manifestations of group B streptococcal sepsis include myositis, fasciitis, and endophthalmitis. Some investigators have expressed concern over the development of tolerance to penicillin in these usually penicillin-sensitive organisms and have suggested adding an aminoglycoside to therapy or using alternative antibiotics until sensitivity and bactericidal tests are available. *S. pneumoniae* may account for up to 10% of the cases of septic arthritis. In one study, 11% of patients with septic arthritis requiring transfer to the intensive care unit had pneumococcal infection.[5] The incidence of penicillin-resistant streptococci, including *S. pneumoniae*, is rising. Polyarticular pneumococcal infections occur, which is not surprising given the high incidence of bacteremia in patients with pneumococcal pneumonia. Elderly adults may be particularly susceptible, and fever or an extra-articular source of infection may not be evident.[29] Antibiotic therapy must be tailored with knowledge of local resistance patterns. *Enterococci* can occasionally infect native or prosthetic joints.[30]

Diagnosis is made on the basis of a Gram stain or preliminary culture showing gram-positive cocci; for initial therapy, vancomycin (1 g every 12 hours, with normal renal function) is a reasonable choice. Definitive therapy should be determined on the basis of culture results.

GRAM-NEGATIVE ORGANISMS

Gram-negative organisms account for 9% to 20% of septic arthritis cases reported at teaching hospitals and occur most frequently in immunosuppressed patients.[1-4] Although certain pathogens have been associated with specific patient subgroups (e.g., *Salmonella* in patients with systemic lupus erythematosus or sickle cell anemia, *Pseudomonas aeruginosa* in intravenous drug abusers), joint infections with these organisms can occur in immunocompetent patients. In sickle cell patients, *Salmonella* more commonly causes osteomyelitis than septic arthritis and may infect multiple sites.[31]

Comorbid medical conditions, prior antibiotic use, and extra-articular infections (particularly urinary tract infections and decubitus ulcers) predispose to gram-negative septic arthritis. Reviews of septic arthritis in intravenous drug abusers over the past decade report a lower percentage of gram-negative pathogens than were reported in earlier series, in which organisms such as *Enterobacter, Klebsiella, Serratia*, and *P. aeruginosa* accounted for more than 80% of infections.[27] Pathogens and sensitivities associated with intravenous drug abuse are specific to geographic regions, and choice of antimicrobial therapy for this patient subgroup must take these factors into account. This same population is also at risk for HIV and viral hepatitis.

Ampicillin is bactericidal for *Salmonella;* however, an increasing number of *Salmonella* infections are resistant to this drug. Chloramphenicol, trimethoprim-sulfamethoxazole, and especially quinolones are used as alternative agents.[31] For other gram-negative infections, cefotaxime (2 g intravenously every 6 hours) or imipenem (0.5 g intravenously every 6 hours) can be used with or without an aminoglycoside until culture results arrive. If pseudomonal infection is suspected, it is reasonable to initiate dual drug therapy, including an aminoglycoside.

H. influenzae joint infections in children are becoming far less common since the widespread institution of immunization programs.

ANAEROBES

Anaerobic joint infections are rare, accounting for at most 7% of cases in reported series; however, they should be considered in patients with deep-tissue or abdominal abscesses. Intra-articular emphysema has been described with anaerobic infection (*Clostridium* species) but is not specific to anaerobes.[32] Empirical treatment for anaerobic septic arthritis is generally not undertaken unless there is a coincident infection with a high likelihood of anaerobic involvement. In those cases, treatment should be based on the suspected organisms and the portal of infection (oral, abdominal, or traumatic).

UREAPLASMA UREALYTICUM

U. urealyticum septic arthritis has been reported in hypogammaglobulinemic patients. These patients, who are often already receiving γ-globulin replacement therapy, may develop a destructive monoarthritis, oligoarthritis, or, in rare instances, polyarthritis[33] with fever and subcutaneous nodules. Positive cul-

tures from affected synovial fluid or tissue are notoriously difficult to obtain. PCR now offers the potential for rapid, definitive diagnosis. Eradication of the infection may require several months of tetracycline therapy. Although rapid recognition and treatment have resulted in complete remission,[34] not all patients respond. The microbiology laboratory should be alerted to the possibility of this infection before fluid samples are taken for culture.

This destructive *U. urealyticum* septic arthritis should be distinguished from the rheumatoid-like, but generally nonerosive, sterile polyarthritis associated with hypogammaglobulinemia. Initial treatment of acute-onset arthritis in this setting should include both a tetracycline (e.g., doxycycline, 100 mg every 12 hours) and aggressive intravenous immunoglobulin replacement until *Ureaplasma* infection is excluded.

PASTEURELLA MULTOCIDA

Pasteurella multocida, a pleomorphic gram-negative coccobacillus parasitic to many cats and dogs, is an infrequent cause of septic arthritis.[35] Infection generally follows inoculation from an animal bite, although in one third of cases no trauma is documented. The organism is almost always sensitive to a penicillin; aminoglycosides are generally ineffective. Initial antibiotic coverage after a recent animal bite should include a penicillin or a third-generation cephalosporin. Ampicillin-sulbactam (1.5 g intravenously every 6 hours) and ceftriaxone (2 g intravenously q.d.) are reasonable initial therapies pending final culture results.

MYCOBACTERIUM MARINUM

Mycobacterium marinum is an atypical mycobacterium acquired through exposure to freshwater, saltwater, swimming pools, or fish tanks. *M. marinum* usually causes cutaneous and subcutaneous infection, but it can cause subcutaneous nodules, tenosynovitis, and septic arthritis.[36,37] Monoarticular, often proliferative, involvement of the metacarpophalangeal and proximal interphalangeal joints is most frequently reported. The arthritis may be only slightly painful with no systemic symptoms. Delays in diagnosis are common (mean, 8 months). Optimal growth of the organism from synovial fluid or tissue requires special attention in the microbiology laboratory. *M. marinum* infection may elicit a positive purified protein derivative (PPD) reaction. Treatment usually consists of prolonged chemotherapy and surgical debridement. There are no evidence-based guidelines to aid in determining the need for initial surgical debridement, although this procedure is frequently utilized, especially when the course of infection is protracted. A reasonable initial therapy is a combination of rifampin (600 mg orally) and ethambutol (15 mg/kg/day; maximum, 1,600 daily), although treatment with trimethoprim-sulfamethoxazole (160/800 mg orally b.i.d.) or ciprofloxacin (500 to 750 mg orally b.i.d.) may also be effective. Although there are no data demonstrating the superiority of combination therapy, there has been anecdotal treatment failure with doxycycline monotherapy. The organisms are usually sensitive to amikacin and clarithromycin.

MYCOBACTERIUM TUBERCULOSIS

Arthritis is an uncommon extrapulmonary complication of tuberculosis[38,39]; osteomyelitis of the low thoracic and lumbar spine occurs more frequently.[40] Recognition of tuberculous peripheral joint and bursa infections are often significantly delayed, partly because of the indolent nature of the inflammation, the rarity of the disease, and the frequent absence of obvious pulmonary disease or a positive PPD test.[38] Although joint motion is frequently maintained, radiographs may show destruction of bone and loss of cartilage. Synovial fluid leukocytosis is modest to marked, usually with a predominance of neutrophils. Acid-fast staining of fluid is usually negative; cultures are usually positive. Limited data suggest that biopsy of synovium may yield a higher percentage of positive cultures than do cultures of fluid. Because *M. tuberculosis* is a rare cause of peripheral arthritis, it is not cost-effective to obtain mycobacterial cultures initially from all patients with acute synovitis. Microbiologic diagnosis takes several weeks; therefore, molecular diagnostic tests for *M. tuberculosis* DNA should be requested only if there is a significant clinical concern about this infection. No large studies have been undertaken to compare diagnostic approaches or treatment regimens for tuberculous arthritis. As with therapy for pulmonary tuberculosis, there is a potential for developing drug resistance; thus, initial therapy should include a combination of at least two drugs, including rifampin (600 mg/day), isoniazid (300 mg/day), and perhaps ethambutol (15 mg/kg/day) for the first few months of a planned 18- to 24-month course of treatment.

TREPONEMA PALLIDUM

The arthritis associated with later stages of syphilis is characteristically a chronic, proliferative, symmetrical polyarthritis involving small and large joints.[41] An acute monoarthritis is not typical of syphilis. Synovial fluid usually contains a predominance of mononuclear cells. Treatment should be based on the stage of disease (usually secondary or tertiary) and the presence or absence of HIV infection [*see 7:VI Syphilis and the Nonvenereal Treponematoses*]. Penicillin remains the antibiotic of choice, although ceftriaxone or doxycycline may be used in some patients without HIV infection.

FUNGAL INFECTIONS

Fungal arthritis is rare and is seemingly more common in immunosuppressed patients. The arthritis is usually subacute or chronic. Osteomyelitis is more common than arthritis in *Cryptococcus, Coccidioides,* and blastomycosis infections.[42,43] Arthritis associated with histoplasmosis may occur with erythema nodosum and may clinically mimic sarcoidosis. Arthritis caused by aspergillosis infection has been reported after systemic infection and iatrogenic inoculation at the time of arthrocentesis. Sporotrichosis arthritis can occur after cutaneous inoculation or, in rare cases, through inhalation.[44] Surgical debridement may be helpful; there are limited data, however, to support initial surgery in addition to antifungal therapy. Except in cases of local inoculation (e.g., rose thorn sporotrichosis), the fungal infection is generally assumed to be systemic, and intravenous amphotericin B should be administered. Intra-articular amphotericin B and oral regimens with azole antibiotics have been utilized. These alternative agents and routes of administration should be considered on an individual basis; consultation with an infectious disease specialist should take place early in the treatment program.

Clinical Subgroups at Risk for Septic Arthritis

Several factors predispose certain groups of patients to septic arthritis. Local risk factors include the presence of inflammatory arthritis, prior intra-articular corticosteroid injection, and the presence of implanted synthetic material.[6] Other factors in-

clude advanced age, a remote focus of infection, diabetes mellitus, indwelling lines, intravenous drug use, and immunosuppression.

ELDERLY PATIENTS

Age older than 60 years has been repeatedly found to be a risk factor for septic arthritis, perhaps in part because of comorbid conditions.[1,6] Prosthetic joints, which also pose an increased risk of infection, are more common in older patients.

The clinical presentation of septic arthritis tends to be more insidious in elderly patients than in younger patients. The absence of fever is common.[29] Older patients are particularly at risk for septic arthritis as a postoperative complication, often after a bacteremic episode. In a retrospective study of 21 patients older than 60 years with septic arthritis, mortality was 21%.[2]

RHEUMATOID ARTHRITIS PATIENTS

Patients with RA have consistently accounted for a disproportionate percentage of patients with septic arthritis; in some series, 50% of septic arthritis patients had RA. These patients may be predisposed to septic arthritis because of poor clearance of bacteria from abnormal joints or because of phagocytic defects acquired secondary to drugs or disease. Patients with longstanding, severe RA are more likely to develop septic arthritis than patients with less severe disease. The majority of RA patients with septic arthritis present with insidious worsening of joint symptoms, and the diagnosis of infection is often delayed.[25] Although there have been reports of so-called pseudoseptic rheumatoid joints characterized by highly inflammatory, sterile synovial fluids that improve with antirheumatic therapy, any isolated, acutely inflamed joint in a patient with RA should be considered infected until proved otherwise.

With septic arthritis, the outcome is significantly worse for RA patients than nonrheumatoid patients, perhaps because of delays in diagnosis. Reported mortality for RA patients with monoarticular infection has ranged from 15% to 22%. When both monoarticular and polyarticular infections are included, mortality reaches 44% in RA patients, compared with 26% in unselected septic arthritis patients. For patients with a combination of polyarticular septic arthritis and RA, mortality is 50%. Joint outcome is also poor; only 35% of RA patients achieve full functional recovery of the infected joint, compared with 70% of nonrheumatoid patients. A retrospective literature review of 181 RA patients reported recurrence of infection in nonprosthetic joints in 20% of patients.[25]

INTRAVENOUS DRUG ABUSERS

Intravenous drug abusers are at risk for repetitive transient bacteremia and direct bacterial inoculation of soft tissue. Bacteremia is thought to be the most common mechanism of infection. Although medium to large joints (such as the wrist and knee) are most commonly involved, fibrocartilaginous joints (sternoclavicular, sacroiliac) and the spine are frequently infected. Gram-positive organisms (especially *S. aureus* and MRSA) are the most common pathogens,[27] followed by gram-negative bacteria (*Enterobacter, Serratia,* and *P. aeruginosa*).

Not all studies of septic arthritis in intravenous drug abusers have specified whether the patients were also HIV positive. Two Spanish studies, one with 25 patients and one with 16 patients, reported no differences in clinical characteristics, infecting organisms, or outcome between intravenous drug abusers with HIV and those without HIV.[45]

HEMODIALYSIS PATIENTS

Hemodialysis patients are at increased risk for septic arthritis because of recurrent vascular infections, intravenous catheterizations, repeated skin trauma, and immune deficits such as decreased clearance of transient bacteremia. Hemodialysis patients are at particularly high risk for *S. aureus* colonization, with reported nasal carriage rates over 40%.

A 10-year review of hemodialysis patients in three tertiary care hospitals identified 11 episodes of septic arthritis, with 82% attributable to *S. aureus*.[26] Almost all of the episodes involved joints above the diaphragm, including one sternoclavicular and one acromioclavicular joint infection.

HIV PATIENTS

Two articular syndromes unique to HIV-infected patients have been reported that can mimic acute septic arthritis. The first, which has been referred to as AIDS-associated arthritis, is characterized by the development over several days of extreme pain and disability involving the knees or ankles, noninflammatory sterile synovial fluid, and an excellent response to nonsteroidal anti-inflammatory drugs (NSAIDs). The reported duration of symptoms is 1 to 6 weeks. The second syndrome, the painful articular syndrome, is characterized by an explosive onset of pain in the shoulders and elbows. The pain resembles gout in its intensity and often requires intravenous narcotics for analgesia. Synovial fluid is noninflammatory, and symptoms last a few hours to several days. The etiology of these syndromes remains unknown.

Despite the multiple immune deficits associated with HIV infection, there have been relatively few reported cases of septic arthritis in patients with HIV. *S. aureus* and *S. pneumoniae* are the most commonly reported organisms.[46] With an increasing degree of $CD4^+$ T cell depletion, infection with *Candida albicans, Cryptococcus neoformans, Histoplasma capsulatum, Nocardia asteroides,* and *Sporothrix schenckii* can occur. HIV patients are also at increased risk for pyomyositis, most commonly occurring secondary to *S. aureus*.[46]

ORGAN TRANSPLANTATION PATIENTS

A review of the University of Pennsylvania renal transplant experience reported the occurrence of septic arthritis in 0.8% of the patient population.[47] All cases occurred within 18 months of transplantation, the period of most intense immunosuppression with high-dose steroids. Infection was caused by bacteria in 66% of cases (half of which were caused by *S. aureus*), mycobacteria in 17%, and disseminated cytomegalovirus infection in 17%. Only three cases of fungal arthritis have been reported in renal transplant patients, but this incidence is likely underreported. With the current ubiquitous use of cyclosporine, gouty arthritis (occasionally polyarticular with atypical joint involvement) is extremely common and may mimic septic arthritis.[48]

INDIVIDUALS WITH PROSTHETIC JOINTS

Prosthetic joint infections, in the absence of wound drainage, are frequently not recognized early and may result in a nonfunctional joint with chronic osteomyelitis. Pain is the predominant or only symptom.[49] Effusions may be small (knee) or impossible to detect clinically (hip or shoulder). Fever and leukocytosis are frequently absent. In studies, *S. epidermidis* was responsible for approximately 40% of both early postoperative and late infections.[49] Although the ESR is usually elevated, it may be normal.[50,51] One study demonstrated a sensitivity of only

Table 2 Initial Empirical Antibiotic Therapy for Acute Septic Arthritis in Adults*

Findings on Gram Stain	*Drug of Choice*	*Alternative Drug*	*Comments*
Gram-positive cocci (small) in pairs and chains	Vancomycin, 1.0 g I.V. every 12 hr†	Cefotaxime, 2.0 g I.V. every 6–8 hr	Smear suggests streptococci or pneumococci; if only single cocci are observed or if cocci are large, treat as for *Staphylococcus aureus* (see next entry)
Gram-positive cocci (large) singly or in small groups	Vancomycin, 1.0 g I.V. every 12 hr	Nafcillin, 2.0 g I.V. every 4 hr, or oxacillin, 2.0 g I.V. every 4 hr‡	Assume that penicillinase-producing *S. aureus* and, possibly, methicillin-resistant strains are present
Gram-negative cocci	Ceftriaxone, 2.0 g I.V. every 24 hr	Imipenem, 0.5 g I.V. every 6 hr	Usually *Neisseria* species; treat with third-generation cephalosporin or imipenem in documented or suspected cases of infections caused by penicillin-resistant *Neisseria* species
Gram-negative bacilli	Cefotaxime, 2.0 g I.V. every 6 hr§	Imipenem, 0.5 g I.V. every 6 hr	Antibiotic susceptibility testing mandatory; fluoroquinolones may be of value
No organisms seen			
Healthy, young patient	Ceftriaxone, 2.0 g I.V. every 24 hr with or without cephalothin, 1 g I.V. every 8 hr; use vancomycin if methicillin-resistant strains are a possibility	Imipenem, 0.5 g I.V. every 6 hr	Probably gonococcal disease, but initial therapy should also treat gram-positive cocci
Patient with underlying disease (e.g., neoplasm, rheumatoid arthritis, intravenous drug use) or immunosuppression	Vancomycin, 1.0 g I.V. every 12 hr, and ciprofloxacin, 400 mg I.V. every 12 hr	Imipenem, 0.5 g I.V. every 6 hr	Broad-spectrum coverage for staphylococci and many types of gram-negative bacilli§

*These recommendations are for nonallergic patients with normal renal function. *Final antibiotic choice should be determined by culture result.* Refer to Table 1 and to text for other special situations.
†Sensitivity of *S. pneumoniae* to penicillin should not be assumed. In geographic areas where penicillin-resistant pneumococcus is not present, a penicillin can be used.
‡It is imperative to document that staphylococci are sensitive to nafcillin or to oxacillin.
§In neutropenic patients or in patients at risk for *Pseudomonas* infection, consider using an aminoglycoside and either ceftazidime or piperacillin.

60% when an ESR threshold greater than 30 mm/hr was used.[50] The CRP assay may be a more sensitive test.[51] Three-phase bone scans are also surprisingly insensitive.[51] If loosening is noted on standard radiographs, bone scanning is of little additional diagnostic value. Arthrocentesis or intraoperative tissue sampling with culture, before antibiotic therapy, remains the gold standard for diagnosis. The value of fluid Gram stain is questionable.[51] Knee replacement can be repeated in some patients as a two-step procedure. Total debridement, followed by 4 to 6 weeks of systemic antibiotic therapy before attempted repeat arthroplasty, is frequently successful.[52]

Treatment of Septic Arthritis

DRAINAGE

Treatment of septic arthritis consists of drainage, parenteral antibiotics (guided by Gram stain, if possible [*see Table 1*]), and initial (not prolonged) joint immobilization for pain control. The controversy surrounding medical versus surgical drainage remains unresolved. A retrospective analysis by Broy and Schmid included pooled data from 80 studies.[53] A slightly larger number of patients who were treated medically (needle drainage) rather than surgically (arthrotomy or arthroscopy) had a good joint outcome (66% versus 57% [$P < 0.05$]) with restoration of normal joint function and minimal residual pain. Perhaps because of increased systemic comorbidity in the medically treated cohort—an inherent problem in nonrandomized studies—medically treated patients had a higher mortality (10% versus 3%; $P < 0.05$). These nonrandomized studies do not permit generation of firm therapeutic guidelines.

Clinicians generally agree that surgical drainage is indicated in the following situations: septic arthritis of the hip or of joints that are difficult to aspirate or monitor for adequate drainage, extensive spread of infection to the soft tissues, and inadequate clinical response to appropriate antibiotics after 5 to 7 days. There is an apparent consensus among rheumatologists that surgical drainage is rarely necessary for patients with gonococcal septic arthritis in whom the response to appropriate antibiotics is characteristically rapid (less than a week) and complete. No prospective or controlled studies support or refute the need to openly drain or lavage an uncomplicated, acutely infected, nongonococcal joint at the initiation of therapy; nonetheless, this orthopedic practice is common in many parts of the country. Surgical drainage should be considered when a previously damaged (e.g., rheumatoid) joint becomes infected, because the data indicate a particularly poor outcome for these patients with medical therapy.[25] The data are insufficient to mandate immediate surgical drainage of infected joints in immunosuppressed patients. In general practice, arthroscopic lavage seems to be supplanting open joint drainage; it permits earlier physical therapy and mobilization of the involved joint.[54]

MEDICAL THERAPY

The choice of antibiotics [*see Table 2*] should be guided by patient characteristics and the local microbiologic sensitivity pattern. Intra-articular antibiotics are not required[55] and may cause a chemical synovitis. Parenteral antibiotics are generally administered for approximately 4 to 6 weeks. Acetaminophen and NSAIDs should be avoided until the diagnosis is solid (i.e., through microbiologic identification or by documented defervescence and clinical improvement with antibiotics alone). High-dose NSAIDs can transiently blunt the inflammatory response and may suggest a response to coadministered antibiotics, which might then be construed as evidence for a culture-negative (e.g., gonococcal) infection. There are no data demon-

strating that NSAIDs prolong the course of infection, and some animal data suggest that anti-inflammatory therapy may be beneficial.[10,11] Narcotics may be used initially for pain control. Joint immobilization for a short period (1 to 3 days) is appropriate to help with pain control, but daily range-of-motion exercises should be started as soon as possible to hasten return of joint function.[56] Once a definitive diagnosis is made, and if there are no contraindications, NSAID therapy may be initiated to facilitate joint mobilization.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XVI OSTEOMYELITIS

Layne O. Gentry, m.d., f.a.c.p.

Osteomyelitis is an infection of bone characterized by progressive inflammatory destruction of bone, bone necrosis, and new bone formation. Osteomyelitis poses a challenge because it is often difficult to diagnose and treat. Even when appropriate antibiotic therapy is instituted promptly, osteomyelitis can cause serious morbidity. Chronic cases are often refractory to treatment. In diabetic patients, amputation to remove the site of infection is often necessary. The etiology of osteomyelitis has evolved considerably over the past 2 decades. Twenty years ago, most cases of osteomyelitis were caused by susceptible strains of *Staphylococcus aureus* and were cured with surgical debridement and 4 to 6 weeks of methicillin therapy. Although *S. aureus* is still a common cause of osteomyelitis, an increasing number of infections are caused by gram-negative organisms, such as *Pseudomonas aeruginosa*, or are polymicrobial. Coagulase-negative staphylococci, once regarded as contaminants, are now considered significant pathogens. Increasingly, osteomyelitis is a complication of reconstructive orthopedic surgery; it is also a complication of median sternotomy after cardiothoracic surgery. The growing incidence of diabetes in the population is also responsible for increasing numbers of osteomyelitis diabetes foot infections. These changes, together with improvements in diagnosis and therapy, indicate a need to reexamine traditional management of osteomyelitis.

Classification

Osteomyelitis is classified on the basis of pathogenesis, duration of disease, extent or type of bone involvement, anatomy of the bone infection, and host characteristics. Osteomyelitis can present as either an acute condition or a chronic infection. Acute osteomyelitis is usually defined as the first clinical episode, complete with the signs, symptoms, and radiographic and histologic findings associated with bone infection. Acute infections often occur soon after an episode of bacteremia and are usually accompanied by fever and bone pain. Chronic osteomyelitis is defined as bone infection that has failed to resolve after one or more treatment attempts. Retained foci of dead bone, or sequestra, are characteristic of chronic osteomyelitis.

Waldvogel and coworkers described three types of osteomyelitis: hematogenous osteomyelitis, osteomyelitis secondary to contiguous focus of disease, and osteomyelitis associated with vascular insufficiency.[1] In hematogenous osteomyelitis, infection is introduced through the bloodstream and usually affects the metaphyses of long bones. Hematogenous osteomyelitis is diagnosed in about 20% of cases of osteomyelitis; it is the most common type of osteomyelitis in children. In osteomyelitis secondary to a contiguous focus of disease, the bone becomes infected from an external source (e.g., penetrating trauma or open fracture) or from the spread of infection from adjacent soft tissue (e.g., abscess or skin infection). Contiguous-focus disease is usually seen in older persons and accounts for 50% of cases of osteomyelitis. Osteomyelitis associated with vascular insufficiency, which is responsible for about 30% of cases, is usually seen in patients with diabetic neuropathy.

Clinical Syndromes

hematogenous osteomyelitis

Hematogenous osteomyelitis is usually seen in children between 1 and 15 years of age and adults older than 50 years or in persons who abuse I.V. drugs. In children, infection usually occurs as a single focus in the metaphyseal area of long bones (particularly the tibia and femur). In older persons, infection of the vertebral bodies is more common. When osteomyelitis is seen in young adults, it is often associated with I.V. drug abuse or sickle cell anemia. Several predisposing factors are associated with the development of hematogenous osteomyelitis. Children may be predisposed to infection by minor trauma that causes a small hematoma, vessel obstruction, and bone necrosis. Thus, hematogenous osteomyelitis may be seen in teenagers who play contact sports. About one third of patients have a history of trauma to the site of osteomyelitis. Some children with local trauma may have a history of infection at a distant site. In adults, predisposing factors include advanced age, immunodeficiency, chronic bacteremia, I.V. drug abuse, long-term indwelling catheters, and sickle cell anemia.

Etiology

Most cases of hematogenous osteomyelitis are monomicrobial. Although *S. aureus* causes 60% to 90% of cases of hematogenous osteomyelitis, certain organisms tend to cause infections in certain age groups. In newborns, group B streptococci and gram-negative bacilli are common. In children, streptococci and *Haemophilus influenzae* are often seen. However, evidence from a retrospective study in Canada showed that vaccination of infants and children succeeded in eliminating *H. influenzae* type b as an infective agent in hematogenous osteomyelitis.[2] Polymicrobial hematogenous osteomyelitis is usually caused by *S. aureus* and a streptococcus.

The incidence of hematogenous osteomyelitis caused by gram-negative organisms is about 25%. *Escherichia coli* is the most common gram-negative organism isolated from hematogenous bone infections. *P. aeruginosa*, which has a predilection for the cervical vertebrae, and *Serratia* species are common pathogens in I.V. drug abusers. Furthermore, *P. aeruginosa* can be isolated from patients with long-term indwelling catheters.[3] *Salmonella* species are frequently associated with osteomyelitis in patients with sickle cell anemia[4] and may also be seen in patients with AIDS and other hemoglobinopathies.

Tuberculous infection of bone may be seen in patients from areas endemic for tuberculosis and in patients with AIDS. Fungal osteomyelitis, usually caused by opportunistic organisms, is found in patients who are severely immunodeficient or neutropenic or who have indwelling venous catheters. Because of their increasing frequency in all types of infection, *Candida* species may be seen more often in bone infections. Recent case reports reviewed 58 cases of candidal vertebral osteomyelitis[5] and 11 cases of deep sternal wounds caused by *C. albicans* after coronary artery bypass grafting.[6] Treatment of these infections is difficult, and therapy needs to be individualized against the specific organism.

Clinical Features

Children with acute hematogenous osteomyelitis usually pre-

sent with fever and localized pain. Leukocytosis may be present. A decreased range of motion and signs of local infection may be seen in the affected area. Drainage is not usually seen. Blood cultures are positive in more than half of patients.[3] Although in most children symptoms are present for 3 weeks or less, some children may present with vague symptoms of 1 to 3 months' duration.

Vertebral osteomyelitis is a form of hematogenous osteomyelitis most commonly seen in older persons and I.V. drug abusers. Most patients present with a constant dull pain that progresses slowly. Percussion over the affected area usually causes intense pain. Neurologic signs are generally absent but, when present, may indicate an epidural abscess. Fewer than half of patients are febrile. Vertebral infection typically involves the vertebral body rather than the spinous or transverse processes; often, two adjacent vertebrae and the disk space between them are affected. The lumbar region is most frequently involved in pyogenic hematogenous osteomyelitis. Thoracic vertebrae are often infected in spinal tuberculosis (Pott disease), and the cervical spine is often the site of infection in patients who abuse I.V. drugs.[7]

In about 10% of patients with acute hematogenous osteomyelitis, the disease progresses to a chronic condition. These patients have recurrent episodes of clinical exacerbations that are usually more indolent than those seen in the acute episode. Patients who are more susceptible to chronic osteomyelitis include those for whom therapy was delayed and those with compound fractures.

Despite the serious nature of hematogenous osteomyelitis, the prognosis is good for most patients. In a retrospective review of 69 children with acute hematogenous osteomyelitis, major sequelae were seen in only 3% of patients and minor problems in 2%. A favorable long-term outcome was associated with early hospitalization and initiation of appropriate antibiotic therapy.[8] Patients with severe underlying conditions have a worse prognosis.

Special Presentations of Hematogenous Osteomyelitis

Brodie abscess In patients with Brodie abscess, the infected portion of bone is completely replaced by pus and forms an intraosseous abscess. The infection, which is contained within a sclerotic membrane, may become quiescent. However, the risk of recurrence is high, and infection may spread. Patients are usually afebrile and may present only with local pain or swelling. Brodie abscess may be misdiagnosed as a bone tumor; the diagnosis of Brodie abscess is confirmed by histologic examination and culture. *S. aureus* is usually the etiologic agent, although *S. epidermidis* is occasionally implicated. Although seemingly benign, Brodie abscess should be aggressively treated. Pus may accumulate and spread through the tissues, causing a draining sinus; if near the joint surface of an intracapsular bone, infection can cause pyogenic arthritis.

Osteomyelitis in patients with sickle cell anemia There are two main differences between hematogenous osteomyelitis in children with sickle cell anemia and that in children who are otherwise healthy. First, infection in children with sickle cell anemia usually localizes in the diaphysis rather than the metaphysis. Second, *Salmonella* species frequently cause infection in this group, although staphylococci are also common.[4] Differentiating between osteomyelitis and thrombotic crisis in patients with sickle cell anemia may be difficult. In both situations, patients may present with bone pain and fever, and the erythrocyte sedimentation rate (ESR) and leukocyte count may be elevated. A bone biopsy is usually required for diagnosis of osteomyelitis.

Table 1 Common Clinical Associations in Osteomyelitis

Organism	*Common Clinical Associations*
Staphylococcus aureus	Found in 50%–70% of cases
Coagulase-negative staphylococci	Infections of prosthetic devices
Gram-negative bacilli	Decubitus ulcers, vascular insufficiency
Pseudomonas aeruginosa	Puncture wounds
Streptococci and anaerobes	Diabetic foot lesions, decubitus ulcers, bite wounds
Pasteurella multocida	Cat bites
Actinomyces	Periodontal infection or sinusitis
Eikenella corrodens	Mandibular osteomyelitis

Multiple sites of bone may be infected. Antibiotics for empirical therapy should be effective against both *Salmonella* and staphylococci. A regimen of a semisynthetic penicillin and an aminoglycoside is recommended [*see* Treatment Overview, *below*].

Hematogenous osteomyelitis in I.V. drug abusers In I.V. drug abusers, hematogenous osteomyelitis is associated with subtle clinical signs and symptoms. Patients may present with localized pain, but fever is usually absent. Although vertebral osteomyelitis is common, infection of the pubis and the clavicle is also seen. Culture of the infected site usually yields *S. aureus* or *S. epidermidis*, although *P. aeruginosa* is often seen. Serial radiographs may be necessary, and surgery may be required to confirm the microbiologic diagnosis.

OSTEOMYELITIS SECONDARY TO A CONTIGUOUS FOCUS OF INFECTION

Osteomyelitis in adults almost always derives from a contiguous source of infection. These bone infections are often complex and heterogeneous. Organisms may be inoculated directly into the bone after an open fracture, a penetrating wound, or a surgical procedure; or they may spread from an adjacent soft tissue infection. Because techniques for joint replacement have improved, the number of artificial joints inserted has increased and so has the number of infections associated with prosthetic joints.

Etiology

The cause of osteomyelitis depends, in part, on the route of entry, the phenotypic characteristics of organisms, and the epidemiologic background of the patient. Thus, the bacteriology of osteomyelitis in a diabetic patient who has had multiple hospital admissions and has been treated with multiple antibiotics over several years differs from that in a patient with a community-acquired infection. Organisms with common clinical associations are listed [*see Table 1*].

Because of virulence factors and adherence characteristics, *S. aureus* is the most common single pathogen in contiguous-focus osteomyelitis and accounts for 50% to 70% of cases.[9] In contrast to hematogenous osteomyelitis, contiguous-focus disease is often polymicrobial; multiple organisms may be isolated from 30% to 50% of such patients. The incidence of osteomyelitis caused by gram-negative bacilli is increasing. Gram-negative pathogens are important in patients who have undergone multiple hospital procedures, have had an extended hospital stay, are in intensive care units, or have had an open fracture. *P. aeruginosa* is often responsible for osteomyelitis associated with comminuted fractures and puncture wounds to the heel.[10] *S. epidermidis* is another common

pathogen in contiguous-focus osteomyelitis, particularly in patients who have infected orthopedic prostheses.

Osteomyelitis caused by anaerobic bacteria usually results from contiguous spread of a polymicrobial infection. Anaerobes should be suspected when osteomyelitis is associated with a human bite or is contiguous to a dental infection, intra-abdominal abscess, decubitus ulcer, or otorhinolaryngologic infection.

Clinical Features

In the initial stages of contiguous-focus osteomyelitis, patients may have pain, fever, swelling, and erythema. However, during recurrent episodes of chronic infection, fever subsides, and pain and drainage from a sinus tract or ulcer are often seen. In patients with generalized vascular insufficiency, the disease starts insidiously in an area of traumatized skin. The patient may present with an ingrown toenail, a perforating foot ulcer, cellulitis, or a superficial or deep wound infection. Fever and systemic signs of infection are not usually present.

Osteomyelitis after replacement of the hip joint may occur soon after surgery or later. Often evident within the first few days or weeks after surgery, acute contiguous infections result directly from infected skin, subcutaneous tissue, or muscle. Fever, pain, erythema, edema, and purulent drainage are often present when early infections are caused by pyogenic organisms such as *S. aureus*, streptococci, or enteric gram-negative bacilli. When early infections are caused by less pathogenic organisms, such as *S. epidermidis* or diphtheroids, the disease presents more insidiously. Chronic contiguous infections are usually diagnosed 6 to 24 months after surgery. The patient usually presents with persistent pain. Most infections are probably introduced during surgery but remain quiescent for a long time.

Sternal osteomyelitis, a serious complication of median sternotomy after cardiothoracic surgery, occurs in 1% to 5% of patients. Patients have fever, a slightly erythematous wound, and persistent pain. Frequent pathogens include *S. epidermidis*, *S. aureus*, gram-negative bacilli, and, more recently, *Candida* species. The presence of sternal wires, used to approximate the sternum, is a major risk factor for chronic recurrent osteomyelitis. Surgical removal of the wires is essential for recovery. The risk of death may be high in complicated cases.[10]

OSTEOMYELITIS ASSOCIATED WITH VASCULAR INSUFFICIENCY

Osteomyelitis secondary to vascular insufficiency occurs most frequently in older patients with diabetes mellitus or severe vascular impairment. In these patients, osteomyelitis usually develops by contiguous spread of infection from soft tissue to underlying bone; often, it occurs in the small bones of the feet in patients in whom soft tissue breaks down over weight-bearing or pressure-bearing areas. Bone infections develop in about 25% of diabetic patients with superficial mild to moderate foot infections; however, of those patients with serious foot infections, over 50% will have osteomyelitis.[11] Extensive debridement is necessary, and about two thirds of cases require bone resection or partial amputation.[12]

Complex foot lesions in diabetic patients result from a combination of neuropathy, atherosclerotic peripheral vascular disease, and repetitive trauma to the area. Atherosclerosis of the tibial and peroneal arteries of the lower leg is common in diabetic patients.[13] Limb ischemia, combined with poor collateral circulation, impairs wound healing in foot ulcers and allows for the contiguous spread of infection to bone. In addition, this anoxic environment contributes to the development of gangrenous changes and anaerobic infections. Furthermore, peripheral vascular disease may compromise the efficacy of antibiotic therapy by preventing the accumulation of adequate drug levels in the infected tissues.

Osteomyelitis should be considered in all diabetic patients with deep or chronic foot ulcers or infections. The Group Health Cooperative of Puget Sound conducted a study to determine the incidence of foot ulcers and the risk of developing serious complications among 8,905 patients with type 1 or type 2 diabetes. Over a period of 3 years, 5.8% developed a foot ulcer, and of those, 15% developed osteomyelitis.[14] Distinguishing between true bone infection and noninfectious destructive neuropathic bone changes in patients with diabetes is challenging and requires diagnostic imaging tests. Although *S. aureus* is the most common pathogen isolated from patients with osteomyelitis associated with vascular insufficiency, multiple organisms, including both anaerobes and aerobes, may be present, especially in hospitalized patients. Mixed gram-positive and gram-negative infections are often seen in patients with chronic or previously treated infections.

Pathogenesis

Pathogens gain access to bone in humans by three methods: direct inoculation, extension from contiguous sites, and hematogenous dissemination. Each type of infection may be further complicated by the presence of a prosthesis.

The sequelae associated with the hematogenous dissemination of bacteria to the bone vary with the age of the patient.[3] In infants, infection can spread via transphyseal vessels to the epiphysis and then to the joint space. Concurrent septic arthritis and epiphyseal destruction may be seen. In children older than 1 year, the growth plate is avascular, and osteomyelitis usually begins in the metaphyseal region of the long bones. Capillary loops do not anastomose in this region, and bacterial emboli can settle in this area and cause a microinfarction. Microscopic metaphyseal hemorrhage and necrosis, caused by insignificant trauma, provide a favorable environment for infection. Once infection is established, it can spread to the periosteum. If pus reaches the subperiosteal space, the periosteum becomes elevated. Osteoblasts beneath the detached periosteum gradually produce new bone.

The pathogenesis of hematogenous osteomyelitis in adults differs from that in children.[8] After growth ceases and the epiphyses close, organisms causing osteomyelitis no longer have a predilection for the metaphyseal area of long bones. The vertebrae, sternoclavicular and sacroiliac joints, and symphysis pubis are often affected. Infection may spread from the subchondral bone to the joint space. Sites of previous injury or trauma often provide the point of seeding of infectious organisms.

Unlike hematogenous osteomyelitis, contiguous-focus disease may invade any traumatized bone. Local inflammatory response or injury can devitalize bone and tissue. Microbes can multiply in these areas of dead bone. Osteomyelitis often complicates decubitus ulcers or cutaneous ulcerations in diabetic patients. Undetected trauma in diabetic patients with neuropathy provides a portal of entry for bacteria. Moreover, compromised blood flow impairs wound healing and allows unchecked bacterial proliferation.

Histologic findings in acute osteomyelitis include microbes, neutrophils, and congested or thrombosed blood vessels [*see Figure 1*]. The local inflammatory reaction contributes to further bone necrosis, which is a distinguishing feature of chronic osteomyelitis. As necrosis progresses, new bone gradually surrounds the infected area of dead bone (sequestrum). The forma-

tion of a functionally inert, nonresorbable substratum—either a sequestrum or a foreign body—upon which bacteria can attach and multiply marks the transition from acute to chronic disease.

Diagnosis

The diagnosis of osteomyelitis should be considered in patients with fever and localized skeletal pain, positive blood cultures, persistently draining wounds, and radiologic findings that suggest a localized inflammatory process. The diagnosis can then be confirmed by the histologic examination and bacteriologic culture of bone specimens obtained either by surgery or by multiple percutaneous needle biopsies. A detailed history with emphasis on previous trauma or surgery is important. Although no laboratory test specifically indicates the diagnosis of osteomyelitis, a complete blood cell count, ESR, and C-reactive protein test may be useful. The white blood cell count is usually elevated only in early stages of the disease. The ESR may be helpful in diagnosing acute hematogenous osteomyelitis in children but is less useful in newborns and children with sickle cell anemia. C-reactive protein is an acute-phase reactant, and although the C-reactive protein test is relatively insensitive and nonspecific, it may be more specific for infection than the ESR.

RADIOLOGIC AND NUCLEAR FINDINGS

There is a plethora of imaging techniques for diagnosing osteomyelitis [*see Table 2*]. The accuracy of imaging studies is affected by the extent of inflammation, the duration and site of infection, the vascularity of the site, and associated pathologic conditions. Osteomyelitis cannot be absolutely confirmed or excluded on the basis of results from any one test.

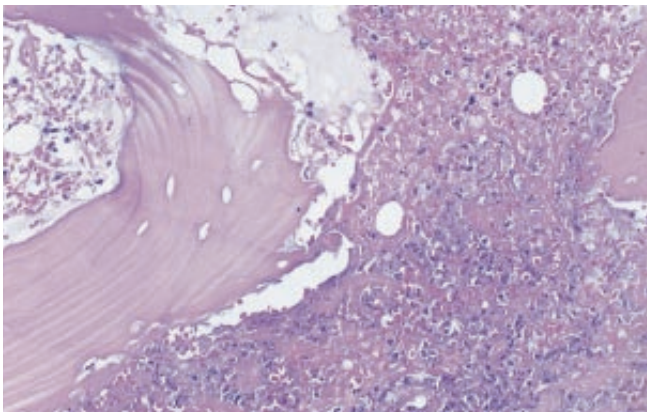
Radiograph

Radiographs, which are relatively inexpensive, should be the initial diagnostic technique for almost all patients suspected of having osteomyelitis. However, findings on conventional radiographs are often normal until at least 2 weeks after the onset of symptoms. Furthermore, radiographic changes can be subtle and nonspecific. In children with hematogenous osteomyelitis, the earliest changes are deep soft tissue swelling, which may be difficult to detect; periosteal elevation; and radiolucent areas of bone destruction, which are not usually detected until 50% to 75% of bone density has been lost.[15] In contiguous-focus disease, the initial radiologic manifestation is periosteal reaction. Radiographs may show the presence of sequestra, sclerosis, and significant bone lysis in patients with chronic disease.

Bone Scan

The technetium-99m (^{99m}Tc) methylene diphosphonate three-phase bone scan is often used to identify osteomyelitis, because it is more sensitive than conventional radiography and can confirm a suspected diagnosis of osteomyelitis within 48 hours after onset of symptoms. The bone scan should be the next imaging study performed in patients with normal radiographs. Classic findings on bone scan are increased blood flow, pooling, and reactive new bone formation. Although sensitivity is good, specificity is poor [*see Table 2*]. Cellulitis and septic arthritis cannot be differentiated from osteomyelitis on bone scan. False positive results may be seen in patients with previous bone injury, tumor, or infarction. Furthermore, bone scans may remain positive for 6 weeks to 6 months after therapy because of bone metabolism and remodeling. In children with uncomplicated hematogenous osteomyelitis, the bone scan has a high sensitivity and specificity; a positive bone scan strongly suggests osteomyelitis, and a negative scan in children older than 3 years excludes the diagnosis.[16] Sensitivity, however, is lower in neonates and in patients with sickle cell anemia.

a



b

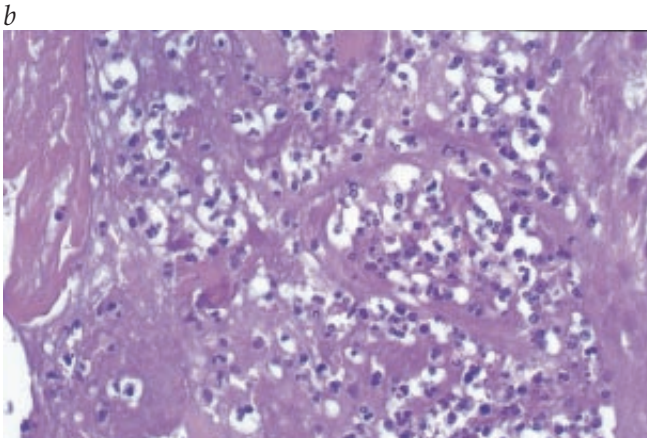


Figure 1 **(*a*) Photomicrograph of a specimen from bone biopsy shows acute osteomyelitis (magnification: × 40). Note missing osteoclastic cells (signifying bone death) and intense inflammatory reaction adjacent to bone fragment. (*b*) Higher magnification (× 100) shows intense polymorphonuclear infiltration at same site.**

Gallium Scan

Gallium scans may be useful in infants and in children in whom bone scans are negative. The low specificity of gallium imaging may be improved if it is combined with bone scans. When interpreted in combination with a bone scan, the gallium scan can in some cases be used to differentiate acute cellulitis from acute osteomyelitis. Disadvantages associated with gallium scans include higher doses of radiation and a 1- to 2-day waiting period for results.

Leukocyte Scan

Indium-111 (^{111}In)–labeled and ^{99m}Tc-labeled leukocyte scans, which are more specific but less sensitive than bone scans, have been used to evaluate patients with osteomyelitis. Leukocyte scans are not useful in patients with chronic, indolent infections. In a patient who is suspected of having osteomyelitis and has recently had a fracture, a leukocyte scan may be the study of choice because results from a bone scan will be equivocal. The cumbersome and expensive technique of leukocyte scanning re-

Table 2 Radiographic and Radionuclide Techniques for Diagnosing Osteomyelitis

Test	*Sensitivity*	*Specificity*	*Indications/Comments*
Radiograph	Good after 3 weeks	Poor	Initial test for most patients
^{99m}Tc bone scan	Good in first 2 weeks	Poor	Use in patients with suspected osteomyelitis who have a negative result on radiograph
Gallium	Moderate after 2 weeks	Poor	Use in infants and children with a negative result on bone scan
Indium	Moderate	Moderate	May be used in patients with a recent fracture; may be useful in diagnosis of infected joint prosthesis 2–4 mo after implantation
CT	Excellent	Moderate	Useful in osteomyelitis of the skull, pelvis, and sternoclavicular junction
MRI	Excellent	Excellent	Reliably distinguishes tumor or infarction from osteomyelitis; useful in surgical planning for diabetes; good for vertebral disease; very expensive
PET	Excellent	Moderate	May be useful in chronic osteomyelitis in patients with negative results on other tests

CT—computed tomography MRI—magnetic resonance imaging PET—positron emission tomography ^{99m}Tc—technetium-99m

quires in vitro cell isolation and radiolabeling, which is time-consuming and potentially biohazardous. However, leukocyte scans, especially in combination with bone scans, may be sensitive and specific in detecting osteomyelitis in diabetic patients.[17-19] In a study of 52 diabetic patients with chronic foot ulcers, both specificity and accuracy were significantly higher with leukocyte scans than with bone scans.[17] The combined use of leukocyte scans and bone scans has effectively differentiated osteomyelitis from soft tissue infections in patients with diabetes; the sensitivity of the combination has ranged from 93% to 100%, and the specificity has ranged from 80% to 83%. ^{111}In-labeled and ^{99m}Tc-labeled leukocyte scanning have been shown to be useful in the diagnosis of prosthetic joints 2 to 6 months after implantation. Biopsy confirmation is necessary for diagnosis.

Computed Tomography and Magnetic Resonance Imaging

Both CT and MRI have excellent sensitivity and resolution and allow simultaneous evaluation of bone and surrounding soft tissues. CT reliably detects sequestra and devitalized bone and is useful for evaluating patients with osteomyelitis of the skull. However, CT is prone to image degradation and is less specific than other tests. MRI, with its excellent specificity, is helpful in distinguishing bone tumor or infarction from osteomyelitis.[20] Furthermore, MRI is particularly reliable in distinguishing normal areas from abnormal areas when surgery is being planned for diabetic patients with osteomyelitis.[21] In addition, MRI is the technique of choice for detecting and assessing the site and extent of infection in the spine. However, the expense of MRI precludes its use on a routine basis. A limited MRI scan with specialized views and minimal use of gadolinium contrast can be used to control costs.[22] Metallic prostheses exclude the use of MRI and distort image reflection on CT, thereby obscuring early changes of infection.

Positron Emission Tomography

Positron emission tomography (PET) has been used as an imaging tool for infections of the bone and osteosynthetic material.[23] PET with fluorodeoxyglucose (FDG) was shown to be superior to bone scans in diagnosing chronic osteomyelitis of the central skeleton.[24] Because of its excellent sensitivity, FDG PET may be an effective technique for excluding chronic osteomyelitis when a bone scan is negative.[25]

CULTURES

The gold standard for diagnosis of osteomyelitis is aerobic and anaerobic culture of a biopsy specimen obtained under direct vision during surgery. Alternatively, culture of multiple specimens obtained by needle biopsy under ultrasound or radiographic guidance has been a reliable, cost-effective means of diagnosing osteomyelitis at our center. Combining surgical debridement with the obtaining of culture specimens is also cost-effective. Blood cultures should also be obtained, especially from patients suspected of having hematogenous osteomyelitis. Results of swab cultures of the sinus tract are usually inaccurate. Studies have shown that the results of cultures of sinus tract and bone biopsy specimens match in only 44% to 57% of patients with chronic osteomyelitis.[26,27]

Treatment Overview

Optimal management of the patient with osteomyelitis entails microbiologic confirmation of the diagnosis by biopsy and complete surgical debridement, followed by institution of antibiotic therapy that is based on culture and sensitivity results [*see Table 3*]. When debridement is inadequate, therapy often fails, despite appropriate antimicrobial therapy; therefore, "a subtle balance between medical and surgical therapy is necessary if a potentially curative outcome is to be achieved."[28]

SURGICAL THERAPY

The type of surgical therapy depends on the extent of infection. Surgical management of acute infection requires debridement of dead tissue, whereas chronic osteomyelitis requires surgical debridement of all devitalized bone and soft tissue and removal of foreign bodies. Adequate surgical management is essential for successful treatment. Inadequate surgical debridement, regardless of antibiotic therapy, is the most common cause of treatment failure. Sequestered dead bone can serve as a nidus for persistent infection. In some cases, a two-staged debridement protocol may be necessary to sterilize the wound.[29]

Surgical therapy entails filling the dead space created by debridement and reestablishing blood supply to the poorly perfused area. Skin, bone, or muscle grafts are used to cover the

wound. Cancellous bone grafts can be used to fill the dead space. Revascularization procedures include the use of local pedicle muscle flaps and myocutaneous flaps. In patients with very large bone defects, the Ilizarov technique has been used to reconstruct large defects in bone and soft tissue. In this procedure, major segmental resections of infected bone are performed, followed by realignment of opposing ends of now noninfected bone so that new bone growth fills in the defect. Each salvage procedure has associated morbidity and expense.

ANTIBIOTIC THERAPY

Oral and I.V. Antibiotic Therapy

The standard treatment for chronic osteomyelitis is I.V. antimicrobial therapy targeting the causative organism. Because of rising hospital costs, alternatives to an extended hospital stay for parenteral treatment of osteomyelitis in otherwise healthy patients are being sought. The economic benefits of oral therapy are obvious: decreased hospital stay, reduced pharmacy and supply costs, no need for surgical insertion of a catheter, and decreased catheter-related complications. For patients who require a complete regimen of I.V. antibiotics, outpatient therapy should be considered. Patients should be educated in the care and use of the catheter while they are still in the hospital. Furthermore, drug toxicity and clinical response should be closely monitored by the physician. Administration of I.V. antibiotics during clinic visits or by a home health agency can substantially reduce costs over in-hospital care.

Alternative Delivery of Antibiotics

Antibiotic-impregnated acrylic beads have been used for local treatment of bone infections; however, they have not been approved for use in the United States. Although the beads deliver a high concentration of antibiotic to the area of infection, bactericidal levels of antibiotic are present locally for only 2 to 4 weeks. Thus, the beads should be used in conjunction with systemic antibiotics. Both biodegradable and nonbiodegradable beads have been used, and both require surgical placement. Nonbiodegradable beads, such as the polymethylmethacrylate beads, must be surgically removed after 2 to 4 weeks. Biodegradable antibiotic beads do not require surgical removal and provide local bactericidal concentrations for extended periods.[30,31]

Choice of Antimicrobial Agents

Staphylococcal infections Methicillin-resistant *S. aureus* infections represent nearly 60% of nosocomial *S. aureus* isolates detected in hospitals and reported to the CDC.[32] For infections caused by susceptible *S. aureus*, a β-lactamase–resistant semisynthetic penicillin is the drug of choice because most strains of *S. aureus* are resistant to penicillin. At our center, only 45% of *S. aureus* organisms are methicillin susceptible, but more than 70% of coagulase-negative staphylococci are resistant to methicillin. The

problem of methicillin-resistant *S. aureus* is worsening, especially in tertiary medical centers. Although vancomycin is the preferred agent for treatment of methicillin-resistant staphylococcal infections, its use as monotherapy has come into question. At our center, the use of vancomycin alone to treat osteomyelitis caused by methicillin-resistant *S. aureus* has failed in the standard 4- to 6-week treatment regimen, and rifampin (300 mg p.o. twice daily) is now routinely added to the regimen, unless there is a contraindication to its use. Similar regimens are used to treat methicillin-resistant *S. epidermidis* infections, especially sternal bone infections after median sternotomy. Unfortunately, because failure of vancomycin alone has been observed with increasing frequency, objective clinical trials to determine efficacy are not likely to be performed, for ethical reasons.

In selected cases, after 2 weeks of parenteral therapy with vancomycin, patients can be switched to oral therapy if the appropriate requirements are met. Those requirements include good response to I.V. therapy, strict patient compliance, microbiologic diagnosis, isolated pathogen highly susceptible to the proposed antibiotic, and a high level of bioavailability of the oral agent (serum bactericidal titers may be useful).

Although oral therapy with ciprofloxacin has been effective in treating staphylococcal osteomyelitis,[33,34] reports of variable efficacy and the development of resistance indicate that ciprofloxacin should not be used as monotherapy in osteomyelitis caused by staphylococci.[35] However, long-term treatment with the combination of ciprofloxacin and rifampin has been successful for implant-related staphylococcal infections in patients who have stable implants and symptoms of short duration.[36] A recent study of 17 diabetic patients with mild to moderate foot lesions associated with 20 osteomyelitic bones received rifampin plus ofloxacin for 6 months; 88.2% of the patients were cured, and cure was maintained by 76.5% at the end of a 22-month follow-up.[37] Quinolones are contraindicated in children and pregnant women.

Enterococcal infections *Enterococcus faecalis* is an increasingly troublesome pathogen, especially in patients with infected prostheses and patients with diabetes who have osteomyelitis in the diabetic foot. Fortunately, *E. faecalis* does not usually cause osteomyelitis of long bones in the absence of prostheses. Because of the serious nature of a possible associated bacteremia in acute infections, aggressive therapy is necessary until acute symptoms resolve and blood cultures become negative.

E. faecalis is becoming a problem in postoperative orthopedic patients and in diabetic patients. The isolation of vancomycin-resistant *Enterococcus* species in tertiary medical centers has increased over the past few years. In a recent study, 89 patients with osteomyelitis were treated with linezolid and were evaluated for clinical efficacy, safety, and tolerability.

The clinical cure rate of 22 evaluable patients was 81.8%. The authors concluded that linezolid (administered either intravenously or by mouth) was successful in treating osteomyelitis caused by resistant gram-positive organisms.[38] However, hematologic complications have been found to be a limiting factor in long-term use of linezolid.[39] More experience is necessary before the ultimate use of linezolid in these patients is determined.

Gram-negative infections Treatment of gram-negative osteomyelitis requires an accurate identification of the organism and antimicrobial susceptibility. Oral ciprofloxacin is an effective and inexpensive choice for treating bone infections caused by Enterobacteriaceae.[22,33,34] Furthermore, studies have shown that ciprofloxacin and ofloxacin have been effective in treating osteomyelitis caused by multiresistant gram-negative bacteria.[40] Because of reports of the development of resistance, however, patients should be carefully monitored when either agent is used as monotherapy in pseudomonal osteomyelitis. Ceftazidime and cefepime are other potent antipseudomonal agents, although neutropenia has been associated with cefepime.[41] In cases of resistant strains of *Pseudomonas*, a regimen of an extended-spectrum penicillin and an aminoglycoside may be used; however, efficacy is not definitive in cases of osteomyelitis, and the toxicity of an extended regimen of I.V. aminoglycosides is a serious concern.

Treatment of Clinical Syndromes

HEMATOGENOUS OSTEOMYELITIS

In children with acute hematogenous osteomyelitis, antibiotic therapy alone may be sufficient. When the disease is recognized early and treated promptly, cure can be anticipated. Surgery should be considered for patients who do not respond to antibiotic therapy. For compliant children with a documented microbiologic infection who respond initially to parenteral therapy and who have no complications, the course of therapy may be completed with oral agents.[42] Cure rates of 95% have been obtained with this regimen. The suggested duration of I.V. therapy ranges from 4 to 14 days, and oral therapy is continued for 14 to 26 days.[43] Although some investigators have suggested that monitoring blood concentrations of antibiotics may be unnecessary,[42] most agree that adequate gastrointestinal absorption of the antibiotic should be confirmed by repeated measurements of serum bactericidal activity.[44] Close outpatient follow-up is essential.

In adults with hematogenous osteomyelitis, surgical debridement and drainage of soft tissue abscesses are often necessary. Antibiotic therapy is usually maintained for 4 to 6 weeks. I.V. administration is used most often; however, oral ciprofloxacin is used to treat gram-negative infections.

OSTEOMYELITIS SECONDARY TO A CONTIGUOUS FOCUS OF INFECTION

The diagnosis of osteomyelitis secondary to a contiguous focus of infection is based on a biopsy of the bone and not of the contiguous lesion. Once bone infection is confirmed by biopsy, treatment should proceed according to general principles of osteomyelitis management [*see* Treatment Overview, *above*].

OSTEOMYELITIS ASSOCIATED WITH VASCULAR INSUFFICIENCY

Prompt, aggressive surgical and antibiotic therapy and proper wound care are the best means of preserving a functional limb and optimizing outcome in patients with osteomyelitis associated with vascular insufficiency. Hyperbaric oxygen therapy, by increasing oxygen levels in ischemic tissues, has improved wound healing and reduced the amputation rate in high-risk patients. Revascularization of lesions in the lower-extremity vasculature by angioplasty and bypass grafting may help oxygenate tissue with critical ischemia, thereby preventing limb amputations. Prognosis for wound healing improves when the tissue oxygen level is greater than 40 mm Hg and when the popliteal pulse is palpable.[11]

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XVII INFECTIONS DUE TO RICKETTSIA, EHRLICHIA, AND COXIELLA

DANIEL J. SEXTON, M.D., F.A.C.P.

Taxonomy

Like other gram-negative bacteria, *Rickettsia* and *Ehrlichia* are members of the alpha group of purple bacteria. In the past, the family Rickettsiaceae was divided into three tribes: Ehrlichiae, Rickettsiae, and Wolbachia. The tribe Ehrlichiae was divided into three genera: *Ehrlichia*, *Cowdria*, and *Neorickettsia*. A new taxonomy of existing organisms has been proposed [*see Figure 1*] that is based on genetic analysis and divides the order Rickettsiales into two families, Rickettsiaceae and Anaplasmataceae; however, this taxonomy is still controversial and is likely to change in the future. The family Rickettsiaceae contains the genera *Orientia* and *Rickettsia*. The genus *Rickettsia* is divided into the typhus and spotted-fever groups, which in turn contain numerous species. For example, over 15 different spotted-fever-group rickettsial species have been named. The family Anaplasmataceae is divided into a complex number of *Anaplasma* and *Ehrlichia* genera. Some organisms previously considered to be *Ehrlichia* have been renamed *Anaplasma*.

Although the term ehrlichiosis is generally used by clinicians to describe tick-borne diseases caused by organisms in the genera *Ehrlichia* and *Anaplasma*, some organisms that were previously considered to be (and are still widely considered to be) *Ehrlichia* have been assigned to the genus *Anaplasma*. For example, the agent of human granulocytic ehrlichiosis (HGE) has been renamed *A. phagocytophilum* (some sources list this as *A. phagocytophilia* or *A. phagocytophila*). Although this chapter uses the old term, HGE, some authors now call this disease human granulocytic anaplasmosis. Moreover, some authors now use the term anaplasmosis instead of ehrlichiosis to describe infection by agents in the family Anaplasmataceae. To make taxonomic matters even more complicated, a surprising number of new spotted-fever-group rickettsial species have been discovered over the past 10 years. Additionally, previously recognized spotted-fever-group *Rickettsia* species (e.g., *R. parkeri*) that were thought not to cause human disease were recently confirmed to be human pathogens.[1]

Biology and Ecology

Rickettsia are gram-negative bacteria that are difficult to see in tissue without the use of special stains. *Rickettsia* can usually be visualized using Gimenez or special immunoperoxidase stains or can be detected in tissue by the use of direct fluorescent antibody staining techniques.

Rickettsia organisms cannot be propagated on cell-free media, but they can be grown in tissue cultures or in the yolk sacs of developing chick embryos. Members of the spotted-fever group, such as *R. rickettsii*, grow in both the nucleus and the cytoplasm of host cells, whereas typhus-group *Rickettsia* organisms grow only in the cytoplasm of infected host cells. Rickettsial cell walls contain lipopolysaccharides and outer-membrane proteins (rOmps). These rOmps are capable of eliciting a protective immune response in animals. Their exact function in arthropods and mammalian cells is uncertain.

Ehrlichia and *Anaplasma* organisms may infect monocytes (in human monocytic ehrlichiosis [HME]) or granulocytes (in HGE).

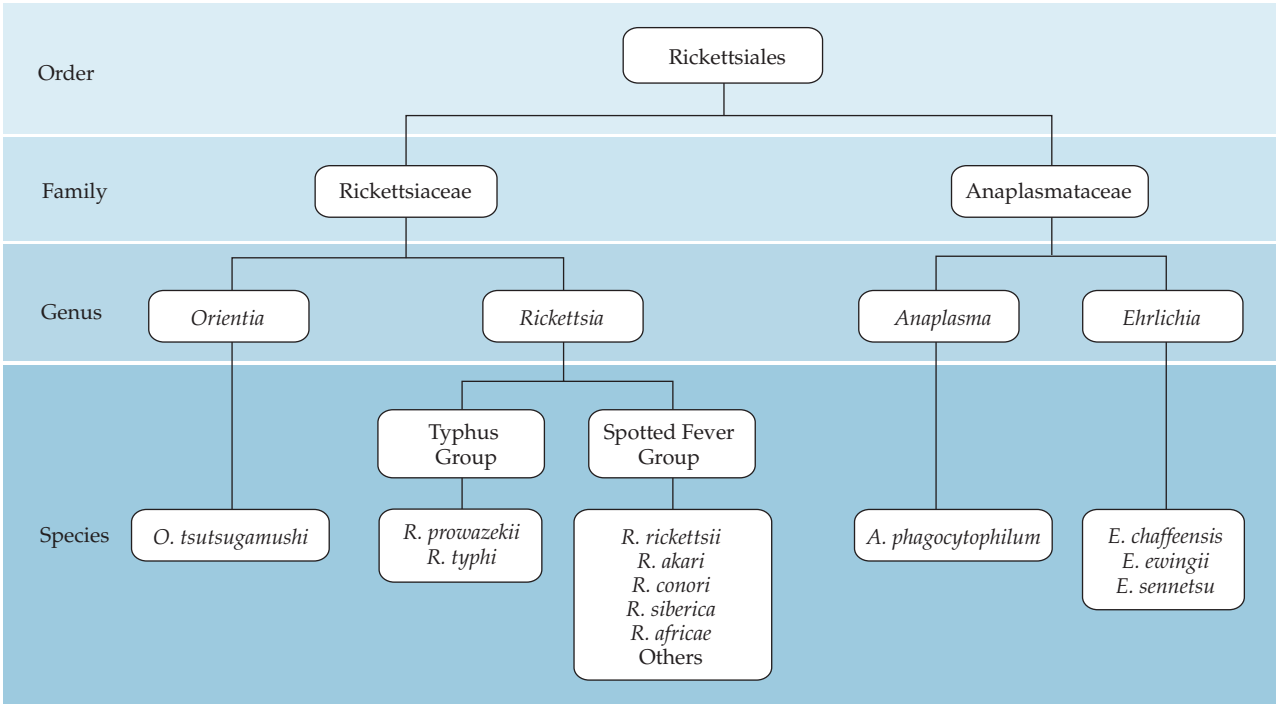

Figure 1 **Taxonomy of the rickettsias.**

Ehrlichia organisms replicate in the phagosomes of the host cell. Like *Rickettsia* organisms, *Ehrlichia* organisms have distinct ribosomes and are surrounded by an outer and inner membrane. *Ehrlichia* organisms can be detected by light microscopy when they exist as single organisms and can be stained with Gram, Giemsa, Wright, or silver stains. *Ehrlichia* organisms cannot be grown on cell-free media and thus far have been cultured only in eukaryotic cells and in yolk sacs.

Most *Rickettsia* and *Ehrlichia* organisms cycle between arthropod vectors and small mammals, infecting humans only as an incidental host. A notable exception to this pattern is *R. prowazekii*, which is primarily maintained in a human-louse cycle.

Pathophysiology

After inoculation into humans, *Rickettsia* organisms proliferate intracellularly and then spread throughout the body via the bloodstream or lymphatics. Spotted-fever-group *Rickettsia* species, such as *R. rickettsii*, have a specific and characteristic tropism for endothelial cells. After attachment to the host endothelial cell plasma membrane via a cholesterol-containing receptor, these organisms enter the cell via pinocytosis and then escape from phagosomes into the cytosol. *R. rickettsii* divides by binary fission and then spreads cell to cell via filopodia derived from host cell membranes.

The hallmark of most rickettsial diseases is cell injury or death associated with an intense vasculitis. Widespread *Rickettsia*-induced vasculitis in humans leads to minute focal areas of hemorrhage and edema (as a result of increased vascular permeability), along with activation of the humoral immune response, inflammation, and coagulation. Vasculitis from rickettsial infection may result in hypotension, shock, widespread organ dysfunction, and death. Although the histopathologic and clinical features of rickettsial infection have been well characterized, the precise cellular mechanism by which most *Rickettsia* organisms produce cell damage to small blood vessels is unknown.

Individual *Ehrlichia* and *Anaplasma* species infect hosts ranging from humans to dogs, sheep, and horses. Four species are known to infect humans: *E. chaffeensis* (the organism responsible for human monocytic ehrlichiosis), *A. phagocytophilum* (the agent of HGE), *E. sennetsu*, and *E. ewingii*.

Ehrlichia organisms enter host cells by phagocytosis and then grow and divide while in the host cell phagosome. After a few days, tightly packed clusters of organisms are observable as intracellular inclusions. Later, additional growth and replication of *Ehrlichia* organisms result in large, mature inclusions called morulae. In vitro growth of *Ehrlichia* and *Anaplasma* in tissue culture or yolk cell systems takes 8 to 36 days. Only a few isolates of *E. chaffeensis* and *A. phagocytophilum* have been cultured from humans, because in vitro cultivation of these organisms from clinical specimens is extremely difficult.

There is no serologic cross-reactivity between *Ehrlichia* and *Rickettsia*, although some cross-reactivity exists between *E. chaffeensis, E. ewingii*, and *A. phagocytophilum*. In animals, both experimentally induced and naturally acquired *Ehrlichia* infections may result in antibody responses, but these responses may not be protective. The relationship between humoral antibody responses and immunity in human ehrlichiosis is still not understood.

How *Ehrlichia* produces human disease is also poorly understood. *Ehrlichia* does not cause vasculitis, nor do human tissues infected with *Ehrlichia* demonstrate cell necrosis, abscess formation, or a severe inflammatory response. Patients infected with *Ehrlichia* may develop lymphadenopathy and perivascular lymphohistiocytic infiltrates without apparent endothelial injury or thrombosis. Some patients with *A. phagocytophilum* infection contract secondary opportunistic fungal infections. There is also no understanding of the mechanism for the thrombocytopenia that occurs, predictably and early, in most forms of ehrlichiosis. Studies in animal models have shown that decreased hematopoietic production, immune-mediated platelet destruction, and splenic sequestration are unlikely to be the primary mechanism for this thrombocytopenia.[2]

Rocky Mountain Spotted Fever

EPIDEMIOLOGY

Rocky Mountain spotted fever (RMSF) is an acute tick-borne illness caused by *R. rickettsii*. RMSF occurs widely in the Western Hemisphere, from southern Canada to Mexico. RMSF also occurs in Central America and has been described in Colombia and Brazil. The primary vectors of RMSF are the Rocky Mountain wood tick in the western United States and the American dog tick in the eastern United States. Other tick vectors are responsible for transmission in Mexico, Central America, and South America. Ticks represent both the reservoir and the vector of RMSF. *R. rickettsii* normally cycles between ticks and small mammals such as moles and rodents; humans are only an incidental host.

Although RMSF occurs sporadically in most of the continental United States in rural, suburban, and urban locations, it is most often reported from the southeastern and south central United States. Cases of RMSF have been reported from Central Park in New York City and from suburban areas such as Long Island, New York. Over 90% of all cases of RMSF occur from early spring to early autumn.

Up to one third of patients with proven RMSF cannot recall a history of tick bite or recent tick contact. Rickettsial transmission in such cases presumably occurs through inapparent or unrecognized tick bite or through contact with infected tick tissues.

DIAGNOSIS

Clinical Manifestations

RMSF typically begins abruptly. The incubation period after tick bite or tick exposure ranges from 2 to 12 days. The early phases of illness are usually marked by nonspecific symptoms such as fever, headache, malaise and myalgias, and nausea and vomiting. Some patients, especially children, have prominent abdominal pain; this pain may be severe enough to mimic an acute surgical abdomen. Rarely, gastrointestinal involvement in the early phases of RMSF leads to an erroneous diagnosis, such as acute appendicitis, cholecystitis, or even bowel obstruction. Hepatic involvement in severe cases can result in jaundice, which may be striking.

The skin rash that gives RMSF its name may begin as a macular or maculopapular eruption and evolve into a generalized petechial rash [*see Figure 2*]. Generalized ecchymosis and even gangrene of the digits, genitals, ears, and nose may rarely occur in severe cases.[3] The rash typically develops on the third to the fifth day of illness. Appearance of the rash may be delayed, however; and in a small percentage of patients, the rash does not develop at all. Delay or absence of the rash greatly complicates clinical diagnosis. In one study, only 14% of RMSF patients had a rash on

Figure 2 **Purpuric macules on the palm and wrist of a patient with Rocky Mountain spotted fever.**

the first day of illness and fewer than 50% developed a rash in the first 72 hours of illness.[4] Absence of rash does not correspond to milder disease; a small percentage of patients with so-called spotless RMSF have fatal illness.[5] Moreover, the characteristic skin rash of RMSF may be overlooked in dark-skinned patients.

Patients with RMSF may occasionally present with a wide variety of neurologic symptoms ranging from confusion to seizures and encephalopathy. Some patients with RMSF have focal neurologic signs that lead to misdiagnoses. Neurologic symptoms may persist after recovery of acute illness in some patients.[6] Other atypical and uncommon presenting features of RMSF include periorbital edema (especially in children) and cough.

The diagnosis of RMSF is notoriously difficult, even for experienced physicians in highly endemic areas. In the first few days of illness, particularly when the characteristic rash is absent, RMSF may mimic an array of nonspecific viral diseases. If early RMSF is mistaken for a bacterial illness and if β-lactams or other antibiotics ineffective against *R. rickettsii* are given, the subsequent appearance of a rash may be tragically mistaken for a drug eruption and lifesaving therapy may be omitted or delayed. RMSF has been confused with measles, staphylococcal bacteremia, hepatitis, leptospirosis, meningococcemia, and infectious mononucleosis.[7] The clinical features of RMSF and ehrlichiosis are often similar [*see Table 1*]. Even experienced physicians cannot always distinguish the two diseases, although the presence of severe leukopenia and the absence of rash favor the diagnosis of ehrlichiosis.[8]

It is axiomatic that the diagnosis of RMSF must be based on the clinical features and an appropriate epidemiologic setting rather than on any single laboratory test. There is no completely reliable diagnostic test for RMSF in the early phases of illness; thus, therapy should always begin before laboratory confirmation is obtained.

Laboratory Studies

The white blood cell count remains normal in most patients with RMSF. In some cases, however, the WBC may be low or elevated. Thrombocytopenia generally occurs in severe cases and is a helpful diagnostic finding. The low platelet count may be accompanied by reduced fibrinogen concentrations and elevated levels of fibrin split products. Other characteristic laboratory abnormalities in patients with RMSF include elevated blood levels of aminotransferases, bilirubin, and creatinine.

Diagnostic proof of RMSF can be obtained by direct immunofluorescent or immunoenzyme staining of skin biopsy samples or, in the convalescent phase of the disease, by the detection of characteristic antibodies. These antibodies typically do not appear before day 8 to 10 of illness; thus, serologic testing has no role in the initial diagnosis of acutely ill patients with suspected RMSF.

Culture of *Rickettsia* from blood samples can be done only in specialized laboratories and the delay in obtaining a result makes positive cultures useful only in retrospect. Polymerase chain reaction technology has been applied to the diagnosis of RMSF, but such testing is neither sensitive nor widely available. Because some patients die before generating an antibody increase against *R. rickettsii* antigen, the diagnosis in fatal cases may be completely missed unless immunohistochemical staining is performed on tissues obtained at autopsy.[9]

TREATMENT

Tetracyclines and chloramphenicol are the only antibiotics known to be effective against *R. rickettsii*. Doxycycline is the preferred agent in all patients except pregnant women, for whom chloramphenicol remains the agent of choice. Therapy should be initiated as early as possible in the course of RMSF. Therapy started more than 5 days after onset is much less likely to be effective than therapy given earlier.[10]

The usual dosage of doxycycline is 200 mg a day in two divided doses. The same dosage can be administered intravenously or orally. Intravenous therapy is preferred for patients who are seriously ill or who are experiencing nausea or vomiting. Children with RMSF should be given doxycycline at a dosage of 2.5 to 3 mg/kg/day in two divided doses. Chloramphenicol given at an initial loading dose of 50 mg/kg, followed by 50 mg/kg/day in four divided doses, is an appropriate alternative for patients who cannot tolerate tetracyclines or who are pregnant [*see Table 2*].

Unfounded fears about the risk of tetracycline therapy in children with suspected rickettsial disease may unnecessarily delay the institution of potentially lifesaving therapy.[11] Because RMSF can normally be cured with a short course of doxycycline therapy, concerns about staining of the teeth should not prohibit the use of doxycycline in young children with suspected RMSF; indeed, such therapy may be lifesaving, and it is considerably safer than therapy with chloramphenicol. In addition to antimicrobial therapy, treatment should include measures to correct associated complications, such as hypotension, heart failure, and electrolyte disturbances. Glucocorticoid therapy has never been shown in a controlled study to be useful in the treatment of RMSF, and it is not recommended.

PREVENTION

The prevention of RMSF relies on avoidance of tick-infested areas or the use of protective clothing and tick repellent while in such areas. Prompt removal of ticks after attachment is particularly important. Ticks should be removed using tweezers, tissue, or cloth to protect the fingers, because crushed tick tissues can be infectious.

PROGNOSIS

In consequence of the difficulty in making a conclusive diagnosis of RMSF in the early phases of illness, delays in the initiation of therapy are common. Such delays are often associated

Table 1 Diagnosis of Diseases Caused by *Rickettsia*, *Ehrlichia*, and *Coxiella* Species

Disease (Pathogen)	*Rocky Mountain Spotted Fever* (Rickettsia rickettsii)	*Rickettsialpox* (Rickettsia akari)	*TIBOLA*	*Murine Typhus* (Rickettsia typhi)	*Epidemic Typhus* (Rickettsia prowazekii)	*Scrub Typhus* (Orientia tsutsugamushi)	*Ehrlichial Diseases*	*Q Fever* (Coxiella burnetii)
Animal Reservoir	Rocky Mountain wood tick (western U.S.), American dog tick (eastern U.S.)	House mouse via bloodsucking mite	Tick (*Dermacentor marginatus*)	Rat, cat, or mouse flea	Human body louse (squirrel lice and fleas in sylvatic form)	Mite (Pacific rim)	White-tailed deer, rodents	Cattle, goat, sheep, cats, dogs, ticks
Transmission	Tick bite	Mite bite	Tick bite	Flea bite	Louse or flea bite	Mite bite	Tick bite	Airborne, direct contact, infected milk
Incubation Period (Range)	2–12 days	2–12 days	3–10 days	8–16 days	7–10 days	7–10 days	3–12 days	29 days (range, 10–39 days)
Clinical Manifestations	Fever, headache, malaise, myalgias, nausea/vomiting; abdominal pain; rash on days 3–5 in most but not all cases; jaundice	Eschar at bite site, then severe headache, fever, chills, myalgias, papulovesicular rash	Localized lesion at bite site; cervical or regional lymphadenopathy; fever and rash in < 10% of cases; alopecia may occur and persist at site of local lesion	Fever, chills, headache, myalgias, GI symptoms; rash at end of first week beginning on trunk, spreading to extremities; cough, dyspnea in severe illness	Acute severe infection, fever, headache, myalgias, cough, abdominal pain, GI symptoms, jaundice; red macular/maculopapular rash on trunk spreading to extremities; neurologic symptoms may occur	Necrotic eschar at bite site; fever, headache, anorexia, malaise, chills; macular/maculopapular rash in half of patients, usually sparing the face; generalized lymphadenopathy; respiratory symptoms; neurologic symptoms may occur	Headache, fever, anorexia, malaise, cough, nausea and vomiting; rash uncommon	Fever, headache, myalgias, anorexia, malaise, chills; chest pain, cough, rales, pneumonia; hepatitis; chronic disease in immunocompromised patients; may cause endocarditis
Laboratory Test Results	Thrombocytopenia, elevated plasma aminotransferase, elevated bilirubin, elevated serum creatinine, positive serology, positive PCR; culture difficult	Thrombocytopenia, mild elevations in plasma aminotransferases; positive serology	Thrombocytopenia, positive serology, positive PCR	Thrombocytopenia; positive serology	Elevated aminotransferases, thrombocytopenia; positive serology	Serology not reliable in early phases; antibodies present 10–20 days after onset	Serology not reliable in early phases, antibodies present 10–20 days after onset; positive PCR; culture difficult	Elevated antibody titer, positive PCR

PCR—polymerase chain reaction TIBOLA—tick-bite–associated lymphadenopathy

with fatal outcome if they exceed 5 days. A number of host factors have been associated with severe or fatal RMSF, including increasing age, male gender, and the presence of glucose-6-phospate dehydrogenase (G6PD) deficiency. Black race and alcohol use have also been associated with more severe disease and a higher fatality, but it is difficult to exclude the role of delay in seeking or receiving antimicrobial therapy in these patients. The biologic causes for the worse outcomes seen in patients older than 40 years and in male patients remain poorly understood. Patients with abnormal renal function at the time of presentation have a worse prognosis than those with normal renal function.[12]

Rickettsialpox

Rickettsialpox is an uncommon mite-borne rickettsial disease caused by *R. akari*. The disease's name is derived from its clinical resemblance to chickenpox.

EPIDEMIOLOGY

R. akari is transmitted to the house mouse by a blood-sucking mite (*Liponyssoides sanguineus*). The mouse serves as a reservoir for the disease, and as with RMSF, humans are only an incidental host. When mouse populations are reduced by vermin-eradication programs, *L. sanguineus* will bite humans and transmit rickettsialpox. Initially, rickettsialpox was recognized only in urban areas such as New York City, Pittsburgh, Cleveland, and Boston. However, cases have now been described in rural areas and in areas outside the previously recognized geographic range for the disease, including North Carolina, the Ukraine, Croatia, Turkey, and the Yucatan region of Mexico.[13]

DIAGNOSIS

Rickettsialpox is usually recognized by the appearance of one or more characteristic skin lesions (eschars) at the site of the bite, followed soon thereafter by the abrupt onset of headache, fever, chills, and myalgias and a papulovesicular

Table 2 Treatment of Diseases Caused by *Rickettsia*, *Ehrlichia*, and *Coxiella* Species

Infection	*Drug*	*Dosage*	*Relative Efficacy*	*Cost*[*]	*Comments*
Rocky Mountain spotted fever, rickettsialpox, murine typhus, infections due to other spotted-fever-group *Rickettsia* species	Doxycycline	100 mg q. 12 hr I.V. or p.o for 5–7 days	First choice	Oral, $6–8	I.V. preferred for adult and pediatric patients who are seriously ill or who have nausea or vomiting
	Chloramphenicol	50 mg/kg initial loading dose, then 50 mg/kg/day in 4 divided doses	—	—	For pregnant women and those who cannot tolerate tetracycline
Epidemic typhus	Doxycycline	Single dose of 200 mg; repeat weekly for prophylaxis	First choice	$1	—
	Chloramphenicol	50 mg/kg initial loading dose, then 50/mg/kg day in four divided doses for 5–7 days	—	—	For pregnant women and those who cannot tolerate tetracycline
Scrub typhus	Doxycycline plus rifampin	Doxycycline, 100 mg q. 12 hr I.V. or p.o. for 3–7 days; rifampin, 600 mg/day for 5–7 days	First choice	Oral doxycycline, $3–8; rifampin, $20–28	This regimen may not be effective in geographic areas where strains with reduced susceptibility to tetracyclines have been documented (see text for details)
	Azithromycin or rifampin	Azithromycin, 500 mg/day for 5–7 days; rifampin, 600 mg/day for 5–7 days	—	Azithromycin, $75–105; rifampin, $20–28	For use in areas with strains with reduced susceptibility to tetracycline; for pregnant women
Ehrlichia, Anaplasma phagocytophilia infection	Doxycycline	100 mg q. 12 hr I.V. or p.o. for 5–7 days	First choice	Oral, $6–8	—
	Chloramphenicol	50 mg/kg initial loading dose, then 50/mg/kg day in four divided doses for 5–7 days	—	—	Efficacy unproven; for pregnant women and those who cannot tolerate tetracyclines
Q fever (acute disease)[†]	Tetracycline	500 mg, p.o., q. 6 hr for 14 days	Equally effective	$15	—
	Doxycycline	100 mg, p.o., q. 12 hr for 14 days	Equally effective	$15	—
	Ciprofloxacin	500 mg, p.o., q. 12 hr for 14 days	Equally effective	$131	—

[†]For recommendations on treatment of chronic Q fever, see text.

rash. Most patients with rickettsialpox are only mildly ill and recover without treatment after 10 to 14 days of illness. Headache is characteristically severe. The skin rash of rickettsialpox can be distinguished from that of chickenpox by the fact that it typically begins as a maculopapular eruption that quickly evolves into a papulovesicular eruption. Most patients with vesicular lesions also have a primary eschar at the site of their mite bite. Lesions in rickettsialpox are often scant, characteristically scab, and resolve without scarring. Unlike the rash of chickenpox, the rash of rickettsialpox does not appear in crops or clusters, nor do the vesicular lesions of rickettsialpox have the characteristic dew-drop appearance of chickenpox lesions. Certain other rickettsial diseases that produce eschars and vesicular rashes can mimic rickettsialpox [*see* Other Spotted-Fever-Group Rickettsial Infections, *below*].

The diagnosis of rickettsialpox is typically confirmed by serologic testing. However, biopsy of the eschar or the rash can be diagnostic if special fluorescent antibody reagents are available to demonstrate *R. akari* in tissue.

TREATMENT

Treatment for rickettsialpox is identical to that for RMSF (see above).

Other Spotted-Fever-Group Rickettsial Infections

Other tick-borne spotted-fever-group rickettsial infections include Mediterranean spotted fever, African tick-bite fever, Queensland tick typhus, Siberian tick typhus, Japanese spotted fever, Flinders Island spotted fever, tick-borne lymphadenopathy (TIBOLA), and *R. parkeri* infection. All of these illnesses respond to treatment with tetracyclines or chloramphenicol. Most are milder in course and severity than RMSF, although Mediterranean spotted fever may, in rare cases, be fatal.

In addition to rickettsialpox, six spotted-fever-group rickettsioses are characterized by localized eschars (Mediterranean spotted fever, African tick-bite fever, *R. parkeri* infection, Queensland tick typhus, and Siberian tick typhus). TIBOLA is not usually associated with a generalized rash; rather, this unusual rick-

ettsiosis is characterized by a localized area of scalp alopecia. The alopecia typically follows the development of a crusted lesion at the site of a resolving tick bite. Localized hair loss may be prolonged. Cervical or regional lymphadenopathy is common in TIBOLA. Only a minority of TIBOLA patients have fever, and rash occurs in fewer than 10% of patients.[14]

Infection with a newly recognized rickettsial agent, *R. mongolotimonae*, has been seen in southern France. In the few cases reported to date, clinical manifestations have typically been similar to those of Mediterranean spotted fever.[15]

A recent report of human infection with *R. parkeri* suggested that some cases of apparent RMSF in the United States, especially those in which an eschar was present at the site of a tick bite, may in fact be infection with the spotted-fever-group agent *R. parkeri*.[16]

Murine Typhus

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

Murine typhus occurs worldwide. It is caused by *Rickettsia typhi,* which is transmitted to humans by the bite of an infected flea. Although house mice, domestic cats, and shrews may be occasional hosts for infected fleas, the principal reservoir of *R. typhi* is the rat. In addition to serving as hosts for infected fleas, rats may become rickettsemic after contact with such fleas and then transmit organisms to other, simultaneously feeding fleas. When such fleas happen to bite humans, murine typhus may result. Murine typhus is uncommon in the United States, although a relatively large number of cases have been reported in southern Texas during the past 20 years. A total of 47 cases of murine typhus were reported in Hawaii during 2003, which is a remarkable increase from previous numbers, and serologic evidence of *R. typhi* infection has been demonstrated in a variety of rodent species in Hawaii.[17]

DIAGNOSIS

Clinical Manifestations

Onset of murine typhus is typically abrupt, occurring after an incubation period ranging from 8 to 16 days. Early manifestations of illness are nonspecific, typically comprising fever, chills, headache, and myalgias. In addition, many patients have gastrointestinal complaints, including nausea, vomiting, abdominal pain, and diarrhea. Rash typically occurs near the end of the first week of illness. The rash is classically described as beginning on the trunk and spreading to the extremities. Rash may be faint or difficult to see, and in some patients, it does not occur at all. Murine typhus is usually a mild illness; even in untreated cases, deaths are rare. However, severe disease with mental confusion, encephalopathy, renal dysfunction, and severe thrombocytopenia can occur. Patients with severe illness may develop cough and dyspnea. As in other rickettsial diseases, the presence of G6PD deficiency and advanced age appear to be associated with more severe or fatal disease.

Laboratory Studies

Thrombocytopenia is present in most cases of murine typhus and is an important laboratory clue to the diagnosis. As in other rickettsial diseases, serology is the most reliable and widely available diagnostic method. Convalescent antibodies typically appear after 8 to 10 days of illness. In severely ill patients with pulmonary manifestations, chest x-rays may show interstitial infiltrates or changes suggestive of pneumonia or pulmonary edema.

TREATMENT

As in other rickettsial diseases, the only effective agents for treatment of murine typhus are tetracyclines and chloramphenicol, with doxycycline the preferred choice in most patients. The dosages of doxycycline in the treatment of murine typhus are the same as those in the treatment of RMSF [*see Table 2*].

Epidemic (Louse-Borne) Typhus

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

Louse-borne, or epidemic, typhus, caused by *R. prowazekii*, killed millions of people in Eastern Europe and Russia during the periodic wars that devastated this geographic area during the past 2 centuries. Fortunately, epidemic typhus is now a rare disease. However, sporadic outbreaks still occur in parts of Russia, Algeria, and Burundi and in the Andes Mountains of South America.[18] War, famine, and human cruelty can result in epidemics; for example, more than 45,000 cases of epidemic typhus occurred in Burundi after the 1993 civil war in that country.[19]

Until 25 years ago, epidemic typhus was thought to involve an exclusive cycle between the body louse and infected humans. However, a sylvatic cycle of infection with *R. prowazekii* is now known to be endemic in the eastern United States. This sylvatic cycle of infection involves flying squirrels (*Glaucomys volans*) and their ectoparasites, but secondary transmission in humans has been recognized when lice that normally infest squirrels seek a host in humans.[20] A case report of epidemic typhus in a patient from the southwestern United States (an area outside the known geographic range of the flying squirrel) suggests the existence of additional vectors or wild-animal reservoirs for *R. prowazekii*.[21]

The principal vector for epidemic typhus is the human body louse (*Pediculus humanus corporis*), although occasionally, the head louse (*P. humanus capitis*) can also transmit infection [*see 2:VIII Parasitic Infestations*]. Both the squirrel flea (*Orchopeas howardi*) and the squirrel louse (*Neohaematopinus sciuropteri*) also act as vectors for *R. prowazekii* in the sylvatic cycle of infection. Infected fleas and lice are capable of producing a rickettsemia in flying squirrels and thus allowing propagation of infection to additional generations of ectoparasites.

In its classic epidemic form, typhus is transmitted by body lice. While taking a blood meal from humans, body lice defecate and regurgitate infective gastrointestinal contents; these highly infective substances are then inoculated into the skin when the person scratches the pruritic feeding site. Lice feces remain infectious for as long as 100 days. Thus, human-to-human transmission of *R. prowazekii* can occur via the sharing of clothes or via transfer of infected lice feces from one human to another.

Transmission of the sylvatic form of epidemic typhus to humans occurs only when humans have direct contact with infected squirrels or when squirrels nesting in the attics of homes are removed or killed, leaving the lice that infested their nests to seek an alternative (human) host.

PATHOPHYSIOLOGY

After entering the human body, *R. prowazekii* spreads via the bloodstream and lymphatics to produce a generalized vasculitis. The precise mechanism by which *R. prowazekii* produces cellular injury is poorly understood, but the net effect of this infection is

widespread endothelial injury. This rickettsial vasculitis may produce diffuse myocarditis, along with macroscopic and microscopic damage to muscles and neural tissue, the spleen, kidneys, and other internal organs. Central nervous system involvement may result in so-called typhus nodules, which comprise perivascular infiltrates consisting of lymphocytes, macrophages, and plasma cells.

DIAGNOSIS

Clinical Manifestations

R. prowazekii infection produces two distinct clinical syndromes. The most common is an acute, severe infection that occurs 7 to 10 days after exposure to infected lice and may result in death. A second, recrudescent form, called Brill-Zinsser disease, may occur from 1 to 5 decades after a primary infection.

Patients with acute epidemic typhus infection typically become abruptly ill with fever, headache, and myalgias. Other nonspecific symptoms, such as cough, abdominal pain, nausea, and diarrhea, are common. Skin rash in patients with epidemic typhus classically begins several days after the onset of symptoms as a red macular or maculopapular eruption on the trunk that then spreads to the extremities. Although skin rash is classically described as sparing the palms and soles, exceptions to this rule occur. In severe cases of epidemic typhus, skin rash may become petechial; rarely, gangrene of the extremities has been described.

In humans, the clinical features of the sylvatic form of typhus are similar to those of the epidemic form. In one series, however, only half of the patients with the sylvatic form of *R. prowazekii* infection had a skin rash.

Patients with epidemic typhus often have neurologic symptoms that may range from mild confusion and drowsiness to coma, seizures, and focal neurologic findings. As in other rickettsial diseases, jaundice and myocarditis may occur in severe cases.

Recrudescent *R. prowazekii* infection (Brill-Zinsser disease) is generally a much milder illness than acute epidemic typhus. The onset of Brill-Zinsser disease is often abrupt, with chills, fever, and headache. Skin rash typically begins 4 to 6 days after the onset of symptoms, and it is often scant or evanescent. Because patients with Brill-Zinsser disease are often elderly or have other chronic medical conditions, their symptoms (e.g., confusion, dyspnea, and lethargy) may be incorrectly attributed to preexisting or coexisting cardiac, cerebrovascular, or pulmonary disease.

Laboratory Studies

Both forms of *R. prowazekii* infection are best diagnosed by serologic testing. The indirect immunofluorescent antibody (IFA) test and an immunoblot technique are reliable serologic methods. A fourfold rise in antibody titers 10 to 21 days after onset of symptoms is considered diagnostic in both forms of *R. prowazekii* infection, although only an IgG antibody response is elicited in Brill-Zinsser disease.

Common accompanying laboratory findings in acute epidemic typhus include increased plasma aminotransferase levels and thrombocytopenia. Patients with severe involvement may have pulmonary infiltrates and other laboratory evidence of myocarditis.

TREATMENT

Tetracyclines and chloramphenicol are effective treatments for both acute and recrudescent *R. prowazekii* infections, but the drug of choice is doxycycline. In one study, 35 of 37 patients with epidemic typhus were cured with a single 200 mg dose of doxycycline.[22] However, the two remaining patients had a relapse 6 and 7 days after initial response. Patients with *R. prowazekii* infection characteristically improve within 48 hours of initiation of antirickettsial therapy. In severe cases, supportive care with vasopressors, intravenous fluids, oxygen, and even dialysis may be necessary.

PREVENTION

Efficacy of prophylaxis for epidemic typhus is directly related to the efficacy of prophylactic measures against lice infestation. Because humans who have contacts with other lice-infested humans can secondarily acquire lice even if they have good hygiene, all louse-infested persons and workers in close contact with such persons should use long-acting topical insecticides such as malathion, lindane, or a pyrethroid (permethrin). Fabrics and clothing treated with permethrin remain toxic to lice even after 20 washings.[23]

In epidemic settings, the use of chloramphenicol or tetracycline for prophylaxis of *R. prowazekii* infection is highly effective. Even a single 200 mg dose of doxycycline taken once weekly by travelers or health care workers in areas where epidemic typhus is present has been shown to protect against infection. Prophylaxis should be continued for 1 week after leaving an endemic or epidemic area.[24]

Inactivated vaccines have been shown to confer protection against experimental *R. prowazekii* infections.[24] Such vaccines are not currently commercially available nor are they likely to become available, in view of the effectiveness of both prophylactic antibiotics and other preventive measures.

PROGNOSIS

In the preantibiotic era, higher mortality from epidemic typhus was associated with older age and male gender. With prompt institution of antimicrobial therapy, however, mortality is now rare.

Scrub Typhus

Scrub typhus is a mite-borne disease, caused by *Orientia tsutsugamushi*, that was first described by Chinese physicians in the third century. Widespread outbreaks of scrub typhus in Allied soldiers in the Pacific theater of World War II led to investigations by military physicians that provided much of our current understanding of the clinical features, diagnosis, and prevention of this highly geographically focal disease.

EPIDEMIOLOGY

O. tsutsugamushi is distributed throughout the Pacific rim and is endemic in Korea, China, Taiwan, Japan, Pakistan, India, Thailand, Malaysia, and northern Australia. Most cases of scrub typhus occur in rural areas, but cases may also occur in suburban areas, such as those around Bangkok, where the seroprevalence in the general population may be as high as 20%.[25]

The reservoir and vector of scrub typhus are trombiculid mites of the genus *Leptotrombidium*. Larval mites (known as chiggers) maintain the infection in successive generations via transovarial transmission. Because the geographic distribution of mites is often highly focal, areas as small as a few hundred square meters of scrub vegetation may contain enormous numbers of infected chiggers. The risk of disease transmission by these chiggers may be extremely high in humans who enter these focal ar-

eas (also called mite islands). Because of the ease of air travel and the long incubation period of scrub typhus (up to 2 weeks), tourists to endemic areas may fall ill after returning home to regions where the illness is not familiar to physicians. Numerous cases of scrub typhus have been described in tourists returning to the United States, Europe, and Canada from endemic regions.

BIOLOGY AND PATHOPHYSIOLOGY

O. tsutsugamushi is distinct serologically and epidemiologically from typhus-group *Rickettsia*. However, this organism shares many of the microbiologic characteristics of typhus and spotted-fever-group *Rickettsia*, such as inability to be propagated on cell-free media. Unlike other *Rickettsia* species, *O. tsutsugamushi* has a trilaminar outer membrane. *O. tsutsugamushi* is also unique in that it is released from infected cells by a peculiar budding process involving the plasma membrane of host cells. Once released from the infected cell, organisms are in turn phagocytosed by adjacent cells and eventually disseminate widely throughout the body.

There are three strains of *O. tsutsugamushi*: Karp, Gilliam, and Kato. Infection with one strain does not preclude infection with a different strain.

DIAGNOSIS

Clinical Manifestations

Onset of scrub typhus typically occurs 7 to 10 days after the person is bitten by an infected mite. The illness may begin gradually or abruptly. In either case, headache, anorexia, malaise, chills, and fever are prominent early symptoms. Approximately one half of patients with scrub typhus develop a characteristic macular or maculopapular rash. In severe cases, this rash may become petechial. Rash from scrub typhus typically spares the face.

A localized necrotic skin lesion or eschar is a hallmark of scrub typhus [*see Figure 3*]. Eschars typically occur at the site of the infected chigger bite and may appear before the onset of systemic symptoms. Some patients have multiple eschars. In various case series, eschars have occurred in as few as 40% and as many as 88% of patients with scrub typhus.[26]

Generalized lymphadenopathy occurs in most patients with scrub typhus; some patients also have splenomegaly. Respiratory involvement occurs more often in scrub typhus than in other rickettsial diseases, and cough may be present in as many as one half of patients. As in other rickettsial diseases producing vasculitis, scrub typhus may be marked by neurologic involvement, which may manifest as aseptic meningitis, seizures, or focal neurologic abnormalities. In some patients, neurologic abnormalities are the dominant symptoms.

DIAGNOSIS

The initial diagnosis of scrub typhus must be based on clinical and epidemiologic features, because serologic testing is not reliably positive in the early phases of illness. Convalescent antibodies, which are best detected by an IFA technique, occur in the majority of patients between 10 and 20 days after onset of illness. Because more than one strain of *O. tsutsugamushi* is capable of causing scrub typhus, a battery of antigens should be used to detect convalescent antibodies. In addition to IFA testing, an enzyme-linked immunosorbent assay (ELISA) and a dot-blot immunoassay have been developed to diagnose scrub typhus.

Although not commonly done, biopsy of the generalized rash or the eschar can help establish the diagnosis of scrub typhus.

Figure 3 **Eschar at the site of a mite bite in a patient with scrub typhus.**

Examination of the biopsy sample will reveal vasculitis with a perivascular collection of lymphocytes and macrophages.

Culture of *O. tsutsugamushi* can be performed in specialized centers with the necessary laboratory facilities and diagnostic reagents; a PCR-based test has also been developed. However, such tests are rarely available in regions of the world where scrub typhus is endemic.

DIFFERENTIAL DIAGNOSIS

Scrub typhus is one of the classic causes of tropical fever in the Pacific Rim, where it is well known to be easily confused with malaria, dengue, or typhoid fever. Coinfection with scrub typhus and leptospirosis has been described in agricultural workers in Thailand. One of these workers, who was treated with penicillin only, died of respiratory failure attributed to untreated scrub typhus infection.[27]

TREATMENT

The treatment of scrub typhus is the same as that of most other rickettsial diseases [*see Table 2*]. Doxycycline is typically the agent of choice. Regimens of doxycycline as short as 1 day have been advocated for the therapy of scrub typhus, but a small number of patients treated with this short course suffer relapse.[28,29] To prevent relapse, most experts recommend a 3- to 7-day course of therapy with doxycycline.

In the mid-1990s, strains of *O. tsutsugamushi* with reduced susceptibility to tetracycline were reported in Thailand.[30] Azithromycin may be effective against strains with reduced susceptibility to tetracycline and, therefore, may be selected for therapy in areas where such strains are known or suspected to exist. However, there is little clinical experience, as well as few in vitro susceptibility data, to support this choice. Azithromycin may also be used to treat pregnant woman infected with typhus.

A randomized trial in northern Thailand compared the efficacy of doxycycline alone with the combination of doxycycline and rifampin for scrub typhus. The median duration of fever was significantly shorter in patients treated with the combined regimen.[31]

PREVENTION

Although there is no vaccine available to prevent the transmission of scrub typhus, several studies have demonstrated that doxycycline is highly effective for prophylaxis when used by nonimmune persons living and working in areas where scrub

typhus is highly endemic. A weekly dose of 200 mg of doxycycline has been shown to be reasonably effective in preventing transmission.

Human Monocytic Ehrlichiosis

EPIDEMIOLOGY

The principal vector of HME is the Lone Star tick (*Amblyomma americanum*) The causative agent of HME, *E. chaffeensis*, was first isolated from a soldier at Fort Chaffee, Arkansas, in 1990. Since then, HME has been recognized as endemic throughout the southeastern and south central United States. In addition, a few cases of HME have been recognized in New England and the Pacific Northwest, and isolated cases have been reported in Europe, Africa, and Mexico.[32]

In some locations, HME is probably more common than RMSF. In a prospective study of 35 consecutive patients from North Carolina who presented to outpatient facilities with fever and a recent history of tick bite, 26% had HME, 17% had RMSF, and one patient was coinfected with *R. rickettsii* and *E. chaffeensis*. Most of these patients received outpatient treatment with doxycycline, and all of them recovered quickly.[33]

Estimates of the incidence of HME have varied widely. A prospective study of febrile patients hospitalized in southeast Georgia in the United States showed that the prevalence of HME was 5.7 cases per 100,000 population.[34] A remarkably higher incidence was described in a golf-oriented retirement community in Tennessee, in which the annual incidence of disease was 660 per 100,000.[35] A serosurvey in the same community revealed that 12.5% of the residents had serologic evidence of past infection. Tick bites, exposure to wildlife, and golfing were associated with an increased risk of infection.

White-tailed deer are thought to be the principal animal reservoirs for *E. chaffeensis* infection. A study from Georgia found serologic evidence of *E. chaffeensis* infection in 27 of 35 deer and isolated *E. chaffeensis* from five of them, confirming that deer are naturally infected in endemic areas.[36] Although the role of wild canids and domestic dogs in the epidemiology of HME is uncertain, in one study 15 of 21 coyotes trapped in Oklahoma were found to be infected with *E. chaffeensis*.[37]

DIAGNOSIS

As with other tick-borne diseases, the diagnosis of HME is usually based on the recognition and synthesis of characteristic clinical and laboratory features in patients who reside in a geographic location where ehrlichiosis is known to occur during a time of year when tick exposure is likely or known. In other words, a history of tick bite or tick exposure during the spring or summer months in a resident of an endemic area, coupled with the presence of leukopenia or thrombocytopenia and abnormal liver function test results, provides strong circumstantial evidence for the diagnosis of HME. Even the presence of some of these findings is sufficient justification for the initiation of therapy.

Clinical Manifestations

After an incubation period of 5 to 14 days, patients with HME typically develop fever along with malaise and headache. Chills occur in approximately two thirds of patients, and gastrointestinal symptoms, including nausea and vomiting, may occur in up to one half of patients. Cough may also be a prominent symptom of HME, leading to diagnostic confusion with a host of respiratory illnesses. Although HME usually presents as an acute illness, subacute infection from *E. chaffeensis* has been described. In one study, for example, six of 41 patients with HME diagnosed at a medical center in Missouri during a 4-year period had protracted fever, ranging in duration from 17 to 51 days.[38] In addition, rare cases of subclinical or self-limiting infection with *E. chaffeensis* have been described.

Skin rash is uncommon in patients with HME, but when present, it may be macular, maculopapular, or petechial. Although skin rash was reported in 36% of cases in one case series of 211 patients with HME, skin rash has been less common in the experience of many clinicians working in HME-endemic regions.[39] The clinical features of HME are highly variable. Some patients present only with headache, anorexia, and malaise, whereas other patients have prominent neurologic symptoms that may include mental-status changes and stiff neck.

Laboratory Studies

The most common laboratory abnormalities seen in patients with HME are leukopenia (often accompanied by a left shift), thrombocytopenia, and elevated levels of aminotransferases (transaminases), lactate dehydrogenase, and alkaline phosphatase. Anemia and an elevated plasma creatinine concentration also may be seen. Later in the course of illness or during recovery, a striking atypical lymphocytosis may occur.

Abnormalities of the cerebrospinal fluid are common in patients in whom a lumbar puncture is performed because of neurologic symptoms. Lymphocytic pleocytosis and elevated CSF protein levels were found in 21 of 38 patients with *E. chaffeensis* infection in one study.[40]

The detection of morulae in lymphocytes in smears of the peripheral blood or buffy coat can occasionally be useful and even diagnostic. Unfortunately, morulae are seen in only a small minority of patients with HME. Thus, such testing has a low sensitivity, even though the finding of morulae is highly specific.

HME can be confirmed serologically with an IFA test using *E. chaffeensis* as the test antigen. IFA tests can be obtained through all state health departments. The current case definition of HME used by the Centers for Disease Control and Prevention requires at least a fourfold rise or fall in IFA titer against *E. chaffeensis* between the acute stage and convalescent stage, with a minimum titer of 1:64.[41] An important limitation of this test is that antibodies first become detectable 2 to 3 weeks after the onset of the illness. Thus, as with RMSF, serology is useful only in confirming infection, not in the decision to initiate therapy

Culture of *Ehrlichia* is extremely difficult. Only a few isolates of *E. chaffeensis* have been made from humans, and in such cases, detection required over 30 days of cultivation.[42] PCR-based testing is available for the diagnosis of HME, but such testing is performed only in special laboratories and remains mostly a research tool.

DIFFERENTIAL DIAGNOSIS

Ehrlichiosis may be easily confused with RMSF, a wide number of common viral illnesses (e.g., mononucleosis), thrombotic thrombocytopenic purpura, hematologic malignancy, cholangitis, the early phases of hepatitis A infection, and community-acquired pneumonia.

TREATMENT

The treatment of HME is the same as that of HGE (see below).

PROGNOSIS

Estimated mortality for patients with HME has ranged from 2% to 5%. The available mortality data are limited and are based on small case series, which may overestimate the actual risk.

Human Granulocytic Ehrlichiosis (Anaplasmosis)

EPIDEMIOLOGY

First described in 1994 in patients from the north central United States, HGE is now known to occur in Wisconsin, Minnesota, Connecticut, New York, Massachusetts, California, and Florida, as well as in western Europe.[43] A population-based surveillance study from northwestern Wisconsin reported an incidence of 9.5 HGE cases per 100,000 population in an area where the incidence of Lyme disease was 57 cases per 100,000 population.[44] Epidemiologic serosurveys have demonstrated that 3% to 15% of asymptomatic persons living in endemic areas may have antibodies to the HGE agent.[45]

A. phagocytophilum, the causative agent of HGE, is primarily transmitted by *Ixodes scapularis*, the tick that is also the vector of Lyme disease and babesiosis. *I. pacificus*, the black-legged tick, is the primary vector of HGE in the western United States, and *I. ricinis* is the presumed vector in Europe.

DIAGNOSIS

The diagnosis of HGE must sometimes be made on a circumstantial basis, by synthesis of the history and the clinical and epidemiologic features of an individual case. Clinicians should consider HGE as a possible diagnosis in any patient with a nonspecific febrile illness who becomes ill in the spring or summer months, who inhabits or has visited an endemic region, or who has a history of recent tick bite or tick exposure. Laboratory studies can support, and sometimes confirm, the diagnosis. However, the absence of such findings—in particular, the failure to detect morulae in leukocytes—should not dissuade clinicians when the overall picture suggests HGE.

Clinical Manifestations

The incubation period (5 to 14 days) and clinical features of HGE are similar to those of HME. Most patients with HGE have nonspecific symptoms such as malaise, myalgia, headache, nausea, vomiting, arthralgias, and cough. In a study of 18 adults with HGE, symptoms appeared an average of 5.5 days after a tick bite was noted.[46]

Clinically, HGE can range from mild to severe. Fatal HGE has been documented: a retrospective case study of 41 patients with laboratory-diagnosed HGE infection found a case-fatality rate of 4.9%.[47] Many of the patients who died had secondary opportunistic infections, such as fungal pneumonia. However, other studies have estimated that the mortality for HGE may actually be less than 1%.[43]

Laboratory Studies

The diagnosis of HGE can be confirmed by finding characteristic intraleukocytic morulae in the peripheral blood [*see Figure* 4] or buffy coat, by serology (using IFA testing), or by PCR testing.

The frequency of detecting morulae in the peripheral smears of patients with HGE has varied in different case series. In one report, typical morulae were found in the peripheral smear in 28 of 35 patients with laboratory-confirmed HGE infection.[47] The percentage of infected neutrophils ranged from 1% to 44% (median, 5%). In another study of patients with HGE, from the upper Midwest and New York, morulae were visible in neutrophils in 86 of 141 patients (61%).[48]

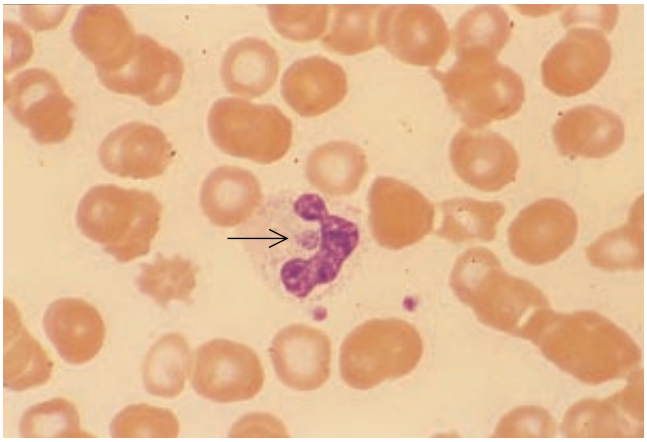

Figure 4 **In a peripheral blood smear from a patient with human granulocytic ehrlichiosis, a typical round ehrlichial morula is seen at the center of the neutrophil, adjacent to the nuclear lobes (arrow). Two platelets can be seen below and to the right of the neutrophil, for comparison. Wright-Giemsa stain was used; original magnification:** x **370.**

The most characteristic laboratory abnormality in patients with HGE is thrombocytopenia. In addition, patients with HGE typically manifest relative and absolute lymphopenia during the early phases of their infection, and significant increases in the band neutrophil counts occur during the first week of illness.[48] It is important to emphasize that automated blood counts are unable to distinguish between band and normal neutrophils or to detect morulae. Therefore, a manual differential WBC should be ordered whenever HGE is suspected.

Diagnosis of Coinfection with Borrelia burgdorferi

Because the agent of Lyme disease and HGE are transmitted by the same vector, it is not surprising that a number of reports have described patients who were coinfected with *B. burgdorferi* and *A. phagocytophilum*.[49] In studies of *I. scapularis* ticks from different locales, 2.2% to 26% of ticks were infected with both pathogens.[50] The diagnosis of HGE can easily be missed in such patients because the typical rash of early Lyme disease (erythema migrans) may mislead the clinician into failing to consider the possibility of coinfection with *A. phagocytophilum*. Such coinfection should be suspected when patients with presumed Lyme disease also have some or many of the following findings: leukopenia, thrombocytopenia, cough, high fever, or abnormal liver enzyme test results. Similarly, when rash is present in a patient with known or presumed HGE, the possibility of coinfection with *B. burgdorferi* should be suspected.

TREATMENT

As with HME, treatment should be initiated in all patients suspected of having HGE. The drug of choice is doxycycline, given orally or intravenously at a dosage of 200 mg/day in two divided doses. Intravenous therapy is preferred for patients who are seriously ill or experiencing nausea or vomiting. Children should be given doxycycline at a dosage of 2.5 to 3 mg/kg/day in two divided doses. There is no consensus on the use of chloramphenicol; many experts advise against its use for any form of ehrlichiosis. Patients who have intolerance or allergy to tetracy-

clines can be treated with rifampin for 7 to 10 days, but such patients require careful follow-up and monitoring, because there is only anecdotal information on the efficacy of this therapy in patients with HGE (and even less information on its efficacy in HME).[43]

At present, there are no guidelines for the treatment of ehrlichiosis in pregnancy. However, a report describing the successful treatment of two cases of HGE using rifampin suggests that other *Ehrlichia* species (e.g., *E. chaffeensis*) may be susceptible to rifampin as well.[51]

In one study, *A. phagocytophilum* was susceptible in vitro to fluoroquinolones and rifampin. However, the most active fluoroquinolone was trovafloxacin, which is not in general use because of concerns about hepatic toxicity.[52]

Even without treatment, most patients with ehrlichiosis probably make a full recovery. There is no evidence that untreated ehrlichiosis produces a chronic illness such as that which occurs with Lyme disease. However, infection may not confer long-lasting immunity. One report describes a patient who experienced two episodes of HGE spaced 2 years apart. At the onset of the second infection, the antibody titer to *A. phagocytophilum* had fallen from 1,280 to 80.[53]

Q Fever

EPIDEMIOLOGY AND ETIOLOGY

Q fever (the Q stands for "query") was first described in 1935 by Edward Derrick, after he investigated an outbreak of febrile illness involving abattoir workers in Queensland, Australia. Q fever is now known to be a worldwide zoonosis with highly variable clinical features. The causative organism, *Coxiella burnetii,* is a strictly intracellular pathogen that replicates and persists in cells in phagolysosomes. Microbial products, including acid phosphatase, help the organism resist the acidic and presumably harsh vacuolar environment.[54] In addition, vegetative *C. burnetii* cells form endogenous sporelike structures that resist extreme environmental conditions; spore formation has been observed in infected cardiac valves.[55] Because of these microbiologic characteristics, *C. burnetii* is capable of surviving prolonged drying in dust and excreta and can remain viable for months in water and milk. *C. burnetii* can be grown in cultured mammalian cells and in small animals but is not able to replicate on cell-free media.

The most common reservoirs for *C. burnetii* are cattle, goats, and sheep. Animals infected with *C. burnetii* are rarely symptomatic, but they shed organisms in their milk, urine, feces, and placentas. Infected placental tissue, postpartum discharges, and feces are presumed to be the principal sources of transmission to other animals and to humans. Domestic cats and dogs may also acquire *C. burnetii* and become sources for zoonotic transmission to humans.[56] Numerous tick species are also naturally infected with *C. burnetii*. Such infected ticks may transmit *C. burnetii* to other generations of ticks transovarially and via tick bites to wild rodents. Livestock sometimes acquire *C. burnetii* infections from infected ticks, but most often, they become infected by inhalation of contaminated dust.

Dairy and slaughterhouse workers are at increased risk for acquiring Q fever. However, sporadic cases of Q fever may occur in humans who acquire infection via infectious aerosols that were generated at relatively long distances from the site of acquisition. Infected milk may also account for some outbreaks of the disease in humans. Human infection from tick bites is extremely rare. *C. burnetii* is highly infectious in the laboratory, and outbreaks have occurred in researchers. Transmission between humans is rare, but transmission during delivery (to an obstetrician)[57] and sexual transmission[58] have been described. Exposure to wild rabbits, parturient cats, and products of feline parturition may lead to Q fever pneumonia in humans, sometimes by an indirect route (e.g., from contaminated clothing). Such cases illustrate an important clinical point: Q fever may occur in urban dwellers without obvious or direct contact with animals.

Q fever is endemic throughout the six populated continents, but it is particularly common in the Mediterranean and Persian Gulf regions. The diagnosis of Q fever should be considered in travelers and military personnel who return to the United States from endemic areas. In the United States and Canada, Q fever still occurs sporadically, particularly in areas where cattle, sheep, and goats are raised. Because of the difficulty in diagnosis and because spontaneous improvement occurs in many patients who do not receive effective antimicrobial therapy, the true prevalence of Q fever in the United States is unknown.

DIAGNOSIS

Clinical Manifestations

Q fever is usually classified into acute and chronic forms. Asymptomatic infection is also common. Acute Q fever may manifest as a self-limiting febrile illness, an influenzalike lower respiratory tract infection, hepatitis, or pneumonia. A small number of well-documented cases of meningoencephalitis from *C. burnetii* infection have also been described.[59] Patients with chronic *C. burnetii* infection may develop granulomatous hepatitis with prolonged fever, myocarditis, pericarditis, or endocarditis.

The incubation period of Q fever ranges from 10 to 39 days, with an average duration of 20 days.[60] The initial manifestations of acute *C. burnetii* infection are systemic and nonspecific—headache, chills, fever, myalgias, anorexia, and malaise. Skin rash does not occur in patients with Q fever. High fevers and headache often persist, and after 4 or 5 days of fever, patients typically manifest pneumonia, cough, chest pain, and inspiratory rales. In most cases, chest radiographs show focal areas of pneumonitis. Radiologic changes may be more marked than symptoms or physical findings. A minority of patients with Q fever pneumonia develop pleural effusions, hemoptysis, and even respiratory failure.[61] Pulmonary involvement occurs in about 50% of patients, but the incidence of this complication may vary with geographic location. In certain parts of the world, hepatitis may be more common than pneumonia in patients with acute Q fever.[62] Hepatitis in patients with acute Q fever usually lasts for 1 to 2 weeks and follows a benign, self-limited course. Complications are rare. However, granulomatous hepatitis with hepatosplenomegaly, jaundice, and abnormal liver function test results can also persist along with fever for up to 3 or 4 weeks.

In approximately 2% to 11% of infected persons, a chronic form of Q fever will develop insidiously a few months to as long as 20 years after the acute illness. Risk factors for chronic Q fever include underlying valvular heart disease and an immunocompromised state.[63] Infective endocarditis caused by *C. burnetii* is a common feature of the chronic syndrome.[64] The disease may affect healthy valves, previously damaged native valves, or prosthetic valves. Q fever endocarditis is sometimes insidious in onset and is often accompanied by granulomatous hepatitis. Other forms of endovascular infection with *C. burnetii* also occur, including infections of aneurysms and grafts.

Laboratory Studies

The diagnosis of acute Q fever is usually established by demonstration of a fourfold or greater rise in complement-fixing antibody titer against *C. burnetii* phase II antigen.[65,66] IFA techniques and ELISA offer greater sensitivity than complement-fixation methods. IFA techniques for the early detection of specific IgM antibody are the serodiagnostic method of choice. The diagnosis of chronic Q fever or Q fever endocarditis is established by detecting elevated titers (i.e., > 1:200) of IgG or IgA antibodies against *C. burnetii* phase I antigen or by a ratio of anti–phase I antibody to anti–phase II antibody of 1 or greater.

C. burnetii can be isolated from blood, sputum, or urine by intraperitoneal inoculation in guinea pigs, inoculation into chick embryos, or inoculation of cultured human fetal diploid fibroblasts. Because this organism is so highly contagious in the laboratory, attempts at isolation should be made only in a special biologic containment facility.

Echocardiography may not be diagnostic in Q fever endocarditis. A study that examined the heart valves removed from 28 patients with Q fever endocarditis showed that infected valves were usually fibrotic and calcified but that most had only slight inflammation. Only two of 16 patients with native Q fever endocarditis and two of 10 patients with bioprosthetic Q fever endocarditis had macroscopic vegetations, yet *C. burnetii* was isolated by culture in 64% of these patients and identified by PCR in 75%.[67]

DIFFERENTIAL DIAGNOSIS

Early in its course, Q fever resembles a variety of acute febrile illnesses, including an array of viral respiratory infections, viral hepatitis, and infectious mononucleosis. In patients with a history of contact with livestock, other zoonoses (e.g., brucellosis and leptospirosis) should be considered along with Q fever. In patients who present with pneumonia, infection with *Mycoplasma pneumoniae*, *Chlamydia pneumoniae* and *C. psittaci*, *Legionella pneumophila*, *Histoplasma capsulatum,* and the agents causing viral pneumonia should also be considered in the differential diagnosis. When hepatitis is present and noncaseating granulomas are found on liver biopsy, a host of causes of granulomatous hepatitis (e.g., tuberculosis, sarcoidosis, brucellosis, and histoplasmosis) must be considered. Q fever should always be considered when the clinical features of endocarditis are present but blood cultures are negative.

TREATMENT AND PREVENTION

Effective treatment for acute Q fever is tetracycline, 500 mg orally every 6 hours; doxycycline, 100 mg orally every 12 hours; or ciprofloxacin, 500 mg orally every 12 hours. Most patients treated early in the course of the infection recover rapidly; however, acute Q fever is usually self-limited.

If left untreated, Q fever endocarditis is fatal. Valve replacement is often necessary, in addition to prolonged antimicrobial therapy. Prolonged antibiotic therapy is necessary both for those who have valve surgery and for those in whom medical therapy alone is used. A study of cardiac valves in patients with Q fever endocarditis found that histologic, microbiologic, or molecular detection of *C. burnetii* was possible in more than 80% of patients who had been treated for less than 1 year; cultures and PCR tests were still positive in 22% and 33% of patients, respectively, who were treated for more than 1 year before valve excision.[67]

Medical regimens employing different antimicrobial agents, either alone or in combination, have been tried with variable success in Q fever endocarditis.[68,69] Some experts recommend treatment with doxycycline plus rifampin or with doxycycline plus a fluoroquinolone for at least 3 years.[70] Chloroquine has been also used as adjunctive therapy because of its ability to block intracellular vacuole acidification and, hence, growth of *C. burnetii*.

Patients with Q fever need not be isolated, because secondary cases do not occur. Killed vaccines made from *C. burnetii* grown in chick embryo cultures are immunogenic and can provide protection for persons at high risk, such as dairy and slaughterhouse workers, woolsorters, tanners, and laboratory workers. However, vaccines against *C. burnetii* are not commercially available for human use in the United States.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XVIII INFECTIVE ENDOCARDITIS

David T. Durack, m.b., d.phil., f.a.c.p.
Adolf W. Karchmer, m.d., f.a.c.p.

Infective endocarditis is a relatively rare but important disease, presenting in a wide variety of forms and manifestations; all are associated with significant morbidity and mortality. The diagnosis and management of infective endocarditis involves many clinical specialties, including internal medicine, cardiology, infectious diseases, microbiology, radiology, cardiovascular surgery, neurology, nephrology, and dentistry.

Definitions and Terminology

Infective endocarditis is a localized microbial infection of cardiac valves or mural endocardium caused by bacteria or fungi. The primary lesion is a vegetation, which is an infected platelet-fibrin thrombus located inside the heart. Native valve endocarditis is an infection of either normal or abnormal natural heart valves, whereas prosthetic valve endocarditis (PVE) involves implanted artificial valves. Nosocomial endocarditis occurs as a complication of medical treatment. On the basis of its clinical course, endocarditis may be classified as either acute or subacute. The acute form, often called acute bacterial endocarditis (ABE), is caused by invasive pathogens and tends to be rapidly progressive, usually leading to hospital admission less than a week after clinical onset and causing death in less than 4 weeks unless successfully treated. The subacute form, often called subacute bacterial endocarditis (SBE), is usually caused by low-grade pathogens or commensal organisms, with symptoms often present for weeks to months before diagnosis. Nonbacterial thrombotic endocarditis (NBTE) and marantic endocarditis refer to sterile vegetations in the heart, which can develop at the same locations as the vegetations of infective endocarditis. Infective endaortitis and infective endarteritis are analogous conditions that are localized on the endothelial surface of the aorta or large arteries, respectively.

Epidemiology

The overall incidence of infective endocarditis ranges from 1.7 to 6.2 cases per 100,000 person-years.[1-3] Although the overall incidence has remained relatively stable over the past 5 decades, the relative frequency of the disease in particular subgroups has changed, as have many other aspects of its epidemiology. The median age of patients with endocarditis has increased; 50% of patients are older than 55 years.[1,4,5]

Among the major predisposing conditions, chronic rheumatic heart disease has become relatively uncommon in developed countries, whereas degenerative valvular diseases, such as calcified aortic stenosis, calcified mitral valve annulus, and mitral valve prolapse have become more important.[6] Cases of endocarditis associated with parenteral drug abuse and prosthetic cardiac valves have become more common, as has nosocomial infective endocarditis. Infections involving implanted intravascular devices other than valves are increasing in frequency.

Etiology

Gram-positive cocci, comprising various species of streptococci and enterococci, as well as *Staphylococcus aureus*, are the leading cause of community-acquired native valve endocarditis[1-3,6] [*see Table 1*]. SBE is usually caused by relatively avirulent bacteria, the most common species being streptococci from the normal oral or gastrointestinal flora. These organisms lack sufficient invasiveness to infect normal heart valves or endocardium, but they can infect deformed heart valves and some congenital cardiac lesions. The leading examples are the α-hemolytic streptococci, a heterogeneous collection of species that are loosely grouped together under the term viridans streptococci because they cause incomplete, greenish hemolysis when grown on blood agar.

Many of the streptococci that cause endocarditis can be categorized according to Lancefield serogrouping. About 20% are group D (mainly enterococci and *Streptococcus bovis*), about 15% are group H (*S. sanguis* and others), and about 15% belong to other serogroups, including B, C, G, and K. About 5% are anaerobic streptococci, and the remaining 40% to 45% are nongroupable viridans streptococci.

Enterococcus faecalis, E. faecium, and the nonenterococcal group D streptococcus *S. bovis*, all of which originate from the GI and genitourinary tracts, are important causes of SBE. The portal of entry for *S. bovis* is often a malignant or premalignant lesion in the colon.[7] Consequently, evaluation for possible colonic lesions is mandated for patients who have developed *S. bovis* SBE.

Coagulase-negative staphylococci (many of which are species other than *S. epidermidis*), and fastidious gram-negative HACEK organisms (*Haemophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella*, *Kingella*) are other important causes of infective endocarditis. Species that less commonly cause infective endocarditis are *Brucella*, *Legionella, Coxiella burnetii, Chlamydia psittaci*, and *Corynebacterium*.[8,9] *Bartonella*, recognized as a cause of infective endocarditis only in the mid-1990s, may account for up to 3% of cases in some regions.[10] *B. quintana* endocarditis occurs more commonly in the homeless, and endocarditis caused by *B. henselae* may be associated with cats.[10-12] Corynebacteria (diphtheroids) usually involve prosthetic heart valves. Endocarditis caused by *Coxiella burnetii*, a notably indolent infection, occurs in the setting of preexisting valvular disease[13] [*see 7:XVII Infections Due to Rickettsia, Ehrlichia, and Coxiella*].

ABE is commonly caused by primary pathogens, microorganisms that are more invasive than most of the species causing SBE. These invasive organisms can infect both normal and abnormal heart valves and mural endocardium; can rapidly destroy cardiac valves; can more readily invade perivalvular tissues to form abscesses; and can establish metastatic suppurative foci at distant sites in the body such as the brain or spleen. *S. aureus* is the most frequent and most important cause of ABE; others include *S. pneumoniae*, group A streptococci, *Neisseria gonorrhoeae, Salmonella* species, other members of the family Enterobacteriaceae, and *Pseudomonas aeruginosa*. *Salmonella* is the most frequent cause of infective aortitis in the elderly; these patients may have a continuous *Salmonella* bacteremia in the absence of a cardiac murmur.

Nosocomial endocarditis is a complication of nosocomial bacteremias or fungemias, often associated with intravascular and other indwelling devices, genitourinary tract manipulation, or wound infections.[14-18] The primary pathogens are *S. aureus*, enterococci, and coagulase-negative staphylococci, most of which are methicillin-resistant *S. epidermidis*. In parenteral drug abusers, *S. aureus* (often methicillin resistant) causes 50% or more of cases of infective endocarditis[19] [*see Table 1*].

Fungal endocarditis can be caused by yeasts or molds.[20,21] The leading causative agents are yeasts of the genera *Candida* and *Torulopsis;* endocarditis from these yeasts arises as a complication of parenteral drug abuse, of prosthetic valves, or of intravascular devices, such as pacemakers. Endocarditis caused by mycelial or dimorphic fungi is relatively rare but can occur in parenteral drug abusers, patients with prosthetic valves, or immunocompromised patients. *Aspergillus* species cause most of these cases; the remainder are caused by *Histoplasma*, *Penicillium*, and a wide variety of other fungi.

Table 1 Causes of Native Valve Endocarditis[2,5,6,18,49,109]

Microorganism	*Representative Percentage of Cases*		
	Community Acquired	*Nosocomial*	*I.V. Drug Abusers*
Staphylococcus aureus	25	55	55
Coagulase-negative staphylococci	3	5	2
Streptococci	35	5	10
Enterococci	10	20	15
Gram-negative bacilli	3	5	8
HACEK	3	rare	rare
Pneumococci	1	rare	rare
Yeasts and fungi	1	5	4
Polymicrobial and miscellaneous	5	3	4
Culture-negative	15	2	2

Note: Reported percentages of cases vary widely between many published series. HACEK—*Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* species, and *Kingella* species

Pathogenesis

HOST FACTORS

Two host factors strongly predispose to development of infective endocarditis: (1) a damaged or otherwise abnormal endocardial surface and (2) high-velocity, turbulent blood flow across a defective valve or a congenital defect. Both factors favor platelet deposition. When blood is driven from a high-pressure area into a low-pressure sink, the dynamics of pressure gradients and turbulent flow favor deposition of platelets on nearby endothelium, especially if that endothelium is already abnormal as a result of previous disease such as rheumatic fever, congenital abnormalities, degenerative conditions, or infective endocarditis. Subsequently, a form of localized thrombosis can occur, resulting in the formation of a sterile platelet-fibrin aggregate known as nonbacterial thrombotic endocarditis.[22] During transient bacteremias, passing microorganisms can adhere to this nidus, which provides them with both nutrition and protection from host defenses, especially leukocytes. The platelet-fibrin layers form an effective physical barrier between the embedded bacteria and leukocytes from the blood. This situation permits luxuriant growth; the organisms often attain vast numbers and form dense colonies within the platelet-fibrin aggregate. The bacteria themselves may promote further thrombosis by elaborating extracellular products that cause platelet aggregation or by eliciting procoagulant tissue factor from the endothelial substrate and local monocytes.[23,24] In this way, the newly infected thrombotic lesion grows to form a macroscopic vegetation; these vegetations constitute the prototypical pathologic lesion of infective endocarditis.[22]

Local host defenses that could inhibit or kill bacteria in the vegetation include leukocytes, antibodies and complement, and platelet-derived bactericidal proteins (thrombocidins).[25,26] These antimicrobial host defenses may succeed in curing some early cases of endocardial infection, but apparently they seldom if ever succeed in eradicating the organisms once a vegetation is fully established.

PATHOGEN FACTORS

The streptococci that most frequently cause SBE—the viridans streptococci (including *S. mutans, S. mitior*, and *S. sanguis* [group H]), and *S. bovis* (group D)—readily adhere to platelet-fibrin thrombi, owing to the presence of dextran and other "sticky" molecules (adhesins) on their surfaces.[27] Streptococcal species that do not produce dextran may also cause endocarditis, but they do so less frequently. Virulent organisms, such as those associated with ABE, may adhere to either normal or abnormal endocardial surfaces. Fibronectin receptors and clumping factor, which occur on the surface of *S. aureus*, appear to facilitate the adherence of these organisms to cardiac valves.[27-29] Bacterial species that are resistant to platelet-derived microbicidal proteins are more likely to cause endocarditis than susceptible strains.

Clinical Presentations

SUBACUTE BACTERIAL ENDOCARDITIS

The constitutional symptoms of SBE usually begin insidiously and often persist for weeks to months. Fevers, sweats, weakness, myalgias, arthralgias, malaise, anorexia, and easy fatigability are prominent. Fewer than 5% of patients are afebrile, and such patients are often elderly, markedly malnourished, or azotemic. Chills and chilly sensations are common, but frank rigors are unusual.

Because of greater awareness of this disease and more frequent use of blood cultures in the evaluation of febrile illnesses, the diagnosis of SBE is now made earlier than in the past; consequently, many of the classic features of longer-standing SBE (e.g., splenomegaly, clubbing, and Osler nodes) are seldom present. Fever and other nonspecific symptoms in the presence of a predisposing cardiac lesion may be the only clinical manifestations of SBE in some patients. The presenting complaints may arise from organs or sites other than the heart, which may confuse the diagnosis. For example, if the patient has meningitis, cerebral emboli, or glomerulonephritis, the physician's attention may be focused on the central nervous system or kidneys as the primary site of illness. Although it was once taught that the symptoms of endocarditis in the elderly are milder than in young patients, current data suggest that the clinical features are fairly similar across age groups.[30]

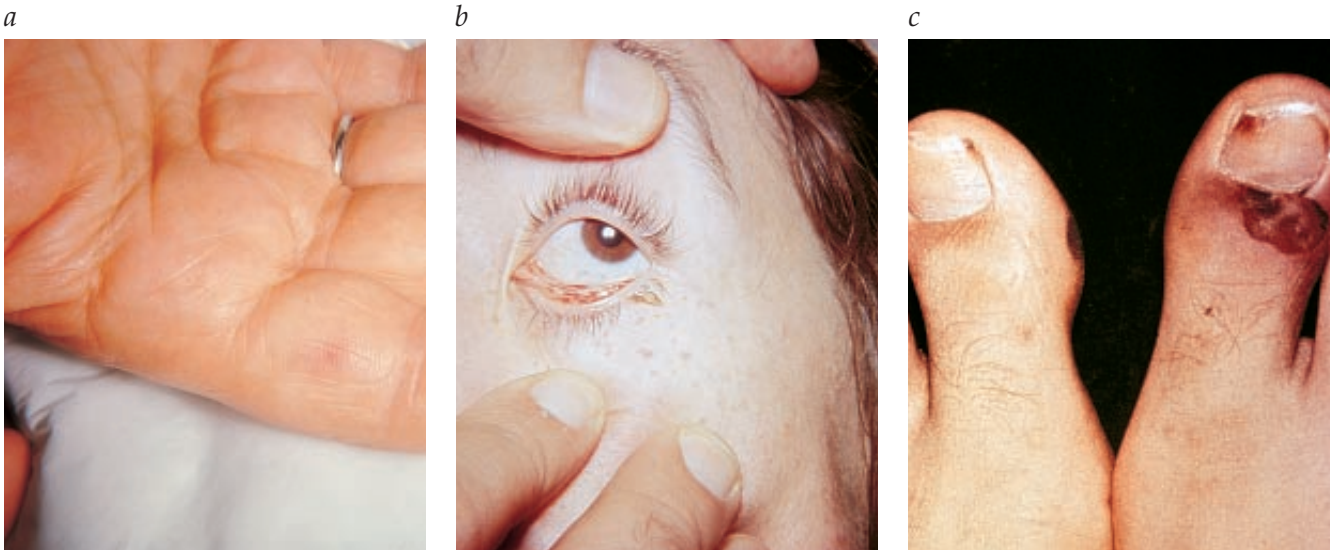

Figure 1 **Findings on physical examination of patients with endocarditis. (*a*) Erythematous, palpable, nontender lesion at the base of the first finger consistent with a Janeway lesion. (*b*) Conjunctival petechiae. (*c*) Pustulonecrotic septic embolic lesions at the base of the nail of the right great toe and at the medial aspect of the left great toe at the level of the distal interphalangeal joint.**

ACUTE BACTERIAL ENDOCARDITIS

The onset of ABE is usually abrupt, and rigors are common.[31,32] Fevers reach 39.4° to 40.6° C (102.9° to 105.1° F) and are often remittent. Cutaneous manifestations, particularly petechiae and small peripheral infarcts, may be prominent, especially in ABE from *S. aureus*. Occasionally, the clinical features in a patient with acute *S. aureus* endocarditis mimic those of acute meningococcemia, with similar skin lesions, including petechiae, purpura, and focal gangrene; similar hematologic changes, including disseminated intravascular coagulation; and neurologic findings of nuchal rigidity and CSF pleocytosis. Pustular petechiae or purulent purpura strongly suggest *S. aureus* endocarditis rather than meningococcemia [*see Figure 1*]. A Gram stain and culture of material from a skin lesion sometimes can reveal the etiologic agent and thus direct antibiotic therapy.

Emboli are common in ABE. Metastatic infections in the spleen, bones (particularly the vertebrae), joints, kidneys, brain, eye (endophthalmitis), and lungs may arise from either septic embolization or sustained bacteremia. These metastatic infections may cause organ-specific symptoms or persistent fever in spite of antimicrobial therapy and may require drainage or surgical intervention. Osler nodes may occur, but less often than in SBE; Janeway lesions occur in 5% to 10% of patients who have *S. aureus* endocarditis [*see* Cutaneous Manifestations, *below*].

The appearance of a new cardiac murmur, particularly one characteristic of valvular insufficiency, strongly suggests valvular destruction and thus helps confirm a diagnosis of ABE. Valvular damage can lead to severe heart failure, necessitating valve replacement surgery. A few patients with ABE have no detectable cardiac murmur.

CARDIAC FINDINGS

The cardiac manifestations of infective endocarditis reflect any underlying valvular or congenital lesions, with superimposed findings from endocarditis itself. Murmurs are present in more than 90% of patients. Changes in the intensity of a systolic murmur may be associated with the development of anemia, high fever, or tachycardia and are often of little significance. However, the appearance of a new murmur indicating valvular regurgitation is a key diagnostic event, which also may have implications for surgical intervention. A new aortic diastolic murmur suggests dilatation of the aortic annulus or eversion, rupture, or fenestration of an aortic leaflet. The sudden onset of a loud mitral pansystolic murmur suggests rupture of a chorda tendineae or fenestration of a mitral valve leaflet.

Heart failure resulting from valvular dysfunction may be progressive, becoming severe in some patients. Extension of infection into the annulus may result in cardiac rhythm disturbances, particularly if the infection progresses through the right coronary and noncoronary leaflet portion of the aortic annulus into the membranous septum and the area of the atrioventricular node.[33] Occasionally, annular infection extends to the pericardium and causes pericarditis [*see* Diagnostic Features of Cardiac Complications, *below*].

CUTANEOUS MANIFESTATIONS

Petechiae commonly occur in the conjunctivae [*see Figure 1*], in the oropharynx, and on the skin; they are particularly common on the lower extremities. Petechiae may continue to appear for some time despite appropriate antibiotic treatment. Linear subungual "splinter" hemorrhages located in the base or in the middle of the nail bed are a feature of SBE, whereas splinter hemorrhages in the distal nail bed are more often the result of trauma. Osler nodes—tender, purplish subcutaneous nodules that develop in the pulp of the fingers and disappear within several days—occur in about 5% of patients with endocarditis. Osler nodes may be caused by small emboli or may result from an immunologically mediated small-vessel vasculitis. Small, flat, nonpainful erythematous or hemorrhagic areas on the palms or soles, called Janeway lesions, are common in ABE and also may occur in SBE [*see Figure 1*].

MUSCULOSKELETAL FEATURES

Myalgias, arthralgias, arthritis, or low back pain occurs in 40% to 50% of patients with SBE; in about half of these patients, such symptoms represent either initial or prominent manifestations of the disease. Painful, warm, red, tender joints may be noted, but joint effusions are rare. Immunologic mechanisms

cause synovial inflammation, articular symptoms, and abnormal laboratory test results. Rheumatoid factor is present in up to 50% of patients with endocarditis of more than 6 weeks' duration; antinuclear antibody is found in some patients; and circulating immune complexes occur in 75% to 90% of patients. Clubbing of the fingers is now seen in less than 15% of patients.

OCULAR FINDINGS

Petechial hemorrhages, flame-shaped hemorrhages, Roth spots, and cotton-wool exudates may be seen in the retinas of patients with endocarditis. Roth spots, which are oval white areas surrounded by a zone of bright-red hemorrhage, are noted in 3% to 5% of patients. Such ocular findings are not pathognomonic of endocarditis; they may be observed in patients with other disorders, such as severe anemia or collagen vascular diseases.

EMBOLIC PHENOMENA

Significant arterial emboli occur in 30% to 50% of patients with endocarditis.[34,35] Symptoms and signs include stroke; monocular blindness with occlusion of the central retinal artery; acute abdominal pain, ileus, and melena from mesenteric arterial occlusion; and pain and gangrene in the extremities. Emboli to the CNS are common and especially important, because they adversely affect survival rates and often result in permanent disability.[35] Coronary emboli, which are found in as many as 50% of endocarditis patients who undergo autopsy, are often asymptomatic but occasionally result in frank myocardial infarction.

Factors associated with increased risk of embolization include vegetations of 10 mm or more in size as seen on echocardiography; vegetations on the mitral valve, particularly the anterior leaflet; vegetations that increase in size despite appropriate antibiotic therapy; and infection by *S. aureus*.[34-36] The incidence of arterial emboli decreases about 10-fold during the initial 2 weeks of antimicrobial therapy.[34] Nevertheless, emboli occasionally occur late, after microbiologic cure has been achieved, and do not necessarily indicate that antimicrobial treatment has failed.

Pulmonary emboli are a common and important complication of right-sided endocarditis, frequently causing pulmonary infarcts or focal pneumonitis. Either may evolve into lung abscess, empyema, or pyopneumothorax, especially when invasive pathogens such as *S. aureus* are involved.

SPLENIC ABNORMALITIES

Splenomegaly occurs in 15% to 30% of patients with endocarditis. Splenic infarcts occur in up to 40% of patients; they may occur with or without splenomegaly. Splenic infarcts may cause sharp left upper quadrant pain, but they are commonly asymptomatic. Splenic abscesses, which develop in about 5% of patients, may manifest as left shoulder, left upper quadrant, or pleuritic left chest pain; fever that persists during antibiotic therapy; or a relapse of bacteremia. Splenic lesions are best imaged by computed tomography, magnetic resonance techniques, and, to a lesser degree, ultrasonography; however, the differentiation of abscesses from infarcts by imaging is difficult.

RENAL MANIFESTATIONS

Microscopic hematuria is observed in about 50% of infective endocarditis patients. Embolic renal infarction may cause flank pain and hematuria, but it rarely causes renal failure. Some degree of acute renal failure occurs in up to one third of patients and is associated with a worse prognosis,[37] but it usually resolves completely if therapy for endocarditis is successful. Diffuse membranoproliferative glomerulonephritis results from immune complex glomerulonephritis, with deposition of IgG, IgM, and complement in a granular or nodular fashion in the glomerular basement membrane or on the basement membrane in subepithelial or subendothelial locations. Bacterial antigen may be identified in these glomerular deposits. In such patients, serum complement levels usually are reduced. Diffuse membranoproliferative glomerulonephritis may cause renal failure, which generally resolves after treatment of the infection. Focal embolic glomerulonephritis, originally thought to result from small bacterial emboli, is now recognized as an anatomic variation of immune complex disease. It occasionally causes renal failure.

MYCOTIC ANEURYSMS

Mycotic aneurysms are arterial aneurysms that develop in association with infections, especially infective endocarditis. Mycotic aneurysms occur in 2% to 8% of infective endocarditis patients and can form in any artery; they are particularly important when they involve cerebral arteries[38,39] [*see* Neurologic Manifestations, *below*]. They may become symptomatic early, during the active phase of endocarditis, or late, after valvular infection has been eradicated.[40] The clinical manifestations, which arise from enlargement or rupture of the aneurysm, include headache, pain, a pulsatile mass, persistent fever despite appropriate antibiotic treatment, focal signs from pressure on adjacent structures, the sudden development of an expanding hematoma, or signs of major blood loss. Small aneurysms (less than 5 mm in size) may resolve during antibiotic therapy. For larger aneurysms, to prevent possible rupture, therapeutic embolization, clipping, or excision is usually indicated when such interventions are feasible without undue risk.

NEUROLOGIC MANIFESTATIONS

Neurologic complications develop in 25% to 40% of patients with endocarditis, causing major morbidity and increased mortality.[41-43] Altered mental status at presentation is associated with higher mortality at 6 months.[44] Cerebral embolism may be an initial manifestation of endocarditis. Strokes caused by cerebral emboli, commonly to the middle cerebral artery or one of its branches, are the most frequent major neurologic complication, occurring in about 15% of patients. Some patients have multiple small embolic infarcts, which may manifest as an altered level of consciousness, seizures, fluctuating focal neurologic signs, or a combination of these symptoms. An intracerebral hemorrhage in a patient with infective endocarditis can be secondary to an embolic stroke or to rupture of a mycotic aneurysm.[42] Cerebral mycotic aneurysms occur in 1% to 5% of patients with infective endocarditis and most commonly affect the distal branches of the middle cerebral arteries.[39] Multiple aneurysms occur in some patients. In patients with symptomatic intracranial aneurysms, the overall mortality is high—above 50%. Patients with mycotic aneurysms may present with headache, focal signs, or, if the aneurysm ruptures, manifestations of acute intracerebral or subarachnoid hemorrhage. A slowly leaking aneurysm may cause mild meningeal irritation. In such cases, the cerebrospinal fluid, although sterile, may contain erythrocytes, leukocytes, and an increased concentration of protein.

In the search for an intracerebral aneurysm, contrast-enhanced CT may provide localizing information by detecting intracerebral bleeding. Magnetic resonance angiography is insufficiently sensitive to reliably detect aneurysms that are 5 mm or

less; therefore, cerebral angiography is the optimal diagnostic test.[45,46] Cerebral angiography for the detection of aneurysms has been advised for patients with focal neurologic signs, especially in the setting of ABE, and for patients with persistent unexplained headache or meningeal irritation, particularly if anticoagulant therapy is planned.

Treatment of a mycotic aneurysm that has been detected by angiography depends on its location and surgical accessibility, the presence or absence of hemorrhage, and changes in size that may occur during antimicrobial therapy. Resolution or healing of mycotic aneurysms during treatment of endocarditis has been demonstrated by angiography.[47] However, a leaking aneurysm, an aneurysm that is large or progressively enlarging, or one that persists after antibiotic therapy should be removed surgically, provided it is accessible. These complex cases should be managed with the input from specialists in infectious disease, neurology, radiology, and neurosurgery.

Brain abscesses are uncommon in SBE. In patients with acute *S. aureus* endocarditis, septic emboli may give rise to multiple intracerebral foci of inflammation or to small abscesses.

Toxic encephalopathy and seizures, which are usually triggered by emboli or strokes, also may complicate active endocarditis. A CSF pleocytosis with polymorphonuclear leukocytes predominating is observed in some patients with ABE caused by pyogenic organisms, especially *S. aureus*. Patients with SBE may have findings of aseptic inflammation in the CSF.

ENDOCARDITIS ASSOCIATED WITH PARENTERAL DRUG ABUSE

The annual incidence of endocarditis in injecting drug users (IDUs) is 0.2% to 2.0%. At the time of their initial attack of endocarditis, 70% to 80% of IDUs have no history or findings of preexisting valvular heart disease. In IDUs, the tricuspid valve is infected more frequently (55%) than the aortic valve (35%) or mitral valve (30%). Multiple episodes of endocarditis are common in IDUs.

S. aureus is responsible for approximately 55% of endocarditis in IDUs [*see Table 1*].[19,48] Although polymicrobial endocarditis, such as simultaneous infection by *P. aeruginosa* and *S. aureus*, is extremely rare in non-IDUs with native valve endocarditis, up to 5% of cases in IDUs involve multiple organisms. In IDU-associated endocarditis, enterococci, streptococci, and *Candida* primarily infect the aortic and mitral valves. *S. aureus* and *P. aeruginosa* infect valves on both the right and the left side of the heart. *S. aureus*, however, accounts for almost 80% of right-sided endocarditis in IDUs. Methicillin-resistant *S. aureus* (MRSA) is often encountered in these cases, possibly associated with repeated self-administration of antibiotics. Blood cultures generally reveal the causative organism. Microbiologic evaluation of surgically removed arterial emboli may be required to identify the cause in a few cases, such as those caused by fungi.

Although many of the manifestations of endocarditis in IDUs are similar to those of ABE in non-IDUs, there are some differences, because of the high frequency of tricuspid valve involvement, the spectrum of infecting organisms, and occasional pulmonic valve infection. High fevers, chills, rigors, malaise, cough, and, especially, pleuritic chest pain are common presenting complaints in right-sided endocarditis in IDUs. Septic pulmonary emboli occur in about 75% of cases, particularly in patients with *S. aureus* infection, and cause sputum production, hemoptysis, and initial radiologic findings that may suggest pneumonia. Cavitation of embolic pulmonary lesions is quite common. Significant cardiac murmurs are heard in most patients at some time during their illness but may not be present initially. The murmur of tricuspid regurgitation, a short ejection systolic murmur that is louder on inspiration, may be difficult to detect. Hemodynamically, significant tricuspid insufficiency is manifested by V waves in the jugular vein and a pulsating liver.

Because *S. aureus* and other pyogenic bacterial species are the predominant causes of infective endocarditis in IDUs, metastatic infections are a frequent complication. Neurologic manifestations and peripheral emboli are common; the latter may occlude major vessels and require surgical management.

PROSTHETIC VALVE ENDOCARDITIS

The incidence of PVE is 1% to 2% at 1 year and approximately 0.5% per year thereafter, resulting in a cumulative incidence of 4% to 5% during the first 5 years after valve implantation.[49-51] Infection may be introduced at the time of valve placement or from transient bacteremia at any time thereafter. The overall risks of infection are similar for mechanical and porcine bioprosthetic valves and for aortic and mitral valve prostheses.[49-51] The leading cause of PVE during the first year after surgery is methicillin-resistant coagulase-negative staphylococci, predominantly *S. epidermidis* [*see Table 2*]. Coagulase-negative staphylococci continue to cause cases of PVE that occur a year or more after surgery; however, these staphylococci are often species other than *S. epidermidis*, and only 20% to 30% are methicillin resistant. *S. aureus*, streptococci, enterococci, and fastidious gram-negative coccobacilli, the leading organisms associated with native valve endocarditis, cause about three quarters of PVE cases after 1 year following valve replacement.[49-51] Coagulase-negative staphylococci are responsible for at least 35% of cases of PVE and, therefore, should not be dismissed as contaminants (which they usually are in other settings) if isolated from the blood of a patient who has a prosthetic valve.

Infection of prosthetic valves is often associated with invasion of perivalvular tissues—resulting in valve-ring abscessses and valvular dysfunction—and occasionally with myocardial abscesses.[41,49,52,53] Necrosis of the annulus from invasive infection can cause partial dehiscence of the prosthesis, resulting in hemodynamically significant paravalvular regurgitation. These pathologic changes can occur with either porcine or mechanical prostheses, particularly when the valves are in the aortic position or when infection occurs during the first postoperative

Table 2 Etiology of Prosthetic Valve Endocarditis[49,90,110,111]

Organism	*Time of Onset after Valve Implantation and Percentage of Cases*		
	≤ 2 Months	*2–12 Months*	*> 12 Months*
Coagulase-negative staphylococci	54	56	15
Staphylococcus aureus	8	9	13
Gram-negative bacilli	12	3	1
Streptococci	rare	3	34
Enterococci	rare	6	11
Corynebacteria	8	rare	1
HACEK	rare	3	14
Fungi	6	6	3
Miscellaneous	6	6	1
Culture-negative	5	9	5

year.[51,54] Occasionally, vegetations may partially obstruct the valve orifice or restrict valve movement, causing functional stenosis. Such changes are more likely with prostheses in the mitral position. When infection is restricted to the leaflets of a porcine bioprosthetic valve, leaflet destruction, obstructing vegetations, and the delayed onset of leaflet stiffness may cause clinically significant valvular dysfunction.[54]

The dominant clinical feature of PVE that occurs during the first 60 days after surgery (early PVE) is fever, whether or not there is a regurgitant murmur associated with the prosthetic valve. Prosthetic valve dysfunction with resulting heart failure is seen in some patients. Petechiae occur in about half of patients with early PVE, but Roth spots, Osler nodes, and Janeway lesions are not common. Emboli are common in early PVE; emboli that occlude large peripheral arteries suggest fungal endocarditis. Because blood cultures are often negative in patients with fungal endocarditis, this diagnosis must often be made on the basis of histologic examination, culture, and sometimes molecular testing of surgical or autopsy specimens or vegetation recovered at embolectomy.

The clinical features of PVE that occurs more than 60 days after surgery (late PVE) are similar to those of acute or subacute endocarditis on native valves, depending on the infecting organism.

Diagnosis

DUKE CRITERIA

Although the diagnosis of endocarditis may be readily evident in patients with the classic syndrome of fever, a murmur associated with valvular dysfunction, typical peripheral signs, and bacteremia, the diagnosis is less evident in most patients.[55] A diagnostic approach known as the Duke criteria has been designed by the Duke Endocarditis Service[56] [*see Tables 3 and 4*]. With these criteria, the diagnosis of endocarditis can be established definitively by either pathologic or clinical criteria. The pathologic criteria include direct evidence gleaned from surgery or autopsy, and the clinical criteria are derived from microbiologic data (culture, serologic or molecular testing), echocardiography, physical examination, and other laboratory findings [*see Table 4*]. In retrospective evaluations of pathologically proven cases of native valve endocarditis and PVE, these clinical criteria have been found to be both sensitive[56-58] and highly specific.[57,59,60] Misdiagnoses rarely resulted when these clinical criteria were

Table 3 Duke Criteria for the Diagnosis of Infective Endocarditis[52,72,112,113]

Definite

Pathologic criteria

1. Microorganisms: demonstrated by culture, Gram stain, histologically, or by a validated molecular test in a vegetation, in a vegetation that has embolized, or in an intracardiac abscess specimen

or

2. Pathologic lesions: vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

Clinical criteria*

1. Two major criteria

or

2. One major and three minor criteria

or

3. Five minor criteria

Possible

Findings consistent with infective endocarditis that fall short of "definite" but are not "rejected"

Rejected

1. Firm alternative diagnosis for manifestations of infective endocarditis

or

2. Resolution of endocarditis syndrome with antibiotic therapy for ≤ 4 days

or

3. No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for ≤ 4 days

*See Table 4 for definitions of major and minor criteria.

Table 4 Definitions of Terms Used in Duke Criteria for the Diagnosis of Infective Endocarditis[56]

Major criteria

1. Positive blood cultures for the following:

Typical microorganism consistent with diagnosis from two separate blood cultures

a. Viridans streptococci, *Streptococcus bovis*, or HACEK organisms

or

b. Community-acquired *Staphylococcus aureus* or enterococci, in the absence of a primary focus

or

Persistently positive blood cultures, defined as microorganisms consistent with diagnosis from the following:

a. At least two blood samples drawn > 12 hr apart

or

b. Three of three or a majority when more than three blood cultures are drawn, with first and last samples drawn at least 1 hr apart

2. Evidence of endocardial involvement

Positive echocardiogram for IE

a. Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation

or

b. Abscess

or

c. New partial dehiscence of prosthetic valve

or

New valvular regurgitation (changing of preexisting murmur not sufficient)

Minor criteria

1. Predisposition: predisposing heart condition or I.V. drug use
2. Fever: temperature ≥ 38° C (100.4° F)
3. Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
4. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
5. Microbiologic evidence: positive blood culture but not meeting a major criterion (see above)* or serologic evidence of active infection with organism consistent with IE
6. Echocardiogram consistent with infective endocarditis but not meeting a major criterion (see above)

*Excludes single positive cultures for coagulase-negative staphylococci, diphtheroids, and organisms that do not commonly cause endocarditis.
IE—infective endocarditis

used to reassess previously pathologically confirmed cases. The specificity and negative predictive values of these criteria have been reported as 99% and 92%, respectively.[59,60] Use of these clinical criteria very rarely results in the rejection of cases considered to be endocarditis on independent expert evaluation.[61]

ECHOCARDIOGRAPHY

The Duke criteria utilize echocardiography for defining the anatomic features of endocarditis. Both the sensitivity and specificity of echocardiography are high when experienced echocardiographers apply specific criteria. In patients with pathologically proven native valve endocarditis, vegetations can be detected in 60% to 75% by use of transthoracic echocardiography (TTE) and in 87% to 94% with transesophageal echocardiography (TEE); the specificity of both techniques is high.[62-64] TEE is notably superior to TTE in the evaluation of patients with suspected PVE[65] [*see* Prosthetic Valve Endocarditis, *above*]. Notwithstanding the increased sensitivity of TEE compared with TTE, if the decision is made to treat all cases identified by the Duke criteria as definite endocarditis and most cases identified as possible endocarditis, then evaluation by TEE rarely alters the treatment decision. Occasional exceptions to this observation are PVE cases that were missed by TTE. Echocardiography is the preferred technique for identification of perivalvular infection and other intracardiac complications of endocarditis. For detection of abscesses, a transesophageal study is significantly more sensitive (76% to 87%) than transthoracic imaging (18% to 28%), with equal specificity.[53,65,66]

All patients in whom endocarditis is seriously suspected should undergo echocardiography. However, echocardiography should not be regarded as a general screening test for patients with a low prior probability of endocarditis (e.g., most patients with acute febrile illnesses). Given its high sensitivity, a negative transesophageal echocardiogram is good evidence against endocarditis in patients at low or intermediate risk of this infection. Conversely, if the prior probability of endocarditis is high, a negative echocardiogram does not fully exclude the diagnosis; the false negative rate for transesophageal echocardiography is 6% to 13%.[67] A repeat transesophageal study in patients with endocarditis reduces the false negative results to approximately 5%.[67] Finally, echocardiography cannot reliably distinguish an infected vegetation from a sterilized vegetation, nonbacterial thrombotic vegetations of marantic endocarditis, or intracardiac thrombi, as seen in the antiphospholipid antibody syndrome.

Transthoracic echocardiography has limited usefulness in the diagnosis of PVE because the prosthesis itself produces echoes that often obscure vegetations and abscesses. Transesophageal two-dimensional and Doppler echocardiography more effectively assess prosthetic valves and perivalvular tissues, especially when a mitral valve prosthesis is present.[68,69] In PVE, the transesophageal technique identified vegetations in 82% of patients, compared with a 36% identification rate with transthoracic echocardiography.[53] Similarly, detection of paravalvular abscesses in patients with PVE is markedly increased by use of transesophageal rather than transthoracic echocardiography.[68]

BLOOD CULTURE

For patients suspected of having endocarditis, identification of the microbial etiologic agent and determination of its antimicrobial susceptibility are of paramount importance for both diagnosis and treatment. In most patients with SBE, blood cultures drawn before initiation of antibiotic therapy will all be positive, reflecting the sustained bacteremia associated with an infected endothelial surface. To optimize the value of blood cultures, best-practice guidelines recommend careful antiseptic skin preparation to minimize contamination of the specimen with skin flora: cleaning, followed by application of 70% isopropyl alcohol, which is allowed to dry, followed by application of an iodophor or chlorhexidine, which is also allowed to dry.[70] Blood should be drawn using three separate venipunctures, at three different sites, that are taken over several hours if the patient presents with a subacute syndrome or that are taken over a few minutes if acute endocarditis is suspected. The ideal volume for each specimen is 12 to 20 ml, which should be divided equally into two culture bottles, yielding six bottles in all. Obtaining a large volume of blood for culture maximizes the yield,[70] but smaller volumes must be accepted from infants and small children. Use of both aerobic and anaerobic broth media also helps maximize yield. If the patient has recently received any antibiotic treatment, use of a medium that contains an antibiotic removal device such as resin will increase the yield by 5% to 15%.[70] Blood cultures should be incubated for 5 days, because modern improved culture media will yield growth for the vast majority of relevant microorganisms within this period. This is true even for most of the so-called fastidious or slow-growing bacteria such as the HACEK group and the nutritionally variant streptococci (*Abiotrophia* species).

Culture-Negative Endocarditis

Blood cultures are negative in 5% to 20% of patients with infective endocarditis[9,71] [*see Tables 1 and 2*]. In about half of these cases, blood cultures are negative as a consequence of previous antimicrobial therapy, even though the vegetation is still infected. Recovery of the causative organism from the blood of these previously treated patients may often be accomplished by repeating blood cultures several days after antibiotics have been discontinued, but some patients remain persistently blood culture negative. Blood cultures may also be negative in some cases of right-sided endocarditis caused by relatively noninvasive organisms. Currently, however, most cases of right-sided endocarditis occur in IDUs and are caused by pyogenic bacteria, such as *S. aureus* and *P. aeruginosa*, which are readily isolated from the blood. Culture of bone marrow or arterial blood does not provide materially more information than can be obtained from culture of venous blood.

Several additional factors can thwart isolation of the infecting agent from blood of patients with infective endocarditis. *Bartonella* species may require more than 5 days for isolation, and certain mycelial fungi such as *H. capsulatum* and *Aspergillus* species are difficult to isolate even with special techniques such as lysis centrifugation. Finally, isolation of *C. burnetii* and *C. psittaci* requires techniques beyond the capabilities of most laboratories.[13,72,73] Endocarditis caused by *Bartonella* species, *Legionella* species, *Brucella* species, *C. psittaci*, and *C. burnetii* can be presumptively diagnosed with serologic tests. These tests should be performed in the evaluation of apparently culture-negative endocarditis, particularly when negative cultures cannot be attributed to prior antimicrobial therapy.[73] Direct cultures on special media, histopathologic examination with special stains, and molecular techniques to recover DNA or 16S ribosomal RNA all can be used to determine etiology from examination of vegetations that have been removed from valves or, having embolized, from peripheral arteries.[73-76]

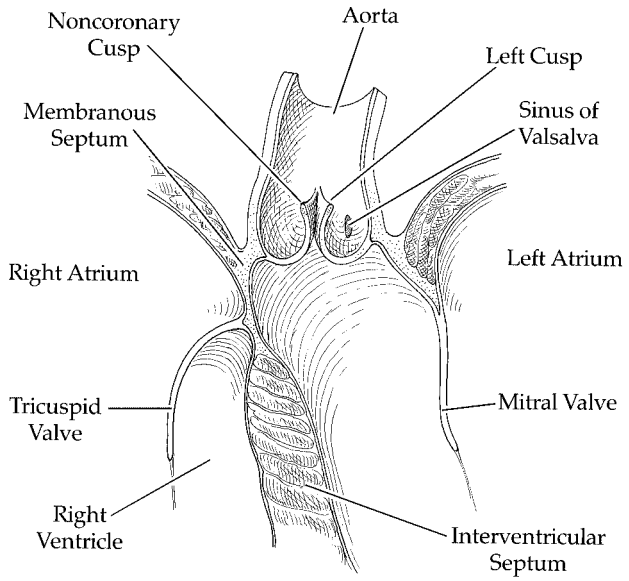

Figure 2 **Anatomic relations between the noncoronary cusp and left cusp of the aortic valve, interventricular septum, membranous septum, tricuspid valve, and mitral valve are shown schematically at the level of the aortic root.**

Bacteremia in Patients with Prosthetic Heart Valves

As in native valve endocarditis, the diagnosis of PVE is usually based on history, physical examination, echocardiography, and the detection of bacteremia. However, only a subgroup of patients with a prosthetic valve who experience bacteremia subsequently develop PVE. Of bacteremic patients with a prosthetic valve whose initial positive blood culture is not sentinel evidence of active PVE itself, only 15% to 20% will develop PVE caused by that blood culture isolate.[17]

Transient bacteremia with gram-negative bacilli from extracardiac sources usually does not result in colonization of prosthetic valves; however, recrudescent or sustained bacteremia that occurs after the extracardiac focus of infection has been eradicated suggests PVE, as does persistent gram-negative bacillary bacteremia with no identifiable extracardiac source, even if a new regurgitant murmur or other signs of endocarditis are lacking. Persistent or high-grade coagulase-negative staphylococcal bacteremia in a patient with a prosthetic valve strongly suggests PVE. Similarly, PVE is likely when coagulase-negative staphylococci that have been isolated sporadically from multiple blood cultures are shown by molecular techniques to belong to a single clone. Blood cultures are negative in about 6% of PVE cases. Negative cultures are usually the result of previous antibiotic therapy or reflect unique characteristics of the infecting organisms.

ADJUNCTIVE LABORATORY TESTS

Results of many laboratory tests are likely to be abnormal in patients with endocarditis because of the systemic impact of the infection and because of injury to various organs. Such tests include the complete blood count, urinalysis, blood urea nitrogen level, creatinine concentration, rheumatoid factor, quantitative immunoglobulins, complement levels, erythrocyte sedimentation rate (ESR), and C-reactive protein level. These adjunctive tests may offer clues to the diagnosis and may be useful for monitoring the progress of treatment for endocarditis, but they usually are not specific and are not critical in establishing a diagnosis; hence, they are not among the Duke diagnostic criteria.

DIAGNOSTIC FEATURES OF CARDIAC COMPLICATIONS

Heart failure is the most frequent cardiac complication of infective endocarditis and may result from a variety of factors. Preexisting valvular disease can be worsened by the effects of infective endocarditis, which can include tears, perforations, and obstruction of valves and rupture of chordae tendineae. These complications can also affect previously normal valves. Damage to the aortic valve by infection can cause rapidly progressive and severe hemodynamic impairment, more so than comparable damage to the mitral valve. Coronary artery embolism can cause silent or overt myocardial infarction, which can contribute to heart failure. A mycotic aneurysm of a sinus of Valsalva or an aortic annulus abscess may rupture through the membranous septum into the right atrium or ventricle [*see Figure 2*]. Flow through the resulting fistula causes a sudden rise in the jugular venous pressure and a continuous or to-and-fro murmur and thrill along the left sternal border. The lungs remain relatively clear. Valvular damage and subsequent dysfunction, as well as intracardiac fistula formation, can be accurately defined with two-dimensional and Doppler echocardiography from a transthoracic or transesophageal approach.

The development of new conduction abnormalities may signal the extension of infection into the septum, affecting its conduction tissues.[33,52] PR interval prolongation, left bundle branch block, or right bundle branch block with left anterior hemiblock suggests the extension of infection from the aortic valve. The proximity of the weakest area of the aortic valve annulus to the membranous septum and the conduction system accounts for the development of these conduction abnormalities [*see Figure 3*]. Similarly, extension of infection from the mitral annulus, which is close to the bundle of His and to the atrioventricular node, may also produce conduction defects, but such extension occurs less frequently than extension from the aortic valve. In the absence of digitalis toxicity or a recent inferior myocardial infarction, the development of nonparoxysmal junctional tachycardia, a Wenckebach block, or complete heart block with a narrow QRS complex serves as a clue to the spread of infection from the mitral annulus into the AV node and proximal bundle of His. Ventricular premature beats in patients with endocarditis who do not have electrolyte abnormalities or digitalis toxicity may reflect myocarditis, myocardial abscesses, or coronary arterial emboli.

The presence of an annular abscess may be suggested by the recent onset of aortic regurgitation, persistent fever during appropriate antimicrobial therapy, and the development of pericarditis.[77,78] Pericarditis caused by extension of a valve ring abscess into the epicardium is more often hemorrhagic or fibrinous than purulent. Occasionally, pericarditis in the course of infective endocarditis is the result of transmural myocardial infarction secondary to coronary emboli. Transesophageal echocardiography is the most sensitive and preferred noninvasive test for detecting valve-ring abscesses in both native valve endocarditis and PVE.

Differential Diagnosis

The possibility of infective endocarditis should be considered in any patient with a heart murmur and fever. The physician must be particularly alert for atypical cases in which the clinical

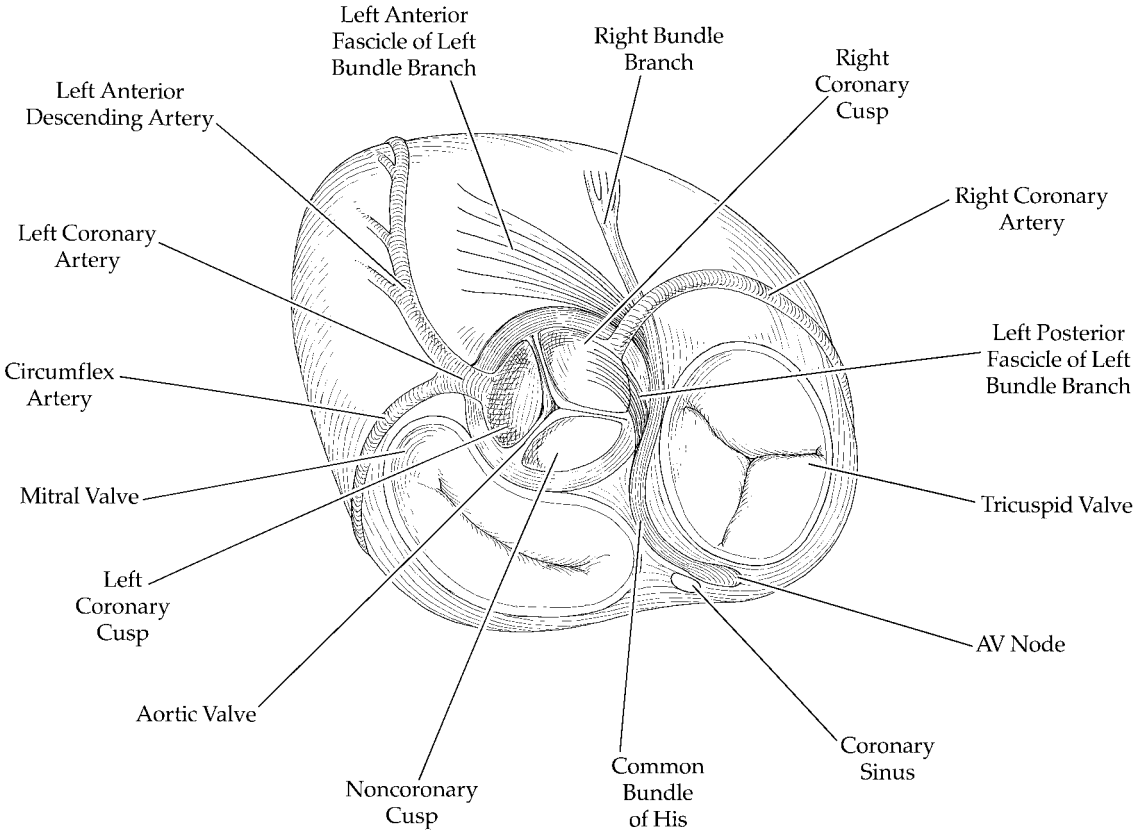

Figure 3 **The close relation of the three cardiac valves and the cardiac conduction system, as seen in this superior schematic view, accounts for the appearance of conduction defects in endocarditis. (AV—atrioventricular)**

findings reflect complications of endocarditis affecting organs other than the heart.

Infective endocarditis can cause fever of undetermined origin (FUO), so the differential diagnosis includes the many other infections that may cause FUO. These include tuberculosis, salmonellosis, and various intra-abdominal and genitourinary infections [*see 7:XXIV Hyperthermia, Fever, and Fever of Undetermined Origin*].

A variety of noninfectious illnesses can mimic infective endocarditis, including immune-mediated diseases and rheumatologic conditions such as juvenile rheumatoid arthritis and polymyalgia rheumatica. Acute rheumatic fever can cause fever, cardiac murmurs, and heart failure, but acute rheumatic fever can be distinguished from infective endocarditis on clinical grounds and by negative blood cultures, raised anti-streptolysin O antibody titer, and response to salicylates [*see 7:I Infections Due to Gram-Positive Cocci*]. Marantic endocarditis, which can give rise to multiple embolic episodes and fever, is usually associated with an underlying neoplasm or chronic wasting disease. In polyarteritis nodosa, the presence of fever, anemia, and renal involvement may suggest SBE, and the findings on biopsy of a lesion in a large artery may even resemble those of a mycotic aneurysm. In both systemic lupus erythematosus and antiphospholipid antibody syndrome, the manifestations of fever, nonbacterial thrombotic vegetations, systemic emboli, and spontaneous thrombotic events can simulate infective endocarditis.

A cardiac myxoma, usually in the left atrium, may mimic infective endocarditis in both clinical and laboratory features, including low-grade fever, weight loss, arthralgias, cutaneous lesions, clubbing of the fingers, emboli to major arteries, and auscultatory findings suggesting mitral stenosis and regurgitation. Cardiac myxoma syndrome may further simulate infective endocarditis by giving rise to cerebral aneurysms at the sites of myxomatous emboli. Negative blood cultures and echocardiography can help establish the correct diagnosis.

Neoplasms may mimic infective endocarditis by inducing marantic endocarditis or by their hemodynamic effects. For example, richly vascular tumors may be associated with fever, anemia, and hyperdynamic circulation with flow murmurs. A left renal tumor mass may be mistaken for splenomegaly. Carcinoid tumors occasionally mimic endocarditis when they produce endocardial and valvular fibrosis that lead to tricuspid insufficiency and pulmonary stenosis.

Treatment

Two major modalities are used to treat endocarditis: (1) antibiotic therapy and (2) surgical debridement of vegetations and infected perivalvular tissue, with valve repair or replacement as needed.

ANTIMICROBIAL TREATMENT

Effective antimicrobial treatment requires identification of the etiologic agent and determination of its antimicrobial susceptibility. Therefore, in the evaluation of a patient with subacute or indolent disease, it is usually best to delay antibiotic therapy until the results of blood cultures are obtained. If recently administered antibiotics have rendered the initial cultures negative, this

delay provides an opportunity to obtain additional blood cultures after the antibiotics and their effects have dissipated. However, if the infection is fulminant or if there is valvular dysfunction that may require urgent surgical intervention, empirical antibiotic therapy must be initiated promptly after blood culture specimens have been obtained. Bactericidal antibiotics are used parenterally in high doses. With the exception of PVE caused by staphylococci, antimicrobial therapy for PVE caused by a specific organism utilizes the same drugs recommended for native valve endocarditis. However, therapy is usually administered over a longer period, typically 6 weeks. Patients must be evaluated frequently to assess the efficacy of antimicrobial therapy and the development of complications of therapy or infection.

Streptococci

Viridans streptococci, once mostly penicillin sensitive, have demonstrated increasing resistance to penicillin and the cephalosporins over the past 20 years.[79] Accordingly, in the planning of endocarditis treatment, all streptococci must be evaluated for susceptibility to penicillin by determining the minimum inhibitory concentration (MIC). Various regimens provide effective treatment for endocarditis caused by those streptococci that are fully penicillin sensitive (MIC < 0.2 μg/ml) [*see Table 5*].[80] One regimen employs parenteral penicillin alone in high doses for 4 weeks. A second regimen utilizes the synergism achieved against most strains of nonenterococcal streptococci by the combination of penicillin and gentamicin. This synergism allows effective treatment with only 2 weeks of combination therapy.[80,81] The short-duration regimen should be considered only for selected cases of native valve endocarditis with favorable prognostic features: streptococcal infections that are not complicated by hypotension, renal failure, thrombocytopenia, mycotic aneurysms, or heart failure caused by valvular dysfunction. The etiologic species should be highly susceptible to penicillin (MIC < 0.2 μg/ml) and should not be a nutritionally variant strain—that is, dependent upon pyridoxal or cysteine for growth. PVE should not be treated with the 2-week regimen. Ceftriaxone, given in a single daily intravenous dose for 4 weeks, is now often recommended for treatment of endocarditis caused by penicillin-sensitive streptococci because this regimen is easily adapted for outpatient treatment and has little toxicity.[49,80] Although short-duration combination therapy for penicillin-susceptible streptococcal endocarditis using single daily doses of both ceftriaxone and an aminoglycoside has been successful, experience with this regimen is limited, and the regimen is not recommended for general use. *S. bovis* is highly penicillin sensitive and can be treated with regimens recommended for other penicillin-sensitive streptococci. When combination penicillin-gentamicin therapy is used to treat endocarditis caused by nonenterococcal streptococci, particularly when short-duration therapy is planned, the streptococcus should be screened for high-level resistance to gentamicin. Although rare in these organisms, high-level resistance would preclude bactericidal synergy and thus indicate the need for an alternative regimen.

Endocarditis caused by relatively penicillin-resistant (MIC = 0.2 to 0.5 μg/ml) viridans or other nonenterococcal streptococci is treated with a higher dose of penicillin G, combined with gentamicin. If the strain is even more resistant to penicillin (MIC > 0.5 μg/ml), the infection is treated with one of the standard regimens for enterococcal endocarditis [*see Table 5*]. Nutritionally variant streptococci (previously called *S. adjacens* or *S. defectivus;* now named *Abiotrophia* species) are often relatively penicillin resistant, so endocarditis caused by these organisms should be treated with the standard regimen for enterococcal endocarditis.[49,80,82] Endocarditis caused by pneumococci or group A streptococci is treated with intravenous penicillin G in a dosage of 20 million units daily for 4 weeks.[49,80] Pneumococci that are found to be the cause of endocarditis must be tested for susceptibility to penicillin. Vancomycin is the preferred treatment for endocarditis caused by penicillin-resistant strains with an MIC greater than 1.0 μg/ml. When pneumococcal endocarditis is complicated by concurrent meningitis, the treatment regimen must ensure adequate penetration of antibiotic into cerebrospinal fluid.[83] The β-hemolytic streptococci belonging to groups B, C, and G have slightly reduced susceptibility to penicillin; for endocarditis, they should be treated as if they were relatively penicillin resistant, with MICs of 0.2 to 0.5 μg/ml.[80,84]

Enterococci

Enterococci are relatively resistant to penicillin, ampicillin, and vancomycin and are fully resistant to cephalosporins. Antibacterial synergism is essential for optimal antimicrobial treatment of enterococcal endocarditis. To achieve this, the enterococcus must simultaneously be exposed to a cell wall–active antibiotic such as penicillin, ampicillin, or vancomycin, at a concentration at or above the organism's MIC, and to an aminoglycoside that will exert a lethal effect.[49,80,85] The ability of some enterococci to grow in the presence of gentamicin at concentrations of 500 μg/ml or higher indicates high-level aminoglycoside resistance; against such organisms, combination therapy will fail to exert a lethal effect regardless of the cell wall–active antimicrobial agent employed. High-level resistance to gentamicin is the consequence of aminoglycoside-modifying enzymes.

Previously, synergistic bactericidal therapy could be reliably anticipated when gentamicin was combined with penicillin, ampicillin, or vancomycin. This provided regimens for treatment of enterococcal endocarditis[49,80] [*see Table 5*].

Currently, antimicrobial resistance in enterococci presents a complex problem that must be carefully considered in the selection of therapy for enterococcal endocarditis.[85] The causative strain must be screened for high-level resistance to gentamicin. Use of gentamicin in combination therapy in the face of high-level resistance exposes the patient to potential toxicity and is without therapeutic benefit. Furthermore, resistance to cell wall–active agents has become increasingly prevalent in enterococci. Intrinsic resistance to penicillin and ampicillin (MIC ≥ 32 μg/ml) is prevalent in *E. faecium*. Penicillin and ampicillin resistance caused by β-lactamase production, which is not detectable with MIC tests but requires screening with the chromogenic cephalosporin nitrocefin, is occasionally seen in *E. faecalis*. Finally, vancomycin resistance (MIC ≥ 16 μg/ml) is being encountered increasingly in *E. faecalis* and *E. faecium*. If an enterococcus is resistant to a cell wall–active agent, that agent cannot participate in the synergistic killing of the strain. Vancomycin is a suitable cell wall–active agent for combination therapy when organisms have intrinsic or β-lactamase–mediated resistance to penicillin or ampicillin; ampicillin-sulbactam is suitable when enterococci have resistance that is mediated by β-lactamase. Enterococci that are resistant to vancomycin may be susceptible to penicillin and ampicillin but more often are resistant to these antibiotics as well. For a few of these enterococci, teicoplanin, a glycopeptide antibiotic that has not been approved for use in the United States but is available elsewhere, remains an effective cell wall–active antimicrobial.[80,85] Endocarditis caused by van-

Table 5 Antimicrobial Therapy for Endocarditis in Adults[49,80,114]

Infectious Agent	*Drug*	*Dosage and Route of Administration*	*Duration of Therapy* (wk)*
Penicillin-susceptible viridans and other non-enterococcal streptococci (minimum inhibitory concentration [MIC] < 0.2 μg/ml)	*Preferred Regimen*		
	Penicillin G	12–18 million units I.V. daily (in divided doses q. 4 hr)	4
	or		
	Penicillin G	12–18 million units I.V. daily (in divided doses q. 4 hr)	2
	plus		
	gentamicin	3 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)†	2
	or		
	Ceftriaxone	2 g I.V. daily (as a single dose)	4
	Alternative Regimen‡		
	Vancomycin	30 mg/kg I.V. daily (in divided doses q. 12 hr)	4
Relatively penicillin-resistant streptococci			
	Preferred Regimen		
MIC 0.2–0.5 μg/ml	Penicillin G	20–30 million units I.V. daily (in divided doses q. 4 hr)	4
	plus		
	gentamicin§	3 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)†	2
MIC > 0.5 μg/ml	Penicillin G plus gentamicin	Dosages same as in previous regimen	4
	Alternative Regimen‡		
	Vancomycin§	30 mg/kg I.V. daily (in divided doses q. 12 hr)	4
Enterococci‖	*Preferred Regimen*		
	Penicillin G	20–30 million units I.V. daily (in divided doses q. 4 hr)	4–6
	plus		
	gentamicin	3 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)†	4–6
	or		
	Ampicillin	12 g I.V. daily (in divided doses q. 4 hr)	4–6
	plus		
	gentamicin	3 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)†	4–6
	Alternative Regimen‡		
	Vancomycin	30 mg/kg I.V. daily (in divided doses q. 12 hr)	4–6
	plus		
	gentamicin	3–5 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)†	4–6
Staphylococci (methicillin susceptible) in the absence of prosthetic material	*Preferred Regimen*		
	Nafcillin or oxacillin	12 g I.V. daily (in divided doses q. 4 hr)	4–6
	plus		
	gentamicin		
	(optional; see text)	3 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)†	3–5 days
	Alternative Regimens‡		
	Cefazolin	12 g I.V. daily (in divided doses q. 4 hr)	4–6
	plus		
	gentamicin		
	(optional; see text)	3 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)†	3–5 days
	or		
	Vancomycin	30 mg/kg I.V. daily (in divided doses q. 12 hr)	4–6
Staphylococci (methicillin resistant) in the absence of prosthetic material	Vancomycin	30 mg/kg I.V. daily (in divided doses q. 12 hr)	4–6
Staphylococci (methicillin susceptible) in the presence of prosthetic material	Nafcillin or oxacillin	12 g I.V. daily (in divided doses q. 4 hr)	6–8
	plus		
	rifampin	300 mg p.o., q. 8 hr	6–8
	plus gentamicin#	3 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)	2
Staphylococci (methicillin resistant) in the presence of prosthetic material	Vancomycin	30 mg/kg I.V. daily (in divided doses q. 12 hr)	6–8
	plus		
	rifampin	300 mg p.o., q. 8 hr	6–8
	plus gentamicin#	3 mg/kg I.M. or I.V. daily (in divided doses q. 8 hr)	2
HACEK organisms	Ceftriaxone**	2 g I.V. daily (as a single dose)	4

*Treatment programs are longer for prosthetic valve endocarditis (6–8 wk).
†Peak serum gentamicin concentration should be approximately 3 μg/ml and trough concentrations < 1 μg/ml. Some authorities prefer a gentamicin dosage of 1.5 mg/kg q. 8 hr, which results in peak concentrations of approximately 5 μg/ml.
‡Alternative regimen is for use in patients with a history of penicillin hypersensitivity.
§Some investigators recommend omission of gentamicin if the MIC is > 0.2 but < 0.5 μg/ml; the role of gentamicin in combination with vancomycin has not been fully established.
‖Enterococci have become increasingly antibiotic resistant (see text); clinical isolates must be fully evaluated for microbial resistance to select optimal therapy.
#Administer during the initial 2 weeks (see text).
**Cefotaxime or another third-generation cephalosporin at a comparable dosage could be used.

comycin-resistant enterococci that are not susceptible to ampicillin requires special, individualized regimens, chosen with the assistance of an infectious disease consultant. All enterococci that cause endocarditis must be tested for susceptibility to antimicrobials that have therapeutic potential. Thereafter, a bactericidal synergistic combination of a cell wall–active agent (e.g., penicillin, ampicillin, vancomycin, ampicillin-sulbactam, or teicoplanin) plus gentamicin can be selected. Single daily dosing of gentamicin should not be used in treating enterococcal endocarditis. If a synergistic combination is not possible because of high-level resistance to gentamicin, prolonged therapy (8 to 12 weeks) with high doses of an effective cell wall–active agent should be administered. To prevent or minimize possible toxicity of gentamicin or vancomycin, it is important to monitor serum levels, renal function, and otologic symptoms every 3 to 5 days throughout therapy.[49,80]

Bactericidal synergistic therapy for enterococcal endocarditis is associated with cure rates approaching 85%. Treatment with an effective cell wall–active agent alone results in cure rates of 40% to 50% at best.[80,86] If bactericidal synergistic therapy is not available, patients with enterococcal endocarditis in whom treatment with a cell wall–active agent alone has failed should undergo excision of the infected valve while suppressive antibiotic therapy is continued.[49,80,85,86]

Staphylococci

Staphylococcus aureus The treatment of choice for *S. aureus* native valve endocarditis is a penicillinase-resistant penicillin such as nafcillin or oxacillin[49,80] [*see Table 5*]. Vancomycin provides an alternative treatment for patients who are hypersensitive to penicillins. Vancomycin, although active against both methicillin-sensitive *S. aureus* (MSSA) and MRSA, is not the first choice, because it is somewhat less effective than the penicillinase-resistant penicillins.[87] However, vancomycin should be added initially because of the increasing frequency of MRSA strains, not only in nosocomial infections but also in community-acquired infections. If the blood culture yields MSSA, the vancomycin should be discontinued; if MRSA is yielded, then vancomycin alone is continued[80] [*see Table 5*]. Penicillin G, 20 to 30 million units daily, should be substituted for the few strains of *S. aureus* that prove to be penicillin sensitive, but only after susceptibility has been confirmed by tube dilution testing and the isolate has been demonstrated not to produce penicillinase. Gentamicin is synergistic with penicillinase-resistant penicillins against *S. aureus* in vitro, and combination therapy may reduce the duration of bacteremia and fever in patients. However, the in vivo benefit is marginal; combination therapy does not improve overall cure rates. If the option to add gentamicin is chosen, it should be stopped after about 3 days to minimize the risk of nephrotoxicity.

Rare strains of *S. aureus* that are partially or even fully resistant to glycopeptides such as vancomycin have been detected. In the unlikely event of endocarditis being caused by such a strain, alternative drugs to be considered include linezolid, quinupristin-dalfopristin, or teicoplanin and daptomycin.

Recommended regimens for treatment of endocarditis in IDUs are usually the same as regimens for treatment in other patients. However, in IDUs who have MSSA endocarditis restricted to the tricuspid valve, without complicating metastatic infection, successful treatment has been accomplished with a penicillinase-resistant penicillin plus an aminoglycoside (e.g., nafcillin plus gentamicin or tobramycin) given for only 2 weeks.[88] Such patients who do not respond promptly and completely to this short-term regimen should receive longer courses of treatment.

Coagulase-negative staphylococci Endocarditis caused by coagulase-negative staphylococci is usually engrafted on a prosthetic valve. More than 80% of the coagulase-negative staphylococci that cause PVE within 1 year after valve implantation are resistant to methicillin and to all β-lactam antibiotics, including cephalosporins.[49,80] Only when the onset of this form of PVE occurs more than a year after surgery does the frequency of β-lactam resistance in the coagulase-negative staphylococci fall below 30%.[89,90] Moreover, the β-lactam resistance may not be detected by standard antimicrobial susceptibility testing, particularly when automated instruments or microsystems are used. Most of these coagulase-negative staphylococci are sensitive to vancomycin and rifampin, but plasmid-mediated resistance to gentamicin is prevalent. For PVE caused by methicillin-resistant organisms that are susceptible to rifampin and gentamicin, the most effective treatment combines vancomycin with rifampin and gentamicin [*see Table 5*].[49,80,90] If the infecting strain is resistant to gentamicin, either a fluoroquinolone or another aminoglycoside to which the strain is susceptible should be substituted for gentamicin. If the staphylococci are susceptible to methicillin, a penicillinase-resistant penicillin should be used in lieu of vancomycin [*see Table 5*]. Antimicrobial therapy for PVE caused by *S. aureus* should utilize the same regimens as those used for coagulase-negative staphylococcal PVE [*see Table 5*].

Rigorous susceptibility testing is required, but the coagulase-negative staphylococci that cause native valve endocarditis are usually sensitive to β-lactam antibiotics unless the infection has been acquired nosocomially. Native valve endocarditis caused by coagulase-negative staphylococci can be treated with the same regimens that are employed to treat native valve endocarditis caused by *S. aureus*.[49,80]

HACEK Organisms

Some HACEK organisms that cause endocarditis have been found to produce β-lactamase, which makes those organisms resistant to ampicillin. Accordingly, endocarditis caused by HACEK organisms should be treated with a third-generation cephalosporin for 4 weeks [*see Table 5*].[49,80]

Corynebacteria (Diphtheroids)

The combination of penicillin and gentamicin acts synergistically in vitro to kill *Corynebacterium* species (diphtheroids) that are susceptible to gentamicin (MIC ≤ 4 μg/ml). Synergism is not achieved against strains that are resistant to gentamicin. For PVE caused by gentamicin-sensitive strains, therapy with intravenous penicillin G (20 million units daily) plus gentamicin (1 mg/kg I.M. or I.V. every 8 hours) is recommended. Vancomycin, which is bactericidal against diphtheroids, is recommended as the initial treatment of diphtheroid PVE, with subsequent treatment determined on the basis of antibiotic-susceptibility test results. Vancomycin is also the drug of choice if the infecting strain is resistant to gentamicin or if the patient is allergic to penicillin.

Gram-Negative Bacilli

Endocarditis caused by gram-negative bacilli should be treated with a potent β-lactam antibiotic, such as a third-generation cephalosporin, with or without an aminoglycoside, depending on the susceptibility of, and the published experience with, the

specific gram-negative bacillus involved. Effective treatment of endocarditis caused by *P. aeruginosa* requires the synergistic combination of ticarcillin or piperacillin (either drug at a dosage of 3 g I.V. every 4 hours) and tobramycin (2.7 mg/kg I.M. or I.V. every 8 hours; 8 mg/kg daily) for at least 6 weeks. Because pseudomonal endocarditis is difficult to cure with antibiotics alone and is often complicated by perivalvular abscesses, aggressive early surgical intervention is recommended.[91]

Fungi

Yeasts Endocarditis caused by yeasts is more difficult to cure than most bacterial infections. The best results are achieved by a combination of antifungal chemotherapy and valve debridement or replacement.[21,92] Amphotericin B is the drug of choice for initial treatment for most patients. Synergism in vitro between flucytosine and amphotericin B has been reported with some strains of *Candida*, and their combined use for this life-threatening infection seems warranted. Serum levels of flucytosine should be monitored to reduce toxicity. The drug, which is cleared by the kidney, should not be given to patients with renal failure, because excessive serum concentrations can induce severe bone marrow depression. Long-term (possibly lifelong) suppressive therapy with oral fluconazole may be effective in patients with *Candida* endocarditis if they have no intracardiac complications. Similarly, long-term suppressive therapy has been advocated for patients with *Candida* endocarditis who have responded to combined antifungal and surgical treatment. Some yeast infections can be suppressed (and a few even cured) by treatment with fluconazole or itraconazole. With optimal therapy, the overall survival rate for patients with yeast endocarditis is about 50%.

Dimorphic and mycelial fungi Endocarditis caused by dimorphic and mycelial fungi is usually fatal despite therapy, with overall survival of less than 10%.[21] Aggressive treatment with amphotericin B and valvular surgery will save a few patients. If the fungus is susceptible to flucytosine, combination treatment with this agent plus amphotericin B may be tried.

Culture-Negative Endocarditis

When blood cultures are negative or culture results are not available, the selection of empirical therapy requires careful consideration of any clinical clues that might suggest the identity of the causative organism. Appropriate special cultures and serologic studies should be pursued in an attempt to identify microorganisms that are difficult to culture.[70,71]

In the absence of information suggesting a probable cause of native valve SBE, the same treatment as that used for enterococcal endocarditis (i.e., ampicillin plus gentamicin) is advised. If the course is acute and *S. aureus* is an etiologic consideration, the addition of vancomycin to this regimen is recommended. Because blood cultures rarely remain negative in patients with ABE, such empirical therapy can usually be revised later on the basis of the culture results. The spectrum of microorganisms causing PVE differs from that implicated in native valve endocarditis, and culture-negative PVE should be treated with a combination of vancomycin, gentamicin, and a third-generation cephalosporin. The third-generation cephalosporin is directed against the HACEK organisms, which are important causes of late PVE and can be difficult to isolate from blood cultures. Before embarking on therapy for culture-negative endocarditis, the physician should carefully consider the possibility that the patient does not have endocarditis, but rather has one of the conditions that mimics endocarditis.

Monitoring Clinical Response

A decrease in fever is usually evident within 1 to 7 days after the start of antibiotic therapy.[93] Fever that persists during the second week of appropriate antimicrobial therapy suggests the possibility of uncontrolled infection, which could be from antibiotic resistance, intracardiac abscess, metastatic foci of infection, or nosocomial complications of therapy. Thorough evaluation is indicated.[78,93] Petechiae and embolic phenomena may occur for several weeks after initiation of recommended treatment; such findings do not necessarily indicate that therapy is ineffective, particularly if other signs indicate that the patient is getting better.

If the patient does not become afebrile within a few days after antibiotic therapy is initiated, repeat blood cultures should be obtained. If the patient is afebrile and otherwise responding well, routine follow-up blood cultures during treatment are usually negative and are not recommended. Similarly, follow-up cultures after the end of antibiotic treatment are unnecessary in most patients, unless nonstandard antimicrobial regimens have been used or there is reason to suspect relapse, such as recurrent fever. Although the ESR slowly returns to normal in the months after effective treatment, this test is not useful for monitoring therapy or as a test of cure. C-reactive protein levels fall within 1 to 2 weeks after starting effective therapy; some clinicians use this test to provide reassurance that treatment is working.[94] The serum bactericidal test, in which dilutions of the patient's serum are tested for bactericidal activity against the organism causing the endocarditis, is no longer recommended for assessment of therapy in patients receiving standard antimicrobial regimens.[80]

SURGICAL INTERVENTION

Operative intervention to debride infected perivalvular tissue or to replace or reconstruct a dysfunctioning valve is important in the management of complicated infective endocarditis that involves either a native or a prosthetic valve.[49,51,80,91,95,96] Overall, surgery is indicated in 25% to 40% of patients with infective endocarditis. Several observations have prompted earlier and more frequent surgical intervention in active endocarditis: (1) the mortality of patients undergoing valve surgery early during active endocarditis is not greater than that for patients treated medically or operated upon later (after microbial cure), and in many series is lower[91,97]; (2) the risk that recurrent endocarditis from the same infecting organism will develop on a prosthesis newly implanted for treatment of endocarditis is very low[97]; and (3) some intracardiac complications of endocarditis can be corrected only with surgery. For patients with PVE, early aggressive surgical treatment is an essential element of therapy in about 45%.

The currently accepted indications for surgical treatment of active native or prosthetic valve endocarditis have been developed through a retrospective analysis of many cases. Moderate to severe heart failure from valvular dysfunction is the most widely accepted indication for valve replacement and accounts for the majority of decisions to operate. Cardiac surgery for these indications has been convincingly shown to improve survival. Bulky vegetations that obstruct the valve orifice may also produce heart failure and are a compelling indication for surgery. Surgical intervention is also indicated when there is clinical evidence of perivalvular invasion and abscess formation

and when infection remains uncontrolled for more than 1 to 3 weeks despite maximal antimicrobial therapy. Fungal endocarditis, especially in patients with intracardiac complications, is commonly treated surgically.[92] Similarly, PVE that occurs within a year after valve implantation and is caused by coagulase-negative staphylococci frequently results in perivalvular invasion. Regardless of the causative agent, if there is evidence that PVE is complicated by perivalvular extension of the infection, particularly if the valve is unstable, the PVE should be managed surgically. Because left-sided native valve endocarditis and, in particular, PVE caused by *S. aureus* are frequently invasive, early surgery should be considered for patients with these infections who do not show prompt and sustained improvement during antibiotic therapy.[51,91,96-99] Endocarditis caused by *P. aeruginosa* or other gram-negative bacilli that has not responded after 7 to 10 days of maximal antibiotic therapy should be treated surgically. Although patients with native valve endocarditis who experience relapses after appropriate antibiotic therapy often can be cured by repeat courses of antibiotics, surgical treatment improves the outcome in patients with PVE who experience relapse.

Arterial embolization, particularly to the brain, is another factor to be considered when deciding whether to operate. Emboli do not constitute an absolute indication for surgery, because the likelihood of recurrent embolization in any individual patient is highly unpredictable. Furthermore, the incidence of embolization falls rapidly after 1 week of effective antibiotic therapy. Choosing whether to operate therefore requires a consideration of relative risks and benefits in the light of multiple clinical, echocardiographic, and microbiologic observations, including embolization. For example, occurrence of an embolus early in the course, with a residual highly mobile vegetation of more than 10 mm in diameter, would be a relative indication for surgical intervention even if the patient did not have heart failure [*see* Clinical Presentations, Embolic Phenomena, *above*].[34,100-102] Surgery may be beneficial if the vegetations are unusually large and mobile.[102] In surgically treated patients with endocarditis, operative mortality is proportional to the degree of preoperative hemodynamic impairment. If surgery is indicated, it should generally be performed promptly. Delaying surgery to administer additional antibiotic therapy in the presence of uncontrolled infection or deteriorating hemodynamic status may result in a less favorable outcome.[97] On the other hand, delaying surgery (when hemodynamic status permits) may be desirable in patients who have experienced a neurologic complication.[43,103] In patients who have sustained a cerebral infarction, the exacerbation rate for cerebral complications is reduced to 10% if surgery is delayed for at least 15 days and is reduced to below 3% if the delay is 28 days. If cerebral hemorrhage has occurred, cardiac surgery should ideally be delayed for at least 14 days—preferably, 28 days or more.[43] Exclusion of a complicating cerebral mycotic aneurysm should be considered in this setting [*see* Clinical Presentations, Neurologic Manifestations, *above*].

Although implantation of a prosthetic valve in a patient who is actively abusing intravenous drugs may be lifesaving, endocarditis is likely to recur if the drug abuse continues, and it is more difficult to cure PVE than it is to cure native valve endocarditis. To avoid these problems, tricuspid or pulmonary valvulectomy without valve replacement has been employed in the treatment of right-sided endocarditis. However, in IDUs with isolated right-sided *S. aureus* endocarditis, surgery should be postponed because most of these cases can be cured medically.[19]

Table 6 Cardiac Abnormalities and Endocarditis Risk[115]

Higher risk	Prosthetic heart valves
	Previous infective endocarditis
	Cyanotic congenital heart disease
	Surgically constructed systemic-pulmonary shunts and conduits
Lower risk	Mitral valve prolapse with regurgitation
	Mitral regurgitation, stenosis, stenosis with regurgitation
	Aortic regurgitation, stenosis, stenosis with regurgitation
	Tricuspid valve disease
	Pulmonary stenosis
	Ventricular septal defect
	Patent ductus arteriosus
	Coarctation of the aorta
	Asymmetrical septal hypertrophy
	Calcific aortic sclerosis
	Degenerative valvular disease in elderly patients
	Surgically repaired intracardiac lesions with residual hemodynamic abnormality
Negligible risk	Mitral valve prolapse without regurgitation
	Minor valvular regurgitation by echocardiography without major structural abnormality
	Isolated atrial septal defect
	Arteriosclerotic plaques and coronary artery disease
	Cardiac pacemakers
	Surgically repaired intracardiac lesions with minimal or no hemodynamic abnormality

ANTITHROMBOTIC THERAPY

Anticoagulant therapy in a patient with endocarditis carries the potential risk of causing or worsening hemorrhage in the brain or other sites. However, the benefits of anticoagulation probably outweigh the risks if a strong indication exists, such as atrial fibrillation, cardiomyopathy, mural thrombus, or deep vein thrombosis. Anticoagulant therapy may be carefully administered to patients with endocarditis when it is so indicated.[104] In patients with prosthetic valves who require long-term warfarin therapy, such therapy should be continued during treatment of endocarditis unless there are specific contraindications. The prothrombin time should be carefully maintained in the lower therapeutic range, at an international normalized ratio (INR) of 2.0 to 3.0. Anticoagulation should be reversed immediately in the event of CNS complications, especially intracranial hemorrhage. Anticoagulation should be interrupted for 1 to 2 weeks after an acute embolic stroke. Heparin therapy should be avoided during active endocarditis if at all possible.

There is no evidence in humans that antithrombotic therapy can prevent arterial embolization of vegetations or otherwise improve the response of endocarditis to standard treatment regimens.

Prophylaxis

Antibiotics can prevent endocarditis in animal models if given before experimentally induced bacteremias, and may do so in humans if given before medical, dental, and surgical procedures that are known to cause bacteremia. However, this has not been proved. Current guidelines support the administra-

Table 7 Procedures and Endocarditis Risk[115]

Higher risk	Dental procedures that involve the gingival crevice Surgical procedures (including biopsies) inside the oral cavity Genitourinary tract procedures when bacterial infection is present Surgical procedures (including incision and drainage) when bacterial infection is present at the site
Lower risk	Injection of local anesthetic Genitourinary tract procedures, in absence of active bacterial infection Surgery involving gastrointestinal or respiratory mucosa, in absence of active bacterial infection Skin biopsies and dermatologic procedures using standard antisepsis Bronchoscopy, with or without biopsy Gastrointestinal endoscopy, with or without biopsy Cardiac catheterization Transesophageal echocardiography Esophageal dilatation and sclerotherapy of esophageal varices Endotracheal tube insertion Tympanostomy tube insertion *In the absence of active bacterial infection*: urethral catheterization, laparoscopy, sterilization procedures, vaginal delivery, vaginal hysterectomy, cesarean section, therapeutic abortion, dilatation and curettage, insertion or removal of intrauterine devices

tion of prophylactic antibiotic to patients who are at higher risk for endocarditis than the general population when they undergo procedures likely to lead to bacteremia with organisms that commonly cause endocarditis.[105-107] The appropriate selection of patients for this intervention remains controversial. Such selections should be made on the basis of an assessment of the combined risk of the underlying cardiac condition, the likelihood that the procedure will cause endocarditis (which is always low), and the potential morbidity and mortality[86] [*see Tables 6, 7 and 8*]. Patients who are at the highest risk for endocarditis are those with a history of previous infective endocarditis, prosthetic valves, cyanotic congenital heart disease, or surgically constructed shunts or conduits. Prophylaxis is merited in all such cases.

Prophylaxis is recommended for patients at high risk for endocarditis who undergo procedures that involve the oral cavity, the respiratory tract, or the esophagus and are likely to cause streptococcal bacteremia. Prophylaxis is also indicated for patients at high risk for endocarditis who undergo procedures that involve the genitourinary tract, the GI tract distal to the stomach, or the biliary tract and are likely to cause bacteremia with enterococci [*see Table 7*]. For patients who are at unusually high risk for endocarditis, some physicians elect to use prophylaxis even for procedures carrying low likelihood of bacteremia (for which prophylaxis would generally not be recommended).

Antibiotic regimens recommended for prophylaxis in high-risk patients have been designed to cover streptococci or enterococci and are assigned in accordance with the anticipated bacteremic organism [*see Tables 8 and 9*]. When urinary tract manipulation is anticipated, an evaluation for urinary tract infection should be undertaken, and infection, if confirmed, should be treated before the manipulation. If procedures must be performed on infected tissues, prophylaxis is directed against the likely pathogen causing the infection. Such prophylaxis would include use of an antistaphylococcal penicillin or a first-generation cephalosporin when the infection involves skin and adjacent soft tissue, joints, or bone.

If a patient who is at risk for endocarditis is receiving or has recently received one of the agents recommended for prophylaxis, it is prudent to choose for prophylaxis an antibiotic from a different class, rather than increase the dosage of the current regimen. The dosage of penicillin used to prevent recurrences of acute rheumatic fever is insufficient to prevent bacterial endocarditis. Moreover, patients taking oral penicillins or cephalosporins may harbor relatively penicillin-resistant strains of bacteria in their oral cavity. Prophylaxis with clarithromycin or clindamycin is suggested when relatively penicillin-resistant streptococci are anticipated.

Most cases of endocarditis are not related to defined events or procedures. It is likely that these infections arise from bacteremias associated with minor unrecognized infections or ordinary activities such as vigorous chewing in patients with gingival disease or use of oral irrigating jets. In patients with vulnerable cardiac lesions, maintaining optimal dental health is essential if the risk of endocarditis is to be minimized. Dental evaluation and treatment, including extractions and necessary restorative work, should be performed under appropriate antibiotic prophylaxis several weeks before the insertion of prosthetic heart valves.

Prognosis

Overall survival for patients with infective endocarditis is about 75% to 80%.[2,44,108] This rate is little better than that in the 1950s and needs to be improved.[108] The outlook depends largely on the promptness of diagnosis and initiation of therapy, the nature of the infecting organism, the presence of comorbid condi-

Table 8 Recommendations for Endocarditis Prophylaxis[115]

*Procedure**	*Preexisting Cardiac Risk Factors†*		
	Higher risk	*Lower risk*	*Negligible risk*
Higher risk	Prophylaxis recommended	Prophylaxis not recommended but optional; clinical judgment needed	Prophylaxis not recommended
Lower risk	Prophylaxis not recommended but optional; clinical judgment needed	Prophylaxis not recommended	Prophylaxis not recommended

*See Table 7.
† See Table 6.

Table 9 Recommended Regimens for Prophylaxis of Endocarditis[116-119]

Category	*Indication*	*Drug and Dosage*
Standard regimen	For general use when prevention of endocarditis is recommended [*see Table 8*]	Amoxicillin, 2 g orally 1 hr before procedure*
Special regimens	Oral regimens for penicillin-allergic patients (oral and respiratory tract procedures only)	Clindamycin, 600 mg orally 1 hr before procedure, then 300 mg 6 hr later* *or* Clarithromycin, 0.5 g orally 1 hr before procedure
	Parenteral regimen for high-risk patients; also for GI or GU tract procedures	Ampicillin, 2 g I.M. or I.V. *plus* Gentamicin, 1.5 mg/kg I.M. or I.V. 30 min before procedure*
	Parenteral regimen for penicillin-allergic patients	Vancomycin, 1 g I.V. slowly over 1 hr, starting 1 hr before procedure, then *add* Gentamicin, 1.5 mg/kg I.M. or I.V. if GI or GU tract involved*
	Cardiac surgery, including implantation of prosthetic valves	Cefazolin, 2 g I.V. at induction of anesthesia, repeated 8 and 16 hr later*† *or* Vancomycin, 1 g I.V. slowly over 1 hr starting at induction, then 0.5 g I.V. 12 hr later*†‡

Note: No regimen has been proved effective for the prevention of endocarditis, and prevention failures may occur with any regimen. These guidelines are not intended as the standard of care and are not intended to cover all clinical situations; practitioners should use their own judgment on safety and cost-benefit issues in each individual case. One or two additional doses may be given if the period of risk for bacteremia is prolonged.

*Pediatric dosages: ampicillin, 50 mg/kg; cefazolin, 30 mg/kg; clindamycin, for children > 60 lb, use the same as for adults, and for children < 60 lb, use half the adult dose; gentamicin, 2 mg/kg; amoxicillin, for children > 60 lb, use the same as for adults, and for children < 60 lb, use half the adult dose; vancomycin, 20 mg/kg.

†Gentamicin, 1.5 mg/kg I.V. may be given with each dose if postoperative gram-negative infections have occurred with significant frequency.

‡This regimen is recommended for units where coagulase-negative staphylococcal prosthetic valve infections have occurred with significant frequency.

tions, and the development of cardiac and neurologic complications.[44,50] Survival is above 90% when the infecting organism is a viridans-type streptococcus or *S. bovis* but is only about 50% in non-IDUs infected with *S. aureus*. Although outcomes are worse in cases of early PVE, survival rates for patients with late PVE appear to be similar to those for patients with native valve infection.[5,6,89] With the incorporation of earlier surgical intervention for patients with endocarditis, cardiac failure is less strongly associated with increased mortality than it once was. However, major CNS complications and uncontrolled infection, especially abscess formation, continue to be associated with increased mortality.[41] The short-term outlook is relatively good for IDUs with right-sided endocarditis.[19] Endocarditis caused by gram-negative bacilli other than HACEK organisms or caused by yeasts is difficult to cure despite optimal antimicrobial therapy and aggressive surgical intervention. Endocarditis caused by mycelial fungi is usually fatal.[21]
