XIII BENIGN PROSTATIC HYPERPLASIA

Michael J. Barry, m.d.

Benign prostatic hyperplasia (BPH) is a very common cause of morbidity in older men in virtually all developed countries. BPH causes lower urinary tract symptoms and occasionally results in such complications as acute urinary retention, urinary tract infection, and even obstructive uropathy. Although increasing appreciation of the relatively benign natural history of this condition and the development of effective medical treatments have reduced the role of surgery, prostatectomy for BPH remains a widely performed procedure. The sheer prevalence of lower urinary tract symptoms attributable to BPH, the impact of these symptoms on patients' quality of life, and the availability of medication for this condition make BPH important in both primary care and urologic practice.

Epidemiology and Risk Factors

Autopsy studies indicate that the prevalence of histologic BPH ranges from about 25% for men in their 40s to about 85% for men older than 80 years [*see Figure 1*].[1] The average prostate volume in young men without histologic evidence of BPH is about 20 ml. A community-based study of men from Olmsted County, Minnesota, has indicated that mean prostate volume increases with age: 23 ml at 40 to 49 years of age, 27 ml at 50 to 59, 32 ml at 60 to 69, and 39 ml at 70 to 79.[2] These volumes were higher in every age category than for men in a Japanese community, where mean prostate volumes ranged from 17 ml for men in their 40s to 21 ml for men in their 70s. In another community-based study, from the Netherlands, the prevalence of a prostate volume greater than 40 ml ranged from 15% in men 55 to 59 years of age to 28% for those 60 to 64, 36% for those 65 to 69, and 55% for those 70 to 74.[3]

Other epidemiologic studies have examined the relationship of peak urinary flow (uroflow) rates (Q_{max}) and age. In the Olmsted County study, mean Q_{max} decreased from about 20 ml/sec in men 40 to 44 years of age to about 12 ml/sec at 75 to 79 years of age.[4] The proportion of men with a flow rate less than 10 ml/sec ranged from about 5% at 40 to 44 years of age to about 25% at 70 to 74 years of age. Another parameter sometimes linked to BPH, postvoid residual volume (PVR), does not appear to be age related.

Of course, BPH without symptoms is more a histologic curiosity than a disease, and not all lower urinary tract symptoms are attributable to BPH. What is the prevalence of symptomatic BPH in older men? The answer depends on how BPH is defined. A Dutch study of a community-based sample of men 55 to 74 years of age found that the prevalence of BPH varied from 4.3% to 19%, depending on which of eight case definitions of clinically important disease was applied.[5] By any definition, however, BPH is a common clinical complaint in older men, at least in Western countries.

Although the prevalence of histologic BPH is remarkably similar across countries with populations of varying races and ethnicities, Asian men appear to have smaller prostates at any given age and undergo less surgery for BPH. Whites and African Americans appear to have similar risks. Studies conflict on whether there may be a positive or negative association between BPH and cigarette smoking. Obesity also has an equivocal relationship with BPH. Cirrhosis of the liver appears to be negatively associated with BPH, probably because of higher circulating levels of estrogens relative to androgens. Men with a family history of BPH may have an increased risk of BPH, especially if the affected relative was diagnosed before age 60, and twin studies indicate a 3.3-fold higher risk in monozygotic twins with affected siblings. Despite the apparent contribution of family history as a risk factor, the genetics of BPH remains poorly understood.[6]

Pathophysiology

The normal prostate consists of epithelial glandular components in a stroma of connective tissue and smooth muscle [*see Figure 2*]. BPH involves hyperplasia of both the epithelial and the stromal compartments. The hyperplastic process begins in the periurethral and transition zones of the prostate; in contrast, prostate cancer preferentially develops in the peripheral zones.[7] Over time, multiple small hyperplastic nodules grow and coalesce into a large central adenoma, which can compress the more peripheral prostate tissue against the fibrous prostatic capsule. This compressed peripheral tissue can create what is in effect a surgical capsule bounding the central adenoma. The capsule serves as the plane of resection when a particularly large adenoma is removed at open prostatectomy.

Eventually, prostatic hyperplasia can result in bladder outlet obstruction, which is defined as increased bladder detrusor pressure relative to the rate of urine flow. Bladder obstruction has both a static component (from luminal narrowing secondary to prostate tissue growth) and a dynamic component (from increased neuromuscular tone in the hyperplastic prostate). Neuromuscular tone in the bladder neck, prostatic capsule, and prostatic stroma is attributable to a relatively high density of $alpha_2$-adrenergic receptors in these tissues. At least three types of $alpha_2$-adrenergic receptors have been identified in the lower urinary tract. Epithelial and vascular tissues, on the other hand, are more richly supplied with $alpha_1$-adrenergic receptors. The bladder

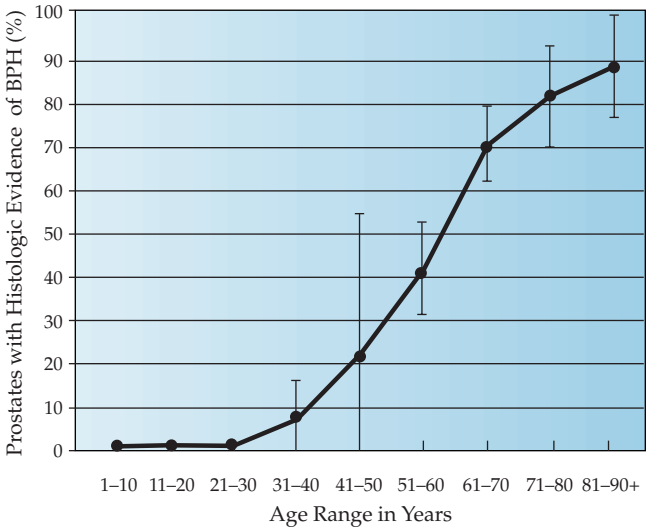

Figure 1 **Prevalence of BPH histology with age in 1,075 human autopsies.[1]**

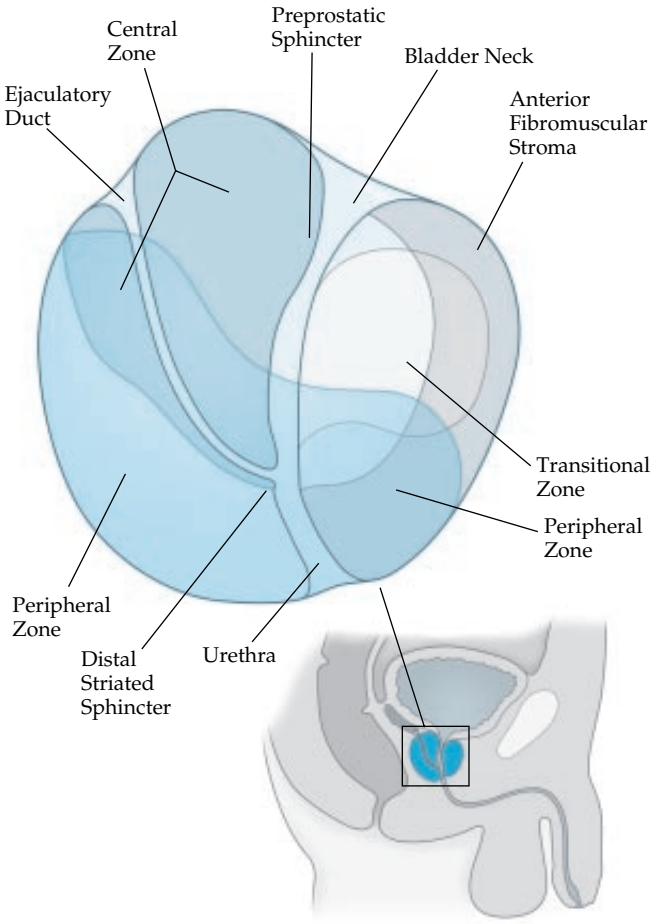

Figure 2 **Sagittal diagram of the prostate and its relationship to the anteromedial nonglandular tissues, along with a three-dimensional representation of the glandular prostate.**

may respond to outlet obstruction with hypertrophy, uninhibited contractions, and, if obstruction is long-standing, fibrosis.

These histologic, anatomic, and pathophysiologic processes may result in lower urinary tract symptoms. Traditionally, such symptoms have been grouped into two categories: bladder emptying (obstructive) symptoms, which presumably result primarily from mechanical obstruction, and bladder filling (irritative) symptoms, which presumably result primarily from detrusor instability (see below).[8]

Although this model of the link between BPH and lower urinary tract symptoms is convenient, it is undoubtedly simplistic. Researchers have documented that the severity of lower urinary tract symptoms correlates poorly with measurements of prostate size, the degree of bladder outlet obstruction, and the severity of uninhibited detrusor contractions. Moreover, improvement in symptoms with treatment does not correlate well with improvements in these ostensibly objective parameters; for some treatment modalities, symptoms may improve despite the absence of changes in these other measures. The scientific uncertainty over the mechanisms that link the histologic process of BPH with lower urinary tract symptoms contributes to clinical uncertainty over how to treat older men who present with bothersome lower urinary tract symptoms.

The pathophysiologic mechanisms underlying the development and progression of BPH are also incompletely understood. Aging and the presence of functioning testes through puberty into adulthood are absolute requirements. Clearly, BPH involves prolonged exposure of the prostate gland to androgens. The conversion of testosterone to dihydrotestosterone (DHT), which is the major intraprostatic androgen, is accomplished by the type 2 5α-reductase isoenzyme; this isoenzyme occurs largely in prostatic stromal cells, although it is also found in some peripheral tissues. In contrast, the type 1 5α-reductase isoenzyme has low activity in the prostate and is expressed predominantly in the skin and liver. DHT serves as a powerful mitogen for prostatic cells. Men who were castrated before puberty do not develop BPH, and medical or surgical castration later in life causes apoptosis of prostatic epithelial cells. Other factors extrinsic to the prostate also appear to be important in prostate growth, including estrogens, possibly a nonandrogenic testicular factor, and environmental factors such as diet and genetics. In the prostate, interactions between epithelial and stromal cells and the extracellular matrix, mediated primarily by locally produced (intrinsic) growth factors, appear important. These peptide growth factors, which include fibroblast growth factors, insulinlike growth factors, and epidermal growth factors, are felt to be the local forces that determine prostate growth.[9]

Diagnosis

The extent of the medical evaluation necessary to establish a working clinical diagnosis of lower urinary tract symptoms attributable to BPH is controversial. In most men older than 50 years, a characteristic history alone may be sufficient. However, not all older men with a typical history will have either prostatic enlargement or evidence of bladder outlet obstruction on pressure-flow studies. In some of these men, environmental factors or systemic diseases may be causing or exacerbating their symptoms. Others may have disorders of the lower urinary tract that are not associated with bladder outlet obstruction, or they may have bladder outlet obstruction that is not caused by BPH.

CLINICAL FEATURES

Slowly progressive difficulties with bladder emptying and filling are characteristic of BPH. Bladder emptying symptoms in men with BPH include straining, hesitancy, intermittency, a weak stream, terminal dribbling, and a sensation of incomplete emptying. Bladder filling symptoms include daytime frequency, nocturia, urgency, and urge incontinence.

HISTORY

When older men present with lower urinary tract symptoms, a careful history will uncover most alternative causes. The physician should look for evidence of systemic diseases that can present with lower urinary tract symptoms, particularly urinary frequency and nocturia. Examples of such diseases include diabetes, heart failure (which can cause a nocturnal diuresis separate from the effect of diuretics), and hyperparathyroidism. Neurologic diseases—including diabetic peripheral and autonomic neuropathy, stroke, and Parkinson disease—may be associated with neuropathic disorders of the bladder. A complete list of medications should be obtained, and the time at which the patient takes medications such as diuretics should be ascertained. Patients should be specifically questioned about the use of over-the-counter medications for cough, cold, and allergy, because the anticholinergic and sympathomimetic agents in these preparations may cause or exacerbate symptoms.

The urologic history should include any genitourinary malignancies (personal or family), hematuria, or acute urinary retention or urinary tract infection. Patients should be asked about urethral strictures, as well as genitourinary trauma, instrumentation, and sexually transmitted diseases, which may result in stricture.

Lower urinary tract symptoms can be quantified using the American Urological Association Symptom Index (AUASI).[10] This seven-item questionnaire, which is widely used in epidemiologic and clinical research, as well as clinical practice, assesses the frequency of seven lower urinary tract symptoms, each on a scale of 0 to 5. The individual item scores can be added to calculate an overall score ranging from 0 (best) to 35 (worst). Scores of less than 8 reflect mild symptoms; 8 to 18, moderate symptoms; and 19 to 35, severe symptoms. The International Prostate Symptom Score (IPSS)[11] contains the same symptom question set as the AUASI, but it also includes a separately scored quality-of-life question addressing the degree of bother caused by the respondent's symptoms [*see Figure 3*]. The IPSS questionnaire is designed for self-administration, but visually impaired patients or patients who cannot read may have an interviewer read the questionnaire to them. Quantifying the severity of symptoms provides objective documentation of the patient's condition and serves as a baseline against which to judge improvement, stability, or worsening over time, with or without treatment. Responses to the individual items, as well as the overall score, should be noted.

Men with symptoms attributable to BPH usually have a balance of filling and voiding symptoms; men with mostly filling symptoms, and particularly nocturia alone, are more likely to have another cause for their symptoms. Patients should also be asked about the time course of the development of their symptoms. Rapid onset of symptoms is uncharacteristic of BPH and should be a red-flag warning of other potential causes, including genitourinary malignancy. Dysuria and pelvic pain are also uncommon in men with BPH; these symptoms are more often seen with prostatitis.[12]

Finally, because BPH and its treatment can affect both sexual function and urinary continence, men should be asked about these issues before any treatment is begun. Urge incontinence may be seen with BPH as a result of uninhibited detrusor contractions; other types of incontinence may be engendered by treatment.

Some clinicians ask patients with lower urinary tract symptoms to keep a voiding diary over a few days to a week.[13] Patients should measure and record the volume of each void, noting any episodes of incontinence. The pattern of voiding reflected in the diary may provide valuable clues to the cause of symptoms, particularly when it reveals nocturnal polyuria.

Perhaps the most important aspect of assessing lower urinary tract symptoms is to ask the patient how much he is bothered by them. Although the level of bother is generally related to symptom severity, some patients tolerate severe symptoms quite well,

	Not at All	*Less Than One Time in Five*	*Less Than Half the Time*	*About Half the Time*	*More Than Half the Time*	*Almost Always*
1. Over the past month or so, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
2. Over the past month or so, how often have you had to urinate again less than 2 hours after you finished urinating?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
3. Over the past month or so, how often have you found you stopped and started again several times when you urinated?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
4. Over the past month or so, how often have you found it difficult to postpone urination?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
5. Over the past month or so, how often have you had a weak urinary stream?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐
6. Over the past month or so, how often have you had to push or strain to begin urination?	0 ☐	1 ☐	2 ☐	3 ☐	4 ☐	5 ☐

7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?

whereas other patients are aggravated by moderate symptoms. Intervention may make more sense for the latter than the former, regardless of symptom score. The patient's answer to the question about bother on the IPSS may serve as a good entry into this discussion [*see Figure 3*].

PHYSICAL EXAMINATION

Patients considering alpha-blocker therapy for BPH should have their baseline blood pressure determined, both supine and standing. Patients considering operative treatment should undergo a general evaluation for risks of complications from anesthesia and surgery.

The physician should perform a targeted physical examination that includes palpation of the lower abdomen for evidence of a grossly enlarged bladder, assessment of the extremities for peripheral neuropathy, and assessment of the perineal area and inner thighs for saddle anesthesia. A patient with neuropathy or saddle anesthesia is more likely to have a neurologic disorder affecting the bladder.

A digital rectal examination (DRE) should be done, and the examiner should note the size, symmetry, and texture of the prostate. BPH characteristically produces a symmetrically enlarged, firm prostate of the consistency of the tip of the nose, but that finding is nonspecific. Asymmetry in consistency or hard nodules suggest prostate cancer, but these findings are likewise not specific.

DRE tends to produce an underestimation of prostate size.[14] When a clinician thinks a prostate is enlarged, it usually is; however, the prostate may well be enlarged even if the clinician thinks it is not. This discrepancy may be important, because for some medical therapies, efficacy is related to prostate size. Moreover, agreement between clinicians, even urologists, on the presence or absence of palpable prostate abnormalities suggesting cancer has also been shown to be only fair.[15]

LABORATORY TESTING

Routine tests performed on men with lower urinary tract symptoms should generally include a urinalysis to screen for hematuria and infection. Many clinicians order serum creatinine and prostate-specific antigen (PSA) tests, although the value of those is arguable for many patients. Less frequently performed tests in this setting include PVR measurement, uroflow measurement, and imaging of the upper urinary tract.

Urinalysis

Pyuria suggests infection, either primary or superimposed on bladder outlet obstruction. Microscopic hematuria may indicate simply that the prostate is enlarged and vascular, but it should prompt further evaluation for genitourinary malignancy.

Serum Creatinine Measurement

An elevated creatinine level may be a clue to the occasional case of obstructive uropathy. However, the rarity of this condition has recently led to the publication of practice guidelines that recommend against routine measurements of serum creatinine in men with lower urinary tract symptoms suggestive of BPH.[16]

Prostate-Specific Antigen Testing

The role of PSA testing in men with lower urinary tract symptoms has been controversial. Prostate cancer screening studies do not confirm that patients with lower urinary tract symptoms suggestive of BPH are more likely to harbor prostate cancer.[17] However, because BPH and prostate cancer are both age related, they may coexist. Therefore, looking for prostate cancer in men with lower urinary tract symptoms and a nonsuspicious DRE is most appropriately considered screening, rather than case finding. The diagnostic yield of PSA measurement as a screening test deteriorates in the setting of BPH, primarily because of lower specificity. Although a PSA level greater than 10 ng/ml is still relatively specific for prostate cancer, only about 25% of men with PSA levels in the range of 4.1 to 10 ng/ml have prostate cancer at biopsy; many of the rest have BPH.[18]

Most urologists doubt the value of early detection of prostate cancer in men whose life expectancy is less than 10 years[19] or who are in average health but older than about 75 years. Clinicians should have a conversation about the possibility of coexisting prostate cancer with patients who present with lower urinary tract symptoms, and the clinician and the patient should decide together whether to pursue such a diagnosis.

A PSA test result of over 4 ng/ml has traditionally been considered an indication for biopsy. However, a number of studies have reported that when men with so-called high-normal PSA levels (2.5 to 4.0 ng/ml) undergo biopsy, only 15% to 20% are found to have prostate cancer.[18] Many attempts have been made to find laboratory features that would indicate the likelihood of cancer in patients with an elevated PSA level, and so improve biopsy yield. In general, however, the performance of these so-called PSA derivatives has been disappointing. For example, measurement of the proportion of total PSA that is circulating in the free form has been proposed for men with total PSA levels of 4.1 to 10 ng/ml and benign DRE results, with a proportion above 25% considered to offer reassurance that cancer is absent. However, only about 20% of men with total PSA levels in this range will have a supposedly reassuring free PSA percentage; and even in those men, the probability of cancer at biopsy is still about 10%.[20]

Another potential reason to consider ordering a PSA test for a man with lower urinary tract symptoms is to help stratify his risk for future problems, such as progression to acute urinary retention or a condition warranting surgery.[21] A PSA level can also help predict the preventive effect of medical therapy with a 5α-reductase inhibitor (see below).

Residual Volume Measurement

An optional test in the setting of lower urinary tract symptoms is the assessment of PVR by catheterization or ultrasonography. Obtaining such measurements is difficult in primary care settings, and substantial day-to-day variation limits their value. Probably only consistent, gross elevations in PVR (> 350 ml) are a reliable indicator of the need for more aggressive treatment.

Urinary Flow Rate

Many urologists measure uroflow rates in their offices. About 90% of men with peak uroflow rates of less than 10 ml/sec have bladder outlet obstruction, compared with about 30% of men with peak flow rates greater than 15 ml/sec. Values between 10 and 15 ml/sec are associated with bladder outlet obstruction in about two thirds of cases.[22] Unfortunately, uroflow rate testing is also limited by within-patient variability, and multiple measurements are necessary to improve reliability. Also, a voided volume of at least 150 ml is needed for a reliable result, and a substantial proportion of patients with lower urinary tract symptoms cannot meet that requirement. Moreover, low flow rates can be seen with weak detrusor contraction in the absence of

outlet obstruction, and strong bladder contraction can maintain flow even in the presence of obstruction. For all of these reasons, uroflowmetry is an optional test.

The simultaneous measurement of bladder pressure and urine flow is considered the gold standard for the diagnosis of bladder outlet obstruction.[23] There are a number of criteria for calling a pressure-flow study positive, all of which are based, in various ways, on documenting a high bladder pressure relative to the uroflow rate. More sophisticated videourodynamics can localize the site of obstruction. These tests require special equipment and training; are somewhat invasive, requiring a urethral catheter; can be expensive; and yield equivocal results in some men. They are usually recommended for patients with atypical presentations; for patients with neurologic diseases, in whom the probability of primary bladder disorders is higher; or for men with persistent symptoms after surgical therapy for symptoms presumed to be from BPH. Few urologists would recommend a pressure-flow study for a typical patient before a trial of medical therapy, but some would routinely recommend such a study before undertaking a prostatectomy after medical therapy fails. There is not universal agreement regarding this recommendation, however, because a substantial proportion of men with lower urinary tract symptoms who do not have unequivocal evidence of obstruction on a pressure-flow study will nevertheless have good symptomatic responses to surgery.[24]

Upper Urinary Tract Imaging

Upper urinary tract imaging (by ultrasonography, computed tomography, or intravenous pyelography) and urethrocystoscopy are not indicated for routine cases of lower urinary tract symptoms attributable to BPH.[25] Cystoscopic findings in particular have not correlated well with the severity of symptoms of bladder outlet obstruction. Such studies should be reserved for selected patients with findings such as microscopic hematuria.

Management

Once the clinician has made a working clinical diagnosis of symptomatic BPH and when the patient is sufficiently bothered by his lower urinary tract symptoms to at least consider therapy, the initial choice of management is usually between a period of watchful waiting and a course of medical therapy. Medical therapies include alpha blockers and 5α-reductase inhibitors. Many patients also use alternative or complementary treatment for prostate problems, especially phytotherapies.

WATCHFUL WAITING

When the bother of a patient's lower urinary tract symptoms is not sufficient, in his mind, to justify the potential side effects, costs, and inconvenience of medication, watchful waiting is the optimal management strategy. Although virtually all patients with mild symptom scores (an IPSS from 0 to 7 points) choose this course, it is also a reasonable course for patients with moderate or severe symptoms who are not very bothered by them. Patients should be advised to take lifestyle measures to improve symptoms, such as avoiding fluids, particularly beverages containing caffeine, just before bedtime. They should also avoid offensive medications, especially nonprescription ones [*see* History, *above*]. Finally, they should report worsening symptoms, particularly an increase in their feeling bothered by the symptoms. Although, on average, symptoms can be expected to gradually increase, individual courses are quite variable, and some men note improvement over time [*see Figure 4*].[26]

MEDICAL TREATMENT

Alpha Blockers

Alpha$_1$-adrenergic blockers work primarily through relaxation of prostatic smooth muscle and relief of the dynamic component of bladder outlet obstruction. However, additional mechanisms have been proposed, including increased apoptosis of prostatic cells. Alpha blockers neither reduce prostate size nor lower PSA levels. Their onset of action is relatively rapid, although most alpha blockers require dose titration to achieve a maximal therapeutic effect while minimizing side effects. Many patients have hypertension and BPH, and both problems may be treated with an alpha blocker; however, data strongly suggest that alpha-blocker monotherapy is not optimal treatment for hypertension.[27]

Many randomized trials have documented the efficacy of alpha blockers over placebo in studies lasting up to 4 years.[28,29] For example, in the largest trial reported to date, over 2,000 men were randomized to receive either placebo or terazosin in doses

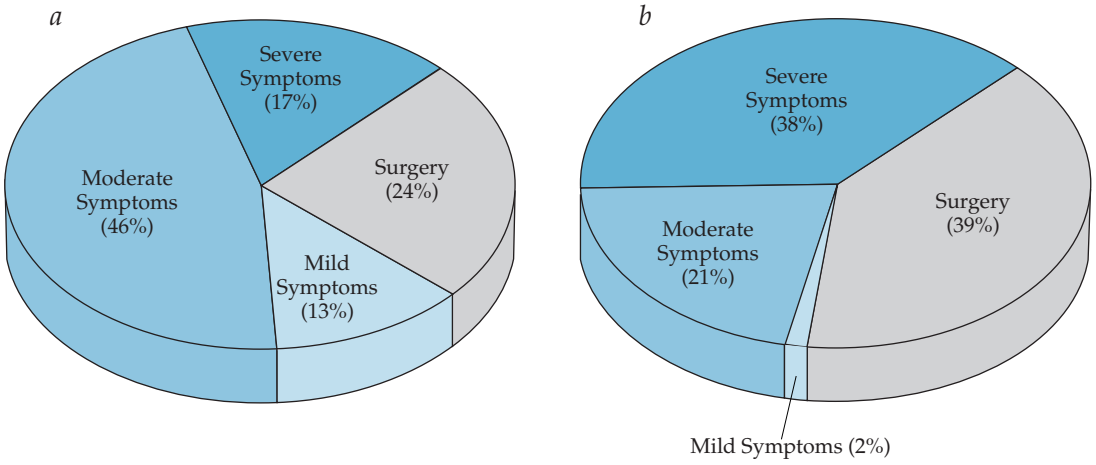

Figure 4 **Four-year outcomes in men with (*a*) moderate (N = 245) or (*b*) severe (N = 66) lower urinary tract symptoms attributed to benign prostatic hypertrophy. These men were considered reasonable surgical candidates but chose watchful waiting instead.[26]**

Table 1 Alpha Blockers Commonly Used in the Treatment of Men with Lower Urinary Tract Symptoms Attributed to BPH

Drug	*Strengths Available*	*Recommended Dose-Titration Steps*
Alfuzosin*	2.5 mg	2.5 mg t.i.d.
Alfuzosin SR*	5 mg	5 mg b.i.d.
Alfuzosin XL	10 mg	10 mg q.d.
Doxazosin	1, 2, 4, and 8 mg	1, 2, 4, and 8 mg q.d.
Doxazosin GITS*	4 and 8 mg	4 and 8 mg q.d.

GITS—Gastrointestinal Therapeutic System

of up to 10 mg daily. IPSS scores dropped about 8 points with the alpha blocker and about 4 points with placebo.[30] Such data highlight the impressive magnitude of the placebo effect on lower urinary tract symptoms in most trials of therapy. Some of this placebo effect may be attributable to regression toward the mean, which is seen when men with particularly marked symptoms are recruited into trials. In clinical practice, patients perceive their change in symptoms from baseline, so their improvement results from a combination of the pharmacologic benefit of the intervention with these other effects. The therapeutic effect of the alpha blockers is independent of prostate size.[31] As is true of all treatments for men with symptoms attributed to BPH, the men with the highest symptom scores can expect the greatest absolute decrease in their symptom scores with alpha blockers. Therefore, many men with symptom scores in the severe range will benefit from a therapeutic trial of alpha blockers before considering more invasive treatment.

Various alpha blockers are used in the treatment of lower urinary tract symptoms attributed to BPH. Although head-to-head trials of alpha blockers are relatively few, the therapeutic effects of different agents appear similar.[28] There is currently great interest in developing alpha blockers with selectivity for the subtypes of the $alpha_1$-adrenergic receptor to maximize the therapeutic effect while minimizing side effects. Tamsulosin and alfuzosin indeed appear more selective than doxazosin and terazosin for the $alpha_{1a}$-adrenergic receptor, which is the predominant subtype in prostatic smooth muscle. However, this difference in pharmacologic selectivity does not appear to translate into major differences in efficacy.[28,32]

Side effects of alpha blockers include orthostatic hypotension, dizziness, and asthenia. The last two side effects are not primarily mediated by low blood pressure.[33] Tamsulosin and alfuzosin do not affect blood pressure, as do the other alpha blockers, but it is unclear whether the risk of side effects other than orthostatic hypotension is appreciably reduced with these agents.[16,28] Abnormal ejaculation has been reported in about 10% of men on tamsulosin.[16] In short-term clinical trials, the proportion of men who withdraw from alpha-blocker treatment because of side effects is generally low, but this proportion is likely to be higher in clinical practice, particularly over time. Caution must be exercised in combining alpha blockers with phosphodiesterase type 5 inhibitors used for the treatment of erectile dysfunction, which commonly coexists with BPH, for fear of inducing hypotension. Sildenafil should not be taken within 4 hours of taking an alpha blocker; vardenafil should not be taken at all by men on alpha blockers; and tadalafil should be combined only with tamsulosin at the lower dose of 0.4 mg daily.

Nonselective $alpha_1$-adrenergic blockers such as doxazosin and terazosin require dose titration [*see Table 1*]. Most clinicians start with a 1 mg dose at bedtime for several days to avoid so-called first-dose hypotension, although the clinical relevance of this phenomenon is poorly documented. In most patients, the dose should be pushed to the highest level if possible; the clinician should monitor supine and standing blood pressure, side effects, and the patient's global impressions of improvement before dose escalation. Follow-up administration of the IPSS may help objectify improvements and aid in the decision whether to proceed to the highest recommended dose. Both doxazosin and terazosin can be given once daily. Many clinicians recommend taking them at bedtime, although it is unclear whether this strategy reduces side effects.

Tamsulosin, extended-release doxazosin (the doxazosin Gastrointestinal Therapeutic System [GITS]), and a new extended-release formulation of alfuzosin are designed for once-daily administration and do not require as many dose-titration steps as doxazosin and terazosin. Titration of tamsulosin and doxazosin GITS is complicated by the fact that they have two recommended dose levels. Doxazosin GITS is not yet available in the United States.

Although alpha blockers have repeatedly been shown to reduce lower urinary tract symptoms, their ability to reduce the risk of BPH complications over the long term, such as progression to surgery or the development of acute urinary retention, appears negligible.[29]

5α-Reductase Inhibitors

The 5α-reductase inhibitors currently available for the treatment of BPH are finasteride and dutasteride. Finasteride selectively and irreversibly binds with the type 2 5α-reductase isoenzyme, which predominates in the prostate, and thereby blocks conversion of testosterone to DHT, the dominant intraprostatic androgen. This agent lowers serum DHT by about 70% and intraprostatic DHT to an even greater degree. Dutasteride is a dual 5α-reductase inhibitor; it blocks both type 1 and type 2 isoenzymes and lowers serum DHT by about 90%.[34] Whether this dual blockade offers any clinical advantage is uncertain.

Men who take finasteride at the recommended dose of 5 mg daily or dutasteride at 0.5 mg daily can expect a 20% to 25% reduction in prostate size over the first year of therapy,[34,35] accompanied by about a 50% reduction in PSA level.[34,36] Despite this effect on PSA, these drugs have not been shown to impair the ability to diagnose prostate cancer in controlled trials. However, PSA levels must be interpreted differently. The most common recommendation is simply to double the measured PSA levels for men on finasteride or dutasteride, then interpret the results as usual.

Like the alpha blockers, finasteride and dutasteride have been shown in a number of clinical trials to produce greater symptom reduction than does placebo. However, the symptom reduction has generally been smaller than for the alpha blockers, averaging 2 to 4 points from baseline IPSS scores.[34,37] The efficacy of finasteride, reflected in the group mean difference between finasteride and placebo in these trials, depends on prostate size. For men with prostates less than 40 ml, the differences between fi-

nasteride and placebo are minimal, but the differences in IPSS scores between finasteride and placebo increase to 1.0 to 1.5 points for men with prostates greater than 40 ml in trials lasting up to 2 years.[37] Dutasteride's efficacy relative to prostate size has not been as well studied.

In a longer-term trial, finasteride resulted in about a 3-point decrease in symptom score from baseline over 4 years, roughly 2 points greater than the decrease shown with placebo.[35] The slow response of symptoms to finasteride was obvious, with nadir scores not reached for at least 2 years. Finasteride also significantly reduced the risk of acute urinary retention (from 6.6% to 2.8%) and of progression to prostatectomy (from 8.3% to 4.2%). In a 2-year trial, the effects of dutasteride on the relative risk of acute urinary retention and on progression to surgery were similar.[34] Data from the finasteride trial indicated that about 15 patients would have to take finasteride for 4 years to prevent the development of acute retention or the progression to surgery in one of those patients. This trial also documented that this preventive benefit of finasteride depends on prostate size and, furthermore, that serum PSA level could be used as a proxy for prostate size to estimate the expected benefit.[38] The estimated number of men who would need to be treated for 4 years to prevent one episode of acute retention or progression to surgery is about 29 for baseline PSA levels less than 1.4 ng/ml, 18 for PSA levels of 1.4 to 3.2 ng/ml, and 9 for PSA levels greater than 3.2 ng/ml.[21]

Finasteride also seems to be effective at reducing the risk of recurrent hematuria in men presenting with hematuria that appears to be from BPH.[39] This effect is probably attributable to finasteride-induced suppression of vascular endothelial growth factors.

Finasteride is relatively well tolerated. About 5% to 10% of men notice decreased libido or ejaculatory abnormalities over the first year of treatment, and fewer than 1% of men have rashes, gynecomastia, or breast tenderness. After the first year of treatment, side effects with finasteride and placebo are essentially identical.[35] The side-effect profile of dutasteride is similar.[34]

In a large cancer prevention trial, the 7-year cumulative likelihood of a prostate cancer diagnosis was 18.4% with finasteride and 24.4% with placebo.[40] The likelihood in both trial arms was higher than expected because of intensive surveillance for prostate cancer during the trial, including end-of-study biopsies (regardless of DRE findings or PSA levels) in most participants. However, the likelihood of a high-grade prostate cancer (defined as a cancer with a Gleason score of 7 to 10) increased from 5.1% with placebo to 6.4% with finasteride. These results raise doubt about whether finasteride would do more good than harm in terms of its effect on prostate cancer morbidity and mortality. This should be considered when prescribing finasteride (and, presumably, dutasteride, which works by the same mechanism) to men for BPH.

Combination Therapy

Given that alpha blockers and 5α-reductase inhibitors work through different mechanisms, combination therapy is an attractive concept. Nevertheless, in head-to-head comparative trials, both terazosin and alfuzosin used alone were found to be superior to finasteride for symptom relief over 6 to 12 months of therapy,[41,42] and the combination of finasteride with terazosin or alfuzosin was found to be no better than either alpha blocker alone in the short term. However, in a subsequent 4-year trial, doxazosin, finasteride, and combination therapy were compared with placebo in terms of their ability to reduce the rate of BPH progression, defined primarily as 4-point increases in IPSS score. The risk of progression at 4 years was 17% with placebo, 10% with either doxazosin or finasteride, and 5% with both.[29] Patients who take combination therapy are exposed to the side effects of both agents, as well as to any higher risk of more aggressive prostate cancers from the use of finasteride.

Phytotherapy

Many patients around the world take phytotherapies for lower urinary tract symptoms. They may take these preparations on their own initiative or at the recommendation of a clinician. Meta-analyses suggest that a number of these phytotherapies, including extracts of the saw palmetto plant,[43] β-sitosterol plant extracts,[44] rye grass pollen extract,[45] and *Pygeum africanum* plant extracts,[46] are effective for reducing some lower urinary tract symptoms. The effects appear to be small, and the trials are generally limited by design problems, particularly short durations of follow-up and incomplete outcome assessments. In particular, few studies used validated symptom scores as outcome measures. The mechanisms of any effects are poorly defined. Moreover, preparations of these phytotherapeutic agents vary, so patients are not assured that any given preparation will afford the same benefits seen in the trials.

SURGERY AND MINIMALLY INVASIVE TREATMENT

Transurethral and Open Prostatectomy

Transurethral prostatectomy (TURP) remains the gold standard for relieving symptoms and reducing the risk of complications for men with BPH. TURP involves resecting the central adenoma of the hyperplastic prostate transurethrally under direct visualization using a resectoscope with an electrified cutting loop. General or spinal anesthesia is usually used.[47] In the United States, patients may have as little as an overnight hospital stay after TURP and may require a urinary catheter for a short period until the initial hematuria induced by the resection begins to clear.

In a randomized trial that compared TURP and watchful waiting, mean IPSS scores fell by about 12 points from baseline with TURP versus 1 point with expectant management by 7.5 months after randomization.[48] Although there are no randomized trials comparing medical therapy with TURP, the decreases in symptom scores with TURP are substantially greater than with any medication. In the largest trial of TURP versus expectant management for men with moderate symptoms, which involved almost 600 men, treatment failures (predominantly deterioration to severe symptoms, acute retention, or the development of a very large residual volume) were significantly reduced by about 50% with TURP.[49] On the other hand, the absolute risks of treatment failure were relatively small—over 3 years, the rate of treatment failure was about 20% with watchful waiting versus 10% with TURP. However, these results must be interpreted in light of the fact that about a quarter of the patients initially assigned to expectant management crossed over to surgery within 3 years.

With the availability of other effective and less invasive treatment options, age-adjusted rates of TURP in Medicare beneficiaries fell by about half from 1984 to 1997.[50] However, the procedure got progressively safer over this period; currently, 30-day mortality is less than 1%. Moreover, TURP provides durable symptom relief, with a 5-year risk for reoperation of about 5%.[50] Although sexual dysfunction and incontinence have been traditionally considered potential side effects of TURP, the risks were

found to be similar for TURP and watchful waiting in the largest comparative trial.[49] Retrograde ejaculation, however, is a common outcome of TURP, occurring in the majority of cases. Men should be warned to expect this result when considering TURP.

A prostatic adenoma can also be resected through an open incision using either a retropubic or a suprapubic approach.[51] To avoid the incision and potential complications such as wound infection, open prostatectomy is generally reserved for men with the largest prostates, in whom a transurethral resection may be especially challenging. An open prostatectomy can also be expected to provide excellent and durable symptom relief.

Transurethral Incision and Electrovaporization

Transurethral incision of the prostate (TUIP) involves making one or two longitudinal incisions in the prostate without resecting tissue. This procedure has been considered especially well suited to younger men with smaller prostates. In a meta-analysis of four small trials, symptom relief at 12 months with TURP was similar to that with TUIP.[52] However, long-term comparative results are not available. The risk of retrograde ejaculation was 73% with TURP but only 21% with TUIP.

Transurethral electrovaporization of the prostate (TUVP) is similar to TURP, but TUVP uses a roller electrode to vaporize superficial layers of prostate tissue while coagulating deeper layers. A meta-analysis of several small trials suggested that the primary benefit of TUVP is fewer bleeding complications, but this advantage has not been determined definitively.[53] The longest trial (5 years) suggested that TURP and TUVP had similar effects on symptoms, but few patients completed 5 years of follow-up.[54] Longer-term comparative results are unknown.

Laser Coagulation and Vaporization

A number of treatment strategies using laser energy to coagulate or vaporize prostate tissue have been explored for men with symptoms attributed to BPH. An early technique of noncontact coagulation has been totally abandoned. In a meta-analysis, short-term symptom responses to a spectrum of laser procedures were somewhat less impressive than for TURP, with higher risks of reoperation, though with fewer transfusions and postoperative strictures.[55] Longer-term trials comparing visual laser ablation of the prostate (VLAP) and contact laser vaporization with TURP have also shown higher retreatment rates with the laser strategies over 3 to 5 years.[56,57] A newer, holmium laser ablation technique appeared to have results comparable to those of TURP in a 1-year trial,[58] but longer comparative studies are needed.

Thermal Therapies

In recent years, a number of minimally invasive treatments have been developed to coagulate prostate tissue with heat generated through various mechanisms. These office-based treatments are designed to reduce symptoms, with less sedation and fewer side effects than seen with surgery. No tissue is resected with thermal therapies, so their mechanism of action is uncertain. Transurethral microwave therapy (TUMT) uses a microwave antenna placed in the urethra to generate heat. The urethra, which is pain sensitive, is protected by a cooling jacket. TUMT reduced symptoms more than terazosin in an 18-month trial[59]; however, in small trials comparing TUMT and TURP, symptomatic outcomes were somewhat less impressive with TUMT.[53] There were fewer side effects related to bleeding with TUMT. Transurethral needle ablation (TUNA) uses two radiofrequency needles placed directly into the prostate via the urethra to heat and coagulate tissue. In one comparative trial, symptom reduction was somewhat less with TUNA than with TURP at 1 year. However, both bleeding and retrograde ejaculation were less common with TUNA.[60] Long-term outcomes are poorly defined for either of these heat-based treatments.

MANAGEMENT OF ACUTE URINARY RETENTION

Acute urinary retention occurs at a rate of 1% to 2% a year in men with lower urinary tract symptoms attributed to BPH. The occurrence of acute urinary retention used to be considered an absolute indication for surgery. However, small case series have documented that up to half of men with acute retention have a successful voiding trial after a period of bladder rest via catheter drainage, and most of the men who experience success will continue to void, at least over the next 6 months. The optimal duration of catheter drainage is poorly defined, with recommended periods ranging from a few days to several weeks. Studies of whether the administration of alpha blockers increases the likelihood of a successful voiding trial have provided conflicting results.[61,62]

Introduction

Dizziness is an inherently neurologic symptom, even if a systemic cause is primarily responsible. Although dizziness is common to diverse diseases, careful evaluation of dizziness and of any accompanying signs and symptoms can provide the gateway to diagnosis, which in turn is the touchstone of successful treatment.

Vestibular Physiology and Anatomy

Dizziness and the postural instability that often accompanies dizziness typically represent abnormalities of inner-ear function. Vestibular sensation and motor responses are mediated by two relatively simple reflexes: the vestibulo-ocular reflex (VOR) and the vestibulospinal reflex (VSR). VOR maintains visual fixation by generating eye movements to counter head movement in space (e.g., when the head moves upward, the eyes move downward). VSR keeps the head and body upright through changes in axial muscle tone.

Within the vestibular labyrinth in each ear, there are three semicircular canals (SCCs) that respond to angular acceleration of the head in three dimensions [*see Figure 1*]. When the head turns, the resulting deflection of the cupula in the ampulla of each SCC generates a signal that is transmitted to the brain via the vestibular portion of cranial nerve VIII. The strength of that signal is proportional to the angular velocity of the head. Information about rotation of the head in space reaches the vestibular nuclear complex in the brain stem [*see Figure 2*], and output from this complex drives the compensatory slow phases of the angular VOR.

The otolith organs (utricle and saccule) respond to linear acceleration during translation of the head (motion in a straight line) and from gravity (uprightness). Linear accelerations cause movement of the gelatinous matrix in the otolithic macula, deflecting the otolith hair cell processes. As these hairs bend, their firing rates change, depending on the direction of acceleration [*see Figure 3*]. Input from the otoliths drives the responses to head tilt and translation for the compensatory slow phases of the linear VOR.

Transmission of sensory information from the vestibular organs (SCCs and otoliths) occurs through the transduction of physical force into changes in electrical potential by hair cells in the sensory neuroepithelium of each organ.[1] Cupular deflection in the SCCs during angular acceleration and otolithic membrane movement within the otolith organs from linear acceleration alter the membrane potential of hair cells, depending on whether the bundle is deflected toward (depolarization) or away (hyperpolarization) from the kinocilium.[2] Generator potentials of the hair cells then modulate the firing rate of primary vestibular afferent fibers in cranial nerve VIII. These fibers have a resting spontaneous firing rate and, therefore, are active even when the head is not in motion. Rotation of the head toward any given SCC causes nerves innervating that canal to increase their firing rate; rotation away from a canal causes a decrease in firing in axons from that canal.

The SCCs and the otoliths detect motion in three dimensions to provide information for the VSR, which maintains balance. Visual (optokinetic) and somatosensory pathways also provide partially redundant and complementary signals for balance, enabling recovery in response to vestibular dysfunction. Optokinetic signals supplant labyrinthine signals for the low-frequency sustained components of the VOR to head rotation. These different

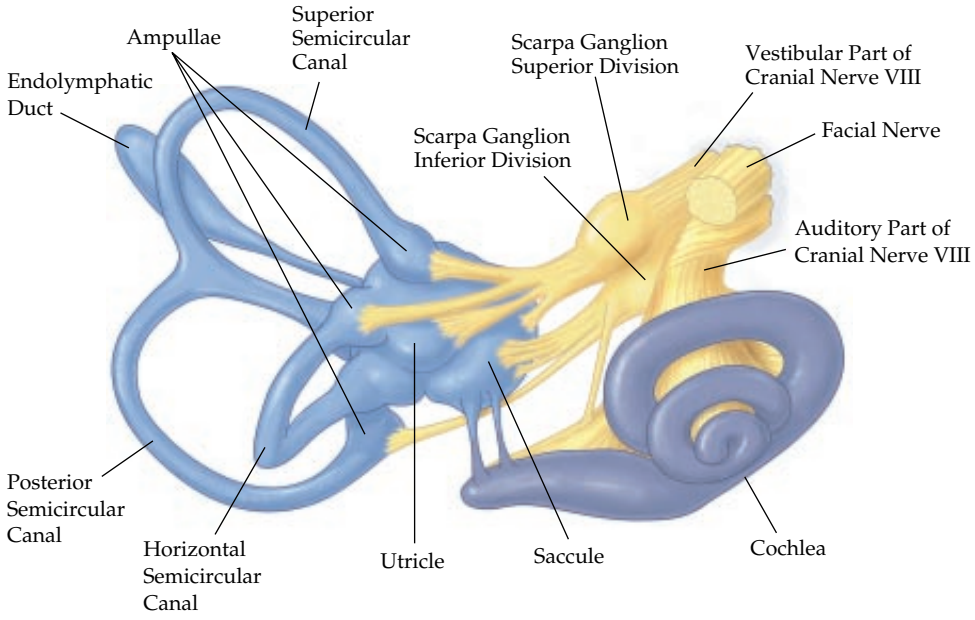

Figure 1 **Soft tissue structures within the bony labyrinth.**

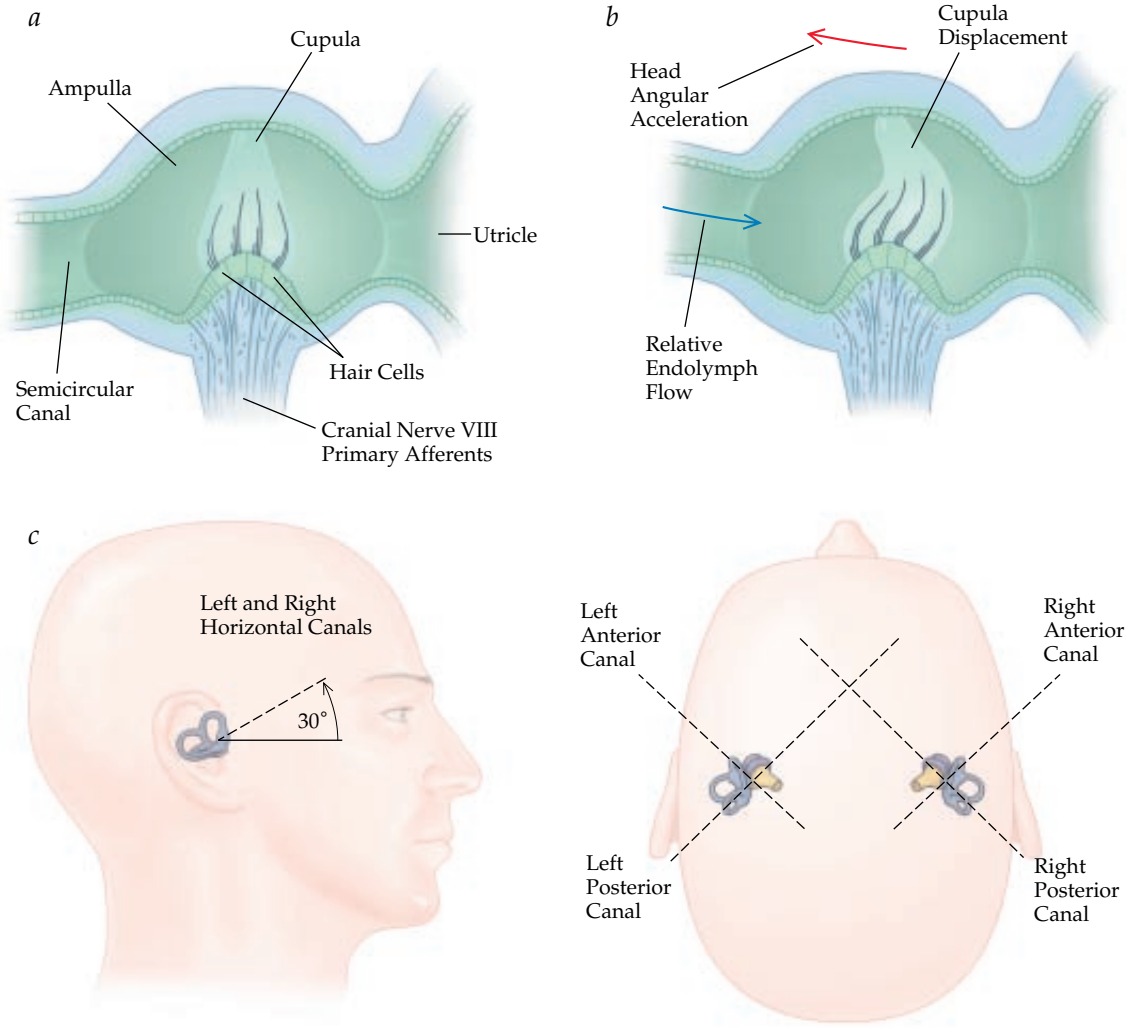

Figure 2 **(*a*) Shown is the functional organization of the cupula and the associated hair cells within the ampulla of the semicircular canals. The cupula changes position depending on the direction of angular acceleration. (*b*) The relation between the hair cell stereocilia and kinocilium is also shown. Movement of the stereocilia (cupula displacement) in a direction toward the kinocilium results in depolarization of hair cell axons, which project through cranial nerve VIII into the brain stem vestibular pathways. Movement of stereocilia in the opposite direction results in hyperpolarization. Similar anatomic arrangements are seen in the saccule and utricle. (*c*) The location of the semicircular canals in the head is shown. In the lateral semicircular canals, the kinocilium is located on the side nearest the utricle, whereas in the superior and posterior semicircular canals, the kinocilium is away from the utricle.**

somatosensory and visual signals that help stabilize posture converge on the same neurons in the vestibular nuclei. Thus, a disturbance in any of the sensory inputs to the vestibular nuclei can lead to a sensory conflict and abnormal vestibular sensations. On occasion, dizziness is produced by visual-vestibular mismatches. A classic example is car sickness: for example, while one reads in the back seat of a moving car, information processed in the visual system informs the brain that the body is not in motion; however, the vestibular system provides information to the contrary. The central neural circuitry of these reflexes is complex. Connections between the vestibular neurons and the oculomotor nuclei form the substrate for the VOR [*see Figure 4*].

For the VSR, the SCCs contribute to postural reflexes via projections to the lateral vestibular nucleus, giving rise to the lateral vestibulospinal tract. The vestibular contribution to sensations of head and body motion and spatial position likely reaches consciousness through the rostral projections of vestibular nuclei to the cerebellum, thalamus, and cerebral cortex.

Clinical Manifestations of Vestibular Dysfunction

Vestibular dysfunction can present in a variety of ways, including oscillopsia (the visual illusion of environmental movement), postural instability, and spatial disorientation. Patients often describe difficulty driving, walking in large open spaces, or walking in crowded environments such as shopping malls and supermarkets. They will avoid head movement. Sensory-rich environments provoke and intensify sensory conflicts, which can produce feelings of disorientation and vegetative symptoms such as nausea and vomiting.[3]

On examination, patients complaining of vertigo may exhibit nystagmus, as a result of abnormalities in the VOR. Vestibular nystagmus has a slow phase, in which the eyes drift during attempted steady fixation, followed by a fast (or quick) phase, in which the eyes reset on the fixation target through rapid eye movements similar to saccades (the eye movements normally made from place to place with the head still or while reading). Nystagmus may be spontaneous or induced by changes in

gaze or body position; the distinction between spontaneous and induced nystagmus, as well as the direction of the nystagmus (i.e., horizontal, torsional, or vertical), has considerable diagnostic utility [*see Tables 1 and 2*]. By convention, nystagmus is named by the direction of the quick phase.

Vestibular signs and symptoms may occur when the head is still, when the head moves, or both. Static disturbances suggest a different set of diagnostic possibilities than dynamic disturbances.

STATIC IMBALANCE

Vestibular disturbance in the absence of head motion is characterized by vertigo and spontaneous nystagmus, which results when a unilateral lesion disturbs the normal balance of tonic discharges from the two labyrinths. Other clinical features of static vestibular disturbance include diplopia (double vision); tilt of the head and body; and vegetative symptoms such as nausea, vomiting, diaphoresis, and occasionally hypotension and syncope.

Skew deviation, a vertical misalignment of the eyes, is the hallmark of an imbalance in the tonic levels of activity underlying otolith-ocular reflexes. Patients with this misalignment often complain of vertical diplopia, sometimes with the illusion of tilt of the visual world, and the head may also be tilted. Skew deviation can be detected clinically by using an ocular cover test. In this test, the physician moves a cover from one of the patient's eyes to the other while watching for vertical corrective eye movement when the cover is switched.

Skew deviation, ocular counterrolling (rotation of the eyes about the line of sight; ocular torsion), and head tilt together constitute the ocular tilt reaction.[4] The ocular tilt reaction can occur with lesions anywhere in the otolith-ocular pathway; this pathway includes the peripheral labyrinth,[5] vestibular nerve, vestibular nucleus in the medulla, medial longitudinal fasciculus in the pons or midbrain, and interstitial nucleus of Cajal [*see Figure 4*]. With peripheral and vestibular nucleus lesions (e.g., vestibular nerve section or Wallenberg syndrome), the lower eye is on the side of the lesion. With lesions above the level of otolith-ocular pathway decussation at the vestibular nucleus (e.g., an internuclear ophthalmoplegia from a lesion in the medial longitudinal fasciculus in the pons or midbrain), the higher eye is on the side of the lesion and the head is tilted toward the lower eye.[6]

Abnormalities in the VSR are assessed with the tandem walking test: the patient places one foot directly in front of the other while keeping the head relatively fixed; the test is done first with the eyes open and then with the eyes closed. Problems with tandem walking suggest an imbalance in vestibular tone—patients will generally veer or fall toward the paretic side.

Static imbalance should also be assessed with the Romberg test, in which the patient stands with feet together and closes the eyes while holding the arms and hands outward with palms up. Excessive sway on the Romberg test can indicate abnormalities in otolith-spinal reflexes.

Past-pointing of the arms or feet to previously seen targets with eyes closed may be another sign of vestibulospinal imbalance. For the arms, past-pointing is best elicited by having the patient repetitively raise both arms over the head, with the index fingers extended, and then bring them down, with eyes closed, toward the examiner's index fingers located at waist level. Errors in pointing generally are in the direction of the weak labyrinth and should be equal in the two arms.

In some cases, the characteristics of spontaneous nystagmus can help localize the lesion. When vestibular damage is peripheral, the nystagmus is characteristically diminished by visual fixation and increased when fixation is eliminated; thus, it is best observed by techniques that impair or remove visual fixation (e.g., occlusive ophthalmoscopy, Frenzel glasses).[7] The slow phases of spontaneous nystagmus generally move toward the side of a peripheral vestibular lesion. For example, in the case of a left vestibular neuritis, right vestibular function is relatively increased; consequently, in such cases, patients exhibit slow eye movements to the left, toward the neuritis, with a corresponding fast phase to the other side (right-beating nystagmus).

Nystagmus with a slow phase toward the side of the lesion is also seen with unilateral lesions in the cranial nerve VIII entry zone or the vestibular nucleus. As with plaques of demyelination from multiple sclerosis (MS), a lesion in the last few millime-

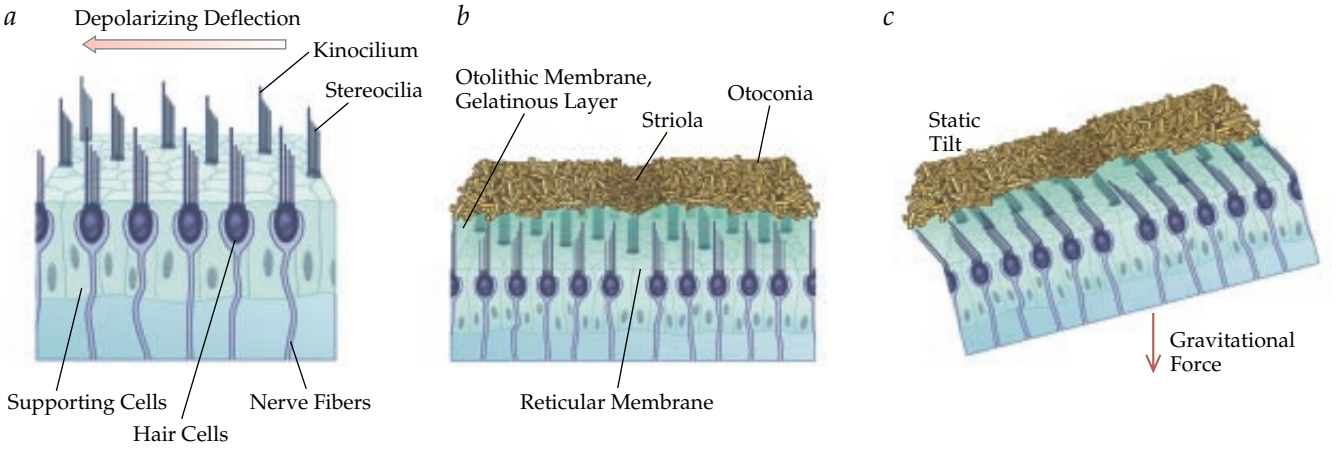

Figure 3 **(*a*) The otolith organs (the utricle and saccule) are specially adapted to detect linear accelerations, including those in the gravitational plane. (*b*) Otolith hair cell stereocilia and kinocilia project into a gelatinous membrane that is covered by crystalline particles of calcium carbonate called otoconia. (*c*) Shearing forces imposed across the membrane occur with static tilt and result in characteristic changes in the movement of stereocilia that can produce either depolarization or hyperpolarization, depending on the direction of movement.**

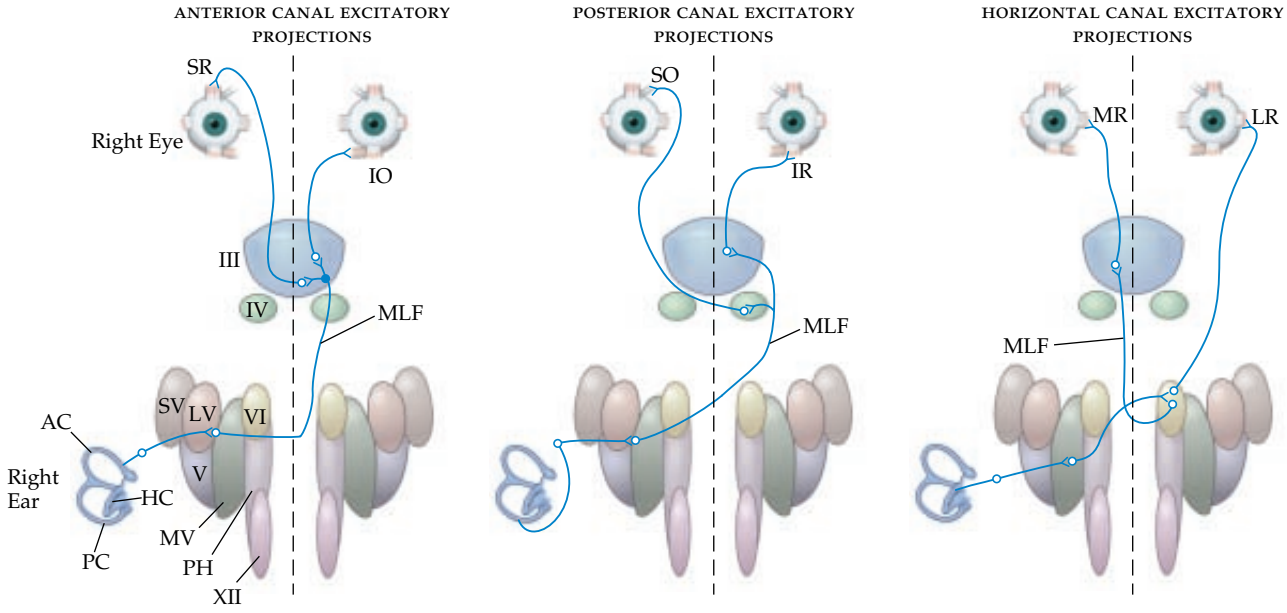

Figure 4 **Shown are the excitatory neural connections that give rise to the three-dimensional vestibular ocular reflex. (*left*) Primary afferents innervating the anterior semicircular canal (AC) synapse onto second order neurons in the vestibular nuclei. Projections cross and ascend in the medial longitudinal fasciculus (MLF) to the contralateral third cranial nerve (oculomotor) nucleus, specifically the inferior oblique (IO) and superior rectus (SR) subnuclei. These motor neurons innervate the inferior oblique muscle on the side opposite the stimulated AC and the ipsilateral superior rectus (via a second decussation) muscle to move the eyes in a vertical upward and torsional direction (upper poles away from the stimulated canal). (*center*) Posterior canal (PC) afferents project centrally to synapse in the vestibular nucleus before decussating and traveling in the MLF to innervate the contralateral third and fourth (trochlear) cranial nerve nuclei. Motor neurons ultimately contact the inferior rectus muscle (IR) on the side opposite the stimulated PC and the ipsilateral superior oblique muscle (via a second decussation). (*right*) Afferent input from the horizontal canal (HC) system projects to the medial vestibular (MV) nucleus and then crosses to innervate two populations of cells in the contralateral abducens (VI) nucleus: motor neurons project to the lateral rectus (LR) muscle, and interneurons cross back over and travel in the MLF to innervate the medial rectus (MR) subnucleus of cranial nerve III, which innervates the ipsilateral MR muscle. (LV—lateral vestibular nucleus; PH—prepositus nucleus hypoglossi; SO—superior oblique muscle; SV—superior vestibular nucleus; III—oculomotor nuclear complex; IV—trochlear nucleus; V—inferior vestibular nucleus; VI—abducens nucleus; XII—hypoglossal nucleus)**

ters of cranial nerve VIII before it enters the brain stem at the pontomedullary junction can be indistinguishable from a process affecting the peripheral labyrinth. However, oscillopsia associated with a peripheral vestibular lesion often resolves quickly as compensatory mechanisms come into play; in contrast, compensation for oscillopsia caused by a brain stem disorder generally does not occur rapidly or to the same extent.

Other central abnormalities are less localizable by the direction of nystagmus. With vestibular cerebellar lesions, the slow phase is typically to the side opposite the lesion—likely because of removal of cerebellar inhibition of the ipsilateral vestibular apparatus. Pure upbeat, pure downbeat, or pure torsional nystagmus almost always has a central origin. A mixed horizontal-torsional or vertical-torsional nystagmus, however, usually indicates a peripheral lesion involving the entire vestibular nerve or all three SCCs in one labyrinth [*see* Nystagmus, *below*].

Gaze-evoked nystagmus commonly occurs as a side effect of certain medications—especially anticonvulsants, hypnotics, and tranquilizers—and with disease of the vestibulocerebellum or its brain stem connections in the medial vestibular nucleus and the nucleus prepositus hypoglossi (both are components of the neural integrator, along with the cerebellar flocculus).[8] It is not present in straight-ahead gaze but is elicited when patients attempt to hold the eyes eccentric in the orbit. The eyes will drift back toward the center, and then a quick phase will follow to move the eyes back into the desired position. When gaze-evoked nystagmus results from toxic or metabolic conditions (e.g., Wernicke encephalopathy, alcohol intoxication), it is direction changing—left beating in left gaze, right beating in right gaze. This distinguishes it from nystagmus caused by labyrinthine weakness, which is always direction fixed.

DYNAMIC IMBALANCE

Dynamic vestibular disturbances are provoked by head motion or change in position. They may reflect unilateral or bilateral abnormalities in amplitude, direction, or timing of the VOR and VSR; or they may reflect mechanical disruptions in the labyrinth (e.g., benign paroxysmal positioning vertigo [BPPV]). Unilateral lesions sometimes cause dynamic disturbances through loss of the normal push-pull relation, whereby activity from one labyrinth increases as that from the other decreases, which results in compensatory eye movement in response to head motion. Bilateral vestibular lesions (e.g., from aminoglycoside toxicity) lead to dynamic disturbances because of an overall loss of function but rarely give rise to vegetative symptoms. Dynamic vestibulospinal function can be clinically assessed by observing postural stability while the patient makes rapid turns during ambulation.

In the case of a dynamic imbalance or bilateral vestibular weakness, angular VOR can be tested clinically by observing the effects of head rotation on visual acuity and on eye movements themselves [*see Table 3*]. For example, dynamic visual acuity is

Table 1 Nystagmus and Its Likely Causes

Type of Nystagmus	*Likely Cause*	*Comments*
Purely torsional	Brain stem disease at vestibular nuclei	Nystagmus from unilateral peripheral vestibular loss can appear purely torsional because of suppression of the horizontal component
Purely vertical Downbeat in primary position Upbeat in primary position	Diverse intrinsic brain stem abnormalities; craniocervical junction (Arnold-Chiari malformation, cerebellar lesion), pontomedullary junction, or pontomesencephalic junction lesion	Often increases in intensity in lateral gaze
Horizontal-torsional	Labyrinthine dysfunction; lesions within cranial nerve VIII or the vestibular nucleus	Horizontal component may be suppressed with vision, causing a peripheral nystagmus to appear purely torsional if viewed with fixation present
Purely horizontal Periodic alternating (jerk, changes direction every 2 min)	Lesion in the cerebellar nodulus	Majority of cases can be treated successfully with baclofen
Primarily horizontal Even during attempted up or down gaze, accented by attempted fixation, diminished by convergence or active eyelid closure, associated with a head turn, sometimes accompanied by reverse (or perverted) smooth pursuit	Congenital	Many patients with congenital nystagmus exhibit normal visual acuity; in one form, latent (occlusion) nystagmus, the slow-phase direction depends on which eye is viewing
Pendular (sinusoidal oscillation rather than unidirectional drift)	Congenital	Nystagmus often appears superficially pendular, but pendular nystagmus may be a sequel to brain stem stroke or a manifestation of various disorders, including multiple sclerosis, Whipple disease, toluene intoxication, acquired visual loss, and Pelzius-Mertzbacher disease
Convergent retraction	Midbrain lesion	Usually coexists with upgaze paralysis (Parinaud syndrome)
Seesaw (one eye ascends and intorts; the other descends and extorts)	Midbrain lesion	—
Dissociated, or disconjugate (greatest or only present in abducting eye)	Internuclear ophthalmoplegia	—

evaluated using a near vision card at 14 in. or a distance acuity chart; the patient's head is passively rotated—horizontally (as in shaking the head, "no"), then vertically ("yes"). The amplitude of the movement is not critical, but the head should pass through the straight-ahead position twice each second. Patients with impaired labyrinthine function usually lose more than two lines of acuity secondary to a reduced VOR gain (eye velocity/head velocity).[9,10]

Corrective saccades during head rotations are also a sign of an abnormal VOR. To assess the VOR clinically, the patient is requested to maintain gaze on the examiner's nose. For yaw (horizontal) and pitch (vertical) rotations, the examiner oscillates the patient's head at a rate of about once every 2 seconds, turning the head across almost the entire ocular motor range [*see Table 1*]. The patient is instructed to continue looking carefully at the examiner's nose and to avoid blinking. During this maneuver, patients can maintain gaze on the target using both the VOR and pursuit eye movements. As the speed of head movements increases, the appearance of any saccadic, rather than slow, eye movements indicates a deficit in the VOR, usually from a peripheral vestibular paresis on the side toward which the head is turning when the rapid eye movements are required. Brief high-acceleration head thrusts are then performed,[11] starting with the head turned about 15° from center and ending with the head facing directly forward.[12] If a corrective (catch-up) saccade is required to move the eyes back onto the target after the rapid head turn, then a canal paresis is present on the side toward which the head had just been turned.

Head-shaking nystagmus is elicited by turning the patient's head vigorously side to side, with the chin pitched slightly downward and the eyes closed, about 20 to 30 times.[13] Any nystagmus present after head rotation stops and eyes are opened is noted; this finding is best assessed using Frenzel glasses so that vision is occluded. Normal individuals show at most a beat or two, whereas a peripheral lesion causing a unilateral loss of labyrinthine function usually produces vigorous nystagmus after head shaking; the slow phases are initially directed toward the side of the lesion, and the fast phases are directed away.[14] Cerebellar dysfunction and other central disturbances may also lead to nystagmus after horizontal head shaking, but generally, the nystagmus is most often vertical (so-called cross-coupled nystagmus).[15] Nystagmus after head shaking can arise from mechanical disturbances in the labyrinth as well (e.g., perilymph fistula, Meniere disease, or abnormality of the cupula).

PURSUIT EYE MOVEMENTS AND VOR CANCELLATION

When the head and eyes track a moving target (pursuit) or when a target is moving at the same velocity as the head (as in

Table 2 Characteristics of Nystagmus Elicited by Eye and Head Position

Lesion Site	*Nystagmus Type (Examination Technique)*		
	Spontaneous (Patient upright; eyes straight ahead)	*Gaze-Evoked (Patient upright; eyes directed right, left, up, then down)*	*Positional (Patient supine; head turned first left, then right; Dix-Hallpike: head rotated 45° with patient sitting upright, then supine)*
Central	Pure vertical or pure torsion Not decreased with fixation Pendular or mixed waveform Alternating direction	Direction changing—quick phases in direction of gaze Unilateral and not present in straight-ahead gaze Downbeating often accentuated in lateral gaze	Nystagmus > vertigo Pure vertical Sustained
Peripheral	Mixed horizontal/torsional Direction fixed Jerk waveform Suppressed by fixation	Direction fixed; must be present in straight-ahead gaze (may need to remove fixation) Can be oblique but not purely vertical	Nystagmus = vertigo Must be in plane of stimulated canal (e.g., upbeat and right torsional in right Dix-Hallpike)

reading a book in a moving vehicle), the VOR is normally suppressed to maintain a stable image: this is VOR cancellation or suppression (VORS). The integrity of VORS can be assessed by asking patients to fix their vision on their outstretched thumbs while horizontally rotating the head and arms together. In normal individuals, the eyes do not move during this maneuver.[16] In patients with cerebellar disease,[17] however, and occasionally in patients with brain stem disturbances that affect pursuit eye movements, one can observe a jerky movement of the eyes, suggesting that VORS is incomplete. A number of drugs that affect the function of the vestibulocerebellum can produce this abnormality, including antiepileptic agents, sedative-hypnotics, and tricyclic antidepressants.

NYSTAGMUS

Nystagmus is a very helpful physical finding in both static and dynamic imbalance. Formal analysis of the slow-phase waveform, as with electronystagmography, can often help localize the causative lesion. Jerk nystagmus, or constant-velocity drifts of the eyes with corrective quick phases, is usually caused by an imbalance of vestibular, optokinetic, or pursuit signals. Lesions of the peripheral vestibular apparatus usually cause a mixed horizontal-torsional nystagmus, with slow phases directed toward the side of the lesion and central pursuit mechanisms generally preserved. Vestibular nystagmus is often suppressed during visual fixation and can easily be assessed by performing occlusive ophthalmoscopy: one eye is covered and the smallest-aperture light is directed at the uncovered eye's optic nerve head (the so-called blind spot), so that no visual stimulus is available to suppress any vestibular nystagmus. Drifts of the optic disk and retinal vessels may appear or increase in velocity if an underlying vestibular imbalance exists. The clinician should note that because the back of the eye is being viewed, an upward drift of the fundus corresponds to a downward drift of the pupil, indicating an upbeating nystagmus.

Nystagmus can also be induced by a change in head position [*see Table 2*]. Positional nystagmus frequently results from degenerative changes in the labyrinth—most commonly, otoconia-derived debris that stimulates the posterior SCC (occasionally affecting the horizontal or anterior SCC) by shifting in response to gravity.[18] In the typical clinical picture of probable benign labyrinthine disease, nystagmus is provoked by the Dix-Hallpike maneuver[19] (also known as the Nylen-Barany maneuver) and is characterized by a latency of up to 30 seconds, with predominant vertical and torsional components parallel to the affected SCC, and a duration of 10 to 60 seconds.[20] This nystagmus may transiently reappear with the slow-phase direction reversed when the patient sits up. Repeat testing with the maneuver may induce further episodes of nystagmus, but fatigability is generally observed.

Peripheral positional nystagmus (i.e., from labyrinthine disease) can be distinguished from positional nystagmus originating in the central nervous system. For positional nystagmus to be considered peripheral, it must be consistent with whichever canal is stimulated by the head position in which it is elicited.[21] Most often, central nystagmus is purely horizontal, vertical, or torsional; is conjugate; is without latency; is nonfatigable; and lasts longer than 30 seconds. Its particular characteristics usually reflect a specific lesion location or disease process [*see Table 1*].

Table 3 Clinical Examination Techniques for Dizzy Patients

Technique	*Associated Disorder or Finding*
Dix-Hallpike, Epley, and Semont maneuvers	BPPV, other benign labyrinthine disease
Ductions and versions	Extraocular muscle palsy, strabismus
Dynamic visual acuity	Bilateral labyrinthine loss
Head shaking	Vestibular asymmetry
Head thrusts (VOR gain)	Unilateral or bilateral labyrinthine loss
Hyperventilation	Compressive cerebellopontine angle lesions
Occlusive ophthalmoscopy	Spontaneous nystagmus
Ocular alignment	Skew deviation
Past-pointing	Vestibulospinal tone imbalance
Pursuit eye movements	Cerebellar dysfunction
Rapid turns during ambulation	VSR dysfunction
Saccades	Brain stem or cerebellar dysfunction
Tragal compression	Perilymphatic fistula
Valsalva maneuvers	SCD syndrome
VOR cancellation	Cerebellar function

BPPV—benign paroxysmal positioning vertigo SCD—superior canal dehiscence
VOR—vestibulo-ocular reflex VSR—vestibulospinal reflex

Diagnosis

When patients complain of dizziness, clinicians should ask themselves a series of key questions to ascertain the underlying mechanism, and they must address whether the patient's abnormality has a vestibular or a general medical basis [*see Table 4*]. Psychiatric factors should also be considered.

With dizziness that appears to be vestibular in origin, the clinician must consider whether the abnormality lies peripherally—at the level of the SCCs, the otoliths, the entire labyrinth, or cranial nerve VIII—or lies within the CNS. Central vestibular dysfunction is most commonly associated with lesions in the brain stem or cerebellum.

HISTORY

In taking the history, the clinician must elicit a clear description of the patient's condition, including the duration of vertigo and any factors that worsen or ease the vertigo. The words that patients use to describe their symptoms may be significant, because a number of seemingly synonymous terms often relate to distinct physiologic mechanisms [*see Table 5 and* Clinical Manifestations, *below*].

Obtaining an accurate account may require persistent, close questioning. For example, a patient may first indicate that the vertigo lasted all day, but further inquiry may reveal that in fact the patient had recurrent episodes throughout the day and that each episode lasted for only 10 to 15 seconds and was brought on by changes in head or body position. The duration of vertiginous episodes often points toward a diagnosis. Episodes lasting only seconds, especially in association with movement of the head, suggest BPPV. Patients who experience vertigo that lasts for minutes may be suffering from vestibular migraine or perhaps vertebrobasilar insufficiency. When vertigo lasts from hours to a day, Meniere disease should be considered. Vertigo lasting for days to weeks raises concern about vestibular neuritis (acute peripheral vestibulopathy) or labyrinthine infarction.

CLINICAL MANIFESTATIONS

Vertigo

Vertigo is generally produced when injury occurs to one vestibular apparatus while the other remains intact or when there is asymmetrical involvement. There is a perception of motion, whether of turning, tilting, or rocking, which persists with eyes closed. A classic example is vestibular neuritis, in which inflammation or infection of cranial nerve VIII on the right or left leads to diminished activity on that side relative to the intact side. This imbalance leads to vertigo and nystagmus.

Patients who complain of vertigo should be asked about the direction of perceived movement of the visual world with eyes open and the sensation of rotation with eyes closed. In the case of left vestibular neuritis, nystagmus slow phases will move toward the left, producing the perception of environmental movement to the right when the eyes are open. A head movement to the right would be necessary to produce a leftward slow phase or vestibular ocular reflex; therefore, with left vestibular neuritis, the patient's perception of self-rotation with the eyes closed will be to the right. Vertiginous patients who fall do so generally in the direction opposite their perceived direction of movement with their eyes closed; therefore, a patient with a lesion on the left side would most often fall to the left. This direction represents a vestibulospinal correction. Unfortunately, many patients are unable to describe the direction of either environmental movement or self-movement during an episode of vertigo because of disturbing vegetative symptoms, disorientation, and altered concentration and attention.

Table 4 Key Questions in the Evaluation of the Dizzy Patient

Is the complaint consistent with an abnormality of the vestibular system?
What level of the vestibular system is involved?
What is the duration of the vestibular disorder?
What factors exacerbate or mitigate the patient's symptoms?
Is there a strong positional component in precipitating symptoms?
Is there associated tinnitus, hearing loss, fullness, or pressure in the ears?
Are there other neurologic accompaniments?
Are there cerebrovascular risk factors?
Does Valsalva maneuver, coughing, sneezing, laughing, or exposure to loud noise have any effect?
Is there a history of seizures?
Is there a history of migraine, and is headache associated with symptoms?
Is there a family history of similar events?

When vestibular insults are bilateral and of similar severity, patients will generally not experience vertigo. They will, however, manifest other features of vestibulopathy, such as gait imbalance and an abnormal VOR.

Light-headedness

Some patients with complaints of dizziness describe their symptoms as light-headedness. This choice of words raises concern about presyncope. The causes of presyncope (and nonvertiginous dizziness) are manifold and include orthostatic hypotension, cardiac arrhythmia, certain metabolic derangements (e.g., hypoglycemia), use of drugs with anticholinergic activity, and autonomic dysfunction.

Disequilibrium

Disequilibrium most commonly refers to the inability to maintain a normal gait and upright posture—often arising from abnormalities in the proprioceptive pathways, as occurs in peripheral neuropathy, such as from diabetes mellitus or Guillain-Barré syndrome—and disease in the dorsal column medial lemniscal system in the upper spinal cord and brain stem, such as from cervical myelopathy or vitamin B_{12} deficiency. Disruption

in the descending vestibulospinal tract, as well as cerebellar and other motor abnormalities (e.g., extrapyramidal parkinsonian syndromes or normal-pressure hydrocephalus), may also contribute to the development of disequilibrium.

Vegetative Symptoms

Many patients with vertigo experience vegetative symptoms such as diaphoresis, nausea, and vomiting. These symptoms are often related to instability in autonomic centers localized in the floor of the fourth ventricle, in close proximity to the central vestibular apparatus. A chemosensitive trigger zone in this region appears to be involved with a number of autonomic responses. Increased vagal tone may predominate, with pallor and hypotension; however, sympathetic responses (e.g., hyperventilation or fear of falling) may also contribute to autonomic imbalance.

Spatial Disorientation

When exposed to sensory-rich environments, patients with vertigo often experience perceptual abnormalities such as spatial disorientation, confusion, and discomfort. These abnormalities are likely to be related to faulty sensory vestibular processing in the cortical vestibular areas. During vertigo, the patient's vestibular sensation represents a conflict between labyrinthine sense and self-referred visual senses.

DIFFERENTIAL DIAGNOSIS

A number of conditions can produce vertigo with characteristic features that often allow the clinician to confirm an etiologic diagnosis [*see Table 6*].

Vestibular Disorders

BENIGN PAROXYSMAL POSITIONING VERTIGO

The most common cause of vertigo in patients presenting for medical attention is BPPV.[22] It is characterized by the vertigo and nystagmus that are associated with changes in head position. BPPV can occur after head trauma or prolonged periods of bed rest, or it can be precipitated by assuming unusual positions such as head extension in a dentist's or hairdresser's chair. Frequently, BPPV is idiopathic, especially in the elderly.

Pathophysiology

Dislocation of otoconia from the utricular macula likely underlies BPPV.[18] These otoconia can migrate into the SCC (most often the posterior SCC), leading to canalolithiasis or possibly cupulolithiasis. A change in head position that promotes movement of the otoconia away from the cupula establishes a gravity-sensitive current, whereby stereocilia in the cupula move toward the kinocilium, resulting in the activation of that SCC [*see Figure 2*]. In the posterior canal, such movement produces depolarization and an irritative response in the vestibular nerve. For example, quickly moving a patient with a right posterior canal BPPV onto his or her right side (during either the Dix-Hallpike or the Semont maneuver) will produce activation of that canal.

The posterior SCC projects centrally to cranial nerve nuclei (IV and III) that mediate downward eye movements by innervating the ipsilateral superior oblique and contralateral inferior rectus muscles. This condition produces intorsion and depression of the ipsilateral (lower) eye and produces extorsion and depression of the contralateral (upper) eye.

Diagnosis of BPPV

Patients with BPPV describe vertigo provoked by head movement—most commonly, when turning over in bed, getting out of bed (matutinal vertigo), and reaching upward (e.g., toward a high shelf) with extension of the neck (so-called top-shelf vertigo). The vertigo is characteristically short-lived, generally not lasting longer than 15 seconds to 1 minute, although the episodes can be recurrent with repeated positional changes.[23] For some patients, this form of vertigo is self-limited, whereas in others it is unrelentingly recurrent. Patients will often sleep with the affected ear up to avoid provoking the vertigo.

Positioning nystagmus can be provoked by performance of the Dix-Hallpike maneuver [*see Table 2*].[24] This maneuver is performed with the patient seated on the examining table: the examiner turns the patient's head 45° either to the right or the left, then rapidly moves the patient into the supine position with the head hanging 30° over the edge of the table.[10] In patients with BPPV, nystagmus and vertigo then develop with a latency of 3 to, in rare instances, 30 seconds. Once the nystagmus subsides, the patient is returned to the sitting position; this may produce a recurrence of the vertigo. The maneuver is then repeated with the patient's head turned to the other side. With repeated maneuvers, the vertigo tends to fatigue.

In patients with BPPV involving the posterior SCC, the Dix-Hallpike maneuver will indicate which labyrinth is affected. For example, when a patient with right posterior canal BPPV is moved into the supine position after the head is turned 45° to the right [*see Figure 5*], the slow phase of nystagmus will have a torsional component such that the upper pole of the eye moves toward the patient's left and the vertical component moves downward (relative to the patient's body). Quick phases of nystagmus will be opposite, with an upbeating vertical component and torsional quick phases beating toward the dependent right ear. (If the patient has not eliminated fixation, the vertical component of the nystagmus may be suppressed and only the torsional component observed.)

Treatment

The treatment of BPPV involves the performance of maneuvers that aim to promote the repositioning of the otoconia from the SCC system (particle repositioning).[25] One such maneuver, the Epley maneuver, begins in a fashion that is identical to the Dix-Hallpike maneuver except that the patient's head is eventually moved through a complete turn rather than limited to only a left or right downward position [*see Figure 5*]. The movement of

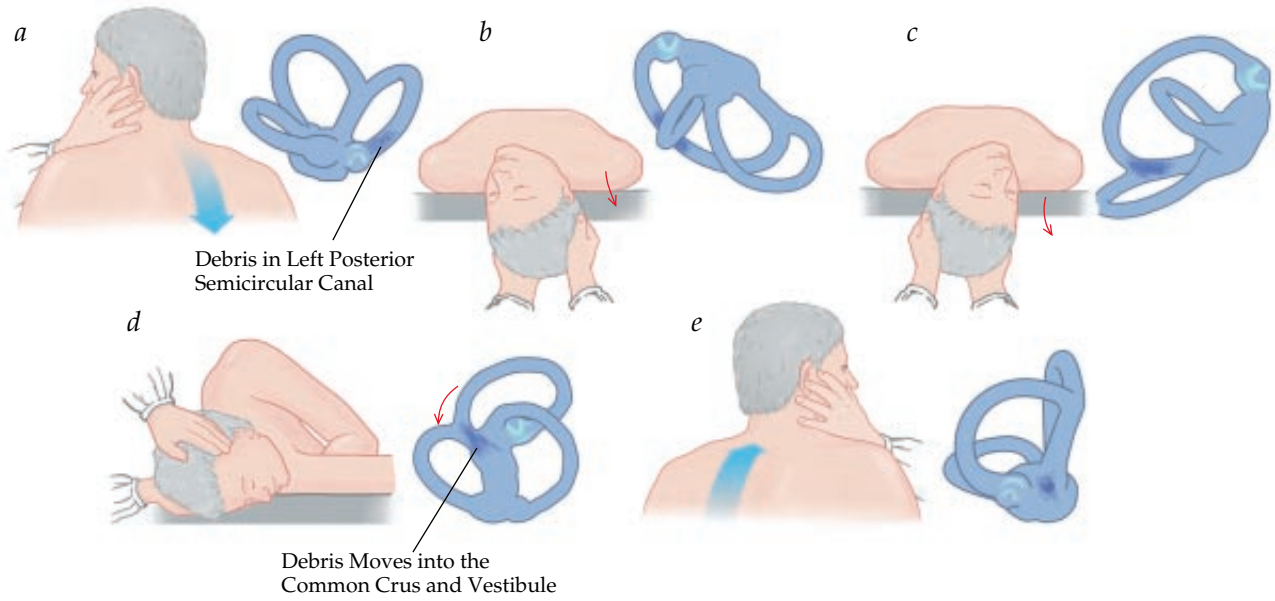

Figure 5 **With the Dix-Hallpike (*a and b*) and particle repositioning (*c through f*) maneuvers, the debris is sequentially moved further into the canal and ultimately to the vestibule, where it is effectively repositioned.**

the head gradually directs the otoconia from the long arm of the canal into the vestibule, where it no longer causes symptoms. During the modified Epley maneuver, the initial head-hanging position with the involved ear down is maintained until the observed nystagmus has fatigued. The head is then turned, with the neck extended, until the noninvolved ear is facing downward. Nystagmus may recur at this point and should be in the same direction as it was when initially elicited. This second position is held until the nystagmus fatigues or for approximately 30 to 60 seconds. The patient is then rolled onto his or her side into a lateral decubitus body position, with the nose pointed downward, for another 30 to 60 seconds. Finally, the chin is tucked toward the chest and the patient is helped up into the seated position. The examiner must maintain contact with the patient at this point, because sitting up will sometimes elicit a vestibulospinal response, which may cause the patient to fall from the table. Two aspects of the original particle repositioning procedure have been found to provide no additional benefit: instructing the patient to sleep upright for 48 hours after treatment[26] and the use of an oscillator over the mastoid during the maneuver.[27,28]

An alternative to the Epley maneuver, the Semont liberatory maneuver, involves the same theoretical elements as the Epley maneuver but utilizes a distinctly different procedure. The Semont maneuver is performed by rapidly moving the patient onto the left or right side and simultaneously rotating the head so that it is pointing toward the ceiling. This position is maintained for 30 to 60 seconds before the patient is rapidly moved into a face-down position on the opposite side of the table.[29]

These maneuvers resolve BPPV in the majority of patients.[30] When this form of therapy fails and BPPV is still the most likely diagnosis, the physician should repeat the Dix-Hallpike maneuver and apply a vibrator to the mastoid bone on the side of involvement while completing a standard particle-repositioning maneuver. The vast majority of patients with BPPV can be effectively treated in this fashion. Very rarely, BPPV is refractory to all conventional treatment interventions. In such cases, alternatives such as surgical neurectomy (singular neurectomy)[31] or SCC occlusion[32] may be necessary.

The use of a vestibular suppressant (e.g., diazepam, clonazepam, or meclizine) is inappropriate for patients with probable BPPV. In general, these agents do not have a role in the treatment of BPPV.

VESTIBULAR NEURITIS

After BPPV, the second most common cause of vertigo is vestibular neuritis, also known as acute peripheral vestibulopathy.[33] The condition was previously called vestibular neuronitis, but it is now believed that inflammation occurs in the nerve itself and not generally in the vestibular ganglion.

Diagnosis

Patients with vestibular neuritis experience severe rotational vertigo, often associated with nausea and vomiting. Typically, the examiner will observe a horizontal-torsional nystagmus beating, with the fast phase toward the normal ear and the slow phase toward the abnormal ear. Hearing is typically preserved, differentiating this condition from labyrinthitis, in which hearing is typically affected. Symptoms often abate in 48 to 72 hours, although complete recovery may take as long as 6 weeks. Vestibular neuritis is often preceded by an upper respiratory tract infection. A number of infectious agents have been associated with vestibular neuritis [*see Table 7*].

Treatment

Corticosteroids are effective for the treatment of acute vestibular neuritis [*see Table 8*].[34] No benefit with antiviral treatment has been found. Symptomatic therapy with antiemetics and vestibular suppressants such as meclizine, diazepam, or promethazine can be used initially, but such agents may prolong the recovery process by preventing CNS adaptation and can also produce excessive sedation that predisposes patients (especially the elderly) to a greater risk of disequilibrium and injury. Hence, vestibular-suppressive agents are recommended only during the initial acute period of vestibulopathy (24 to 72 hours). They can be used in combination with stimulants such as caffeine and methylphenidate (5 to 10 mg every 6 to 8

hours), thereby minimizing daytime sleepiness. In patients with dehydration secondary to vomiting and diaphoresis, rehydration is obviously also essential.

Vestibular neuritis is generally self-limited, but occasionally, a failure of the compensation process that is required to adapt to a residual loss of function will cause patients to have continued symptoms. If, after an initial monophasic vestibular event, patients continue to complain of dizziness provoked by head movement, then rehabilitation with daily home exercises is indicated. Such rehabilitation, which can be supervised by physical or occupational therapists or even primary care nurses or physician extenders, results in significant improvement in the majority of patients.[35] BPPV also frequently occurs weeks or months after vestibular neuritis.

MENIERE DISEASE

Pathophysiology

Meniere disease is thought to involve the accumulation of excessive endolymphatic fluid within the labyrinth. The term endolymphatic hydrops[36] is sometimes applied to Meniere disease, on the basis of the pathologic appearance of the temporal bone in postmortem examinations, although this finding is often present in temporal bones from asymptomatic persons.[36] Idiopathic periodic microruptures in the labyrinthine sac allow mixing of potassium-rich endolymph with perilymph. Cranial nerve VIII, located in the perilymph, becomes hyperpolarized when exposed to potassium-rich endolymph. The consequence of unilateral cranial nerve VIII hyperpolarization is a vestibular functional asymmetry culminating in nystagmus, vertigo, postural instability, and vegetative symptoms.

Diagnosis

Meniere disease involves attacks of vertigo that are typically associated with hearing loss, tinnitus, and a sensation of pressure or fullness in the affected ear. Both clinical and laboratory criteria are used for diagnosis [*see Table 9*]. Attacks are paroxysmal and generally last between 2 and 24 hours. Often, a history of high sodium intake hours before an attack can be elicited. Patients with Meniere disease may experience sudden falls, and they usually describe the perception of being thrown to the floor (otolithic crisis of Tumarkin). This probably results from abnormal excitation of the otolith organs leading to inappropriate vestibulospinal responses.[37]

The nystagmus observed in patients with Meniere disease is similar to that observed in patients with other forms of peripheral vestibulopathy, such as vestibular neuritis. As such, the nystagmus is mainly horizontal with a torsional component and will decrease in intensity with visual fixation.

Patients with Meniere disease typically lose hearing over time. Low-frequency hearing is most affected early in the disease course, whereas high-frequency hearing loss is a late manifestation. These losses, together with relative preservation of middle-frequency hearing, produce a characteristic audiogram pattern referred to as a peak audiogram [*see Figure 6*].[38] Results of transtympanic electrocochleography are also abnormal in most patients with Meniere disease, suggesting an inner-ear fluid imbalance.[39] This test is rarely used in clinical practice, however.

The differential diagnosis for patients presenting with a Meniere-type disease is varied [*see Table 10*]. A number of familial autosomal dominant conditions are associated with periodic vertigo. For example, in its chronic stages, otosclerosis leads to conductive hearing loss and can involve the labyrinth, producing sensorineural hearing loss and vestibulopathy.[40]

Treatment

Conservative treatment of Meniere disease consists of dietary-salt restriction and diuretic agents. Betahistine, a histamine analogue, is prescribed for Meniere disease in many countries, but it has not been approved for use in the United States and the balance of evidence does not support its use.[41]

For acute attacks of vertigo, vestibular suppressants are often helpful in combination with antiemetics. In cases that do not respond to medical treatment, the standard therapy is becoming intratympanic gentamicin, which results in a partial chemical labyrinthectomy, with a small risk of hearing loss.[33] Surgical resection of the vestibular nerve is also effective, albeit more invasive.[42] Endolymphatic shunting is sometimes performed but has not clearly been shown to be beneficial. Pressure devices are currently undergoing study and may become a minimally invasive treatment option.[43]

PHOBIC POSTURAL VERTIGO

Diagnosis

With phobic postural vertigo, patients report a subjective balance disturbance despite normal results on balance testing.[44] Common complaints include postural vertigo and fluctuating

Table 9 Diagnostic Criteria for Meniere Disease[82]

Possible	Episodic vertigo of the Meniere type without documented hearing loss *or* Sensorineural hearing loss, fluctuating or fixed, with disequilibrium but without definitive episodes
Probable	One definitive episode of vertigo Audiometrically documented hearing loss on at least one occasion Tinnitus or aural fullness in the treated ear
Definite	Two or more definitive spontaneous episodes of vertigo lasting 20 min or longer Audiometrically documented hearing loss on at least one occasion Tinnitus or aural fullness in the treated ear
Certain	Definite Meniere disease, plus histopathologic confirmation

Note: all classifications require that other causes are excluded [*see Table 10*].

unsteadiness, often associated with anxiety and vegetative symptoms. Attacks of vertigo are typically associated with particular perceptual stimuli, such as exposure to malls, bridges, staircases, or specific social situations.

Phobic postural vertigo is most commonly observed after the onset of a stressful event or recent illness, especially a vestibular disorder. Many patients who experience vestibulopathy initially use adaptive behavioral mechanisms (e.g., walking with assistive devices and utilizing furniture and walls for stability) to avoid falling. Unfortunately, many patients persist in utilizing these mechanisms long after the vestibulopathy or stressful event has resolved. Ultimately, most of these patients exhibit elements of anxiety and phobia that are most prominent when ambulating. This condition should not be confused with malingering; rather, it is a defensive reaction, often with associated autonomic features (e.g., hyperventilation[45] and tachycardia) that exacerbate the dizziness and perpetuate the maladaptive behavior.[46]

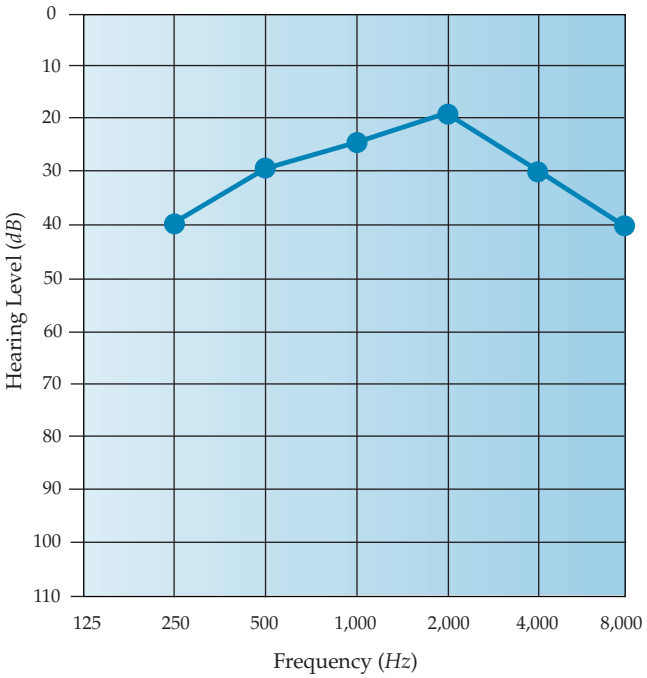

Figure 6 **The audiogram demonstrates the characteristic pattern of hearing loss observed in patients with inner-ear fluid imbalances such as Meniere disease. The reduction in low-frequency and high-frequency hearing and the relative preservation of middle-frequency hearing is referred to as a peak pattern.**

Treatment

Patients with phobic postural vertigo are highly responsive to vestibular rehabilitation, counseling, and exercise. Initially, it is explained to patients that their vertigo is related to disturbed sensory integration. Further, it is emphasized that behavioral strategies that were appropriate during a period of vestibulopathy or other stressful life event may ultimately become maladaptive if they persist. An exercise program and desensitization with psychotherapy are prescribed.

Pharmacotherapy can be a useful adjunct. The usual choice is a vestibular suppressant such as clonazepam or diazepam. These agents should be used at the lowest dose possible because they can also retard the process of vestibular compensation. For patients with a concomitant mood or anxiety disorder, selective serotonin reuptake inhibitors are often useful.[47]

VERTEBROBASILAR INSUFFICIENCY

Two thirds of patients with vertebrobasilar insufficiency will complain of dizziness at some point during the disease.[48] Of patients with completed posterior-circulation strokes, 15% to 20% will have had antecedent isolated attacks of dizziness. These attacks generally last on the order of minutes. It is important to recognize that vestibulopathy related to vertebrobasilar insuffi-

Table 10 Differential Diagnosis of Meniere Disease

Type of Disorder	*Diagnosis*
Vascular	Giant cell arteritis Migraine headache Microvascular compression Posterior-circulation stroke Vertebrobasilar transient ischemic attack
Infectious	HIV Syphilis
Inflammatory/ immune mediated	Cogan syndrome Lupus Multiple sclerosis Chronic inflammatory demyelinating polyneuropathy Sarcoidosis Susac syndrome Idiopathic progressive bilateral sensorineural hearing loss
Structural	Neoplasia Perilymphatic fistula
Other	Superior canal dehiscence Episodic ataxia type 2 Seizure Thyroid disease

ciency can be the result of ischemia in the brain stem, cerebellum, or inner-ear labyrinth, secondary to disease in the branches of the basilar artery. With completed strokes, the vertigo can persist for hours or longer.

Pathophysiology

The principal source of blood supply to the labyrinth is the anterior inferior cerebellar artery. This branch of the basilar trunk gives rise to the internal auditory artery, which ultimately divides into the anterior and posterior vestibular arteries. The anterior branch perfuses the anterior and horizontal SCCs, as well as the utricle, and the posterior branch serves the posterior SCC, the cochlea, and the saccule. Hence, an embolic event that specifically involves the anterior vestibular artery can engender a partial labyrinthine infarction, producing vertigo without hearing loss[49] or vertigo with bilateral hearing loss.[50] Transient bilateral hearing loss may herald a catastrophic basilar artery occlusion.[51] Complete labyrinthine infarction can produce profound and lasting hearing loss and vestibular loss. Even though this would be considered a peripheral rather than a central lesion, the risk of further posterior-circulation strokes is the same as that after a pontine or cerebellar infarction.

Diagnosis

Vertebrobasilar ischemia that affects the brain stem and cerebellum can produce a broad array of neurologic manifestations. These include nystagmus, diplopia, tinnitus, sensory changes, ataxia, dysarthric speech, facial pain, Horner syndrome, weakness, and postural abnormalities. The nystagmus can be highly varied and can have characteristics of either a central or a peripheral type.

Because vertebrobasilar insufficiency is potentially life threatening, it should be actively excluded as a cause of dizziness in patients with a compatible clinical picture, especially those with cerebrovascular risk factors such as hypertension and diabetes. Magnetic resonance imaging of the brain is useful to look for evidence of posterior fossa lesions suggestive of stroke. High-resolution magnetic resonance angiography is increasingly utilized to visualize the patency of the basilar and vertebral arteries. With further refinements, this imaging technique may largely replace conventional angiography as the gold standard for assessing the anatomy of the posterior cerebral vasculature. Patients with cerebellar or brain stem hemorrhagic stroke may present similarly but with a more prolonged duration of symptoms. Emergent imaging is indicated in such cases.

Treatment

In patients with established vertebrobasilar insufficiency, a critical aspect of therapy is the reduction of modifiable risk factors, such as smoking, hypertension, and hyperlipidemia. Antiplatelet or anticoagulation therapy must also be carefully considered [*see 11:IV Cerebrovascular Disorders*].

DRUG-INDUCED VERTIGO

Many drugs can produce dizziness by their effects on the vestibular system and cerebellum [*see Table 11*]. Alcohol changes the specific gravity of endolymph in the cupula and can lead to nystagmus and vestibulopathy. It also impairs cerebellar function, which can produce ataxia, speech changes, postural instability, and nystagmus. Lithium therapy can result in cerebellar dysfunction and can be a cause of downbeating nystagmus.

Table 11 Drugs That Can Cause Vertigo

Drug or Category	*Mechanism*
Alcohol	Peripheral: alteration of endolymph specific gravity Central: gaze-evoked nystagmus, cellular atrophy
Anticholinergics, antihypertensives, smooth muscle relaxants (e.g., alpha blockers)	Orthostatic hypotension
Anticonvulsants	Cerebellar dysfunction
Aminoglycoside antibiotics	Vestibular hair cell damage (causes imbalance rather than vertigo)
High-dose aspirin	Ototoxic damage to vestibular hair cells
Chemotherapeutic agents (e.g., cisplatin)	Hair cell damage

Other agents commonly associated with dizziness include tranquilizers and antihypertensive medications, which cause dizziness by producing orthostatic hypotension; anticonvulsant agents, which produce cerebellar dysfunction; and antibiotics, which can damage vestibular hair cells bilaterally, leading to gait instability and oscillopsia. Additional sources of vestibular toxicity include high-dose aspirin[52] and chemotherapeutic agents such as cisplatin.

One of the most ototoxic agents is gentamicin, which can produce profound vestibular dysfunction by causing bilateral damage to inner-ear hair cells. The symmetrical damage explains the absence of vertigo and nystagmus. In one study, vestibulopathy was found to begin as long as 1 week after gentamicin was discontinued, and onset was delayed in 32 of 36 patients.[53] Half of the affected patients did not have abnormal peak or trough antibiotic levels. Metronidazole given concurrently with gentamicin may increase the risk of vestibulotoxicity.[54] Dynamic visual-acuity testing can be helpful in early recognition of gentamicin-associated vestibular toxicity. Prompt termination of gentamicin treatment may confer a more complete recovery in such patients. There may be a genetic predisposition to gentamicin ototoxicity related to an abnormality in ribosomal messenger RNA, although most cases of ototoxicity occur in patients who do not have this mutation.[55]

VESTIBULAR MIGRAINE

Migraine headache often has neurologic accompaniments, the most common of which are visual distortions. The second most common neurologic manifestation of migraine is vestibulopathy, principally characterized by vertigo.[56] Central nystagmus is the typical type observed in patients with migraine.[57] The most extreme form of vestibular migraine, basilar artery migraine, was first described and named by Bickerstaff. This migraine occurs in adolescents and young adults; typically presents as visual loss or aura, vertigo, ataxia, dysarthria, and dysesthesia lasting up to 45 minutes; and is always followed by a throbbing headache, frequently with vomiting.[58] Much less dramatic, but more common, is so-called migrainous vertigo, which combines vestibular symptoms with characteristic features of migraine.[59]

In up to 30% of patients with vestibular migraine, vertigo oc-

curs completely independently of headache (i.e., acephalgic migraine). A family history of migraine is common, as is a personal history of car sickness in childhood. Uncommonly, sudden hearing loss is attributable to migraine.[60] On the other hand, patients considered to have Meniere syndrome who have no documented hearing loss may in fact have migraine. Patients who complain of "sinus headaches" that include vestibular symptoms most likely have vestibular migraine. Most patients with vestibular migraine have episodes of dizziness that generally last for minutes, although in some, the episodes last for hours. The vertigo may be position induced and can occur in association with central-pattern nystagmus. Some women have a greater disposition for vestibular migraine around the time of their menses (so-called catamenial migraine).

The treatment of vestibular migraine is similar to that of other forms of migraine [*see 11:VIII Headache*] and includes elimination of habitual use of caffeine and over-the-counter analgesics and prophylactic treatment with beta blockers, tricyclic antidepressants, calcium channel blockers, valproic acid, and, occasionally, acetazolamide. Triptans may play a role in therapy, but their efficacy has not yet been determined.[61,62]

PERILYMPHATIC FISTULA AND SUPERIOR CANAL DEHISCENCE SYNDROME

Perilymphatic fistulas are abnormal communications between perilymph and the outside world.[63] Generally, these fistulas occur between the middle and inner ear at the oval or round windows. Precipitating causes include head trauma, Valsalva maneuvers that increase intracranial pressure, vigorous exercise, stapes surgery, barotrauma, erosive lesions in the petrous bone (e.g., a neoplastic lesion or cholesteatoma), inflammatory conditions such as syphilis, and congenital conditions.

Superior canal dehiscence (SCD) syndrome involves the opening of a third window into the labyrinth because of the absence of bone overlying the superior canal.[64] Although the syndrome probably results from congenital thinness of the temporal bone in this area, symptoms may not appear until adulthood, often after head trauma.

Diagnosis

Patients with perilymphatic fistula show hearing loss that is generally similar to that which occurs in Meniere disease. Position-induced vertigo and nystagmus may also occur. Vertigo and nystagmus can also be induced by tragal compression or with swallowing. A useful clinical test for diagnosing fistula involves insufflation of the external ear, which in some patients can produce nystagmus (Hennebert sign). This has been incorporated into platform posturographic testing.[65]

Vertigo in patients with perilymphatic fistula is often secondary to activation of the SCC. Patients with either perilymphatic or otolithic fistula can experience vertigo that is provoked by exposure to loud noise (the Tullio phenomenon), a response that may also be seen in Meniere disease. Patients with SCD also experience the Tullio phenomenon, sometimes even from their own voice. A Valsalva maneuver performed against pinched nostrils, which results in increased middle-ear pressure, will induce a nystagmus consistent with excitation of the superior canal—namely, a mixed torsional-vertical nystagmus with fast phases directed downward and with the upper pole beating toward the affected ear. Hearing loss is often mixed, with both a conductive and a sensorineural component, predominantly in the lower frequencies. Some patients report that when a tuning fork is placed on the ankle, they can hear it in the affected ear. A useful laboratory test, although not widely available, is measurement of the vestibular evoked myogenic potential (VEMP).[66] This test measures electromyographic activity in the sternocleidomastoid muscle by modulating loud clicks in each ear. The VEMP is elicited at a lower threshold than normal in an ear with SCD.

Treatment

Patients with a fistula are generally treated conservatively, with bed rest, fluid hydration, elevation of the head, and avoidance of straining that may cause a Valsalva response. If conservative measures fail, surgical occlusion of the fistula site can be attempted. This generally involves patching the oval and round windows with fatty tissue. Success is variable.[67]

Surgical resurfacing of the arcuate eminence, the area of bone overlying the superior canal, can effectively reduce or eliminate symptoms of SCD.[63] This involves a craniotomy and middle fossa approach.

STRUCTURAL ABNORMALITIES ASSOCIATED WITH VERTIGO

A variety of structural abnormalities have been associated with the development of vertigo. Cerebellopontine angle tumors (e.g., acoustic neuromas) and Arnold-Chiari malformation may present as new-onset vertigo associated with asymmetry in sensorineural hearing thresholds or with new-onset or atypical headache. Consequently, such findings are accepted indications for brain imaging with contrast. Other structural lesions that can produce vertigo include primary brain tumor, metastatic lesion, neurofibroma, traumatic labyrinthine fracture, dermoid and epidermoid lesions, and vascular malformation.

Some patients who have stereotypical paroxysmal episodes of vertigo may suffer from a vascular compression syndrome.[68] This syndrome is produced by a vascular ectasia in one of the posterior-circulation arteries that leads to compression of the caudal brain stem or cranial nerve VIII. Such patients experience rotational or fore-and-aft vertigo. Attacks last seconds to minutes, are generally provoked by particular head positions, and can be associated with hyperacusis or tinnitus. Results of vestibular or auditory function testing may be abnormal. Hyperventilation or exercise-induced symptoms are typical of, but not specific for, microvascular compression syndromes. Most patients respond to membrane-stabilizing agents such as carbamazepine, phenytoin, clonazepam, and baclofen. Medically refractory cases may be responsive to vascular decompression surgery.[69]

CEREBELLAR ATAXIA

Patients with cerebellar disease from any cause may complain of vertigo and oscillopsia because of spontaneous or positional nystagmus. Subacute development of imbalance, dysarthria, and incoordination over weeks to months should prompt a search for paraneoplastic antibodies and an occult malignancy.[70] A family history should be sought and molecular testing for the various spinocerebellar atrophies considered under the appropriate circumstances. Episodic ataxia type 2 (EA2; familial acetazolamide-responsive episodic or periodic ataxia syndrome) is an autosomal dominant condition caused by mutations in the calcium channel gene (*CACNA1A*), located on chromosome 19[71] [*see 11:X Inherited Ataxias*]. This is the same gene that is involved in spinocerebellar ataxia type 6 and famil-

ial hemiplegic migraine. Treatment with acetazolamide is generally effective in reducing the frequency and severity of attacks. However, patients often have interictal abnormalities, including downbeating nystagmus. Fortunately, 4-aminopyridine (4AP) or the related compound 3,4-diaminopyridine have been reported to decrease downbeating nystagmus.[72] Some patients benefit from treatment with clonazepam, baclofen, or gabapentin. Bilateral vestibular loss and cerebellar ataxia can occur as part of the same syndrome and can be recognized by a failure of visual-pursuit mechanisms to enhance the VOR during head rotation in light.[73]

VESTIBULAR SEIZURE

In rare cases, patients present with stereotypical episodes of vertigo on the basis of seizure activity.[74] These episodes have been referred to as tornado epilepsy. Such attacks appear to involve discharges from primary vestibular cortical zones that produce symptoms of vertigo and, on occasion, the perception of environmental tilt. It is of interest that Penfield,[75] in his original human cortical stimulation experiments, was able to elicit vertigo by stimulation of the parietal insular regions of the brain, though frontal areas have also been implicated.[76] Fortunately, these seizures often respond to treatment with standard anticonvulsant agents [*see 11:XII Epilepsy*]. It should be noted that a normal interictal electroencephalogram does not exclude the presence of an epileptic focus. Nystagmus, however, is not uncommon during a seizure and may have some localizing value.[77]

MULTIPLE SCLEROSIS

Although vertigo is an uncommon initial presentation of MS, accounting for less than 5% of cases, up to 20% of MS patients will experience vertigo at some time over the course of the illness. Vertigo secondary to demyelination most commonly arises from lesions in the vestibular nucleus and the root entry zone of cranial nerve VIII.[78] Nystagmus from such lesions can appear to be of central or peripheral origin (e.g., mixed torsional-horizontal, pendular, or pure vertical).[79] When a patient with MS has vertigo resulting from inflammatory lesions, appropriate treatment includes corticosteroids and vestibular suppressants. BPPV must be excluded in any MS patient with vertigo, given the ease of BPPV diagnosis and the high response rate to treatment.[80,81]

II DISEASES OF THE PERIPHERAL NERVOUS SYSTEM

COLIN H. CHALK, M.D., C.M.

Anatomy of the Peripheral Nervous System

The peripheral nervous system (PNS) comprises all of the cranial nerves (except the first and second), the nerve roots, the spinal ganglia, the segmental nerves, the nerve plexuses, and the limb nerves. The role of the PNS is simple but vital: to link the central nervous system to the external environment and the milieu intérieur of the body.

Peripheral nerves are composed of fascicles of endoneurium, containing several thousand axons and various supporting cells [*see Figure 1*]. Each endoneurial fascicle is enveloped by the perineurium (several concentric layers of fibroblast-like cells). Nerve trunks are composed of several endoneurial fascicles bound together by the epineurium (a loose framework of collagen and fibroblasts). There are two complementary networks of blood vessels in nerves: (1) an epineurial system of arterioles and venules, which are tributaries of the major limb vessels, and (2) a series of capillary-like microvessels in the endoneurium. The anastomoses between these two networks are extensive, resulting in a robust supply system.

Each axon is a longitudinal extension of a neuron cell body. The functioning and maintenance of axons depend on the cell body's biochemical and genetic machinery. An energy-dependent bidirectional system of axonal transport shuttles structural and signaling molecules between the cell body and the axon terminal. Motor, sensory, and autonomic axons are intermingled in most nerves, but the cell bodies are grouped separately in the spinal cord and brain stem (motor), the dorsal root ganglia (sensory), and the paravertebral and somatic ganglia (autonomic).

Roughly one quarter of the axons in the PNS are myelinated. Myelin is produced and maintained by Schwann cells, the most important of the supporting cells in the endoneurium. During development, Schwann cells elaborate increased amounts of cytoplasmic membrane to form a spiral around some axons. The cytoplasmic membrane forms the lamellar wrapping of myelin. A single Schwann cell myelinates 0.2 to 1.8 mm of cytoplasmic membrane along the length of a single axon, meaning that the myelin along the entire length of a single axon is the collective product of the actions of several hundred consecutive Schwann cells. The more numerous unmyelinated axons are also intimately associated with Schwann cells. Normal development of axons and normal development of Schwann cells are interdependent, and many details of their complex interactions are known.[1]

Clinically Significant Features of the Peripheral Nervous System

To early anatomists, dividing the nervous system into central and peripheral parts was intuitively reasonable. This division is not arbitrary; several differences between the PNS and the CNS are of clinical importance. The most apparent difference between the two is the functional simplicity of the PNS. In essence, the PNS is a simple relay system carrying motor, sensory, and autonomic signals between the CNS and somatic structures. The clinical correlate is the limited repertoire of symptoms and signs produced by malfunction of the PNS. One can infer relatively little about the cause of a peripheral nerve disorder from the symptoms and signs alone.

A second distinctive feature of the PNS is its accessibility. Unlike the brain and the spinal cord, which are well protected by bony cases, most of the major peripheral nerves reside for much of their course only a short distance beneath the skin. This accessibility simplifies direct study of the electrical and histologic characteristics of the peripheral nerves. Clinical evaluation of PNS diseases has been greatly facilitated by nerve conduction studies and nerve biopsies, which can be performed with essentially no risk to the patient.

Regenerative capacities differ between the PNS and the CNS. In the mature CNS, little or no regrowth of axons occurs after injury. However, an injured peripheral nerve can often regenerate over long distances and reestablish functional connections. Thus, many peripheral nerve disorders have the potential for significant recovery of function with treatment.

The difference in regenerative capacity was long thought to be related to some intrinsic property of PNS neurons. However, it appears that the critical issue is the environment to which neurons are exposed.[1] If a bundle of CNS nerve fibers (e.g., the optic nerve or the spinal cord) is transected and then immediately reanastomosed, there is little axonal outgrowth. However, if the proximal end of the same lesion is anastomosed to a peripheral nerve graft, axonal sprouts will extend many millimeters through the peripheral nerve graft and may even establish functional connections with target CNS neurons.

The cellular and molecular basis for this difference between PNS and CNS supporting tissues is not fully understood. The Schwann cell (which is exclusive to the PNS) appears key, although other cells (e.g., fibroblasts and macrophages) are probably involved. It is thought that the Schwann cell and the extracellular milieu of the peripheral nerve provide a favorable environment for axonal growth, attracting and perhaps guiding axonal sprouts. Two major classes of molecules influence the growth and development of sprouting axons in vitro: growth factors and adhesion molecules. Some of these molecules (e.g., nerve growth factor, N-cadherin, and laminin) have been well characterized.[1]

General Approach to Peripheral Nerve Diseases

CLINICAL MANIFESTATIONS

PNS disorders produce combinations of motor, sensory, and autonomic symptoms. These symptoms are primarily determined by the class of nerve fibers affected (e.g., motor or sensory fibers) and by the location of the lesions, rather than by the etiology of the process. Motor symptoms include weakness (a common presenting complaint), muscle atrophy, fasciculations, and cramps; the last two motor symptoms may be discovered only by specific questioning of the patient. Sensory symptoms include the loss of certain types of sensation and the presence of prickling, pins-and-needles, and burning sensations. The patient's own description of the quality and distribution of sensory symptoms is often more revealing than the sensory examination.

Pain is a common symptom in peripheral nerve disorders,

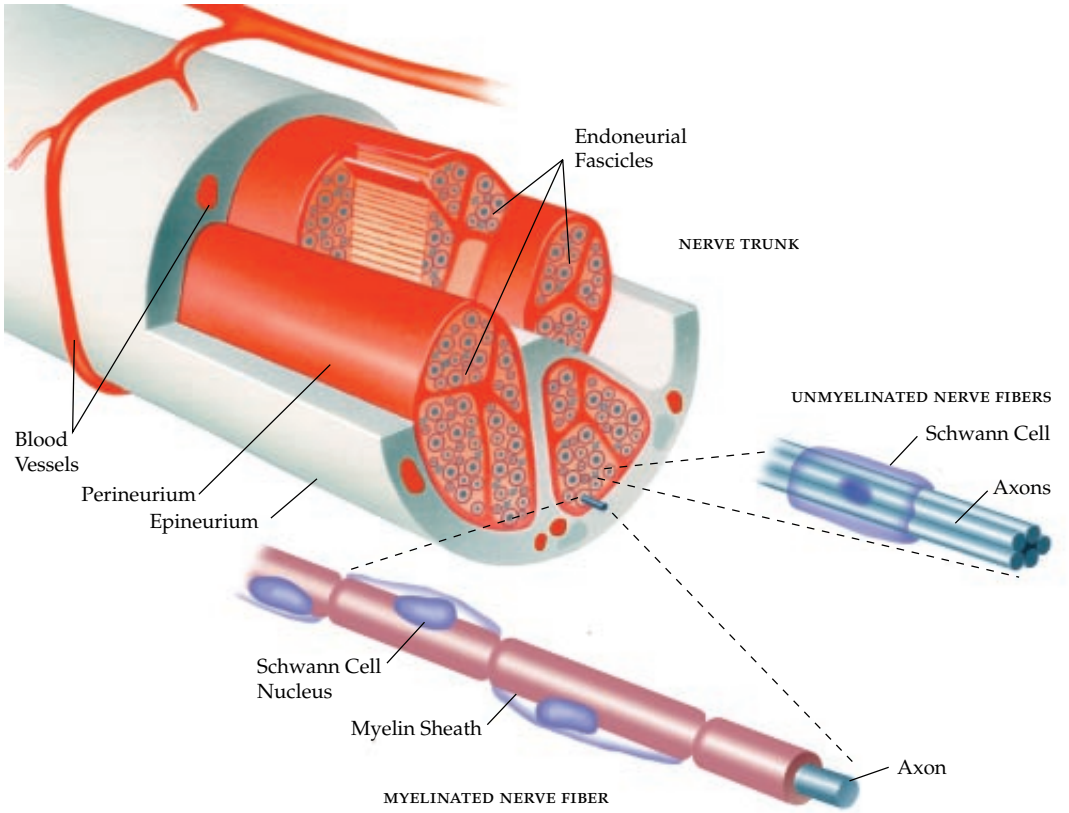

Figure 1 **Peripheral nerves are composed of several fascicles of endoneurium, each enveloped by perineurium and bound together by loose connective tissue, the epineurium. Each fascicle of endoneurium contains up to several thousand axons. Blood is supplied to the endoneurium by a network of capillary-like microvessels derived from arterioles and venules in the epineurium, which in turn are branches of major limb vessels.**

and it often occurs in association with other neuropathic symptoms. If pain is the only symptom, its cause is probably related to structures other than the peripheral nerves. Autonomic symptoms are heterogeneous and are often discovered only by direct inquiry because they may not seem especially neurologic to the patient. Common autonomic symptoms are orthostatic faintness or dizziness, excessive or diminished sweating, impotence or ejaculatory failure, and impaired gastrointestinal motility (particularly, delayed gastric emptying).

LABORATORY TESTS

Laboratory investigations are often required to clarify the nature of a peripheral nerve disorder. In addition to testing used in the evaluation of other types of neurologic diseases (e.g., lumbar puncture), techniques for the direct study of peripheral nerve physiology and histology are available. Neurophysiologic testing (especially nerve conduction studies) can be considered a routine part of the evaluation of any patient with polyneuropathy. Nerve biopsy, on the other hand, is best reserved for patients with disabling neurologic symptoms and signs.

Nerve Conduction Studies

Nerve conduction studies can provide support for a diagnosis of neuropathy and are a relatively objective way to follow the course of the disease. These studies may also allow a clinician to infer whether a disease is affecting primarily axons or their myelin sheaths—an important distinction in the differential diagnosis of polyneuropathy. Nerve conduction studies provide an indication of the numbers of functioning large myelinated motor and sensory axons in various nerves and the speed of impulse transmission in these fibers. The procedure consists of depolarizing a short segment of nerve with a brief electric shock and recording the resultant volley of action potentials as they propagate down the nerve. Both motor and sensory fibers are activated by this procedure; the motor and sensory responses are distinguished from each other by recording either from a cutaneous branch of the nerve (sensory) or from an innervated muscle (motor). If the nerve conduction studies show decreased motor and sensory amplitudes but preserved conduction velocities, the underlying pathologic process is probably loss of or destruction of axons. By contrast, if amplitudes are relatively preserved but there is marked slowing of conduction velocity or conduction block, an abnormality of the myelin sheath is likely.

Needle Electromyography

Needle electromyography is a complementary investigation that is usually performed at the same time as nerve conduction studies. In a patient with peripheral neuropathy, electromyography is helpful in detecting small degrees of axon loss that may go undetected by nerve conduction studies. Electromyography can also be helpful in pinpointing the precise location of the lesion in a mononeuropathy. The procedure entails recording electrical activity in muscle by use of a needle electrode inserted into the muscle. Muscles are examined at rest and during mild voluntary contraction. If the electrical activity produces an abnormal pattern, the electromyographer can determine whether a patient's weakness is the result of a diseased muscle or a diseased motor nerve.

Nerve Biopsy

Nerve biopsy can be diagnostically useful in carefully selected patients. Nerve biopsy can provide a specific diagnosis (e.g., necrotizing vasculitis) but more often gives less specific information that can be useful in combination with the other clinical data. Apart from alteration in the number or size of axons, the most common abnormality found by nerve biopsy is inflammation, usually related to altered immune function. On occasion, a disease that affects both the CNS and the PNS (e.g., metachromatic leukodystrophy) can be conveniently diagnosed by nerve biopsy. The sural nerve is preferred in most instances because sural nerve biopsy results in a small area of generally well-tolerated sensory loss along the lateral side of the foot.

Proper pathologic examination of a nerve biopsy specimen requires techniques that are often available only in specialized laboratories. When such facilities are not available locally, the patient should be referred to an appropriate center.

TREATMENT OF NEUROPATHIC SYMPTOMS

The symptoms of neuropathy may be treatable even if the cause of the neuropathy is untreatable or unknown. With simple measures, many patients can have meaningful relief of symptoms.

The ankle-foot orthosis is a simple device that compensates for footdrop. The main benefit offered by an ankle-foot orthosis is greater stability at the ankle, resulting in better balance and overcoming the tendency to catch the toes on edges of steps, curbs, and carpets. A lightweight, properly fitted ankle-foot orthosis that slips into the shoe is usually the most comfortable. Patients with weakness of wrist and finger extensors may be helped by a brace that keeps the wrist and fingers in a neutral position. Unfortunately, this type of splint is of little help when there is significant concomitant weakness of intrinsic hand muscles.

Pain, particularly in the feet, often accompanies the sensory disturbances of neuropathy. Paradoxically, in polyneuropathies with prominent pain, the neurologic deficits are often minor and there is a dissociation between the actual disability and the level of the patient's distress. Patients may interpret pain as a sign of a serious disorder that threatens their independence or their life. Sometimes, simple reassurance, emphasizing how little neurologic function has been lost, helps the patient cope effectively with neuropathic pain.

Nonpharmacologic measures may be as effective as medications. Careful attention should be paid to footwear. Loose-fitting, soft-soled shoes and thick socks are advisable. Neuropathic pain tends to be aggravated by extremes of temperature—especially heat—and open-toed sandals may give relief. Prolonged weight bearing often worsens neuropathic pain; patients whose work requires them to be on their feet may be helped by frequent short sitting breaks.

Foot soaking produces short-lived relief in many patients. Soaking the feet in ankle-deep cold tap water (without ice) for 15 to 20 minutes can be particularly helpful at bedtime. Although the relief is short-lived, it may be sufficient to allow the patient to fall asleep and to sleep well. For some patients, warm water is better than cold water, and others find that alternating cold and hot water (so-called contrast soaks) provides the best relief. Daily inspection of the feet for undetected injuries—an important habit that patients with neuropathy should develop—can be conveniently combined with nightly foot soaks.

Medications can be useful in the management of neuropathic pain, but the goals of therapy should be realistic. Complete pain relief is unlikely. Therefore, the aim of therapy should be to make the pain more tolerable without adding intolerable side effects of medication. Of the many drugs that can be tried for neuropathic pain, tricyclics (especially amitriptyline) and carbamazepine are still most frequently used, although gabapentin is increasingly used as a first-line agent. Lancinating, paroxysmal pains may be more likely to respond to carbamazepine (200 mg t.i.d.), whereas amitriptyline (10 to 30 mg at bedtime) is the preferred agent for the more common, continuous burning numbness. Several randomized, controlled trials in patients with neuropathic pain of various etiologies have shown a clear benefit of gabapentin over placebo in several measures of pain relief.[2] Effective dosages of gabapentin vary considerably; in most patients, a good initial dosage is 300 mg three times a day, which can be titrated upward over several weeks to 1,800 to 3,600 mg daily or higher, according to response.

At least 1 month of treatment should be undertaken before any conclusions are drawn about the usefulness of a drug for neuropathic pain. In addition to tricyclics, carbamazepine, and gabapentin, salicylates and other simple analgesics give relief to some patients. As is the case with other types of chronic pain, the usual practice has been to avoid narcotics, but a new appreciation for the potential benefits of opioids in managing chronic neuropathic pain is developing.[3] Second-line drugs for neuropathic pain include baclofen, mexiletine, valproic acid, and topiramate. Topical capsaicin ointment causes depletion of the neurotransmitter substance P in the dorsal horn of the spinal cord and helps some patients. For most patients, however, the expense and inconvenience of topical capsaicin outweigh any benefits.

In some patients, the pain remains refractory to all of these measures. These patients present difficult management problems. Concurrent depression can complicate the situation, and psychiatric referral may be worthwhile. Referral to a multidisciplinary pain management center can also be considered.

Peripheral Nerve Diseases

It is helpful to divide PNS diseases into those that affect single nerves (mononeuropathies) and those that involve the PNS diffusely (polyneuropathies). A mononeuropathy may involve any cranial or limb nerve. In general, mononeuropathies occur in otherwise healthy patients, cause troublesome symptoms but no major disability, and often improve spontaneously with time.

CRANIAL MONONEUROPATHIES

Neuropathies can arise in any individual cranial nerve [*see Table 1*]. The seventh (facial), fifth (trigeminal), and third (oculomotor) cranial nerves account for most cranial mononeuropathies encountered in clinical practice.

Facial Neuropathy

Acute, idiopathic facial neuropathy (Bell palsy) is the most common cranial neuropathy, with an annual incidence of about 25 per 100,000 persons. The main symptom is unilateral facial weakness that begins abruptly and is often preceded by or accompanied by pain behind the ear. In some patients, a mild upper respiratory tract infection may have occurred up to 2 weeks earlier. The facial weakness usually reaches its zenith within 24 hours after onset and is of the lower motor neuron type, affecting both the upper and the lower face. Some patients experience altered taste on one half of the tongue and hyperacusis. Patients often complain of numbness of the face, but sensory loss is not found.

Table 1 Common Cranial Neuropathies

Cranial Nerve	*Effects of Lesion*	*Causes*
Olfactory (I)	Loss of smell	Trauma, olfactory groove meningioma
Optic (II)	Loss of vision (monocular or bitemporal hemianopsia)	Optic neuritis, pituitary tumor, ischemic optic neuropathy, optic nerve glioma, Leber disease
Oculomotor (III)	Weakness of adduction, elevation, and depression of eye Ptosis Dilated, nonreactive pupil	Trauma, microvessel ischemia, compression by aneurysm or mass, brain stem stroke or tumor, orbital tumor
Trochlear (IV)	Weakness of depression and intorsion of eye	Trauma, microvessel ischemia, brain stem stroke or tumor, orbital tumor
Trigeminal (V)	Weakness of chewing and other jaw movements Loss of facial sensation and corneal reflex	Trigeminal neuralgia (tic douloureux), scleroderma and other connective tissue diseases, tumor of petrosal bone
Abducens (VI)	Weakness of abduction of eye	Trauma, raised intracranial pressure, microvessel ischemia, brain stem stroke or tumor, orbital tumor
Facial (VII)	Weakness of half of face Loss of taste Hyperacusis	Bell palsy, Lyme disease, sarcoidosis, herpes zoster, cerebellopontine angle tumor, pontine stroke or tumor
Vestibulocochlear (VIII)	Unilateral deafness Vertigo Nystagmus	Vestibular neuronitis, acoustic schwannoma
Glossopharyngeal (IX)	Dysphagia Weakness of elevation of palate Loss of gag reflex	Motor neuron disease, jugular foramen tumor, nasopharyngeal carcinoma, metastases to skull base, glossopharyngeal neuralgia
Vagus (X)	Dysphagia Dysarthria Weakness of elevation of palate Loss of gag reflex	Motor neuron disease, jugular foramen tumor, metastases to skull base, nasopharyngeal carcinoma
Accessory (XI)	Weakness of sternocleidomastoid and trapezius muscles	Trauma (surgical and other), jugular foramen tumor
Hypoglossal (XII)	Weakness of tongue	Motor neuron disease, skull base tumor, carotid artery dissection or trauma

When the history and examination are typical of Bell palsy and the condition is mild and nonprogressive, no tests are needed. Severe or progressing cases should be referred to a neurologist to confirm the diagnosis and decide whether intervention is needed. Occasionally, sarcoidosis, Lyme disease, and herpes zoster (shingles) present as facial neuropathy; testing to exclude these conditions may be appropriate. When the neurologic examination reveals more than a unilateral facial neuropathy or when the weakness has evolved over weeks or months, an alternative diagnosis should be sought, such as a cerebellopontine angle tumor or a brain stem lesion.

The natural history of untreated Bell palsy is generally favorable: 85% of patients recover fully within 1 year. However, some clinical features are associated with a poorer prognosis, including old age, complete facial palsy, and the presence of hyperacusis or altered taste. Hemifacial spasm (a syndrome of painless, brief, involuntary contraction of the facial muscles) occasionally develops after Bell palsy and other types of facial neuropathy.

Although there is general agreement that the pathogenesis of Bell palsy involves facial nerve inflammation, there is debate about whether the condition is a postinfectious autoimmune phenomenon or the result of a direct viral infection of the facial nerve. Herpes simplex virus type 1 has been implicated by the presence of its DNA in facial nerve specimens from 11 of 14 patients with Bell palsy but not in patients with other causes of facial neuropathy, including herpes zoster.[4]

Because of the presumed role of an inflammatory response, Bell palsy is often treated with glucocorticoids. Several studies have suggested that glucocorticoid therapy speeds recovery. However, a meta-analysis of the few placebo-controlled trials concluded that clear evidence for the efficacy of glucocorticoids had not been demonstrated.[5] Nevertheless, for patients seen within a few days after onset of Bell palsy, it is reasonable to follow the common practice of prescribing a short, tapering course of glucocorticoids (e.g., prednisone, 60 mg/day for 5 days, tapering to zero over the next 10 days). A controlled trial of acyclovir plus prednisone versus prednisone alone found a modest but significant improvement in clinical outcome in the acyclovir-treated group.[6] On the basis of this study, the combination of acyclovir and prednisone can reasonably be considered for most patients with Bell palsy, although the natural history of the condition is generally benign, regardless of treatment.

Prevention of corneal desiccation with an eye patch is important for patients who cannot fully close the eye. Facial nerve decompression was once widely used, but the procedure has been largely abandoned because its efficacy is unproved. Injections of botulinum toxin are helpful in treating hemifacial spasm.

Trigeminal Neuralgia (Tic Douloureux)

Trigeminal neuralgia, or tic douloureux, is a distinctive facial pain syndrome of middle-aged and elderly persons in which intense, paroxysmal pain occurs several times to dozens of times daily. The pain is often likened to an intense electric shock. The pain lasts for seconds and is localized to the trigeminal distribution, usually the maxillary or mandibular territories. Paroxysms of pain may be triggered by minor tactile stimuli on the affected side of the face, such as shaving, washing, or chewing. Between paroxysms, patients may have dull background pain but not numbness or paresthesia. Trigeminal neuralgia may be mistaken for dental pain if the characteristic features are not recognized. A similar but much less common syndrome, glossopharyngeal neuralgia, produces paroxysms of throat or pharyngeal pain.

Examination of the cranial nerves is often difficult in patients with trigeminal neuralgia, because paroxysms of pain may be triggered by the examination. Nevertheless, sensory loss or other signs are not found. Cranial nerve and other neurologic signs should prompt investigation for structural lesions of the trigeminal nerve or nucleus or for a brain stem lesion. Multiple sclerosis is the most likely diagnosis in this situation, but this diagnosis has usually been well established before episodes of trigeminal neuralgia occur.

The cause of trigeminal neuralgia is subject to debate, although many investigators believe that compression or distortion of the trigeminal nerve by pulsations from an ectatic superior cerebellar artery is responsible. Spontaneous remissions may occur but are seldom of lasting duration.

The mainstay of medical treatment is carbamazepine, 600 to 1,200 mg daily. Alternative therapies are baclofen, 30 to 60 mg daily, and gabapentin, 300 to 1,200 mg three times a day. If trigeminal neuralgia becomes refractory to medication, surgical approaches can be tried and are usually successful. The appropriate trigeminal branch can be injected with alcohol or phenol, or a lesion can be made percutaneously in the trigeminal ganglion. However, with these procedures, the patient is trading pain for varying degrees of anesthesia, which is not always preferable. Microvascular decompression to relieve the hypothesized effects of the superior cerebellar artery seems to be highly effective in the hands of an experienced surgeon, but this procedure requires a posterior fossa craniotomy.

Oculomotor Neuropathy

Isolated third-nerve palsies are not common, but they present a difficult differential diagnosis between life-threatening and benign causes. The onset is abrupt, diplopia and headache being the usual symptoms. The diplopia is both horizontal and vertical, and the relation between the two images changes with the direction of gaze. The headache may be retro-orbital or diffuse. Most patients are aware of ptosis, and some may note pupil dilatation.

The main considerations in a patient with an isolated third-nerve palsy are compression by an expanding mass (particularly an aneurysm of the posterior communicating artery) and a so-called microvascular lesion, in which the oculomotor palsy is assumed to be ischemic and to be caused by a disease of the nerve's blood supply. Once it is clear that the only signs are those of a unilateral third-nerve palsy, examination may help distinguish between a compressive and a microvascular lesion. If there is pupillary paralysis, a compressive lesion is more likely, and cranial imaging with CT or MRI and cerebral angiography are indicated. A pupil-sparing third-nerve palsy is probably microvascular; patients are typically elderly, diabetic, and hypertensive. However, in a young patient who is neither diabetic nor hypertensive, cranial imaging is advisable regardless of whether the pupil is spared. For vascular imaging, magnetic resonance angiography and CT angiography, which are noninvasive, are increasingly replacing conventional cerebral angiography.

MONONEUROPATHIES OF LIMB NERVES

Mononeuropathies of limb nerves are common. Mechanical compression of the nerve at a vulnerable location is often assumed to be the cause, but this assumption is not always convincingly proved. An identical clinical picture may be caused by other rare pathologies, such as a nerve tumor. The autosomal dominant syndrome of inherited susceptibility to pressure palsies should be considered in a patient with recurrent compressive mononeuropathies or when the precipitating trauma is trivial compared with the resulting deficit.[7]

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is caused by compression of the distal median nerve as it traverses the tunnel in the wrist formed by carpal bones inferiorly and the carpal ligament superiorly [*see 15:XII Back Pain and Common Musculoskeletal Problems*].

Diagnosis In CTS, the patient complains of numbness in the hand (e.g., prickling sensations, sensory loss, or both) that is unpleasant or painful. The numbness is usually within the median sensory distribution, but some patients report involvement of all digits or discomfort in the forearm. The symptoms are characteristically episodic and occur at night (often waking the patient) and during activities in which the wrists are held in flexion or extension, such as knitting or holding a steering wheel. Vigorously shaking the hand often produces prompt relief, and this is very suggestive of CTS. Numbness may make it difficult or uncomfortable for the patient to use the hand properly, but true weakness is uncommon. When present, impaired prehensile grip related to weakness of the thenar muscles may interfere with activities such as holding a pen. In some patients (particularly the elderly), sensory complaints may be minimal and symptoms of thenar weakness may predominate.

In most patients, CTS probably develops because of a congenitally narrow carpal tunnel. Certain occupations that require repetitive flexion and extension of the wrist (e.g., carpentry, sewing, and use of a computer keyboard) may predispose a patient to CTS. The syndrome is common in pregnancy (presumably because of generalized fluid retention) and may occur after injuries such as a Colles fracture. On occasion, CTS occurs in the context of a systemic illness that decreases leeway in the carpal tunnel, such as rheumatoid arthritis, myxedema, amyloidosis, and acromegaly. Patients with diabetic and certain other polyneuropathies may be predisposed to superimposed CTS and other mononeuropathies. In patients with diabetes, increased stiffness and volume of the carpal ligament may be an important factor.

Examination may reveal sensory or motor deficits in a median distribution, but it is often normal, particularly in young patients with intermittent symptoms. Percussion over the median nerve at the wrist may produce transient paresthesia in median-innervated digits (Tinel sign). Holding the wrist in forced extension or flexion for 1 to 2 minutes may precipitate the patient's sensory symptoms, which are promptly relieved by hanging the arm loosely at the side without angulation at the wrist (Phalen sign). Neither the Tinel sign nor the Phalen sign is entirely specific or sensitive.

Nerve conduction studies often help support a clinical diagnosis of CTS. The essential principle is to show slowing of median nerve conduction in the carpal tunnel relative to the neighboring ulnar or radial nerves. Nerve conduction studies have a high diagnostic sensitivity in CTS but may be normal in mild cases. Study results usually improve but do not return to normal even if the patient's symptoms are completely relieved by surgery.

Treatment Patients who have mild symptoms but have no deficits may need only reassurance. A splint that holds the wrist in the neutral position is often effective for nocturnal symptoms. Some patients are helped by periodic injections of glucocorticoids into the carpal ligament. Surgical sectioning of the carpal ligament, which is a low-risk procedure, is widely used for CTS; and the procedure seems to result in substantial, long-lasting improvement in most patients. There is conflicting evidence about whether endoscopic techniques allow for faster recovery than open surgical procedures.[8] Surgery is advised for patients with troublesome symptoms that are unresponsive to nonsurgical treatments and for those patients with progressive motor or sensory deficits.

Ulnar Neuropathy

Ulnar neuropathy most often results from mechanical injury at the elbow, where the nerve lies subcutaneously and rests on the unyielding floor of the epicondylar groove. Distal to the elbow, the nerve can be compressed as it passes under the aponeurosis of the flexor carpi ulnaris into the deep muscle compartment of the forearm. At the wrist, the nerve again becomes relatively superficial and may be compressed by excessive weight bearing on the hands, as with long-distance cycling.

Diagnosis Patients with ulnar neuropathies present with varying degrees of motor and sensory symptoms. Observant patients will notice that the sensory disturbance involves the medial half of the ring finger, in addition to the little finger and medial hand. Weakness, when present, is usually confined to the hand. The hand may seem generally weak, or there may be specific complaints, such as difficulty holding a pen or spreading the fingers.

Weakness and wasting are most easily identified in the first dorsal interosseous muscle (between the thumb and index finger) and the hypothenar muscles. Complete loss of ulnar sensation is uncommon, but sensation is often altered in the ulnar distribution. Comparing the medial (ulnar) and lateral (median) sides of the ring finger may provide convincing evidence of an ulnar neuropathy. Production of numbness or electrical sensations in the hand with gentle manipulation of the nerve at the elbow favors the elbow as the site of the pathology. Electrodiagnostic testing is useful in ulnar neuropathies both to confirm the diagnosis and to localize the precise site of the lesion.

In rare instances, ulnar neuropathy can result from compression in the upper arm or in the hand. Because of the arrangement of the motor and sensory branches in the wrist and hand, ulnar compression in the hand may involve motor branches only. This condition results in hand weakness but no pain or sensory symptoms and may be mistaken for early motor neuron disease. This type of ulnar neuropathy is caused by weight bearing on the hands, as may occur with the use of a four-point walker or with prolonged cycling.

Treatment The appropriate treatment for ulnar neuropathy at the elbow is unclear. Although the condition is common, there is surprisingly little good information about its natural history. Spontaneous improvement is frequent, particularly in patients with a clear precipitating episode of compression. In patients in whom repeated minor trauma to the nerve is thought to be the cause, ulnar neuropathy often improves if they avoid leaning on their elbows.

Several surgical procedures are used in the treatment of ulnar neuropathy at the elbow.[9] In selected patients who have progressive symptoms and signs despite conservative therapy, surgery may be considered, but the relative merits of surgery versus nonoperative treatments have not been carefully studied.

Brachial Plexus Neuropathy

Brachial plexus neuropathy (also known as neuralgic amyotrophy and Parsonage-Turner syndrome) is uncommon but probably underdiagnosed. The history is distinctive. The patient experiences severe, aching, bursitislike pain in the shoulder without an apparent precipitant. After several days to 2 weeks, the pain subsides and the patient becomes aware of weakness in the arm. Most often, the shoulder girdle muscles are affected, but the hand or forearm may be involved. Sometimes, the weakness is strikingly focal or patchy. There may be sensory loss in an epaulet distribution, but it is not a prominent feature. Patients gradually recover, and 90% have little or no deficit 1 to 2 years after onset. In some patients, the two arms are affected either simultaneously or sequentially, and some patients have recurrent episodes.

Brachial plexus neuropathy is most common in young and middle-aged men but can affect both sexes and all age groups. Biopsies of the brachial plexus have shown florid lymphocytic inflammation, and the disorder is believed to be immune mediated.[10] However, immunomodulation therapies are of no proven benefit. An autosomal dominant form of brachial plexus neuropathy also exists and is characterized by recurrent episodes of shoulder pain and weakness.

Peroneal Neuropathy

Peroneal neuropathy is most often the result of injury to the peroneal nerve at the point where the nerve winds around the head of the fibula, passing from the popliteal fossa to the anterior compartment of the leg. Distal peroneal branches are superficial at the ankle, where they are sometimes compressed by tight-fitting shoes.

Diagnosis Patients with peroneal neuropathy at the knee usually present with unilateral footdrop caused by weakness of ankle dorsiflexors. However, footdrop may be caused by an L5 radiculopathy, a lumbosacral plexopathy, a proximal sciatic neuropathy, or a lesion in the contralateral cerebral motor cortex. L5 radiculopathy, the most common differential diagnosis, is suggested by the presence of back pain radiating to the leg and by weakness of ankle invertors and hip abductors in addition to the footdrop. Electrodiagnostic testing may be particularly helpful in localizing the lesion in patients with footdrop.

Trauma (e.g., fracture of the fibula) is often responsible for peroneal neuropathy at the knee. Compression during states of altered consciousness (e.g., during anesthesia and coma) is another common cause. Herniation of a Baker cyst may compromise the nerve. In patients without such precipitants, peroneal neuropathy at the knee is often attributed to habitually sitting with legs crossed—a plausible explanation, although difficult to prove.

Treatment Management of peroneal neuropathy at the knee is usually conservative. In most patients who have suffered trauma to the nerve, improvement will occur with time, particularly when there is some residual function in the distal peroneal nerve. In severe trauma, the nerve is sometimes completely transected, in which case the outcome is usually poor and surgical anastomosis offers the best hope of recovery. When no other cause of the peroneal neuropathy is apparent, patients can be advised to avoid sitting with legs crossed; slow improvement may result. Regardless of the cause, an ankle-foot orthosis should be tried to compensate for the footdrop; most patients find that this simple device greatly improves their walking [*see* Treatment of Neuropathic Symptoms, *above*].

Meralgia Paresthetica

Meralgia paresthetica is characterized by sensory symptoms in the distribution of the lateral cutaneous nerve of the thigh. Patients report some combination of sensory loss, prickling paresthesia, and hypersensitivity over the anterolateral thigh. The boundaries of the abnormal area are typically sharply defined, with no associated motor or reflex abnormalities. Meralgia paresthetica is usually attributed to compression of the lateral

*Usually present as symmetrical polyneuropathy.

cutaneous nerve by the inguinal ligament as it passes from the retroperitoneum to the anterior thigh. The syndrome is more common in the obese, perhaps because of increased mechanical stress on the inguinal ligament. In rare instances, the lateral cutaneous nerve is injured during surgery, or it may be compromised by enlarged inguinal lymph nodes or other masses. Most patients require only reassurance, because the symptoms often subside with time. Treatment with medications, such as amitriptyline, can be tried for bothersome, persistent symptoms. Surgical exploration of the inguinal region is a last resort.

Lumbosacral Plexopathy

Lumbosacral plexopathy resembles brachial plexus neuropathy. The typical history of lumbosacral plexus involvement begins with pain in the anterior thigh, usually severe and continuous, lasting for several weeks. As the pain subsides, weakness appears, most often involving the quadriceps and hip flexors. Often, the weakness causes no symptoms until the patient falls, giving the misleading impression of an acute event. Impressive wasting of the quadriceps may occur, and the knee jerk is absent. Sensory signs are minimal. Sometimes, the initial symptoms and signs involve only the lumbar or sacral parts of the plexus, but there is a tendency for the process to spread to the whole plexus and to involve the contralateral side. Very gradual recovery is the rule.

Lumbosacral plexopathy characteristically affects middle-aged and elderly men. Patients often have diabetes (in which case the terms diabetic amyotrophy, diabetic femoral neuropathy, proximal diabetic neuropathy, and diabetic lumbosacral radiculoplexus neuropathy are sometimes used), although an identical syndrome can occur in nondiabetic patients. The pathogenesis of lumbosacral plexopathy is debated. An ischemic basis was long favored, particularly because the condition frequently occurs in patients with microvascular complications of diabetes. However, the balance of evidence from biopsy studies now favors an inflammatory process, resembling a restricted form of necrotizing vasculitis in some cases.[11]

Electrodiagnostic testing is helpful in supporting the diagnosis of lumbosacral plexopathy. Imaging studies of the pelvis to exclude malignant invasion of the lumbar plexus, retroperitoneal hematoma, and psoas abscess are often needed.

Immunomodulation has been recommended for treatment of lumbosacral plexopathy. Agents for this use have included corticosteroids, azathioprine, and intravenous immunoglobulin. Clear evidence of efficacy is lacking, but controlled trials are in progress. Pain that lasts more than a few weeks may be helped by drugs such as amitriptyline.

POLYNEUROPATHIES

Determining that a patient has a polyneuropathy is usually not difficult. However, because the hundred or so possible causes of polyneuropathy produce similar symptoms and signs, arriving at a specific diagnosis can be challenging. The differential diagnosis can be simplified by the following questions:

1. Do the symptoms and signs fit a pattern other than that of a symmetrical sensorimotor polyneuropathy? Several distinctive syndromes, unlike symmetrical sensorimotor polyneuropathy, have short differential diagnoses. Examples include multiple mononeuropathies (also known as mononeuritis multiplex), ataxic sensory neuropathy, pure or predominantly autonomic neuropathy, and acute-onset polyneuropathy [*see Table 2*].
2. Do nerve conduction studies suggest demyelination? After history and examination, nerve conduction studies are the next logical step. If marked slowing of conduction velocity or other electrophysiologic evidence suggesting demyelination is noted, the differential diagnosis is short [*see Table 3*].
3. Is the polyneuropathy acquired or inherited? This question is an important consideration in all patients with a chronic symmetrical polyneuropathy. Inherited neuropathy is the most frequently overlooked cause of undiagnosed polyneuropathy.[12] Pes cavus and hammer toes can be important clues toward a diagnosis of inherited neuropathy and should always be specifically sought. Inherited neuropathies are often mild, nondisabling, and very slowly progressive. Thus, they often do not present until middle age or later and often go unrecognized in families [*see Table 4*].

Further investigation of symmetrical, sensorimotor, axonal neuropathies can be guided by collateral information in the history. If inherited neuropathy is possible, first-degree relatives should be examined. The cause of an acquired neuropathy may

Table 3 Differential Diagnosis of Demyelinating Polyneuropathy

- Guillain-Barré syndrome (acute inflammatory demyelinating polyradiculoneuropathy)
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Monoclonal protein–associated neuropathy
- Osteosclerotic myeloma
- Diphtheria
- Perhexiline maleate toxicity
- Hereditary motor and sensory neuropathy type 1
- Hereditary susceptibility to pressure palsies

be one of the patient's medications [*see Table 5*] or a concomitant medical illness, with diabetes mellitus and chronic renal failure being the most common. On occasion, neuropathy may be the presenting feature of systemic vasculitis or an occult malignancy.

For adult patients, reasonable routine laboratory tests may include a fasting blood glucose level, glycosylated hemoglobin concentration, serum creatinine level, complete blood count, chest x-ray (for smokers), erythrocyte sedimentation rate or C-reactive protein, rheumatoid factor, antinuclear antibody, and, in patients older than 50 years, immunofixation of plasma and urinary proteins. Nerve biopsy can be valuable when specific information is being sought. Biopsy is not a routine test, and it is seldom helpful when done as a last resort.

Diabetic Polyneuropathy

Peripheral neuropathy is common in patients with diabetes mellitus. Of the various types of diabetic neuropathy, by far the most common is a distal, symmetrical sensorimotor neuropathy, commonly referred to as diabetic polyneuropathy. Estimating the incidence and severity of diabetic polyneuropathy has been difficult because of (1) how the condition is defined, (2) the populations that have been studied, and (3) efforts to ensure that other causes of neuropathy have been excluded. In one prospective, population-based study of Americans mainly of northern European ancestry, diabetic polyneuropathy was found in 54% of patients with type 1 diabetes mellitus and 45% of patients with type 2 diabetes mellitus.[13] However, symptomatic polyneuropathy occurred in only 15% of the cohort, and none of the patients had disabling neurologic deficits. The severity of the polyneuropathy correlated more closely with the degree of hyperglycemia (mean glycosylated hemoglobin) than with the duration of diabetes.[14] In this study and other large studies, the prevalence of diabetic polyneuropathy increased with the duration of diabetes, and a strong correlation existed between the presence of diabetic polyneuropathy, retinopathy, and nephropathy. An important practical corollary of these observations is that a diagnosis of diabetic polyneuropathy in a patient with newly diagnosed diabetes but without other diabetic complications is likely to be incorrect.

Pathogenesis The pathogenesis of diabetic polyneuropathy continues to be debated. A popular theory is that increased activity of the polyol pathway, brought about by chronic hyperglycemia, leads to accumulation of sorbitol and depletion of *myo*-inositol in the nerve. Decreased *myo*-inositol, in turn, is postulated to produce reduced Na^+,K^+-ATPase activity, leading to altered nerve conduction and structural alterations of the axon. In diabetic animals, some of these abnormalities can be demon-

Table 4 Basic Features of Inherited Neuropathies

	Hereditary Motor and Sensory Neuropathy	*Hereditary Sensory and Autonomic Neuropathy (HSAN)*	*Hereditary Motor Neuropathy*
Clinical features	Distal muscle wasting, weakness, and sensory loss Pes cavus	Distal sensory loss Variable dysautonomia Neurogenic arthropathy Plantar ulcers	Muscle wasting and weakness, most often proximal
Site of abnormality	Axon or Schwann cell	Dorsal root and autonomic ganglia neurons	Anterior horn cells
Inheritance	Most cases are autosomal dominant Some cases are autosomal recessive or X-linked	Autosomal dominant Autosomal recessive	Autosomal dominant Autosomal recessive
Known genetic defects	Charcot-Marie-Tooth disease type 1 Duplication or point mutation of *PMP22* gene (chromosome 17) Point mutations of *Po* gene (chromosome 1) Point mutations of *Cx32* gene (X chromosome) Point mutations of early growth response gene (chromosome 10) Mutation of *LITAF/SIMPLE* gene (chromosome 16) Various genes cause autosomal recessive forms of the disease (mostly single kinships) Charcot-Marie-Tooth disease type 2 Linkage to 1p, 3q, and 7p Mutations of *KIF 1Bβ* (chromosome 1), *RAB7* (chromosome 3), *NF-L* (chromosome 8) genes, and linkage to other loci	HSAN type 1 (dominant) Mutation in serine palmitoyl transferase gene (chromosome 9) HSAN type 2 (recessive) Unknown HSAN type 3 (recessive) Mutation in 1κB kinase complex–associated protein gene (chromosome 9) HSAN types 4 and 5 (recessive) Mutations in tyrosine kinase A receptor gene (chromosome 1)	Werdnig-Hoffmann disease (and other childhood-onset types) Linkage to 5q Kennedy syndrome (X-linked bulbospinal muscular atrophy) Defect in androgen-receptor gene (*CAG* triplet repeat)

Table 5 Drugs That May Cause Polyneuropathy

- Antineoplastics
  - Cisplatin (ataxic sensory neuropathy is dose limiting)
  - Bortezomib
  - Suramin
  - Taxoids (docetaxel, paclitaxel)
  - Vinca alkaloids (vincristine, vinblastine; neuropathy is dose limiting)
- Antiretrovirals
  - Didanosine (dideoxyinosine)
  - Stavudine (d4T)
  - Zalcitabine (dideoxycytidine)
- Other antimicrobials
  - Chloramphenicol
  - Dapsone (mainly motor neuropathy; higher doses than in leprosy therapy)
  - Isoniazid (preventable by pyridoxine supplementation)
  - Metronidazole (prolonged courses)
  - Nitrofurantoin
- Drugs used in rheumatologic diseases
  - Chloroquine
  - Colchicine
  - Gold
  - Thalidomide
- Miscellaneous
  - Amiodarone (antiarrhythmic)
  - Disulfiram (Antabuse)
  - Perhexilene (demyelinating neuropathy)
  - Phenytoin (after years of use; very mild neuropathy)
  - Pyridoxine (megadoses cause ataxic sensory neuropathy)
  - Simvastatin

strated and corrected by inhibiting the polyol pathway, but in nerves in humans with diabetes, the *myo*-inositol content is normal. In clinical trials, small improvements in motor nerve conduction velocity have been observed during treatment with aldose reductase inhibitors, which suppress polyol-pathway activity. Whether such treatment is clinically useful is disputed.[15]

An ischemic-hypoxic basis for diabetic polyneuropathy is an alternative or complementary hypothesis.[16] Degeneration of pericytes and reduplication of capillary basal laminae occur in nerve and other tissues in diabetic patients, which may implicate microvessels in the pathogenesis of complications such as neuropathy. In diabetic rats, a reduction in nerve blood flow and endoneurial oxygen tension can be demonstrated, and partial correction of nerve conduction abnormalities can be achieved with oxygen supplementation. In biopsy specimens from persons with diabetic polyneuropathy, the degree of nerve fiber loss has been shown to be quite variable from fascicle to fascicle, a pattern seen in neuropathies with a clearly established ischemic basis, such as vasculitic neuropathy. At present, the hypoxic hypothesis is perhaps the most widely accepted, but this hypothesis does not necessarily exclude a role for the polyol pathway or other metabolic derangements.

Diagnosis Diabetic polyneuropathy has the classic so-called glove-and-stocking distribution of symptoms, usually a combination of sensory loss and an unpleasant feeling of numbness or burning. Sensory loss in the feet and fingers and mild weakness in the feet and ankles are typical. Diabetic polyneuropathy can be expected to worsen slowly over years,[17] although this progression may be influenced by treatment of the diabetes. Disabling neurologic deficits and rapid worsening are not expected in diabetic polyneuropathy; if present, they should prompt a search for other causes.

Treatment Data on the effect of glycemic control on diabetic polyneuropathy continue to accumulate. Of the patients with type 1 diabetes who were followed in the Diabetes Control and Complications Trial, polyneuropathy developed in 5% of those whose therapy included rigorous glycemic control and in 13% of those who were treated conventionally.[18] A follow-up study of a cohort of recipients of pancreas transplants showed significant improvement in nerve conduction parameters and perhaps a modest clinical improvement; in control patients treated with conventional insulin regimens who did not receive transplants, conditions worsened over the same period.[19] By contrast, the United Kingdom Prospective Diabetes Study, which involved nearly 4,000 patients with type 2 diabetes, failed to show a difference in the prevalence of neuropathy between patients treated conventionally and those treated with tight glycemic control during up to 10 years of follow-up.[20] Thus, optimal glycemic control appears to lower the risk of developing diabetic polyneuropathy in patients with type 1 diabetes, but no protective effect has been demonstrated in patients with type 2 diabetes. In established neuropathy, tight glycemic control may have a beneficial effect, but whether clinically significant improvement over several decades is possible remains to be shown.

The hope that additional pharmacologic interventions will prevent or alleviate diabetic neuropathy has spawned numerous clinical trials that have evaluated such drugs as aldose reductase inhibitors, acylcarnitine, aminoguanidine (decreases advanced glycation end products), evening primrose oil (an enriched source of linoleic acid), α-lipoic acid (an oxygen free-radical scavenger), and nerve growth factor. To date, some of these trials have suggested modest benefits, but problems of trial design (e.g., duration of treatment and whether results are clinically meaningful) have prevented formation of a consensus about the practical use of these agents.[21] A large, randomized, placebo-controlled trial of recombinant human nerve growth factor given over 12 months failed to show improvement in various clinical and laboratory measures of function, despite promising results of phase II trials.[22]

Patients with diabetic polyneuropathy should be counseled about good foot care, including daily careful inspection of the plantar surfaces, so that minor injuries can be detected early and so that major complications such as plantar ulcers or osteomyelitis can be prevented. Measures for the management of neuropathic pain are often needed.

Other Diabetic Neuropathies

The other varieties of diabetic neuropathy usually occur on a background of diabetic polyneuropathy. Two mononeuropathies (diabetic ophthalmoplegia and proximal diabetic neuropathy) may occur in diabetic patients, as well [*see* Oculomotor Neuropathy *and* Lumbosacral Plexopathy, *above*].

Diabetic autonomic neuropathy Some degree of diabetic autonomic neuropathy is found in most patients with diabetic polyneuropathy, although in some patients, the autonomic symptoms and signs predominate. Orthostatic hypotension, impaired gastrointestinal motility (including gastroparesis), and blunting of the sympathetically mediated warning symptoms of hypoglycemia are important management problems. Some au-

tonomic symptoms can be treated effectively; for example, gastroparesis can be treated with metoclopramide, and orthostatism can be treated with support hose, volume expansion, and vasopressors such as midodrine.

Diabetic truncal neuropathy Diabetic truncal neuropathy is a painful sensory syndrome affecting one or several thoracic dermatomes, usually unilaterally. Clinically, the process is a thoracic radiculopathy with abrupt development of tactile hypersensitivity or sensory loss in a dermatomal distribution. Motor involvement can usually be demonstrated by electromyography, and sometimes, an asymmetrical bulging of the abdomen occurs because of unilateral weakness of the abdominal muscles. The main alternative diagnosis is herpes zoster radiculopathy, usually distinguished by vesicular skin eruption. Diabetic truncal radiculopathy is self-limited, although aggravating symptoms may persist for weeks. Administration of analgesics, supplemented by amitriptyline, gabapentin, or other drugs for neuropathic pain, is the main management approach.

Other Metabolic Disorders

Polyneuropathy develops in up to 60% of patients with chronic renal failure. The risk of uremic neuropathy is related to the duration and severity of renal failure. Slowing of motor conduction velocity is seen when the creatinine clearance falls below 10% of normal, although conduction slowing is only roughly correlated with symptoms. Uremic neuropathy is sensorimotor in nature, with distal predominance of symptoms and signs. Once established, uremic neuropathy tends to worsen slowly, the main troublesome symptom being unpleasant dysesthesia in the feet. Disabling motor weakness is rare. The chief pathologic finding in uremic neuropathy is axonal degeneration, which is most abundant in the most distal parts of the PNS. Etiologically, impairment of neuronal soma or axon function probably results from the buildup of a neurotoxic substance or substances normally excreted by the kidneys, but the details are not known. Both dialysis and renal transplantation generally have a beneficial effect. Dialysis can prevent, stabilize, or often decrease the severity of neuropathy. The effects of renal transplantation may be striking, and even severe uremic neuropathy can be expected to improve in the months after transplantation. The widespread availability of these treatments has made symptomatic uremic neuropathy relatively uncommon.

Mild distal axonal polyneuropathy sometimes occurs in patients with hypothyroidism, acromegaly, or polycythemia. These neuropathies are not disabling, but sensory symptoms may be troublesome. Patients in intensive care units with multiple organ dysfunction syndrome and sepsis sometimes experience a severe axonal polyneuropathy. The pathogenesis of this condition, known as critical illness polyneuropathy, is unknown.[23] Critical illness polyneuropathy is usually suspected either when a patient in an intensive care unit cannot be weaned from the ventilator despite adequate cardiopulmonary function or when limb weakness occurs in an alert ICU patient. Because it is difficult to examine the PNS properly in critically ill patients and because critical illness polyneuropathy is a diagnosis of exclusion, clearly establishing the diagnosis can be difficult. A similar clinical picture can also be caused by a critical illness myopathy, particularly in patients treated with high-dose glucocorticoids and long-acting neuromuscular blockers (e.g., vecuronium). Limited data suggest that critical illness neuropathy improves in patients who survive the illness.[24]

Inherited Polyneuropathies

Inherited polyneuropathies are common and frequently overlooked, especially in adults.[12] Patients often remain relatively asymptomatic for many years and, therefore, may not seek medical advice until middle age or later. A very slow progression of symptoms over years is suggestive of an inherited cause. Patients with inherited polyneuropathies may complain of numbness, by which they usually mean decreased sensation. Symptoms of prickling or pins-and-needles paresthesia in a patient with polyneuropathy favors an acquired cause. However, the complaint of burning feet is nonspecific, occurring in both inherited and acquired polyneuropathies. As a rule, inherited neuropathies begin and progress symmetrically; asymmetrical progression suggests an acquired polyneuropathy.

Once inherited polyneuropathy is suspected, proving the diagnosis may require considerable effort. Simply asking the patient about a family history of neuropathy is seldom productive. Questioning should be more general, such as whether anyone in the family has foot complaints, has a foot deformity (especially high arches), or requires special shoes, canes, or braces. A negative family history does not exclude a diagnosis of inherited neuropathy. Because of its chronicity or mildness, or both, the condition often goes unrecognized in a family. In recessive cases, by definition, neither parent is affected, and siblings may be spared. Paternity may be less well established than it appears. The most effective next step is to examine first-degree relatives, particularly those with any history of foot or walking troubles. Although this procedure is time-consuming, it has a good yield and is more cost-effective than a barrage of laboratory tests that may all prove negative.

Knowledge about the specific genetic defects related to various inherited neuropathies is expanding rapidly,[25] but clinical classification remains important. Traditionally, the inherited neuropathies are divided into three main categories according to clinical features: (1) hereditary motor and sensory neuropathy, (2) hereditary sensory and autonomic neuropathy, and (3) hereditary motor neuropathy (also called spinal muscular atrophy) [*see Table 4*]. Genetic testing for some inherited neuropathies is now available (e.g., *PMP22* gene [Charcot-Marie-Tooth disease type 1], *connexin-32* gene [X-linked Charcot-Marie-Tooth disease]). Although there are still no specific therapies for inherited neuropathies, correct diagnosis remains important for prognosis, education, and genetic counseling. In general, the deficits in inherited neuropathies progress very slowly, life expectancy is normal, and most patients remain ambulatory all their lives.

Immune-Inflammatory Polyneuropathies

Guillain-Barré syndrome Guillain-Barré syndrome (GBS), or acute inflammatory demyelinating polyradiculoneuropathy, is the most common cause of acute generalized paralysis in the Western world. Most large general hospitals care for several patients with GBS every year, and the management of these patients often falls to general physicians. The natural history of GBS is favorable in most cases, but a good outcome depends on meticulous medical and nursing care during the peak of neurologic disability.

The diagnosis of GBS is not difficult once the signs are full-blown. However, in the first few days, symptoms can be vague and the signs equivocal. It is common for a patient to be discharged from the emergency room with a diagnosis of anxiety, only to return a day or two later with obvious progressive limb weakness. Most often, the first symptom is prickling paresthe-

sia, beginning in the feet and spreading proximally hour by hour. Weakness is noticed some hours to a few days later. Some patients have only motor symptoms without sensory symptoms. Classically, symptoms begin symmetrically in the distal limbs and proceed proximally (so-called ascending paralysis), and nerve conduction studies provide evidence of a demyelinating process affecting spinal roots and peripheral nerves (a demyelinating polyradiculoneuropathy). Variations on this classic presentation are common and include syndromes in which cranial nerve (e.g., Miller Fisher syndrome) or autonomic involvement predominate, as well as syndromes that are primarily axonal rather than demyelinating.[26] It is evident that Guillain-Barré syndrome must be regarded as a rather elastic category, although all clinical variants share the key features of being acute-onset, immune-mediated disorders of the PNS, with a self-limited monophasic course. In addition to motor, sensory, or autonomic symptoms, many patients have pain, most often manifested as a deep ache in the back or limbs or as dysesthetic limb pain.[27]

Autonomic dysfunction may be a significant problem in some patients with GBS, particularly those with severe weakness. Marked blood pressure fluctuation and refractory hypotension are the major problems, although hyperthermia, pupillary paralysis, and cardiac dysrhythmias may occur.

Muscle weakness can be expected to increase during the first few days and then remain stable for days to weeks. Weakness may range from mild (e.g., slight weakness of ankle dorsiflexion) to severe; flaccid quadriparesis with respiratory muscle paralysis occurs in as many as 30% of patients. It is impossible to predict within the first 2 days how much weakness will develop in a given patient. Therefore, it is advisable to observe any patient with GBS in the hospital until the severity is apparent. As a general rule, weakness reaches its maximum within 14 days. The ensuing period of stable weakness, before recovery begins, lasts days to months, with a median duration of 4 weeks. A rough correlation exists between the severity of weakness and the interval before the onset of recovery. Once recovery begins, the patient usually makes noticeable gains on a weekly basis. A year after onset, most patients have made a complete or substantial recovery, but as many as 15% remain bedridden or wheelchair bound. Recurrent episodes of GBS, sometimes spread out over many years, occur in about 3% of patients.

The fundamental pathologic event in GBS is the stripping of myelin from axons by macrophages, which occurs in a patchy fashion throughout the PNS. A cascade of events involving cell-mediated and humoral immune mechanisms is assumed to be activated, and lymphocytic inflammatory infiltrates are often found in nerve and nerve roots examined by biopsy or at autopsy. The triggers and specific molecular targets of the immune attack are unknown. There is a lingering concern about influenza vaccination as a precipitant of GBS; retrospective epidemiologic studies have found a small relative risk of GBS among vaccine recipients in the 1992 through 1994 influenza seasons.[28] Studies of the pathogenesis of GBS have focused on the potential roles of antecedent *Campylobacter jejuni* infection and the production of antiganglioside autoantibodies, both of which occur in a large number of patients with GBS.[29]

The differential diagnosis of an acute sensorimotor polyneuropathy is short [*see Table 2*]. Before the development of the polio vaccine, the major differential diagnosis was between GBS and poliomyelitis, but poliomyelitis is now rare. If signs of systemic illness accompany an acute polyneuropathy, consideration should be given to vasculitic neuropathy, lymphomatous infiltration of the nerve roots, acute intermittent porphyria, diphtheria, and arsenic poisoning. An ischemic lesion of the pons may initially produce acute flaccid quadriparesis and mimic GBS before clear upper motor neuron signs develop. With cranial nerve variants of GBS (e.g., Miller Fisher syndrome), myasthenia gravis and botulism must be excluded.

GBS is diagnosed primarily from the clinical features, but laboratory tests can help support the diagnosis and exclude other causes of acute polyneuropathy. The cerebrospinal fluid in GBS characteristically shows elevated protein levels, normal glucose levels, and no pleocytosis. If a mononuclear pleocytosis is found, meningeal infiltration by lymphoma or carcinoma must be seriously considered. An acute polyradiculopathy similar to GBS but with CSF pleocytosis may occur at the time of HIV seroconversion [*see* Polyneuropathies Caused by Infectious Diseases, *below*]. Nerve conduction studies in GBS usually demonstrate widespread slowing of conduction velocities or, more commonly, proximal conduction block and can provide some prognostic information. Neither the CSF nor the nerve conduction abnormalities are diagnostic of GBS, and both tests may be normal, particularly during the first few days of the disease.

Once a diagnosis of GBS is made, the first priority is to monitor respiratory muscle function closely and be prepared to intervene if ventilatory failure develops. Frequent bedside measurements of vital capacity or maximum inspiratory force, or both, and clinical evaluation for signs of respiratory muscle fatigue are important. A patient with a vital capacity of less than 20 ml/kg is likely to experience frank ventilatory failure, and elective intubation should be strongly considered.

Several large clinical trials have shown that two therapies—plasma exchange and intravenous immunoglobulin (IVIg)—improve the rate of recovery in patients with moderate to severe GBS (e.g., patients who are unable to walk).[30-32] Both treatments appear to modulate the inflammatory process that produces nerve injury, but they are not thought to promote remyelination or nerve regeneration. A beneficial effect can be shown only if plasma exchange or IVIg is begun within 2 weeks after onset of neuropathic symptoms. It is probably wise to begin treatment as soon as the diagnosis has been made, if the weakness is sufficiently severe, or if the signs progress while the patient is under observation. Usually, five treatments are given over 5 to 10 days; some patients may relapse and require further treatments (e.g., twice weekly for 3 weeks). Combined treatment (plasma exchange followed by IVIg) offers no clear advantage over either treatment alone,[30] and glucocorticoids conferred no additional benefit when added to plasma exchange in a large controlled trial[33] and have no benefit when used alone.[34] Plasma exchange and IVIg appear to be equally effective and have similar costs and relapse rates, but many clinicians believe IVIg is the treatment of choice because it is considerably easier to administer than plasma exchange. Because IVIg is made from pooled blood, it is difficult to completely eliminate concerns about infectious risk, even though multiple purification procedures are now used, and there have been no proven cases of IVIg-transmitted infection for over a decade. There is also uncertainty about whether the supply of IVIg is adequate to meet the demand. A new therapeutic strategy is CSF filtration; a small controlled trial found this modality to be at least as effective as plasma exchange, with fewer complications.[35]

Because many patients remain bedridden for months, meticulous nursing care is essential. Measures to prevent pressure

sores and venous thrombosis are necessary, and the patient is also in constant danger of urinary and pulmonary infections. Pain is a major problem for some patients and seems to be related partly to immobility and partly to nerve inflammation and dysfunction. Regular range-of-motion physiotherapy exercises and judicious use of analgesics and agents such as amitriptyline are beneficial. A particular challenge for all staff members is psychological support of the patient; there are several eloquent accounts of the patient's perspective in GBS.[36]

Chronic inflammatory demyelinating polyradiculoneuropathy Like GBS, chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is an immune-mediated neuropathy. The fundamental pathologic event is the stripping of myelin from axons by macrophages, which slows or blocks nerve impulse conduction, causing weakness and sensory loss. Clinically, CIDP differs from GBS in several important respects. The onset of CIDP is insidious, with symptoms and signs developing over weeks to months, compared with the rapid initial course of GBS. Unlike the monophasic, self-limited course of GBS, the natural history of CIDP is variable. The usual pattern of CIDP is slow worsening over months, producing chronic moderate disability. Some patients have a relapsing and remitting course, and a few experience gradual spontaneous remission. Major autonomic or respiratory involvement, which is common in GBS, is unusual in CIDP.

No single clinical or laboratory finding is pathognomonic for CIDP, and the diagnosis is made from a combination of an appropriate history, signs of neuropathy, electrophysiologic evidence of demyelination, and an acellular CSF with an increased protein level. Nerve biopsy can support the diagnosis but is usually unnecessary. A similar type of chronic neuropathy can occur in patients with monoclonal gammopathy, osteosclerotic myeloma, and HIV infection.

The efficacy of a number of treatments for CIDP has been demonstrated in controlled trials. Plasma exchange[37] and IVIg[38] produce improvement in 2 to 3 weeks in most patients, but the improvement is short-lived, and patients need either repeated treatments or alternative long-term therapies. High-dose prednisone is also effective,[39] but the response is usually less impressive and slower, and the patient faces the potential complications associated with long-term glucocorticoid use. A double-blind crossover trial of interferon beta in treatment-resistant CIDP showed no benefit,[40] but there is anecdotal support for other immunomodulating drugs, including cyclosporine, azathioprine, interferon alfa, cyclophosphamide, and mycophenolate mofetil. Careful monitoring of neurologic impairment and treatment by neurologists experienced with CIDP are important.

Monoclonal protein–associated polyneuropathy Polyneuropathy and a monoclonal gammopathy may occur in some patients who have amyloidosis, multiple myeloma, osteosclerotic myeloma, Waldenström macroglobulinemia, or lymphoma. If none of these hematologic conditions is found, then the patient is considered to have monoclonal gammopathy of undetermined significance (MGUS). The relation between MGUS and neuropathy is unsettled, but epidemiologic and pathologic evidence suggests that MGUS causes the neuropathy.

MGUS neuropathy has variable clinical and electrophysiologic features. There is often electrophysiologic and pathologic evidence of prominent demyelination, and the clinical picture closely resembles that of CIDP. Some patients have a painful, axonal neuropathy with mild deficits. IgM-associated neuropathy tends to be more severe, with more ataxia and more evidence of nerve conduction slowing and dispersion, which indicates that some relation exists between the class of immunoglobulins and the features of the neuropathy.[41]

MGUS neuropathy is generally slowly progressive, though the degree of disability is variable. Therapeutic approaches aim either to suppress production of the monoclonal protein or to remove it from the circulation. Anecdotal reports exist of responses to chlorambucil, melphalan, and prednisone. A controlled trial showed plasma exchange to be beneficial in patients with IgG and IgA gammopathies but not in those with IgM gammopathy.[42] IVIg appears to be beneficial in IgG MGUS neuropathy, but a controlled trial has not been conducted.[43]

Amyloid neuropathy Polyneuropathy characterized by amyloid deposition in nerve occurs in two settings: (1) as a feature in about 15% of patients with systemic amyloidosis, in whom the amyloidogenic protein is immunoglobulin, and (2) as an autosomal dominant disorder, familial amyloid polyneuropathy (FAP), in which the amyloid most commonly consists of mutated forms of transthyretin, a normal serum protein.[44] Both types feature a symmetrical sensorimotor polyneuropathy distinguished by the frequent presence of important or predominant autonomic features. Amyloidosis is also a rare cause of carpal tunnel syndrome.

The diagnosis of amyloid neuropathy is made by nerve biopsy. Acquired amyloid neuropathy and inherited amyloid neuropathy are histopathologically similar but can be distinguished by immunohistochemical analysis. Trials of melphalan, glucocorticoids, and colchicine have had little impact on the outcome of patients with primary amyloidosis, including any improvement of the neuropathy. Unlike in primary amyloidosis, neuropathy is usually the major cause of disability in FAP, and most patients survive for a decade or more after diagnosis. Liver transplantation may halt progression of the neuropathy in FAP.[45]

Osteosclerotic myeloma Osteosclerotic myeloma is a variant of myeloma in which patients have one or sometimes several osteosclerotic bony lesions. Biopsy reveals malignant plasma cell proliferation. Commonly, these bony lesions occur within a constellation that includes polyneuropathy, organomegaly, endocrine abnormalities, monoclonal gammopathy, and skin changes (POEMS syndrome). The polyneuropathy is typically demyelinating and resembles CIDP. POEMS syndrome is important to recognize because there may be significant clinical improvement with irradiation of the bony lesion.

Paraneoplastic neuropathy Several distinctive nonmetastatic neurologic syndromes that develop in cancer patients have been described since the 1950s. Paraneoplastic syndromes are believed to have an immunologic basis, developing as a consequence of the host's attempt to mount an immune response to the cancer [*see 11:VI Neoplastic Disorders*].

Vasculitic neuropathy Neuropathy is a frequent manifestation of certain systemic vasculitides. Vasculitic neuropathy is ischemic, a consequence of involvement of nutrient vessels of nerve by the inflammatory process. Because of the robust blood supply of nerve and its relative resistance to ischemic injury, the development of neuropathy in vasculitis implies extensive vessel involvement. The vasculitis tends to be patchy, and asymme-

try of nerve involvement is common, so individual nerves are often affected while neighboring nerves are spared; this is the classic syndrome of multiple mononeuropathies. However, as the involvement of nerve blood supply advances and more nerves become involved, a pattern of multiple mononeuropathies may become more difficult to identify. About 30% of cases of vasculitic neuropathy are symmetrical polyneuropathies at initial diagnosis, 30% are asymmetrical polyneuropathies, and 40% are multiple mononeuropathies.[46]

Among patients with vasculitic neuropathy, the main associated systemic vasculitides are polyarteritis nodosa, rheumatoid vasculitis, Sjögren syndrome, Wegener granulomatosis, and allergic granulomatous angiitis (Churg-Strauss syndrome). Neuropathy is particularly common in polyarteritis nodosa, occurring in at least half of all cases. The clinical and neuropathologic features of the neuropathy in these disorders are similar, and a specific diagnosis depends on the systemic, nonneurologic features. Vasculitic neuropathy can often be suspected from the clinical setting alone, but definitive diagnosis depends on nerve biopsy. Antineutrophil cytoplasmic antibodies are often found in vasculitic neuropathy, but false positive test results limit their diagnostic usefulness.[47]

Vasculitic neuropathy is managed by treating the underlying systemic vasculitis. This therapy generally requires high-dose prednisone, cyclophosphamide, or both. In vasculitis, neuropathy is seldom a cause of death, although it may produce significant disability. If life-threatening events, such as renal or cardiorespiratory failure, can be successfully treated, the prospects for neurologic improvement are good, although improvement may take many months.[48]

Patients with clinical and neuropathologic features of vasculitic neuropathy sometimes have no evidence of systemic vasculitis. This syndrome, termed nonsystemic vasculitic neuropathy, appears to have a more benign natural history than does systemic vasculitis. Corticosteroids are often used if the patient has significant or progressive neurologic disability, although there are no controlled trials. The largest retrospective series of patients with nonsystemic vasculitic neuropathy suggested that combination immunotherapy (corticosteroids plus cyclophosphamide) was more effective than corticosteroids alone in inducing remission and improving disability.[49]

Neuropathies related to other connective tissue diseases Peripheral neuropathy may occur in other connective tissue diseases, such as systemic lupus erythematosus [*see 15:IV Systemic Lupus Erythematosus*], although it can be difficult to ascertain whether the neuropathy is a direct complication of the connective tissue disease or a secondary effect of another complication (e.g., secondary to renal failure). It is usually assumed that neuropathy in such cases has an inflammatory basis, but few pathologic studies exist to support this belief. An ataxic sensory neuronopathy, clinically very similar to the paraneoplastic syndrome [*see 11:VI Neoplastic Disorders*], has been described in patients with Sjögren syndrome and is caused by an inflammatory infiltration of dorsal root ganglia.[50] Inflammatory sensory neuropathies also occur in patients with sicca syndrome who lack extraglandular features of Sjögren syndrome.[51]

Neuropathies Caused by Toxins and Nutritional Deficiencies

Substances toxic to peripheral nerves include a variety of industrial chemicals, naturally occurring compounds, and drugs. Most toxic neuropathies begin distally, progress insidiously over weeks to months, and have electrophysiologic features of an axonal neuropathy. With some exceptions, nonspecific axonal degeneration is the main histologic feature, and nerve biopsy is seldom helpful in making the diagnosis.

Drugs Drug-induced neuropathy is a common problem, particularly in a hospital-based practice. A careful drug history is an important part of the investigation of any polyneuropathy. Peripheral neuropathy is a well-established adverse effect of many drugs [*see Table 5*]. In ideal circumstances, before a drug is labeled as potentially neurotoxic, the affected patient should be found to be free of other potential causes of neuropathy, and cessation of the drug should lead to some clinical improvement. It is important to realize that recovery may take many months. In some toxic neuropathies, the patient experiences the phenomenon known as coasting, in which the neuropathy continues to worsen for some weeks after exposure has ceased. For most well-established peripheral nerve toxins, there is experimental evidence of toxicity in animals and neuronal cell culture. With some antineoplastics (e.g., cisplatin), neuropathy may be the dose-limiting side effect. In animal models, cisplatin neuropathy may be prevented or alleviated by coadministration of neurotrophins, such as NT-3, a strategy that may prove applicable to humans.[52]

Industrial chemicals A patient's occupational history may be important because a number of industrial chemicals are known to be neurotoxic [*see Table 6*]. Most of these compounds were found to be neurotoxic after clusters of cases appeared in workers in specific industries, and subsequent awareness of the dangers of these compounds has reduced the incidence of cases. Most of these chemicals produce axonal neuropathies with nonspecific pathologic changes. Proving that a neuropathy is caused by exposure to a chemical requires careful epidemiologic work supported by animal or tissue culture studies.

Metals In addition to drugs containing gold and platinum, poisoning by other metals may produce neuropathy. Exposure is often the result of homicidal or suicidal intent, so the history may be of dubious value. Diagnosis must be made from the associated clinical features. For example, lead neuropathy is predominantly motor, with a predilection for the upper limbs, and is associated with abdominal pain, constipation, and anemia. In addition to causing neuropathy, arsenic poisoning produces abdominal pain, vomiting, diarrhea, skin and nail changes, and pancytopenia. Thallium neuropathy is distinguished by alopecia and abdominal pain. Organic and inorganic mercury compounds can produce neuropathy, but CNS effects usually predominate [*see 8:I Management of Poisoning and Drug Overdose*].

Table 6 Industrial Chemicals That May Cause Polyneuropathy

Acrylamide	Methyl bromide
Allyl chloride	Methyl butyl ketone*
Carbon disulfide	Organophosphorus esters
Dimethylaminopropionitrile	Polychlorinated biphenyls
Ethylene oxide	Trichloroethylene
Hexane*	Vacor

*Exposure to these compounds also occurs as a result of glue sniffing and other solvent abuse.

The diagnosis of metal neuropathy hinges on demonstrating increased urinary excretion of the metal or increased levels in the hair or nails. Requests for such assays should be prompted by clinical suspicion and are not part of the routine investigation of polyneuropathy.

Ethanol A distal, often painful neuropathy is common in chronic alcoholics. The main symptoms are burning, stabbing pains and numbness in the feet and sometimes in the hands. Sensory loss or painful hypersensitivity in the feet, loss of the ankle reflexes, and mild distal weakness form the typical picture. Whether the neuropathy is caused by a direct toxic effect of ethanol, malnutrition, or both remains unresolved.

Attempts to produce neuropathy with ethanol in well-fed animals have been unsuccessful, although in neuronal cell cultures, growth inhibition can be produced with moderately high concentrations of ethanol. A Danish study that carefully examined a cohort of alcoholic beer drinkers with neuropathy found no clinical, electrophysiologic, or histologic differences between those who were well nourished and those who were malnourished.[53] Danish beer is supplemented with thiamine and pyridoxine, so it is unlikely that deficiency of these vitamins was the cause of neuropathy in these patients.

Although the pathogenesis of neuropathy in alcoholics is debated, the clinical setting is characteristic in that other signs and symptoms of alcoholism are generally present, including chronic liver disease, memory impairment, and ataxia of gait. Estimates of ethanol intake are notoriously unreliable, but in the Danish study, neuropathy developed only in patients who consumed 3 L of beer or 300 ml of spirits daily for at least 3 years. An important corollary of these observations is that in a patient with neuropathy who drinks moderately, is well nourished, and is free of signs of chronic liver disease, alcoholic neuropathy is unlikely; therefore, in such a patient, other causes of neuropathy should be sought.

Treatment of alcoholic neuropathy is simple in principle but difficult in practice. Ethanol ingestion must be stopped and adequate nutrition ensured. If such measures can be achieved, gradual improvement can be expected, although it may take months and be incomplete.

Nutritional deficiencies Polyneuropathy can be a manifestation of starvation, as seen in famine victims or in prisoners of war. The precise dietary components responsible for neuropathy in starvation are unclear, although one or more B vitamins are assumed to be critical. Certain vitamin deficiencies can cause neuropathy in specific situations, but there is no physiologic basis for routinely prescribing multivitamins for neuropathy in patients with normal diets.

Thiamine (vitamin B_1) deficiency produces beriberi, the main features of which are polyneuropathy and cardiac failure. The neuropathy is distal and axonal, with painful sensory symptoms. With progression, distal weakness may develop. Cranial nerve involvement was described in older accounts of beriberi.

Pyridoxine (vitamin B_6) deficiency is responsible for the neuropathy caused by isoniazid, which increases excretion of pyridoxine. Administration of pyridoxine with isoniazid prevents the neuropathy. However, excessive doses of pyridoxine (a fad in the 1970s) produce a severe sensory neuronopathy.

A mild polyneuropathy may be part of the neurologic syndrome produced by cobalamin (vitamin B_{12}) deficiency. However, vitamin B_{12} deficiency probably does not present as polyneuropathy alone; the main clinical features are the result of myelopathy (subacute combined degeneration).

Vitamin E deficiency from malabsorption may result in an ataxic syndrome caused by degeneration of the peripheral and central processes of dorsal root ganglia neurons. Cerebellar involvement may be present in some patients.

Polyneuropathies Caused by Infectious Diseases

Leprosy Leprosy, a mycobacterial infectious disease of peripheral nerves, is probably the most common cause of polyneuropathy in the world [*see 7:II Infections Due to Mycobacteria*]. Most cases occur in tropical and subtropical regions, although there are endemic foci along the Gulf Coast of Florida and Louisiana. Most patients with leprosy in North America and Europe are immigrants from countries where leprosy is common.

Sensory loss is the cardinal symptom of leprosy. It is often discovered because of a painless injury. Because of the temperature requirements of *Mycobacterium leprae*, cutaneous sensory and mixed nerves in parts of the body with low ambient temperature are most likely to be affected. The result is a distribution of signs unlike those of any other polyneuropathy, with sensory loss over the external ears, the zygomatic arches, and extensor surfaces of joints. Major nerves are most likely to be affected where they travel close to the surface (e.g., the ulnar nerve at the elbow). Involvement of cutaneous nerves is generally sharply demarcated, especially in the tuberculoid form of leprosy, and the overlying dermis and epidermis are affected, producing the classic anesthetic macule. Motor weakness does not occur until sensory loss is well established. Weakness is usually patchy and asymmetrical and may suggest other causes of multiple mononeuropathies. The diagnosis of leprosy is made by nerve or skin biopsy, using the Fite method to stain and identify *M. leprae*.

Leprosy is a curable disease. The degree of recovery in advanced cases may be limited, so it is important that the disease be diagnosed and treated before major neuropathic deficits develop [*see 7:II Infections Due to Mycobacteria*].

HIV infection Several PNS disorders occur in patients with HIV infection, some in the early stages of infection and some only after progression to AIDS [*see 7:XXXIII HIV and AIDS*]. Distal, painful neuropathy is very common in patients with AIDS. The main symptom is continuous burning discomfort, mostly in the feet, where some degree of sensory loss is apparent. Motor involvement is usually minor, although the patients are often debilitated by concomitant infections and weight loss. The cause is sometimes identifiable—for example, vitamin B_{12} deficiency or treatment with a retroviral agent known to be neurotoxic (e.g., 2,3-dideoxycytidine or zalcitabine)[54]—but the cause in some patients remains unclear. The HIV genome has been detected in dorsal root ganglia neurons and satellite cells in patients with AIDS and neuropathy,[55] and expression of the HIV genome in transgenic mice produces peripheral nerve disease.[56] Whether neuropathy in humans with HIV is actually caused by direct infection of nerves by HIV remains to be proved.

Neuropathy is a frequent dose-limiting side effect of nucleoside analogue antiretrovirals (e.g., zalcitabine), but fortunately, neither zidovudine (AZT) nor the protease inhibitors appear to cause neuropathy. In a phase II trial, nerve growth factor, compared with placebo, reduced neuropathic pain in HIV-infected patients who had distal sensory neuropathy, although injection-site pain produced impaired masking in a substantial portion of treated patients.[57]

GBS and CIDP typically occur early in the course of HIV infection. They may be the presenting features of HIV infection, and HIV testing should be considered in patients with GBS or CIDP. The neurologic picture and response to treatment in patients with HIV are similar to those in non–HIV-infected patients, except that there is usually a lymphocytic pleocytosis in the CSF.

A syndrome of multiple mononeuropathies may occur in HIV-positive patients. Nerve biopsy may show perivascular inflammatory infiltrates, necrotizing vasculitis, or cytomegalovirus (CMV) inclusions. Patients with evidence of CMV infection may respond to ganciclovir[58] [*see 7:XXVI Herpesvirus Infections*]. Patients with HIV infection that is complicated by the diffuse infiltrative lymphocytosis syndrome may experience a subacute axonal neuropathy; nerve biopsies in these patients have shown striking perivascular $CD8^+$ lymphocyte infiltrates, and the neuropathy seems to abate with corticosteroids or zidovudine.[59]

Acute lumbosacral polyradiculopathy is a devastating syndrome of leg weakness, leg and perineal sensory loss, and urinary retention that develops over 1 to 2 weeks, usually in patients with advanced AIDS. The CSF shows a distinctive polymorphonuclear pleocytosis. In most cases, there is evidence of concomitant CMV infection, and the neurologic picture is caused by invasion of lumbosacral nerve roots by CMV. Prompt diagnosis and treatment with ganciclovir may produce improvement [*see 7:XXVI Herpesvirus Infections*]. A similar picture may be produced by lymphoma.[60]

Lyme disease Lyme disease is caused by the spirochete *Borrelia burgdorferi*, which is transmitted to humans by ixodid ticks. The disease occurs worldwide but is most common in the northeastern United States and northern Europe [*see 7:VII Leptospirosis, Relapsing Fever, Rat-Bite Fever, and Lyme Disease*]. Peripheral neuropathy may occur in early or late disseminated Lyme disease. It is unclear whether the neurologic manifestations are caused directly by spirochetal invasion of nerve tissue or by the host's immune response to the organism.

The main early neurologic features are cranial neuropathies, spinal radiculopathies, or both.[61] Headache and neck stiffness may accompany the peripheral nerve symptoms, reflecting meningeal inflammation. Facial neuropathy is the most common cranial neuropathy, and a misdiagnosis of Bell palsy is often made. However, unlike in idiopathic Bell palsy, bilateral facial neuropathy is common in Lyme disease. Other cranial neuropathies occur less often.

Spinal nerve root involvement typically begins with pain in a radicular distribution, followed by weakness in 1 to 4 weeks. The weakness is often asymmetrical and patchy, resembling multiple mononeuropathies. In addition to the predominant radicular signs, there is frequently electrophysiologic evidence of a mild widespread polyneuropathy. Both cranial and spinal neuropathies in early-stage Lyme disease have a favorable natural history, with recovery in weeks to months. Treatment with antibiotics may hasten recovery.

In late-stage Lyme disease, patients may experience either a mild distal polyneuropathy or radicular pain with sensory signs. Many of these patients will have had previous symptoms of localized or early disseminated disease. Unlike cranial neuropathy and radiculoneuropathy of early-stage disease, the peripheral neuropathy of late-stage disease tends not to resolve without treatment.

The diagnosis of Lyme neuropathy rests on a history of possible tick exposure, compatible symptoms and signs, and positive serologic testing for *B. burgdorferi*. In early-stage disease, neurologic involvement is almost always accompanied by a lymphocytic CSF pleocytosis, but in late-stage disease, pleocytosis is exceptional and the CSF may be normal. Sural nerve biopsy in early- or late-stage disease shows axonal degeneration and perivascular inflammatory infiltrates, but these findings are nonspecific. Particularly in late-stage disease, response to a course of antibiotics may provide the most convincing evidence of the diagnosis [*see 7:VII Leptospirosis, Relapsing Fever, Rat-Bite Fever, and Lyme Disease*].

Varicella-zoster virus infection Varicella-zoster virus (VZV), a member of the human herpesvirus family, is the most common viral pathogen in the PNS [*see 7:XXVI Herpesvirus Infections*]. After initial VZV infection, which usually occurs during childhood in the form of varicella (chickenpox), some VZV virions may enter cutaneous sensory axons and are carried by retrograde axonal transport to sensory neuron cell bodies in the dorsal root or cranial ganglia, where they remain in an inactive form.

Years later, the virus can return to an active, proliferative state because of alterations in immune function that are incompletely understood. The cytopathic effects of VZV replication and the ensuing immune response produce an intense inflammatory necrotic ganglionitis, resulting in dermatomal sensory alteration, pain, and the dermatomal vesicular skin rash known as herpes zoster.

Herpes zoster is most common in persons older than 60 years, although it also occurs in younger persons. The incidence is much higher in immunocompromised patients, in whom there is also a risk of disseminated VZV infection, which has considerable mortality. Herpes zoster is usually unilateral, involving one to three adjacent dermatomes. Thoracic and trigeminal (especially ophthalmic) dermatomes are most often affected.

The initial symptom is dermatomal pain, followed in 3 to 7 days by the vesicular eruption. Sensory loss is difficult to demonstrate until the skin lesions begin to heal. Motor weakness is reported in as many as 30% of patients but may not be noticed by a patient distracted by pain. The cutaneous lesions persist for 7 to 10 days and then resolve, often leaving depigmented areas and scarring. Motor weakness can be expected to improve spontaneously in most patients. Pain also improves slowly, except in patients who experience postherpetic neuralgia (PHN).

PHN is usually defined as pain persisting more than 4 to 8 weeks after healing of the skin lesions. The risk of PHN after an episode of herpes zoster increases with age, reaching as high as 45% in patients older than 65 years. Patients with PHN experience a continuous burning dermatomal pain, on which brief, lancinating pains may be superimposed. Often, there is also allodynia in the affected dermatome, so that the touch of clothes or even hair may cause excruciating pain. Some patients with PHN experience gradual improvement over weeks to months, but persistence of symptoms for years is not unusual. Prevention of PHN is probably the main rationale for using antiviral agents in an immunocompetent patient. A large placebo-controlled trial of famciclovir showed a clear reduction in the incidence of PHN, especially in the elderly.[62] It is assumed that acyclovir offers a similar benefit, but this assumption is unproved. In one study, the addition of prednisolone to 7- or 21-day courses of acyclovir did not alter the frequency of PHN,[63] although glucocorticoids may reduce acute-phase pain.

PHN presents a formidable therapeutic challenge. Amitriptyline or other tricyclic medications have been the usual first-line agents, but gabapentin is being increasingly used and was shown to be superior to placebo in a controlled trial.[64] Lancinat-

ing pain may be reduced by carbamazepine or other anticonvulsants. Topical application of local anesthetics and long-term use of opioids are advocated by some clinicians.[65]

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III DISEASES OF MUSCLE AND THE NEUROMUSCULAR JUNCTION

Marinos C. Dalakas, m.d.

Approach to Patients with Neuromuscular Disease

The diseases of muscle and the neuromuscular junction constitute a heterogeneous group of acquired and hereditary disorders. At presentation, symptoms are varied and include fatigability, skeletal muscle weakness, atrophy, muscle cramps, and impaired function of respiratory, pharyngeal, facial, and ocular muscles. In general, the proximal muscles are more selectively and severely affected than the distal muscles. Thus, patients experience difficulty climbing stairs, rising from a low chair, running, combing their hair, and lifting themselves or turning in bed. Most myopathies affect only skeletal muscles, but smooth muscle and cardiac muscle may also be impaired. Patients with myopathy do not have sensory disturbances or autonomic dysfunction, because peripheral nerves and the autonomic nervous system are spared.

Clinical examination is aimed at localizing findings to muscle and excluding diseases that may cause myopathic symptoms and signs, such as motor neuron syndromes, motor neuropathies, and psychogenic diseases. A complete family history and examination of family members are often necessary to exclude a hereditary disease. Useful laboratory evaluations include (1) studies to exclude a systemic disease, exogenous factors, toxins, or viruses that may induce myopathy; (2) electromyography (EMG) to localize the lesion to the muscle or the neuromuscular junction and to exclude motor neuron or peripheral nerve disorders; (3) determination of serum levels of muscle enzymes; (4) measurement of specific autoantibodies directed against known or putative muscle antigens; (5) muscle biopsy for enzyme histochemistry, immunocytochemistry, electron microscopy, biochemical measurement of a specific muscle enzyme or protein, and genetic studies; (6) ischemic exercise test to measure the production of lactate and ammonia in metabolic myopathies; (7) genetic tests on peripheral blood lymphocytes if the gene is known; and (8) muscle imaging, as dictated by the specific clinical problem being investigated.

Most myopathies are disabling or catastrophic if left untreated. Therefore, diagnosis must be established quickly to initiate early therapy. For patients with untreatable disorders, proper supportive care, rehabilitation, and genetic counseling are critical.

In this chapter, the most common myopathies and disorders of the neuromuscular junction are described, with emphasis on the clinical picture, pathogenesis, diagnosis, and therapy.

Muscular Dystrophies

The muscular dystrophies constitute a heterogeneous group of congenital muscle diseases characterized by severe muscle weakness, atrophy, elevation of serum muscle enzyme levels, and destructive cytoarchitectural changes of muscle fibers. The traditional classification of muscular dystrophies into Duchenne, Becker, limb-girdle, and congenital has changed because genetic defects in muscle proteins responsible for most of these diseases have been identified and the deficiency of specific muscle proteins has been demonstrated as the cause of these diseases.

Molecular, biochemical, and immunocytochemical studies[1,2] have identified the dystrophin-glycoprotein complex as a key multisubunit complex of proteins linking the cytoskeleton with the extracellular matrix [*see Figure 1*]. Deficiencies in certain components of this system cause sarcolemmal instability resulting in muscle fiber necrosis and specific clinical syndromes.[1-3] The muscular dystrophies are now best classified according to the gene and the defective protein involved; the defective protein may be a component of the nucleus, the cytosol, the cytoskeleton, the sarcolemma, the extracellular matrix, or the intermediate filament. The most common muscular dystrophies, categorized in accordance with current molecular genetic analysis and mode of inheritance, are listed [*see Table 1*]. The role of each protein in supporting, reinforcing, or connecting the nucleus with the cytoskeleton, the sarcolemma, and the extracellular matrix [*see Figure 1*] is discussed in the sections that describe each specific disorder.

X-linked recessive muscular dystrophies

Dystrophinopathies

Dystrophinopathies are caused by a deficiency of dystrophin, a 427 kilodalton rod-shaped cytoskeletal protein. Dystrophin constitutes 5% of all sarcolemmal cytoskeletal proteins and serves to anchor F-actin (the filamentous form of actin) to the plasma membrane (sarcolemma) of muscle [*see Figure 1*].[2-7] Dystrophin appears to reinforce and stabilize the plasma membrane during the stress of muscle contraction by maintaining a mechanical link between the cytoskeleton and the extracellular matrix. Deficiency or absence of dystrophin is associated with various dystrophinopathies, the prototype of which is Duchenne muscular dystrophy (DMD).[4-7]

Duchenne muscular dystrophy Duchenne muscular dystrophy, an X-linked recessive disorder [*see Table 1*], is caused by mutations in the *dystrophin* gene on the short arm of the X chromosome at position Xp21. The *dystrophin* gene spans more than 2,000 kilobases of DNA. In 65% to 70% of cases, DMD results from large deletions (several kilobases) in the *dystrophin* gene and a consequent lack of muscle dystrophin. Spontaneous mutations are also frequently noted in DMD patients.[4-7] The absence of dystrophin weakens and disrupts the sarcolemmal membrane, thereby allowing calcium entry, which causes muscle fiber necrosis. The deletions, detected in the DNA extracted from peripheral blood lymphocytes, disrupt the open reading frame of the messenger RNA (mRNA) triplet codons and result in severe forms of DMD. Partial gene duplications account for 6% of the dystrophin mutations.

A multiplex polymerase chain reaction (PCR) test that examines so-called hot spots in two exons detects almost two thirds of cases of DMD by screening DNA from the blood. However, this technique does not detect small mutations (e.g., point mutations and splicing errors) that produce a truncated dystrophin protein and account for as many as 30% of DMD cases. A highly sensitive single-strand conformation polymorphism method screens all 79 exons of the dystrophin gene and detects 90% of DMD mu-

tations by DNA analysis of the peripheral blood.[7] Similar results are obtained with PCR followed by direct sequence analysis (i.e., single condition amplification internal/primer sequencing [SCAIP]).[8]

DMD occurs in one in 3,000 male births. Affected boys become symptomatic after they begin to walk, usually from 2 to 3 years of age. DMD occurs in girls only in extremely rare circumstances [*see* Female Carriers and Dystrophinopathy in Women,

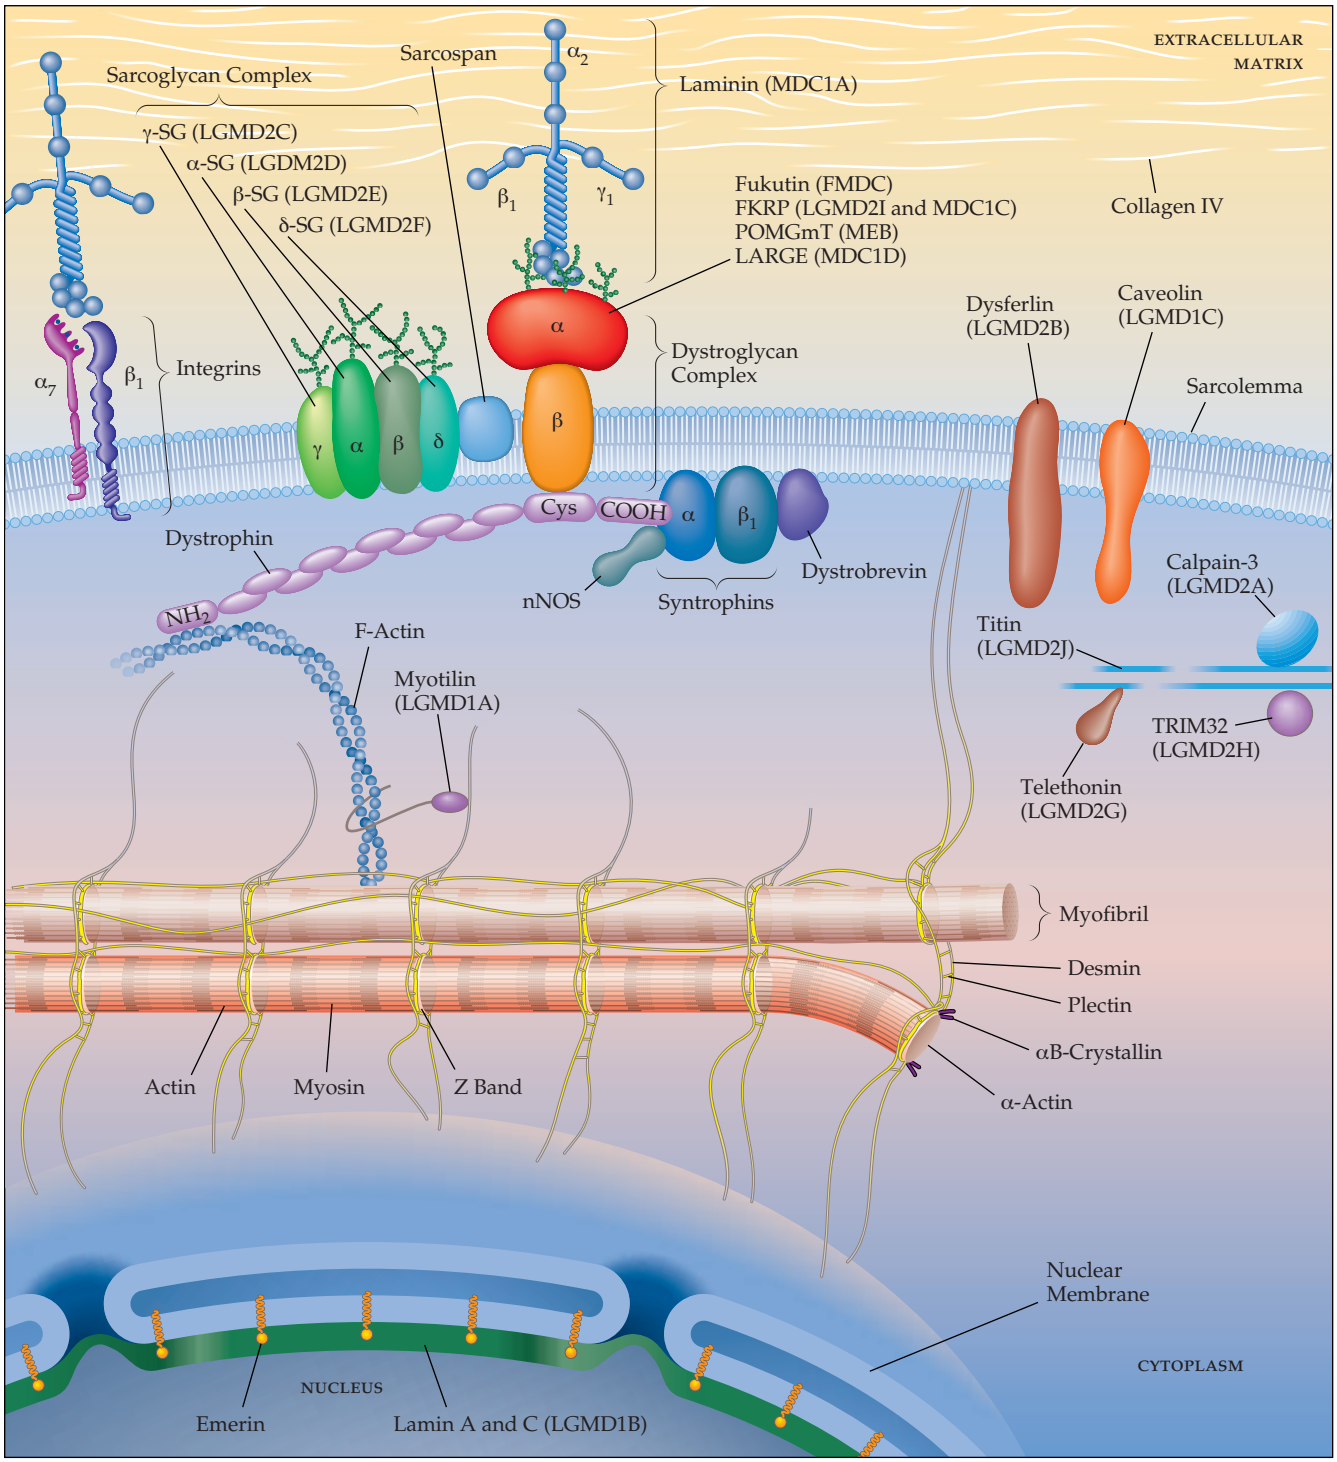

Figure 1 **The current conception of the molecular organization of the dystroglycan complex at the extrajunctional sarcolemma. The deficiency or absence of various proteins results in particular muscular dystrophies. Mutations in the gene for dystrophin produce Duchenne muscular dystrophy (DMD) or Becker muscular dystrophy (BMD); mutations in the genes for the sarcoglycan complex produce various subtypes of limb-girdle muscular dystrophies (LGMDs); and mutations in the gene for α_2-laminin (merosin) produce congenital muscular dystrophy (MDC). Other proteins in the region of the dystrophin-glycoprotein complex include caveolin, neuronal nitric oxide synthase (nNOS), dystrobrevin, the syntrophins, and actin. Collagen VI is a component of the basal lamina. (COOH—carboxyl terminus; Cys—cysteine-rich domain; NH2—amino terminus)**

below]. Clumsiness of gait, lordotic posture, calf hypertrophy, joint contractures, and toe-walking are early manifestations. These are followed by progressive muscle weakness and wasting; getting up from the floor or a low chair, climbing stairs, and arm raising become difficult. Delayed gastric emptying can cause sudden episodes of vomiting and abdominal pain. The disease is relentlessly progressive. By 12 years of age, affected children are wheelchair bound, and by 25 years of age, they die of complications of respiratory failure. Although DMD is a disease of skeletal muscle, cardiac muscle is often affected, and congestive heart failure and arrhythmia may occur later in the disease.[9] Mild, nonprogressive central nervous system involvement also occurs and manifests as irritability, hyperactivity, or cognitive dysfunction. Patients with cognitive impairment have been found to have abnormal electroretinograms owing to defects in a dystrophin isoform expressed in the retina.[7]

Routine laboratory studies of patients with DMD initially show serum creatine kinase (CK) levels as high as 20,000 IU/L, which steadily decline as the muscle mass is depleted. Muscle biopsies reveal a severe destructive myopathy; some $CD8^+$ T cells are often present and invade muscle fibers; a large number of macrophages are associated with phagocytosis of necrotic fibers; the amount of connective tissue is increased; and hypercontracted muscle fibers are common. Diagnosis is confirmed by the absence of dystrophin or by levels lower than 3% of the normal dystrophin concentration; dystrophin levels are demonstrat-

Table 1 Muscular Dystrophies with Gene Locations and Products

Disease	*Gene Locus*	*Gene Product*	*Allelic Disorders*
X-linked recessive muscular dystrophies			
Duchenne muscular dystrophy	Xp21	Dystrophin	Isolated cardiomyopathy, Becker muscular dystrophy
Becker muscular dystrophy	Xp21	Dystrophin	Isolated cardiomyopathy, Duchenne muscular dystrophy
EDMD	Xq28	Emerin	LGMD1B
Autosomal dominant LGMD			
LGMD1A	5q22-5q31	Myotilin	Myofibrillar myopathy
LGMD1B	1q11-21	Lamin A and C	Autosomal dominant EDMD
LGMD1C	3p25	Caveolin-3	
LGMD1D	7q	Unknown	
LGMD1E	7 q	Unknown	
Autosomal recessive LGMD			
LGMD2A	15q15	Calpain-3	
LGMD2B	2p13	Dysferlin	
LGMD2C	13q12	γ-Sarcoglycan	
LGMD2D	17q12-q21	α-Sarcoglycan	
LGMD2E	4q12	β-Sarcoglycan	
LGMD2F	5q33-q34	δ-Sarcoglycan	
LGMD2G	17q11-q12	Telethonin	
LGMD2H	9q3-q34	TRIM32	
LGMD2I	19q13.3	Fukutin-related protein	MDC1C, FMDC
LGMD2J	2q24.3	Titin	
MDCs			
MDC1A "classic" MDC	6q22	α_2-Laminin (merosin)	
MDC1B	12q13	α_7-Integrin	
MDC1C	19q13.3	Fukutin-related protein	LGMD2I
MDC1D		LARGE	
FMDC	9q31-q33	Fukutin	
Muscle-eye-brain disease	1p32-p34	POMGnT	
Walker-Warburg syndrome	?	POMGnT	
Other MDCs			
MDC with rigid spine myopathy	1q35-36	Selenoprotein N	
Bethlem autosomal dominant myopathy	21q22	Collagen VIα1, α2	
Ullrich myopathy	2q37	Collagen VIα3	
Intermediate filament myopathy			
Desmin	2	Desmin	
αB-Crystallin	11q21-23	Desmin, αB-Crystallin	
Epidermolysis bullosa and muscular dystrophy	8q24-qter	Plectin	
Myotilin	5q22-5q31	Myotilin	
Autosomal dominant dystrophies with a unique phenotype			
Myotonic dystrophy			
DM1	19q13	Myotonin-protein kinase	
DM2	3q21	Zinc finger protein 9	
Facioscapulohumeral muscular atrophy	4q35		
Oculopharyngeal muscular dystrophy	14q11.2-q13	Poly A binding protein 2	

EDMD—Emery-Dreifuss muscular dystrophy FMDC—Fukuyama congenital muscular dystrophy LGMD—limb-girdle muscular dystrophy MDC—congenital muscular dystrophy

ed either by immunocytochemistry on muscle biopsy sections or by immunoblots prepared from muscle biopsy specimens stained with antidystrophin antibodies.

Treatment is entirely symptomatic, with emphasis on providing systematic respiratory and physical therapy as well as psychosocial support for both the patient and the family. Genetic counseling is highly appropriate. The presence of endomysial inflammation has prompted the use of steroids to treat DMD. In a controlled study, use of steroids resulted in temporary, mild improvement and slowed disease progress.[10] The long-term use of steroids is restricted by severe side effects, especially obesity, fractures, osteoporosis, diabetes, and hypertension. Deflazacort, a steroid with fewer mineralocorticoid side effects, appears to be a little safer.[11] Creatine supplementation is often used, although its benefit is marginal.[12] In a modified form of gene therapy, human myoblasts carrying normal dystrophin were injected into the muscles of patients with DMD, but the procedure failed to change the recipients' muscle function.[13] Several prospective, randomized, placebo-controlled trials involving repeated myoblast injections to the same muscles failed to demonstrate any improvement in strength. The finding in dystrophic mice that aminoglycoside antibiotics can "read through" nonsense mutations and generate a full-length protein, thereby restoring dystrophin function,[14] led to a trial examining the efficacy of gentamicin therapy in DMD patients who had a premature stop codon. The results were disappointing, although mild reduction in the serum CK level was noted.[15] Future gene therapies may prove efficacious if proper vectors are found that can be used to effectively insert the gene into the muscle.[16]

Becker muscular dystrophy Becker muscular dystrophy (BMD) and DMD are allelic disorders [*see Table 1*], but BMD generally starts later and progresses more slowly.

About 65% of patients with BMD have in-frame deletions in the *dystrophin* gene, but the produced protein is often truncated and only semifunctional.[2-6] Instances of duplication of the *dystrophin* gene have resulted in a longer dystrophin rod. Immunocytochemistry of BMD muscle using antidystrophin antibodies demonstrates preserved but attenuated sarcolemmal staining (not absence, as in DMD) and reveals membrane fragmentation in the immunostained areas of the sarcolemma. Immunoblots detect a reduced amount of a smaller than normal or larger than normal dystrophin.

The age at onset of BMD is variable. Cases may be recognized by as early as 3 years of age or as late as 70 years of age; the mean age at onset is 12 years. The spectrum of phenotypic expression of BMD is also wide. Mild forms manifest only as muscle cramps, exercise intolerance, myoglobulinuria, asymptomatic elevation of serum CK levels, mild muscle weakness, or quadriceps myopathy.[2-6] Calf pain on exercise is often a presenting symptom, and calf enlargement is frequent. Most patients lose ambulation by the age of 40 (range, 10 to 70 years of age). The age of death also varies, from 23 to 89 years (mean age, 42 years). Patients present with proximal muscle weakness and serum CK levels as high as 20 times normal. The muscle biopsy findings are similar to those in DMD patients but are not as severe. In patients younger than 8 years, the presentation of BMD is usually indistinguishable from that of DMD. Cardiac manifestations are common, and cardiomyopathy can be severe. The severity of cardiac symptoms, however, is unrelated to the severity of the myopathy. There is no effective therapy for BMD.

Female carriers and dystrophinopathy in women Careful history and clinical examination of asymptomatic female carriers may reveal mild muscle weakness, muscle cramps, isolated calf hypertrophy, fatigue, and elevated serum CK levels.[3-7] Muscle biopsy reveals dystrophin-negative fibers. In heterozygotes, when the specific deletion-prone exons within the dystrophin gene are amplified using quantitative PCR, the deletions are recognized as a 50% reduction in the intensity of the amplified DNA band, compared with the band of the wild-type exons.[4-7] This method detects about 98% of the deletions. Not infrequently, however, the affected boy's mother does not carry his mutation in her blood. Such cases, linked to newly recognized DMD mutations, account for as many as 20% of new DMD cases and result from maternal gonadal mosaicism; that is, the mutations are found only in the oocytes.[4-7] Women with these mutations may produce affected males or carrier females. Daughters of these women should be studied to identify carriers; however, because the mutation occurs in the oocytes, a woman's sisters could not have inherited the mutations from their parents and need not be studied as potential carriers.[4-7] The manifestation of DMD in heterozygote females occurs when the normal paternal X chromosome that harbors the normal dystrophin gene is inactivated in a large proportion of embryonic cells (Lyon hypothesis). The disease in these females may be as severe as in males.

X-linked dilated cardiomyopathy X-linked dilated cardiomyopathy results from dystrophin deficiency in cardiac but not skeletal muscle. Patients present with a progressive cardiac disorder; congestive heart failure occurs in the second or third decade of life. Female carriers manifesting the disease have a slow-onset cardiomyopathy that presents by the fifth decade. Deletions near exon 1 of the dystrophin gene, which affect the expression or function of dystrophin in cardiac muscle, have been proposed to cause the disease.[4-7]

Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy (EDMD) has two genetic forms, an X-linked recessive disease mapped to Xq28 (XL-EDMD) and a less common autosomal dominant form (AD-EDMD) mapped to 1q11-q23. The two forms are clinically indistinguishable. XL-EDMD is caused by mutations in the nuclear membrane protein emerin [*see Figure 1*][17]; the AD-EDMD is caused by mutations in the *lamin A/C* gene, which encodes two proteins of the nuclear lamina, lamin A and lamin C.[18] Mutations in the *lamin A/C* gene most often cause cardiomyopathy and conduction defects.[19] The integral nuclear membrane proteins interact closely with nuclear lamins, which are intermediate filament proteins found on the nucleic side (inner side) of the nuclear membrane [*see Figure 1*]. Emerin binds lamin A, one of the lamin A/C gene products.

Patients with EDMD present with a triad of symptoms: (1) a humeroperoneal distribution of muscle involvement with prominent wasting and weakness in the biceps, triceps, anterior tibial, and peroneal muscles that progresses slowly in a scapulopelviperoneal pattern to include pectoral and pelvic muscle involvement; (2) early development of contractions at the elbows, flexors, Achilles tendon, neck, and spine, which may occur before there is significant muscle weakness; and (3) cardiac involvement, which presents as conduction defects with bradycardia and a prolonged PR interval. Isolated atrial paralysis strongly suggests EDMD.

Female carriers of XL-EDMD generally do not have skeletal muscle weakness; however, they can develop heart block.

EDMD begins within the first two decades of life. Diagnosis is made on the basis of clinical presentation and muscle biopsy and confirmed by mutation analysis; however, a slightly elevated CK level is suggestive. Muscle biopsies reveal nonspecific myopathic features, but the absence of emerin as evidenced by applying antibodies to emerin on immunocytochemistry or Western blot assay on specimens derived from muscle biopsies of patients and their families may support the diagnosis. Available genetic tests identify the carriers who may have cardiac conduction defects. Prompt recognition and cardiac pacing can prevent sudden death or syncopal attacks.

No specific treatment is available, but physical therapy may slow the development of contractions.

LIMB-GIRDLE MUSCULAR DYSTROPHIES

Limb-girdle muscular dystrophies (LGMD) comprise a heterogenous group of disorders designated as autosomal dominant (LGMD1), autosomal recessive (LGMD2), or congenital (MDC) [*see Table 1*]. [4,6,20]

Autosomal Dominant Limb-Girdle Muscular Dystrophies

The autosomal dominant forms of LGMD1 [*see Table 1*] are generally uncommon disorders representing less than 10% of all LGMDs; they present with slowly progressive proximal and distal muscle weakness and elevations of serum CK levels. They tend to be milder than other LGMD presentations. The diagnosis is made by identifying the missing protein on muscle biopsy preparation and the genetic defect on mutation analysis. There is no specific treatment for this group of disorders.

LGMD1A LGMD1A results from mutations in myotilin, a protein necessary for normal assembly and maintenance of the sarcomere.[21] In addition to proximal and distal muscle weakness, symptoms may include dysarthria, hypophonia, and a nasal voice. This disorder is allelic to the form of myofibrillar myopathy caused by myotilin mutation [*see* Myopathies Due to Mutations in the Intermediate Filament Proteins, *below*].[21]

LGMD1B LGMD1B is caused by mutations in *lamin A/C*; the phenotype for this disorder is identical to that of AD-EDMD [*see* Emery-Dreifuss Muscular Dystrophy, *above*]. In addition to having LGMD symptoms, some patients have familial partial lipodystrophy characterized by reduced subcutaneous fat, insulin resistance, increased triglyceride levels, low levels of high-density lipoproteins (HDLs), diabetes mellitus, and increased risk of atherosclerotic vascular disease.[6]

LGMD1C LGMD1C is caused by mutations in the *caveolin-3* gene.[19,22] Caveolin-3, a 21 to 24 kd internal membrane protein, may play a role in the regulation of muscle glycolysis. Patients may have different clinical phenotypes; they may present with LGMD, isolated hyperCKemia, rippling muscle disease, or distal myopathy.

LGMD1D, 1E, 1F These three disorders represent rare mutations; linkage analysis has determined the chromosomal loci of the causative mutations, but the pertinent genes have not been identified.

Autosomal Recessive Limb-Girdle Muscular Dystrophies

At present, 10 forms of LGMD2 have been identified, and more are likely to be recognized [*see Table 1*].[20,23]

LGMD2A LGMD2A is caused by mutations in the *calpain-3* gene.[24] Calpain deficiency is the most frequent form of LGMD. Calpain-3 is a calcium-activated protease that plays a role in muscle differentiation.

Disease onset occurs in patients 8 to 30 years of age. Patients with calpain-3 deficiency present with weakness in the pelvic girdle muscles, especially glutei, that spares the hip abductors. Scapular winging and posterior thigh involvement are commonly seen. The serum CK level can range from 100 IU/L to more than 9,000 IU/L. Mutations in the gene encoding calpain-3, which is located on chromosome 15q15.1–q15.3, have been identified.[24] The diagnosis is confirmed with Western blot assay. There is no specific treatment for this disorder.

LGMD2B LGMD2B is caused by mutations in the *dysferlin* gene,[25,26] which is a membrane-associated protein not part of the dystrophin-glycoprotein complex [*see Figure 1*]. Dysferlin interacts with caveolin and may be involved in membrane repair. Mutations in the *dysferlin* gene cause two types of myopathy: the Miyoshi myopathy, which is characterized by very high serum CK levels and early involvement of the gastrocnemius muscle, and LGMD2B, which may present as distal and proximal muscle weakness in patients in their late teens or early 20s. Identical mutations can cause either Miyoshi myopathy or LGMD2B.[25,26]

Some patients with dysferlinopathy present with prominent distal weakness but do not have the phenotype of Miyoshi myopathy. Dysferlinopathies are common disorders. The diagnosis is confirmed by finding absence of dysferlin in the sarcolemma of muscle biopsy specimens using immunohistochemistry and antidysferlin antibodies. The defect can also be seen in peripheral blood monocytes using Western blot assay. The absence of dysferlin could lead to perturbation of membrane resealing and interference with the repair of damaged muscle fibers, possibly resulting from defects in vesicular trafficking within the muscle fiber.[6,20,23] There is no specific treatment for this disorder.

LGMD2C, 2D, 2E, 2F These four disorders are caused by mutations in the genes encoding the four members of the sarcoglycan complex: LGMD2C (γ-sarcoglycan gene mutation mapped to chromosome 5q33), LGMD2D (α-sarcoglycan, mapped to 17q12), LGMD2E (β-sarcoglycan, mapped to 4), and LGMD2F (δ-sarcoglycan, mapped to 13q12).[20,23] In all four disorders, the three other components of the sarcoglycan complex are lost or partially absent, but the dystroglycan complex is normal.[4,6,20,23,27]

Mutations in the sarcoglycan genes have been identified in various European and American families who have autosomal recessive LGMDs; these mutations include missense, nonsense, and in-frame deletions that result in an LGMD phenotype of varying clinical severity. The mutations cause an improper assembly of the sarcoglycans with the dystroglycan complex proteins, disrupting the linkage between sarcolemma and extracellular matrix [*see Figure 1*].

The transmembrane components of the sarcoglycan complex are specific to skeletal and cardiac muscle, and their integrity is critical for normal muscle physiology.

The autosomal recessive LGMDs 2D, 2E, and 2F are similar in presentation to a severe form of DMD; they affect males and fe-

males. Patients present with mild to severe weakness of the proximal muscles (especially in the legs), an elevation of the serum CK level to about 3,000 IU/L, dystrophic changes in the muscle, and frequently calf hypertrophy. The age at onset is variable. Results of immunocytochemistry and immunoblot analysis of muscle biopsy specimens for dystrophin are normal, but sarcoglycan is absent or severely deficient. Deficiency in the sarcoglycan proteins—easily detected using the proper antibodies—is found in 20% of patients with the presentation of LGMD. Mutations in the respective genes have been reported in as many as 60% of patients.

There is a great variability in the severity of muscle weakness, which probably depends on the degree of residual sarcoglycan expression. Of note, cardiomyopathy may also be present either as an isolated manifestation of dilated cardiomyopathy or in conjunction with the skeletal myopathy. There is no specific treatment for this disorder.

LGMD2G LGMD2G is caused by mutations in the gene encoding telethonin, which is a sarcomeric protein localized to the Z disk of skeletal muscle. Mutations in the *telethonin* gene cause disruption of the sarcomeric structure.[28] LGMD2G is a rare, relatively mild autosomal recessive disorder.[28]

Disease onset occurs at 2 to 15 years of age, often with distal muscle involvement. Disease progression is variable. Muscle biopsy may show vacuoles within the muscle fibers. The serum CK levels are increased 10-fold to 30-fold above normal. The absence of telethonin as detected by immunocytochemistry confirms the diagnosis.

LGMD2H LGMD2H is a very rare disease identified only in the Manitoba Hutterite population. It is caused by mutations in the *TRIM32* gene (the Tripartite-motif-containing gene) on chromosome 9q33.1, which is probably related to an E3-ubiquitin ligase.[29]

LGMD2I LGMD2I is caused by mutations in the *fukutin-related protein (FKRP)* gene, on chromosome 19q13.32.[30] This disorder and the Fukuyama congenital muscular dystrophy (FMDC) are allelic disorders [*see* Fukuyama MDC, *below*]. Both are related to changes in the α-dystroglycan (α-DG) expression resulting from defects in glycosylation. LGMD2I is not uncommon; in some countries, such as the United Kingdom,[31] it is one of the most common forms of LGMD.

Onset of LGMD2I is variable, occurring in early childhood or in adulthood. Patients present with proximal muscle weakness similar to that found in BMD; enlarged calves; an elevated serum CK level; sometimes, an enlarged tongue; and, very commonly, involvement of the respiratory and cardiac muscles. Intelligence is normal. Secondary reduction of α-DG expression on muscle biopsy or reduced molecular weight protein on immunoblot assay, accompanied by reduction of α_2-laminin by immunocytochemistry, raises suspicion for the diagnosis of LGMD2I.

LGMD2J LGMD2J results from mutations in the *titin* gene, on chromosome 2q31. This disorder, which has been reported in Finland,[32] is allelic with the tibial muscular dystrophy, an automosmal dominant disease that has been reported in Finland.

Congenital Muscular Dystrophies

MDCs are autosomal recessive disorders characterized by muscle weakness in early infancy. Frequently, these disorders are associated with brain malformations and cognitive abnormalities.[33-35] In the neonatal period, the serum CK level is highly elevated, often into the thousands. MDCs represent disorders of neuronal migration, referred to as cobblestone cortex. They result in abnormal glycosylation of α-DG that disrupts the interaction between the membrane and the extracellular matrix in muscle and brain [*see Figure 1*]. They are often referred to as α-dystroglycanopathies [*see Table 1*].

MDC1A MDC1A is the classic form of MDC, accounting for more than 40% of cases of MDC. The disease is linked to chromosome 6q22 and is caused by a defect in merosin (α_2-laminin), which represents the structural backbone of the basement membrane [*see Figure 1*]. In contrast to other forms of MDC, there is no brain malformation or mental retardation in MDC1A. This disease occurs in children but can also occur in young adults. The patients have α_2-laminin deficiency in the skeletal muscle basal lamina.[4,6,35] Some patients have partial merosin deficiency resulting either from a mild mutation or from secondary causes, most often mutations in the genes encoding fukutin or FKRP.

MDC1A may be associated with an MRI-defined leukoencephalopathy (without overt signs of intellectual deterioration), neonatal hypotonia, elevated serum CK levels, delayed motor milestones, axonal neuropathy, and respiratory muscle weakness. The degree of the clinical phenotype varies from moderate to severe. In patients who lack α_2-laminin, the dystroglycan complex is deranged, and consequently, the muscle membrane becomes defective.[4,6,35] Because α_2-laminin, together with β_1-laminin and γ_1-laminin, are also present in Schwann cells, some MDC patients have neuropathic findings.

MDC1B This disorder is caused by mutations in the *α_7-integrin* gene on chromosome 12q13. In patients with this disorder, *α_7-integrin* is absent from the sarcolemma.[36] The clinical presentation of MDC1B is identical to that of MDC1A.

MDC1C MDC1C is a rare disease caused by mutations in *FKRP* on chromosome 19q13.3. MDC1C and LGMD2I are allelic disorders. Onset of muscle weakness occurs in the first week after birth; affected children do not achieve independent ambulation. The disease is marked by respiratory involvement; in contrast to most other MDCs, in MDC1C intelligence may be normal. The disease is suspected by the variable reduction or absence of α-DG in the muscle or reduced α-DG size on immunoblot.[33,34]

MDC1D MDC1D is caused by a mutation in the *LARGE* gene. This is a rare disorder resulting in severe mental retardation and dystrophy. Diagnosis is confirmed by the absence of α-DG on muscle biopsy.[33,34]

Fukuyama MDC This disorder is the most common congenital muscular dystrophy in persons of Japanese descent. FMDC is caused by a mutation in the *fukutin* gene that results in a deficiency of fukutin and decreased glycosylation of α-DG detected by reduced α-DG staining in muscle. Patients have brain malformations, profound mental retardation, and ophthalmologic abnormalities. The disease starts before the age of 9 months, and the patients never learn to walk. They die by the age of 20.[33,34]

Muscle-eye-brain disease Muscle-eye-brain disease (MEB) is caused by a mutation in a glycosyltransferase *POMGnT* gene, which results in a deficiency of α-DG, as confirmed by immuno-

cytochemistry. Patients with MEB present with hypotonia, weakness, mild to moderate hydrocephalus, cortical or cerebellar hypoplasia, and eye abnormalities (e.g., myopia, microphthalmia, and optic nerve hypoplasia).[33,34]

Walker-Warburg syndrome This disorder results from mutations in an O-mannosyl transferase *POMGnT$_1$* gene. It is the most severe MDC, and it shares clinical features of both FMDC and MEB. Patients usually die by age 3.[33,34]

MDC with joint contractures Three forms of MDC are characterized by joint contractions; patients with these disorders have neither a defect in glycosylation nor mental retardation. These diseases are congenital muscular dystrophy with rigid spine syndrome (RSMD), Ullrich myopathy, and Bethlem myopathy. No specific therapy is available.

RSMD results from mutations in selenoprotein N (SEPN$_1$) on chromosome 1q35-36.[37] Patients with this disorder present with muscle weakness; hypotonia; facial weakness; and a distinctive spinal rigidity that results in inability to flex the neck, scoliosis, and respiratory difficulties.

Ullrich myopathy is caused by mutations in one of the polypeptide chains that form collagen VI, which is needed to interact with the extracellular matrix.[38] Patients have excessive distal mobility combined with proximal contractures, rigid spine at birth, and muscle weakness. Muscle biopsy shows absence of collagen VI. Ullrich myopathy and Bethlem myopathy are allelic disorders.

Bethlem myopathy is an autosomal dominant disease caused by mutations in subunits of the extracellular matrix proteins, collagen VI α_1, α_2 and α_3.[39] Disease onset is in childhood or adolescence. Clinical manifestations include mild muscle weakness and contractures in multiple joints, which may be present even at birth.

MYOPATHIES DUE TO MUTATIONS IN THE INTERMEDIATE FILAMENT PROTEINS

Intermediate filaments play a critical role in providing mechanical integration for the myofibrils and in protecting the muscle fiber from repeated mechanical stress. The protein desmin is the chief intermediate filament of the skeletal and cardiac muscle; it maintains the structural and functional integrity of the myofibrils and functions as a cytoskeletal protein, linking Z bands to the plasma membrane [*see Figure 1*]. The heat shock protein αβ-crystallin acts as a chaperone protein in protecting the desmin filaments from stress-induced damage. Desmin filaments encircle the Z bands and are fastened to them and to one another by plectin filaments. Myotilin is a Z-disc protein that interacts with α-actinin and filamin C and directly binds to F-actin [*see Figure 1*].[21]

Defects in intermediate filaments cause myofibrillar myopathies; the prototypic myopathy in this group is the desmin myopathy caused by mutations in the desmin gene.[40-42] The desmin myopathy is of dominant or, rarely, sporadic inheritance; patients may present either with cardiac conduction defects or with a distal-onset skeletal myopathy that progresses to involve proximal, facial, or respiratory muscles.

Mutations in the *αB-crystallin* gene cause a skeletal myopathy similar to desmin myopathy.[43] A case of myopathy associated with mutant plectin has also been reported.[44] Mutations in the myotilin also cause myofibrillar myopathy.[21] As in other myofibrillar myopathies, patients with myotilin mutations present with distal muscle weakness; over time, they develop cardiomyopathy. The diagnosis is suspected when myofibrillar products are accumulated on muscle biopsy, as evidenced by enzyme histochemical stains; it is confirmed by mutation analysis.

There is no specific treatment for these disorders, but early recognition may lead to the identification of potential candidates for insertion of a cardiac pacemaker to prevent sudden death from arrhythmias.

AUTOSOMAL DOMINANT DYSTROPHIES WITH A UNIQUE PHENOTYPE

Myotonic Dystrophy

Myotonic dystrophy (DM) is the most common adult muscular dystrophy. It has an incidence of one per 8,000 population and a prevalence of about five per 100,000 population. The disorder comprises two subsets: DM1 (the classic myotonic dystrophy, Steinert disease) and DM2 (proximal myotonic myopathy [PROMM]) [*see Table 1*]. Both are autosomal dominant multiorgan syndromes; they exhibit striking similarities in clinical manifestations.[45,46]

Diagnosis DM has a unique distribution: (1) ptosis of the eyelids, without extraocular muscle involvement; (2) atrophy of the masseters and the temporal muscles, which results in a unique, narrow facial configuration; (3) sternocleidomastoid muscle atrophy with relatively preserved posterior neck and shoulder girdle muscles (a clinical sign that differentiates DM from facioscapulohumeral muscular dystrophy [FSHD]); (4) distal muscle group atrophy, with slight proximal involvement in the earlier stages of disease; and (5) involvement of the palatal and pharyngeal muscles, which may produce dysarthria and dysphagia.[4,6,45,46]

Myotonia, defined as the slowing of relaxation of a normal muscle contraction, is an important clinical sign. To elicit myotonia during examination, a patient is requested to make a firm hand grip and let it go rapidly; in myotonia, an inability to immediately release the grip is evident. Percussion of the thenar eminence or the extensor digitorum also shows the characteristic slow relaxation of myotonia. Systemic features include cardiac conduction defects, mild mental dysfunction (often with silly or inappropriate behavior and expressions), testicular atrophy, frontal baldness, cataracts, gastrointestinal tract involvement (with delayed motility and emptying), hypersomnia, and a diminished response to hypoxia, which leads to poor concentration and apathy. Clinically DM2 resembles adult DM1; however, the degree of expression of the systemic features may vary from that found in DM1. The most important factors distinguishing DM1 from DM2 are the preferential proximal muscle involvement in DM2, the lack of congenital DM2 forms, the rare incidence of anticipation (see below) in DM2 , and the rare incidence of cognitive dysfunction in DM2.

Children of affected mothers may have reduced fetal movements and early life symptoms of severe hypotonia, feeding difficulties, bilateral facial weakness, and respiratory distress (congenital myotonic dystrophy). Myotonic dystrophy must be distinguished from myotonia congenita, which follows recessive and dominant inheritance patterns. Patients with myotonia congenita present with myotonia and often with muscle hypertrophy. In contrast to myotonic dystrophy, however, myotonia congenita is not associated with muscle weakness, atrophy, or systemic symptoms; it results from a distinct genetic defect that affects chloride channels [*see* Ion Channelopathies, Periodic Paralyses, and Nondystrophic Myotonias, *below*].

The clinical diagnosis of myotonic dystrophy is confirmed by EMG, which shows the myotonic discharges. In difficult cases, slit-lamp examinations may show early cataract formation. The clinical expression of myotonic dystrophy is variable, and the disorder may remain undiagnosed until patients have had children. In DM1 the age at onset is progressively earlier in successive generations (a phenomenon known as anticipation). It is not unusual to see families in which a grandmother's only symptom was early cataracts, and yet her daughter, who did not know that she herself was affected, gave birth to a child with severe congenital myotonic dystrophy. Anticipation is common in DM1 but rare in DM2.

Genetic counseling and genetically targeted therapy DM1 is caused by an unstable CTG (cytosine, thymine, guanine) trinucleotide repeat sequence in the nonprotein coding region of a protein kinase gene, called *DMPK*, on chromosome 19.[45-48] In mildly affected persons, a polymorphic CTG repeat region in the protein kinase gene expands by 50 to 80 repeats; in severely affected persons, more than 2,000 repeats may be present. The size of the CTG expansion increases over generations, which accounts for the anticipation. Measurements of the CTG expansion length can be used to confirm the presence of myotonic dystrophy in family members, for prenatal diagnosis, or for effective genetic counseling of asymptomatic persons who are at risk for myotonic dystrophy.

DM2 is also caused by an expanded repeat in a nonprotein coding region involving a tetranucleotide CCTG repeat in the *ZNF9* gene (zinc finger protein 9), on chromosome 3q21, which codes a transcription factor. The pathogenic factor of DM1 and DM2 is the RNA product of the mutant gene, not the protein product. This is the first disease known to be caused by harmful RNA. The mutant RNA forms inclusions in the nucleus (ribonuclear inclusions). It has been shown that the RNA repeat binds to proteins in the *muscleblind* family and interferes with the normal function of RNA processing.[48] These new data suggest that therapy for DM should be aimed at eliminating the harmful RNA.

Treatment At present, therapy for DM is symptomatic. Emotional support and education regarding the precautions necessary to avoid falls and injuries are essential. Careful monitoring of the cardiac status, especially during the administration of anesthesia, is important. Drugs such as quinine, procainamide, mexiletine, phenytoin, and beta blockers may help relieve the myotonia but not the weakness. Of these agents, mexiletine appears to be the most effective. Testosterone has failed as therapy for DM. Creatine monohydrate may offer minimal relief from myalgia. Modafinil may reduce excessive daytime somnolence, improve mood, and decrease fatigue.

Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy (FSHD) is the third most common form of muscular dystrophy. It usually begins during the second decade of life.

FSHD is linked to chromosome 4q. It is an autosomal dominant disease, but 25% of cases are the result of new mutations.[49] There is significant heterogeneity in this disease. Some patients with the deletion mutation do not have the typical FSHD features [*see* Diagnosis, *below*]; instead they may present with distal myopathies characteristic of LGMD. In some family members, only minimal facial muscle involvement may occur. In 10% of families, germline mosaicism occurs; this means that more than one sibling is affected in a given generation without involvement of either parent.

Diagnosis Patients present with facial muscle weakness (especially of the orbicular muscle of the eye); the extraocular and masseter muscles are spared. Early weakness of the scapular muscles produces prominent scapular winging and gives the shoulders a forward, sloped appearance. Weakness in the anterior tibial muscles, which leads to footdrop, is always present. The disease progresses slowly, and there are long periods of stability. Tongue atrophy is not unusual. Progression occurs in a descending manner: involvement of the shoulder girdle muscles is followed by involvement of the biceps, triceps, and pelvic girdle muscles. A large majority of patients have retinal capillary abnormalities, retinal detachment, and impaired hearing; these findings are more frequent in the infantile form of FSHD.

The serum CK level in FSHD is slightly elevated, and cardiac muscle is spared. Muscle biopsy findings are variable and may include the presence of inflammatory cells. The diagnosis is suspected on clinical grounds and confirmed by DNA analysis. The disease is caused by a deletion within a series of 3.3 kb repeats (D4Z4) on chromosome 4. When the number of repeats falls below a critical number (approximately 10), there is clinical expression of the gene. About 95% of patients have a deletion resulting in a DNA short fragment that is less than 35 kb in length, as determined by the use of certain restriction enzymes.[49]

Treatment In controlled trials, use of prednisone or the $beta_2$-adrenergic agonist albuterol has shown no benefit in the treatment of FSHD**,** although the latter may increase muscle mass.[50]

Oculopharyngeal Muscular Dystrophy

Oculopharyngeal muscular dystrophy (OPMD) is a rare autosomal dominant disease that manifests from the fourth to the sixth decades of life. It is characterized by ptosis and dysphagia, both of which can be severe. Mild distal muscle weakness may occur. The mutation responsible for OPMD is caused by a trinucleotide GCG expansion repeat in the first exon of the poly(A) binding protein 2 gene (*PABP2*), on chromosome 14q11.2. PABP2 is localized to the intramuscular aggregates of muscle fibers and is causally related to these inclusions.[51]

Malignant Hyperthermia

Malignant hyperthermia (MH) occurs in one in 50,000 to one in 100,000 adults during general anesthesia, especially when halothane is used alone or in conjunction with succinylcholine and other depolarizing muscle relaxants. MH is characterized by a rapid increase of aerobic and anaerobic metabolism, during which the body temperature may exceed 43° C (109.4° F). In addition, the concentrations of carbon dioxide and lactate increase (the arterial carbon dioxide tension [P_aCO_2] may exceed 100 mm Hg), and the blood pH may fall below 7.

ETIOLOGY

Triggers for MH include potent volatile anesthetics, such as halothane, enflurane, desflurane, cyclopropane, ether, and succinylcholine. Although MH occurs in some patients without a known muscle disease, patients at risk include those who have multiple congenital musculoskeletal abnormalities, isolated congenital hip dislocation, or central core disease; it has also been known to occur in some patients with DMD or BMD.

PATHOGENESIS

Susceptibility to MH is inherited as an autosomal dominant trait; in up to 50% of the pedigrees, mutant alleles have been found on the ryonidine receptor (RyR),[52] on chromosome 19q13, or on the *CACNA1S* gene on chromosome 1q, which encodes the α_1 subunit of the dihydropyridine-sensitive L-type voltage-dependent calcium channel.[52] Some other loci have been found on a second dihydropyridine receptor locus (*CACNLA*$_2$) on chromosome 7q. MH appears to be precipitated by an inability to control calcium concentrations within the muscle fibers because of a malfunctioning sarcoplasmic reticulum (SR) and mutations in the *RyR* gene. The RyR is the calcium release channel of the SR and bridges the gap between the SR and the transverse tubule. Mutations in the receptor affect communication between the SR and the transverse tubule such that accelerated calcium release from the SR occurs when depolarization of the transverse tubule takes place.

DIAGNOSIS

MH presents with tachycardia, muscle rigidity (caused by muscle contracture that may progress to rigor or death), increased muscle permeability (resulting in increased serum levels of K^+, Ca^+, and Na^+ and muscle edema), excessive release of myoglobulin from the muscle, and myoglobinuria. Trismus or masseter muscle spasm that occurs during induction of anesthesia may be indicative of MH. MH must be distinguished from (1) postanesthetic rhabdomyolysis after muscular stress; (2) toxic reaction to drugs; (3) porphyria; (4) thyroid storm precipitated by surgery and anesthesia; and (5) the neuroleptic malignant syndrome precipitated by psychoactive drugs (e.g., haloperiodol and phenothiazines) that block central dopaminergic pathways.[52]

The in vitro caffeine-halothane contraction test, which is performed on muscle biopsy specimens, is used to screen patients for MH. The sensitivity and specificity of this test, if performed properly, may be as high as 97% and 80%, respectively.[53]

TREATMENT

Dantrolene is an effective treatment for MH. It decreases calcium release from the SR without altering calcium reuptake. Dantrolene use has reduced the mortality of this condition to 7%. The acute episode of MH is treated symptomatically. Intravenous dantrolene (2 to 10 mg/kg every 5 minutes) must be given early in the episode, while there is still adequate muscle perfusion. For patients who are known to be susceptible to MH, dantrolene can be administered at a dosage of 2 mg/kg 10 to 15 minutes before anesthesia administration. The best way to prevent MH episodes in susceptible persons is to use safe anesthetic agents (e.g., nitrous oxide and thiopental) and nondepolarizing muscle relaxants.

Metabolic Myopathies

PRINCIPLES OF MUSCLE ENERGY

As a group, the metabolic myopathies are characterized by deficiency of energy production caused by disorders of glycogen, lipid or mitochondria.

The two major sources of energy for muscle are glycogen and fatty acids whose metabolic pathways converge into acetyl coenzyme A (acetyl-CoA) for final oxidation within the mitochondria through the Krebs cycle and the respiratory chain.[54,55] At rest, muscle energy is mostly derived from oxidation of free fatty acids (FFAs). During high-intensity aerobic exercise, glycogen is the main source of fuel for oxidative phosphorylation. Muscle glycogen stores are depleted after 90 minutes of exercise. If exercise is prolonged, utilization of FFAs and blood glucose increases. Because the availability of FFAs from adipose tissue is almost unlimited, a healthy person can perform moderate exercise for many hours. In patients with metabolic myopathies, symptoms become evident during activities that require increased metabolic demands, such as exercise. Metabolic myopathies result from defects in the metabolism and utilization of glycogen, glucose, or lipid by the muscle. The myopathies caused by glycogen and glucose utilization are categorized according to the sequence of the enzyme defects along the glycogenolytic or glycolytic pathways [*see Figure 2*] and characterized by two main presentations: (1) exercise intolerance, myalgia, cramps, and, finally, myoglobinuria; and (2) fixed, progressive weakness.

GLYCOGENOSES

Muscle Phosphorylase Deficiency

Muscle phosphorylase deficiency (also known as McArdle disease) is the prototypical glycogenosis: glycogen breakdown is inhibited, which leads to pyruvate shortage and impaired energy output [*see Figure 2*]. It is the second most common cause of recurrent myoglobinuria after carnitine palmitoyltransferase (CPT) deficiency.

Diagnosis This autosomal recessive disease presents as exercise intolerance and myoglobinuria in patients older than 15 years. If patients rest briefly after exercise-induced myalgia and stiffness, they can resume activity with better endurance (second-wind phenomenon), owing to increased mobilization and utilization of FFAs and glucose. Fixed muscle weakness may develop later in life. The resting serum CK level is often elevated. The inability to produce venous lactate after exercise has been traditionally examined with the ischemic forearm exercise test. This test, however, is falling out of favor as a diagnostic tool because it produces false positive results, is not specific, can be painful, and may result in focal muscle damage. A nonischemic exercise test is of equal diagnostic value and does not have the drawbacks of the ischemic test. Muscle biopsy shows an absence of phosphorylase, the presence of subsarcolemmal vacuoles, and increased glycogen accumulation. The diagnosis is confirmed by biochemical analysis of muscle and molecular analysis of blood cells. The defect is caused by mutations in the muscle isoform of phosphorylase on chromosome 11q13 and can be detected in the leukocytes in more than 90% of patients.

Treatment No treatment is available for McArdle disease, but aerobic exercise training and a high-protein diet can be helpful. Vitamin B_6 supplementation has also been reported to be helpful. The results of a controlled trial indicate that creatine supplementation may improve muscle function.[56] Most encouraging was the result from a recent study showing that 75 g of sucrose before exercise markedly improved exercise tolerance and may protect against exercise-induced rhabdomyolysis.[57] Experimentations with gene therapy are ongoing.

Phosphofructokinase Deficiency

Phosphofructokinase (PFK) is an enzyme with three genetically distinct structural subunits: M, expressed in muscle, heart, and brain; L, expressed in liver and erythrocytes; and P, expressed in platelets. PFK deficiency is an autosomal recessive disease. Distinct mutations in the M subunit, localized to chro-

mosome 1, cause myopathic symptoms and chronic hemolysis and an increased serum bilirubin level and reticulocyte count.[58]

Diagnosis Because PFK deficiency is a glycolytic defect [*see Figure 2*], the functional consequences of PFK deficiency are similar to those observed in McArdle disease. PFK deficiency should be suspected in patients who experience exercise intolerance, nausea, and myoglobinuria. Fixed muscle weakness may develop later in life. A long history of mild, compensated hemolysis, a high reticulocyte count, a high bilirubin level, and hyperuricemia also indicate PFK deficiency, especially in certain ethnic groups, such as Japanese and Ashkenazi Jews. The diagnosis is confirmed by biochemical studies on muscle and molecular analysis of blood cells.[58]

Treatment There is no specific treatment for PFK deficiency. Patients should avoid high-carbohydrate meals. Recently, a ketogenic diet has been advocated.

Phosphoglycerate Kinase Deficiency

Phosphoglycerate kinase (PGK) deficiency is a rare X-linked recessive disorder that presents with exercise intolerance, episodes of myoglobinuria, hemolytic anemia, myopathy, and, occasionally, mild mental retardation[54,55] [*see Figure 2*].

Phosphoglycerate Mutase Deficiency

Phosphoglycerate mutase (PGAM) deficiency is a very rare disease that affects only muscle. In the United States it has only been identified in African Americans [*see Figure 2*].

Acid Maltase Deficiency

Acid maltase deficiency (AMD) is an autosomal recessive glycogen storage disease caused by deficiency of α-glycosidase, an enzyme encoded in a gene localized to chromosome 17q23.[55] Mutations or small deletions that cause abnormal splicing affect α-glycosidase expression.[59,60]

There are three clinical forms of AMD: infantile, childhood, and adult.[59,60] The infantile form (Pompe disease) presents within the first few months of life as hypotonia, weakness, and enlargement of the heart, tongue, and liver; respiratory and cardiovascular changes lead to death before 2 years of age.

In the childhood form of AMD, patients present with a myopathy characterized by delayed motor milestones, proximal muscle weakness, respiratory muscle involvement, and calf enlargement. The disease leads to death by the second decade of life.

The adult form of AMD manifests in persons older than 20 years as a proximal muscle weakness that resembles polymyositis or limb-girdle dystrophy. Respiratory muscle weakness may be the presenting symptom in one third of AMD cases in adults. Accumulation of glycogen occurs predominantly in the muscle. However, the enzyme is deficient in muscle, liver, heart, and cultured fibroblasts. Patients have elevated serum CK levels; EMG shows prominent myotonic discharges (without clinical myotonia), especially in the paraspinal muscles; and the muscle biopsy shows multiple vacuoles with high glycogen concentrations that react strongly with acid phosphatase, indicative of increased lysosomal activity. Because the utilization of glycogen and glucose is not compromised [*see Figure 2*], AMD causes fixed weakness but not exercise intolerance or myoglobinuria. The muscle fiber undergoes an autophagic process because of abnormalities in the lysosomes.

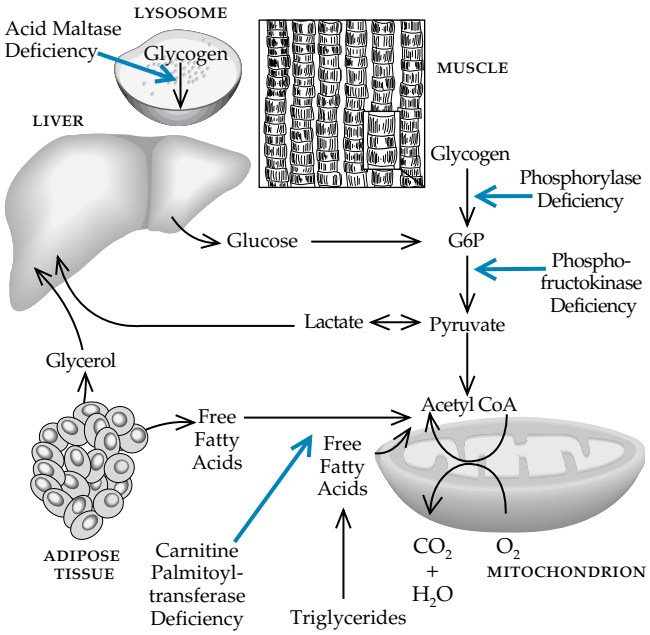

Figure 2 **Scheme of glycogen metabolism, glycolysis, and utilization of fatty acids. Some of the most common myopathies are those that result from deficiencies in the enzymes acid maltase, muscle phosphorylase, phosphofructokinase, and carnitine palmitoyltransferase.**

The diagnosis is confirmed by biochemical assay of the enzyme level in the muscle, cultured fibroblasts, lymphocytes, or urine. Molecular genetic analysis is now available. There is no specific treatment.

Other Rare Glycogenoses

Rare muscle glycogenoses include disorders caused by a deficiency of specific muscle enzymes; these include lactate dehydrogenase (LDH), β-enolase deficiency, debrancher enzyme deficiency, brancher enzyme deficiency, and aldolase deficiency.[55,56]

LIPID STORAGE MYOPATHIES

During sustained exercise, long-chain fatty acids (LCFAs) are the main energy source for the muscle. LCFAs are derived from food or, during fasting conditions, from adipose tissue. LCFAs first need to be transported to the mitochondria for oxidation; their transfer across the inner mitochondrial membrane requires L-carnitine and two enzymes, the carnitine palmitoyltransferases (CPT I and CPT II), which are located in the outer and the inner mitochondrial membranes, respectively. Inside the mitochondria, α-oxidation is facilitated first by the acyl coenzyme A (acyl-CoA) dehydrogenases and then by the transfer of electrons through flavoproteins to the respiratory chain proteins.[54,55] Lipid storage myopathies are caused by impaired fatty acid oxidation by the mitochondria, which results from defects in (1) carnitine and CPT, impairing the transport of fatty acids across the mitochondrial membrane, (2) the enzymes associated with β-oxidation, and (3) the respiratory chain proteins and electron-transferring flavoproteins.[54]

Carnitine Deficiency

Carnitine is mostly derived from the diet, but 25% is synthesized in the liver from lysine and methionine. Carnitine is crucial for the oxidation of LCFAs.[54] The burden of carnitine deficiency

is dysfunction of the liver, heart, and muscle tissues, which are highly dependent on LCFA oxidation.

Primary carnitine deficiency (PCD) is an autosomal recessive disorder caused by mutations in the *SLC22A5* gene, which encodes the sodium ion-dependent cation transporter–2 (OCTN2). These mutations cause a deficiency in the number of functional high-affinity carnitine receptors, which results in defects in carnitine transport across cell membranes.[54] PCD is an uncommon disorder seen more often in childhood.

The most common causes of carnitine deficiency are secondary. They result from (1) defective β-oxidation, which is associated with organic acidurias; (2) mitochondrial dysfunction and defects in the respiratory chain proteins; (3) renal disease, such as Fanconi syndrome, nephropathic cystinosis, or chronic hemodialysis; and (4) treatment with drugs, especially zidovudine (AZT) and valproate.[61]

Diagnosis Patients with PCD experience progressive cardiomyopathy, episodes of hypoketotic hypoglycemia (because of hepatic dysfunction), and proximal myopathic weakness. Lipids accumulate in the muscle, forming small lipid droplets.

Treatment Carnitine supplementation has produced variable treatment results.

Carnitine Palmitoyltransferase Deficiency

In infants, CPT I deficiency manifests as Reye syndrome, with hepatic encephalopathy, hypoketotic hypoglycemia, and hyperammonemia. In adults, carnitine deficiency syndrome most often results from CPT II deficiency, caused by mutations in the gene for CPT II, located on chromosome 11p11-p13.[55] CPT deficiency represents the most common cause of myoglobinuria in young adults. Patients present with attacks of muscle stiffness, cramps, myalgia, and myoglobinuria hours after prolonged or sustained exercise, especially after fasting or when muscle energy depends on utilization of LCFAs and not on the utilization of glycogen or glucose. CPT II–deficient patients do not have reduced exercise tolerance, second-wind phenomena, or warning signs of myalgia that prevent them from further exercise. Between attacks, muscle strength and the serum CK level are normal. Diagnosis is established by measuring CPT II enzyme activity in the muscle or by genetic testing.

It is unclear why CPT deficiency causes intermittent attacks of myoglobinuria and why lipid does not accumulate in the muscle. There is no therapy to prevent myoglobinuric attacks. However, a high-carbohydrate and low-fat diet, frequent meals, and extra carbohydrate intake before and during sustained exercise are recommended.

Mitochondrial Myopathies and Encephalopathies

Mitochondrial myopathies and encephalopathies constitute a diverse group of disorders that affect not only muscle and the nervous system but also other organs. These disorders are characterized by a primary defect in mitochondrial energy output. Genetic defects of mitochondrial energy enzymes may be caused by either nuclear DNA genetic mutations or mitochondrial DNA (mtDNA) mutations. Three types of mutation are responsible for this varied group of diseases: (1) sporadic mtDNA mutations, which cause large-scale deletions of mtDNA, are responsible for multisystem disorders (e.g., Kearns-Sayre syndrome) that can affect the heart, brain, endocrine system, and gastrointestinal tract; (2) maternally inherited mtDNA point mutations, which affect the brain and muscle, cause such disorders as MELAS syndrome (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), MERRF syndrome (myoclonic epilepsy and myopathy with ragged-red fibers), and Leber hereditary optic neuropathy; and (3) tissue-specific depletion of mtDNA causes a multiorgan syndrome that can affect muscle, liver, kidney, and brain.

PATHOGENESIS

The main function of mitochondria is to generate energy for the cell by producing adenosine triphosphate (ATP) through oxidative phosphorylation (OXPHOS). OXPHOS relies on five enzymatic complexes, which include coenzymes and transition metal components (iron, copper), located in the inner mitochondrial membrane. These complexes (designated as I, II, III, IV [cytochrome-c oxidase], and V) sequentially collect and transfer electrons, derived from the catabolism of fats, proteins, and carbohydrates, to O_2. The coupling of oxidation and phosphorylation, which occurs via a proton gradient across the inner mitochondrial membrane, enables the phosphorylation of adenosine diphosphate (ADP) to produce ATP.[62-65]

Mitochondria contain their own extrachromosomal DNA (mtDNA), which is distinct from nuclear DNA. It is a double-stranded, circular molecule that encodes 24 structural RNAs, 2 ribosomal RNAs (rRNAs), 22 transfer RNAs (tRNAs), and 13 mRNAs. The mRNAs encode several polypeptides of the respiratory chain. The remaining subunits of OXPHOS and other mitochondrial proteins are encoded by nuclear genes. The organization of mtDNA is highly compact; it has no introns. As a result, random mutations in mtDNA usually strike a coding sequence and frequently cause disease. In addition, mtDNA is susceptible to oxygen-radical damage because of its proximity to oxygen-radical production by OXPHOS and because of its minimal repair mechanisms.[62-65] The entire mtDNA of each person is exclusively maternally inherited (nonmendelian inheritance) because the sperm cell contributes only its nuclear DNA to the zygote during fertilization. Occasionally, diseases of OXPHOS may occur as the result of mutations in some of the nuclear-encoded OXPHOS genes; such diseases follow a mendelian inheritance pattern.

Muscle biopsy results of patients with OXPHOS defects are abnormal and reveal ragged-red fibers on trichrome stain, or ragged-blue fibers on succinate dehydrogenase stain. These findings result from the accumulation of mitochondria in the periphery of the muscle fibers, and accumulation of fibers that are negative for cytochrome-c oxidase. On electron microscopy, the mitochondria have paracrystalline inclusions or abnormal cristae.[44] Specific mutations, deletions, or depletions are detected by study of the mtDNA.

SPORADIC MTDNA DELETIONS

Kearns-Sayre Syndrome

Kearns-Sayre syndrome presents in patients younger than 20 years as ophthalmoplegia, ptosis, retinitis pigmentosa, and myopathic weakness. Short stature, cardiac conduction defects, elevated levels of cerebrospinal fluid protein, cerebellar syndromes, sensorineural hearing loss, and elevated serum lactate levels are common. Muscle biopsy reveals ragged-red fibers. In persons older than 20 years in whom ophthalmoplegia is the predominant phenotype, KSS is classified as chronic progressive external ophthalmoplegia (CPEO).[62-65]

KSS and the more limited CPEO are characterized by a single, large mtDNA deletion that is between nine and 50 base pairs. Most often, the deletion occurs sporadically and is rarely maternally inherited. OXPHOS is defective, and the levels of activity of complex I and complex IV are reduced. Variants of CPEO, which are characterized by multiple mtDNA deletions in the nuclear DNA–encoded genes of OXPHOS, may be transmitted in an autosomal dominant or recessive fashion.

Mitochondrial Neurogastrointestinal Encephalomyopathy

A special form of autosomal recessive CPEO is a multisystem syndrome known as MNGIE (mitochondrial neurogastrointestinal encephalomyopathy). Disease can occur in persons 20 to 60 years of age. Patients present with progressive external ophthalmoplegia accompanied by intestinal dysfunction, peripheral neuropathy, and leukoencephalopathy. Patients with MNGIE have increased serum levels of thymidine and decreased activity of thymidine phosphorylase on leukocytes; these findings, along with mutations in the thymidine phosphorylase nuclear gene, which impair the replication and repair of mtDNA, confirm the diagnosis.

MATERNALLY INHERITED MTDNA POINT MUTATIONS

MELAS Syndrome

Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes combine to form the MELAS syndrome. Muscle biopsies in affected patients reveal ragged-red fibers. Patients may also have hearing loss, short stature, cardiomyopathy, diabetes, or pigmentary retinal degenerations resembling KSS or CPEO. As many as 80% of patients have mtDNA point mutations in the tRNA leucine gene. These mutations, like the other mtDNA mutations, are heteroplasmic, meaning that normal and mutant mtDNA coexist in a cell. A cell normally contains between two and 10 mtDNA molecules, which allows an otherwise lethal mutation (i.e., lethal impairment of OXPHOS) to persist in viable organisms.

MERRF Syndrome

The MERRF syndrome consists of myoclonic epilepsy and myopathy with ragged-red fibers. In addition, ataxia, dementia, deafness, weakness, wasting, and cardiac abnormalities are common, although their expression is variable and depends on the degree of heteroplasmy. Approximately 80% of MERRF patients have a mutation in the tRNA lysine gene.[48]

Leber Hereditary Optic Neuropathy

Leber hereditary optic neuropathy (LHON) is the most common cause of blindness in young adults (the prevalence is higher in men than in women). Patients present with painless, subacute, and bilateral vision loss. In at least 90% of the families, several mtDNA mutations have been observed. Some patients with LHON and distinct mutations may have other associated conditions, such as encephalopathy, deafness, ataxia, myelopathy, or dystonia.[62-65]

MTDNA DEPLETION SYNDROME

mtDNA depletion syndrome is an autosomal recessive disorder that is usually fatal by 3 years of age. It affects the muscle, liver, kidneys, and brain; death is caused by encephalopathy or respiratory failure. The mitochondrial defect is quantitative rather than qualitative. The disorder results from imbalances in the mitochondrial nucleotide pool which, in turn, impair mtDNA replication and repair.

Treatment of all the mitochondrial disorders is supportive and symptomatic. Ubiquinone, creatine, vitamins C and K_3, carnitine, and vitamin E are often used. Moderate exercises are recommended.

Ion Channelopathies, Periodic Paralyses, and Nondystrophic Myotonias

Ion channelopathies that affect muscle-fiber excitability produce a range of disorders that include periodic paralysis, myotonia, and episodic ataxia-myokymia. These represent a rare group of disorders that usually start in childhood and typically present with attacks of paralysis. During paralytic attacks, alterations in the level of serum potassium are common. Myotonia is also common in some forms. The disorders are suspected when there is a history of similar attacks in family members, especially if attacks are provoked by rest after exercise or certain carbohydrate-enriched meals; the diagnosis is confirmed by genetic analysis of blood DNA.

PATHOGENESIS

After excitation at the neuromuscular junction, action potentials are propagated through ion fluxes across the sarcolemmal membrane, which depend on the opening (activation) and closing (inactivation) of the appropriate ion channel. In muscle and nerve cells, opening of the voltage-gated Na^+ channel causes a rapid increase in Na^+ permeability and hence membrane depolarization. For the membrane to initiate the next action potential, however, the Na^+ channels must close.[66-68] The voltage-gated K^+ channels open and K^+ ions flow out of the cell, creating a hyperpolarized voltage across the cell membrane. The Cl^- channels contribute to repolarization by stabilizing the membrane potential.

Disturbances in membrane excitability can lead to myotonia with or without periodic paralysis. Myotonia, as a symptom in nondystrophic myotonias, occurs in sodium or chloride channel disorders. Myotonia manifests as painless stiffness after a period of inactivity, which improves after continuous movements (warm-up phenomenon). Myotonia that develops after exposure to cold and worsens with exercise is called paradoxical myotonia. The other manifestation of membrane excitability is periodic paralysis, characterized by paralytic attacks associated with either hyperkalemia caused by mutations in the Na^+ channel genes or hypokalemia caused by mutations in the voltage-gated calcium channel gene. Patients with cardiodysrhythmic periodic paralysis (Anderson syndrome) and those with episodic ataxia-myokymia have mutations in the potassium channel gene.

SODIUM CHANNEL DISORDERS

In the skeletal muscle, sodium channel disorders result from mutations in *SCN4A*, the sodium channel gene. Mutations in *SCN4A* can produce the clinical phenotypes of hyperkalemic and normokalemic periodic paralysis (hyperKPP), paramyotonia congenita, and potassium-aggravated myotonia (previously called acetazolamide-responsive myotonia or myotonia fluctuans). Patients with these allelic disorders demonstrate varying degrees of myotonia of eye closure, chewing, swallowing, and gripping of the hands.

HyperKPP and paramyotonia congenita (also called paradoxical myotonia) are autosomal dominant diseases. They are characterized by attacks of weakness that begin in infancy or early childhood. HyperKPP attacks are precipitated by rest after exercise, stress, administration of K^+, cold, and certain foods. Mild myotonia may be present, and paradoxical myotonia of the eyelids is common. Patients with paramyotonia congenita develop paradoxical myotonia, which worsens with repetitive exercise; when exposed to cold, they develop stiffness, especially in the face, tongue, eyelids, and hands. Episodic attacks of weakness are also common, resembling those seen with hyperKPP, and they are accompanied by myotonia. The symptoms in patients with paramyotonia congenita, including the frequency of attacks and the interattack weakness, are treated with carbonic anhydrase inhibitors, such as acetazolamide and dichlorphenamide.[69]

POTASSIUM CHANNEL DISORDERS

Point mutations in the potassium channel gene *KCNA1,* on chromosome 12, have been associated with episodic ataxia-myokymia. Mutations in other potassium channel genes cause long QT syndrome. Andersen syndrome is caused by mutations in potassium channel gene *KCNJ2*, which encodes the inward-rectifying K^+ channel gene, *Kir21*, on chromosome 17q. Andersen syndrome is characterized by periodic paralysis, which may be accompanied by fixed weakness; long QT syndrome with cardiac ventricular arrhythmias; and dysmorphic craniofacial features, such as micrognathia, low-set ears, short stature, and syndactyly. Anderson syndrome, as well as the other potassium channel disorders, usually responds to carbonic anhydrase inhibitors.

CALCIUM CHANNEL DISORDERS

Calcium channel disorders present as hypokalemic periodic paralysis (hypoKPP). This is an autosomal dominant disease localized to chromosome 1q31-q32 and caused by mutations in the dihydropyridine-sensitive L-type calcium channel gene.[70] HypoKPP presents as episodic paralytic attacks that begin in the first or second decade of life, usually during sleep. They are precipitated by high carbohydrate consumption, rest after exercise, and excitement. During attacks, the serum K^+ concentration decreases and urinary retention of Na^+ and water occurs. Between attacks, many patients develop a permanent, slowly progressive myopathy.

The disease should be distinguished from all the causes of secondary hypokalemias that can cause weakness, including diuretic use, kidney disease, hyperaldosteronism, licorice intoxication, laxative abuse, and potassium-losing GI diseases. In secondary hypokalemias, the paralytic attacks do not occur unless the K^+ concentration falls below 3 mEq (usually below 2.5 mEq). In contrast, in hypoKPP the attacks occur even when the serum K^+ concentration is closer to the normal level.

HypoKPP can be associated with thyrotoxicosis, especially in persons of Asian descent. In such cases, hypoKPP responds to propranolol or resolves after reversion of the patient to a euthyroid state. Although hypoKPP is dominantly inherited, one third of patients may have sporadic disease. A provocation test, with insulin and glucose infusion under cardiac and respiratory monitoring, was necessary for the diagnosis until genetic identification became available. The frequency of the attacks and the interattack weakness respond to carbonic anhydrase inhibitor, acetazolamide, and dichlorphenamide.[71,72]

CHLORIDE CHANNEL DISORDERS

Chloride channel disorders include autosomal dominant myotonia congenita (Thomsen disease), which occurs in the first decade of life and is often associated with muscle hypertrophy, and autosomal recessive myotonia congenita (Becker-type myotonia) (BMD), which comes later in life and can be more severe.[67,68] Both of these diseases have been linked to distinct mutations on the chloride channel gene on chromosome 7q32, designated as the *CLCN1* locus.[66-68] Patients with these disorders do not have periodic paralysis or weakness, although in Becker-type myotonia, transient but sometimes severe weakness may occur; such weakness improves with exercise. Typical percussion myotonia and generalized myotonia, experienced by the patient as stiffness and hypertrophy of the legs and buttocks, are characteristic findings. Myotonic stiffness improves with exercise (warm-up phenomenon). The myotonic symptoms may variably respond to phenytoin, mexiletine, or tocainide.

ISOLATED NEUROMYOTONIA (ISAAC DISEASE)

Autoimmune acquired neuromyotonia occurs as an isolated neuromyotonia (also called Isaac disease) and as neuromyotonia associated with neuropathy, myasthenia gravis, and thymoma [*see* Neuromyotonia with K^+ Channel Autoantibodies (Isaac Syndrome), *below*]. The isolated form of the disease is characterized by (1) myokymia, which is a rippling muscle twitching that occurs during rest; (2) impaired muscle relaxation and stiffness at rest; (3) painful cramps; and (4) increased sweating. It is caused by hyperactivity of the peripheral motor nerve endings, and it is correctly called neuromyotonia because the continuous muscle fiber activity is abolished by curare but not by proximal nerve block. Neuromyotonia occurs sporadically, but familial cases have occurred.[73,74] Electromyography confirms the presence of neuromyotonia, and determination of K^+ channel autoantibodies identifies the autoimmune nature of the disease.

Treatment is symptomatic (phenytoin, carbamazepine, and mexiletine are used); in resistant cases, immunotherapy with intravenous immunoglobulin or plasmapheresis may be necessary.

Drug-Induced Toxic Myopathies

Although drug-induced myopathies are not uncommon, their diagnosis may be elusive in clinical practice. The clinician should suspect a toxic myopathy in a patient who does not have a preexisting muscle disease, whose myopathy develops acutely or subacutely (sometimes slowly) with muscle pain and weakness, who manifests myoglobinuria after the administration of a known or putative myotoxic agent, or who improves upon withdrawal of a putative toxic drug [*see Table 2*].[75,76] Myotoxic agents can cause myopathy by directly affecting a muscle organelle, such as the mitochondrion or thick filaments; by altering muscle antigens, thereby inducing an immunologic inflammatory reaction; or by inducing such secondary systemic effects as electrolyte disturbance, nutritional deprivation (e.g., the agent competes with vitamins), and malabsorption. Several drugs can be myotoxic either alone or in combination with other drugs. In addition to knowing which drugs are myotoxic, the clinician should always be alert to the potential myotoxicity of newly marketed drugs. The most common myotoxic drugs are discussed in the following sections.

ZIDOVUDINE MYOPATHY AND TOXICITY OF OTHER NUCLEOSIDE ANALOGUES

The clinical features of zidovudine myopathy are proximal muscle weakness, myalgia (predominantly in the thighs and

calves), fatigue, myopathic changes on EMG, and elevated serum CK levels, which often increase with exercise.[61,77-79] Weight loss and elevation of the serum lactate level may herald the onset of zidovudine myopathy. Zidovudine can cause myopathic symptoms after 1 year of administration. Symptoms resolve 4 to 6 weeks after zidovudine is discontinued.[78,79]

The unique histologic features of zidovudine myopathy are ragged-red fibers containing lipid accumulation and numerous cytochrome-c oxidase–negative fibers; both findings are suggestive of mitochondrial abnormalities.[61,78,79] Zidovudine is a DNA-chain terminator that inhibits the γ-DNA polymerase in the mitochondrial matrix; termination of mtDNA synthesis then occurs, and as much as a 78% depletion of muscle mtDNA results.[78,79] Among the other nucleoside analogues used in the treatment of AIDS, stavudine may also be myotoxic. The others, such as dideoxycytosine, dideoxyinosine, and lamivudine, cause a painful axonal neuropathy but not myopathy. A syndrome of lipodystrophy, lactic acidosis, and myopathy has been seen with highly active antiretroviral therapy consisting of one of the newly introduced protease inhibitors in combination with two nucleoside analogues, especially stavudine (d4T).[80]

MYOPATHY CAUSED BY CHOLESTEROL-LOWERING AGENTS

Several cholesterol-lowering drugs [*see Table 2*] cause an often reversible myopathy that is characterized by proximal muscle weakness, myalgia, elevation of the serum CK level, and myopathic changes on EMG. Because cholesterol is the major sterol constituent of muscle membranes, reduction of the normal cholesterol pool available for membrane synthesis can increase membrane fluidity, leading to an unstable sarcolemma, myotonic discharges, and, in advanced cases, rhabdomyolysis. Statins also inhibit the production of ubiquinone, thereby interfering with mitochondrial ATP and energy metabolism within the myocyte. EMG findings include fibrillation potentials and myotonic or complex repetitive discharges.[76,77,81,82] Gradual recovery can occur after withdrawal of the offending drug.

Although a transient increase in the serum CK level and myalgia is not unusual after treatment with statins, the drugs have been associated with clinically overt myopathic symptoms in fewer than 5% of treated patients. Coadministration of cyclosporine and lovastatin to patients with heart or kidney transplants and hyperlipidemia increased the incidence of myopathy with rhabdomyolysis. In a recent review, cerivastatin was the statin most commonly associated with myopathic symptoms; this was followed sequentially by lovastatin, fluvastatin, atorvastatin, simvastatin, and pravastatin.[81,82] The risk for statin-induced myopathy is increased with use of higher doses, statins that have a lipophilic action (which includes all except pravastatin and rosuvastatin), and concomitant therapy with drugs such as gemfibrozil, colchicine, or cyclosporine; elderly patients are at increased risk for myopathy when treated with statins.[81,82]

MYOPATHY ASSOCIATED WITH CRITICAL ILLNESS

In patients with prolonged paralysis induced by such nondepolarizing blocking agents as pancuronium, an acute myopathy may develop after mechanical ventilation is discontinued. Most of these patients received high doses of corticosteroids for status asthmaticus or another systemic illness for which artificial paralysis was induced to secure an aggressive pulmonary toilet.[77,82,83] The combination of blocking agents and corticosteroids has been consistently implicated in the development of critical illness myopathy, but sometimes patients have had only minimal exposure to one of these two agents.[77,82-85]

Table 2 Myopathy-Inducing Agents

- *Prescribed Medications and Vitamins*
  - Amiodarone
  - Amphetamines
  - ε-Aminocaproic acid
  - Chloroquine
  - Colchicine
  - Cyclosporine
  - Emetine
  - Fialuridine
  - Hypocholesterolemic drugs
    - 20,25-Diazacholesterol
    - Fibric acid derivatives
      - Bezafibrate
      - Biclofibrate
      - Clofibrate
      - Etofibrate
      - Fenofibrate
      - Gemfibrozil
    - 3-Hydroxy-3-methylglutaryl coenzyme A inhibitors
      - Lovastatin
      - Pravastatin
      - Simvastatin
    - Nicotinic acid (niacin)
  - Interferon alfa
  - Isotretinoin
  - Labetalol
  - Minocycline
  - Neuroleptics (in the absence of neuroleptic malignant syndrome)
    - Clozapine
    - Risperidone
    - Olanzapine
    - Haloperidol
    - Loxapine
    - Melperone
  - D-Penicillamine
  - Pancuronium
  - Procainamide
  - Steroids
    - Prednisone
    - Dexamethasone
  - Vincristine
  - Vitamin E
  - Zidovudine (AZT)
- *Nonprescription Drugs*
  - Cocaine
  - Ethanol
  - Heroin
  - Phencyclidine (PCP)
- *Intramuscular Injections*
  - Meperidine
  - Pentazocine
- *Other*
  - Diuretics
  - Laxatives
  - Licorice

The clinical presentation of myopathy associated with critical illness is characterized by severe generalized weakness of all extremities, failure to wean from mechanical ventilation, muscular atrophy, a normal or moderately elevated serum CK level, and myopathic changes on EMG. The weakness usually slowly improves.[77,82-85] Blocking agent–corticosteroid myopathy may coexist with an axonal neuropathy, but the consensus now is that the paralytic disease is predominantly caused by a myopathy. The differential diagnosis should include neuromuscular transmission defects, such as myasthenia gravis; Guillain-Barré syndrome; inflammatory or acute necrotizing myopathy; and periodic paralysis. Muscle biopsy shows extensive morphologic abnormalities, which result from the selective loss of thick filaments without signs of necrosis, inflammation, or phagocytosis. With adenosine triphosphatase (ATPase) staining, striking areas of central pallor are seen in many fibers.[77] Calpain expression is markedly enhanced, implicating an altered calcium homeostasis and enhanced proteolysis. Electron microscopy reveals selective and extensive loss of thick myofilaments; the thin myofilaments and Z disks are preserved.

High doses of steroids should be used with caution in patients receiving paralytic agents for prolonged periods. The myopathy improves slowly with intense rehabilitation.

VITAMIN E INTOXICATION

A necrotizing myopathy with proximal muscle weakness and elevation of the serum CK level has been reported to occur in pa-

tients self-medicated with high doses of vitamin E.[75,76,86] This condition is very rare and has not been clearly substantiated.

CHLOROQUINE MYOPATHY

The antimalarial drug chloroquine is often used by rheumatologists for the treatment of various collagen vascular diseases. It can cause macular and corneal degeneration, peripheral neuropathy, and myopathy. The myopathy is seen with long-term administration of high doses of chloroquine (500 mg daily). The myopathy has interesting morphologic features that resemble those that occur with acid maltase deficiency: multiple vacuoles with acid phosphatase-positive material, myeloid bodies within the vacuoles, and enlarged lysosomes with increased lysosomal enzyme activity.[75]

COLCHICINE MYOPATHY

Colchicine interferes with the growth of microtubules, thereby affecting mitosis. After long-term use, colchicine causes a vacuolar myopathy and an axonal neuropathy, often in patients who are between 50 and 70 years of age and who have gout and a mild, chronic renal insufficiency.[87] The concomitant use of statins increases the risk of myopathy. Symptoms include proximal muscle weakness, elevation of the serum CK level, distal sensory involvement, and areflexia. Symptoms resolve 4 to 6 weeks after discontinuance of the drug.

STEROID-INDUCED MYOPATHY

Patients with hyperadrenocorticism (i.e., Cushing syndrome) may develop weakness. Similar changes can occur during long-term administration of prednisone (usually at dosages greater than 20 mg daily) or dexamethasone, especially in poorly mobilized patients. The steroid-induced myopathic weakness is mild, spares the neck flexor muscles,[77] and may aggravate the weakness caused by the underlying immune disease or malignancy for which steroids are administered. Lowering the dose of the drug reverses the myopathy. The serum CK level is normal, the muscle biopsy shows only type II fiber atrophy, and the EMG is not informative.

MYOPATHY ASSOCIATED WITH ALCOHOLISM

Patients with alcoholism most often develop an axonal peripheral neuropathy and, occasionally, an acute or chronic myopathy. The acute myopathy presents with tightly swollen, painful, and tender muscles; it occurs in chronic alcoholics, frequently after a heavy bout of drinking. Acute myopathy can be localized (resembling thrombophlebitis) or generalized and severe (presenting as rhabdomyolysis and myoglobinuria).[75,82] It can recur if the patient resumes drinking. Acute myopathy in patients with alcoholism may also be related to hypokalemia when the serum K^+ concentration is below 2.5 mEq. This myopathy is painless, not accompanied by muscle swelling, and quickly reversible.

Proximal muscle weakness in patients with long-term alcoholism is often multifactorial and not necessarily a primary toxic effect of alcohol to the muscle; for example, poor nutrition, inactivity, or neurogenic disease may be involved.[58] Histologically, type II fiber atrophy is most common. Some long-term drinkers may experience an asymptomatic elevation of the serum CK level—as much as 20 times higher than normal levels—that is aggravated by physical activity.

DRUG-INDUCED INFLAMMATORY MYOPATHY

Patients with Wilson disease, rheumatoid arthritis, or progressive systemic sclerosis can develop polymyositis or myasthenia gravis during treatment with D-penicillamine. The disease responds to discontinuance of the drug or the administration of steroids. In single, unconfirmed reports, procainamide, propylthiouracil, and cimetidine have been reported to cause a polymyositis-like disease.

Contaminated L-tryptophan was responsible for an outbreak of a syndrome of eosinophilic fasciitis, myositis, thickening of the skin, axonal neuropathy, and other systemic manifestations. An immune process against fibroblasts in the extracellular matrix triggered by the contaminant was implicated in the cause of this syndrome, called the eosinophilia-myalgia syndrome.[88] The disease has left several patients with residual skin thickening, myalgia, and fatigue. Macrophagic myofasciitis is an entity encountered in France and resulting from aluminum-containing vaccines. Patients present with myalgia and fatigue. Biopsy at the sites of vaccines shows accumulation of macrophages in the epimysium, perimysium, and endomysium.

Interferon alfa (IFN-α), now commonly used for certain malignancies and hepatitis, causes fatigue, arthralgias, and, at times, myalgia. The exact mechanism of the muscle fatigue and myalgia is unknown, but rare cases of myositis and myasthenia-like disease have been noted. The cytokine interleukin-2, used for renal cell carcinoma, can exacerbate preexisting polymyositis or dermatomyositis.

Disorders of Neuromuscular Transmission

The main areas of the neuromuscular junction are (1) the presynaptic region, with active zones that contain parallel double rows of voltage-gated calcium channels (VGCCs) and synaptic vesicles that contain acetylcholine (ACh), (2) the synaptic space, and (3) the postsynaptic region, consisting of the junctional folds that contain the acetylcholine receptors (AChRs) [*see Figure 3*]. Functionally, neuromuscular transmission depends on the release of ACh from the motor nerve terminal, interaction of ACh with AChR, and the resulting depolarization of the muscle fiber. In a resting state, there is a random release of ACh from a single vesicle. ACh binds to AChR and opens its cation-selective ion channel, allowing Na^+ to enter the end-plate region; this creates a depolarization potential called the miniature end-plate potential.[89-91] ACh is then disassociated from AChR and rapidly hydrolyzed by acetylcholinesterase (AChE). When AChE is inhibited, as occurs during treatment with such anticholinesterase drugs as pyridostigmine, more ACh molecules bind to AChR and open multiple ion channels.

When the action potential reaches the nerve terminal, the VGCC opens and Ca^{2+} ions flow into the nerve terminal. The entry of Ca^{2+} triggers the fusion and exocytosis of the synaptic vesicles and the release of ACh molecules (each vesicle contains 6,000 to 10,000 ACh molecules) that diffuse and spread over the junctional folds. The simultaneous release of ACh by the fusion of 50 to 300 vesicles results in the end-plate potential (EPP). If the EPP exceeds a certain threshold, a muscle action potential (MAP) triggers muscle contraction. Normally, the interactions between the released ACh and ACR are more than sufficient to produce an EPP capable of triggering an MAP. The difference between the actual EPP amplitude and the EPP amplitude required to trigger an MAP is called the safety margin.

There are three main disorders affecting neuromuscular transmission: myasthenia gravis (MG), the Lambert-Eaton myasthenic syndrome (LEMS), and the various congenital myasthenic syndromes.

Myasthenia gravis (MG) is a prototypical autoimmune disease; it fulfills all the immunologic criteria [89-91]: the antigen is AChR; antibodies directed against AChR are detected and measured in the serum of affected patients; the disease can be transmitted to animals with the patient's pathogenic IgG; serum immunoglobulin binds to AChR, causing a complement-fixing destruction of the receptors, which affects neuromuscular transmission; and removal of the antibodies results in clinical improvement.

In MG, antibodies against AChR reduce the number of available receptors. Consequently, the released ACh cannot bind to enough AChR; thus, the generated EPP is insufficient to trigger an MAP, and neuromuscular transmission fails. When neuromuscular transmission failure occurs in many neuromuscular junctions, the muscle cannot be fully activated; this results in fatigue and muscle weakness. During repetitive nerve stimulation in healthy persons, the amount of ACh released is reduced after the first few impulses, because the nerve cannot sustain its original release rate; however, neuromuscular transmission does not fail, because the safety margin is sufficient. In patients with MG, the EPP is already small. During repetitive nerve stimulation, the EPP is depressed further because the decreasing amounts of ACh released per subsequent impulse are not sufficient to bind to the reduced number of AChR; this results in a further decrement of the MAP. Repetitive nerve stimulation studies are used diagnostically to demonstrate impaired neuromuscular transmission in MG patients. Because MG affects the nicotinic AChR at the neuromuscular junction, only motor systems are affected.

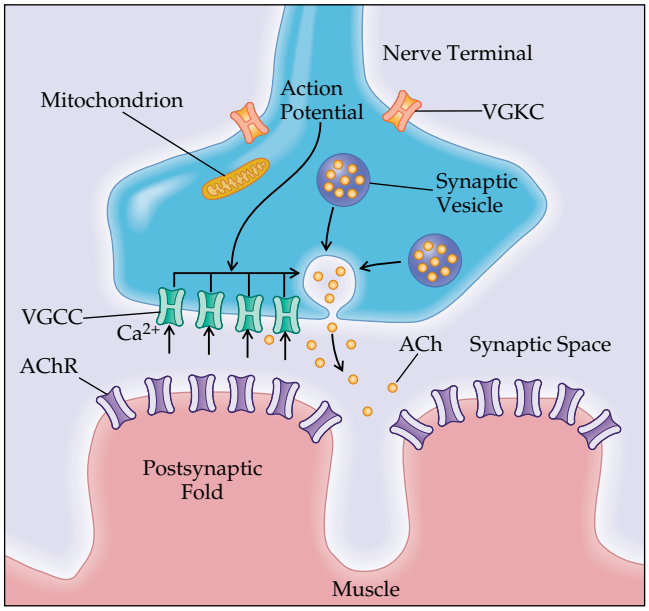

Figure 3 **Transmission from the nerve ending at the neuromuscular junction takes place at localized sites (active zones). The presynaptic region contains the voltage-gated calcium channels (VGCCs) and synaptic vesicles that hold 6,000 to 8,000 molecules of the neurotransmitter acetylcholine (ACh). When the action potential reaches the nerve terminal, the VGCCs open and Ca^{2+} flows into the nerve terminal. The entry of Ca^{2+} triggers the fusion and exocytosis of the synaptic vesicles. ACh is released into the synaptic space and binds to the acetylcholine receptor (AChR) located in the end-plate region of the muscle membrane (postsynaptic folds). Activation of AChR by ACh causes ions to flow through AChR across the membrane, initiating the electrical response of the muscle called the end-plate potential (EPP). The EPP spreads from the end-plate region to the surrounding muscle membrane and initiates the impulse response of the muscle that ultimately leads to muscle contraction.**

Epidemiology

The prevalence of MG is approximately four to six cases per 100,000 population. The annual incidence varies, but two peaks are recognized: one is associated with women in their second or third decade of life, and the other is mostly associated with men older than 60 years. The mean age at onset is 28 years in women and 42 years in men. There is recent documentation that MG is underdiagnosed in patients older than 70 years.[92] Classic autoimmune MG can also develop during childhood and responds well to thymectomy or anticholinesterases. MG can be associated with thymoma in as many as 15% of adult patients, or it may develop after removal of a thymoma. In addition, as many as 5% of patients with MG have other systemic autoimmune conditions, as many as 15% of patients have various autoantibodies, as many as 20% of patients have thyroid disease, and as many as 5% of patients have a family history of another autoimmune disease. Pregnancy has a variable effect, but for most patients, weakness increases in the postpartum period. About 12% of children born to mothers with MG develop transient neonatal MG as a result of transplacental transfer of circulating anti-AChR antibodies from the myasthenic mother to the fetus. These infants develop weakness, feeding difficulties, respiratory problems, a weak cry, and facial weakness within the first few hours after birth. The condition lasts as long as 3 weeks, coinciding with the half-life of IgG.

Immunopathogenesis

Autoantibodies MG is mediated by pathogenic autoantibodies that bind to AChR and cause a functional loss of the receptors and focal destruction of the postsynaptic junctional folds, interfering with the depolarization of the postsynaptic membrane [*see Figure 4*]. Between 10% and 15% of MG patients, especially those with mild, childhood, or localized (e.g., ocular) forms, do not have detectable antibodies. Most of these patients, although seronegative, have an antibody-mediated disorder. Among the 15% seronegative patients, about 6% have antibodies against MuSK,[93] a muscle-specific kinase needed for the development and clustering of the AChR at the neuromuscular junction [*see Figure 4*]; the other 9% of seronegative patients contain poorly characterized IgG antibodies that reversibly inhibit AChR function or IgM antibodies that indirectly inhibit AChR function.[94]

Other antibodies associated with MG include antistriational cell antibodies. These are found in as many as 80% of patients with thymoma and MG, 25% of patients with thymoma without MG, 30% of adults with MG (55% when MG begins after age 60), 6% of patients with LEMS, 3% of patients with lung cancer, and frequently in patients with autoimmune liver disease.[94] Anti-titin antibodies are also present in 55% of AChR-positive patients with late-onset MG, regardless of whether the patients have thymoma. Antibodies to thyroid microsomes and thyroglobulin are frequently present in patients with ocular MG and in patients with LEMS without cancer.

Immunoregulation The AChR is a T cell–dependent antigen. In MG, the $CD4^+$ cells are sensitized and respond to stimulation with AChR or to synthetic immunodominant peptides of AChR.[89-92] Because lymphocytes from normal, healthy persons also respond to such peptides, albeit to a lesser degree, the

AChR-specific T cells are part of the normal immune repertoire. This suggests that MG is a disease of abnormal immunoregulation. Induction of MG by microbial antigens (e.g., antigens to *Escherichia coli* and *Klebsiella*) or herpes simplex viruses have been postulated because these bacteria and viruses share sequence homology with peptides of the alpha subunit of AChR.

Approximately 75% of patients with MG have thymic abnormalities, either hyperplasia with germinal center formation or thymoma (15% of all patients with MG). Removal of the thymus results in clinical improvement or remission. Additional evidence implicating a role for the thymus in MG is based on several findings: (1) the thymus of an affected person contains a greater population of B cells that could secrete AChR antibodies than the thymus of a normal, healthy person; (2) the thymus of an affected person possesses myoid cells that contain AChR proximal to the interdigitating dendritic cells; and (3) the number of T cells sensitized to AChR is greater in the thymus of an affected person than in the thymus of a healthy person.

In MG, breaking of self-tolerance may begin in the thymus. AChR on the myoid cells may thus be recognized by the thymic dendritic cells that present the antigen to $CD4^+$ cells, which in turn stimulate the antibody-producing B cells to make anti-AChR antibodies. Subsequently, these antibodies recognize and cross-react with AChR in skeletal muscle.

MG is frequently associated with other autoimmune conditions, including collagen vascular diseases, polymyositis, pemphigus, autoimmune thyroid diseases, and graft versus host disease. The use of D-penicillamine has induced classic MG, which improves when the drug is discontinued.

Diagnosis

Clinical manifestations Patients with MG present with skeletal muscle weakness and fatigability. The weakness often affects elevation of the eyelids and movement of the extraocular muscles, which causes a characteristic asymmetrical ptosis and diplopia. The neck extensors are often weak, and the head droops. Patients with MG may have weakness of facial and bulbar muscles that causes a facial snarl when a patient smiles; nasal or dysarthric and low-volume dysphonic speech; and dysphagia, which can result in regurgitation and choking. Proximal skeletal muscle weakness and fatigue produce difficulty in walking, climbing steps, combing hair, and carrying objects. Respiratory muscle weakness can be significant. Symptoms fluctuate and are often better in the morning. Fatigability is usually worse at the end of the day or after repeated or continuous activity. If a patient is asked to keep the arms abducted, a gradual decline in arm height is noted. If a patient is asked to talk continually, the voice may become husky, nasal, slurred, and finally inaudible. Sensation and cognition are normal. Tendon reflexes, especially from nonatrophic muscles, tend to be brisk or normally active. The toes are downgoing. The symptoms worsen during or before the menstrual period and during viral or bacterial infections.

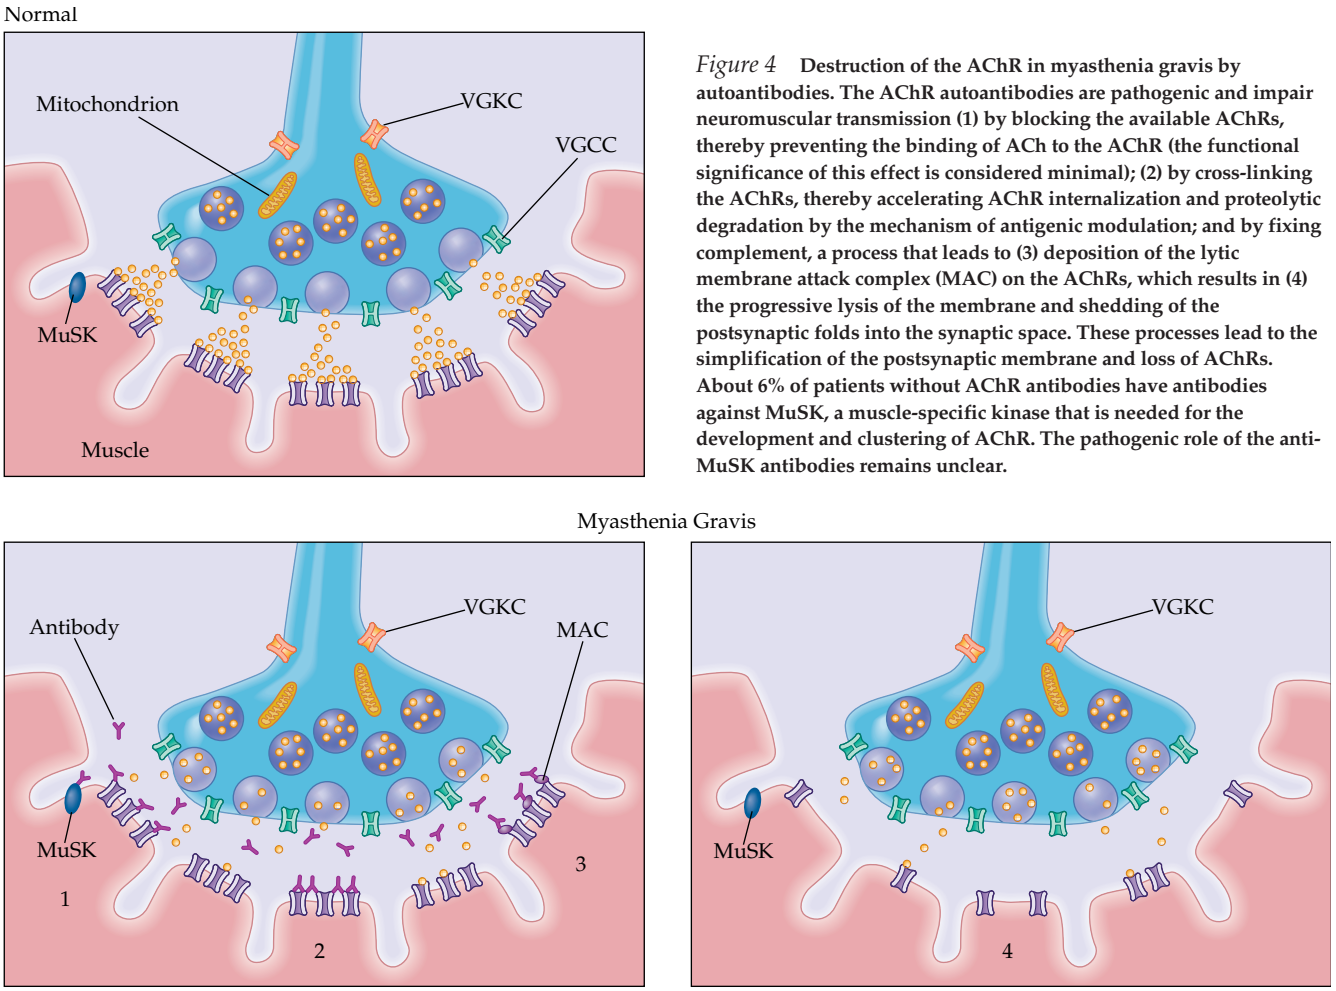

Figure 4 **Destruction of the AChR in myasthenia gravis by autoantibodies. The AChR autoantibodies are pathogenic and impair neuromuscular transmission (1) by blocking the available AChRs, thereby preventing the binding of ACh to the AChR (the functional significance of this effect is considered minimal); (2) by cross-linking the AChRs, thereby accelerating AChR internalization and proteolytic degradation by the mechanism of antigenic modulation; and by fixing complement, a process that leads to (3) deposition of the lytic membrane attack complex (MAC) on the AChRs, which results in (4) the progressive lysis of the membrane and shedding of the postsynaptic folds into the synaptic space. These processes lead to the simplification of the postsynaptic membrane and loss of AChRs. About 6% of patients without AChR antibodies have antibodies against MuSK, a muscle-specific kinase that is needed for the development and clustering of AChR. The pathogenic role of the anti-MuSK antibodies remains unclear.**

Patients with MuSK antibodies tend to be women; disease onset in these patients occurs at 20 to 60 years of age. Frequently, patients present with prominent neck, shoulder, or respiratory muscle weakness and bulbar signs.[95] Others present with predominantly oculobulbar signs.

Laboratory tests In addition to demonstration of fatigue and weakness on examination, the clinical diagnosis can be confirmed by an edrophonium or neostigmine test. These drugs inhibit AChE, which allows ACh to interact repeatedly with the remaining AChR, and as a result, muscle strength improves. Repetitive nerve stimulation studies demonstrate a rapid reduction (> 12%) in the amplitude of the MAP. Single-fiber EMG demonstrates increased jitter and blocking in more than 90% of patients. An MRI of the chest should be performed to search for thymic hyperplasia or thymoma. MG must be differentiated from diseases or exogenous agent–induced toxic disorders that have similar clinical pictures, such as botulism, organosphosphate poisoning, D-penicillamine toxic reaction, mitochondrial myopathy, compressive lesion affecting cranial nerves, LEMS, and congenital myasthenic syndromes. The serologic diagnosis of MG is made by detecting AChR or MuSK antibodies with a radioimmunoprecipitation assay.[90] The AChR antibodies are present in as many as 85% to 90% of patients with generalized MG and in as many as 70% of patients with ocular MG; they are also found in as many as 30% of patients with autoimmune liver disease, 10% of patients with pernicious anemia, and as many as 13% of patients with LEMS.[96] Generally, AChR antibody titers do not correlate with clinical severity.

Treatment

The term gravis is now a misnomer because MG responds fairly well to the available therapies. Although the sequence in which the various therapeutic modalities are applied may differ among physicians, the initial choice in mild cases is generally an anticholinesterase drug given every 4 hours while the patient is awake. Thymectomy is done in most centers through the transsternal approach in patients beyond puberty and up to 55 years of age. The beneficial effect of thymectomy, however, has been questioned and has necessitated a large multicenter study.[97] Thymoma should always be removed, followed by radiation therapy.

Prednisone is the first-line immunotherapeutic drug therapy. The preferred dosage is 60 to 80 mg as a single daily dose in the morning for an initial period of 3 to 4 weeks. Then, over an 8-week period, the dose on alternate days is gradually reduced by 10 mg a week (more often if side effects are severe) until the lowest dose that controls the disease is reached. Some physicians prefer to start with lower dosages of prednisone (i.e., 20 to 40 mg/day) and gradually increase the dosage to prevent an occasionally noted transient worsening. Plasmapheresis or intravenous immune globulin is generally reserved for crisis and severe cases and to strengthen a patient before thymectomy. Cyclosporine, mycophenolate, or azathioprine may be used as a second-line therapy to maintain remission after lowering the steroid dosage.[89,90] Azathioprine, for example, given orally in dosages of up to 3 mg/kg/day has been shown in a controlled study to be effective in maintaining remission of symptoms after more than 12 months of administration, permitting a reduction in steroid dose.

Patients with MuSK antibodies do not improve with thymectomy, and their response to cholinesterase inhibitors is variable. The response to immunotherapy is generally good but variable: some patients may develop permanent facial, pharyngeal, or tongue weakness and atrophy.

LAMBERT-EATON MYASTHENIC SYNDROME

In LEMS, specific antibodies against VGCCs cause antigenic modulation and depletion of VGCCs [*see Figure 4*]. This restricts Ca^{2+} ingress into the motor nerve terminal and reduces ACh release during a nerve impulse. The amount of ACh released can generate only a small EPP that cannot trigger an MAP; this results in neuromuscular transmission failure and muscle weakness. An important observation in LEMS is its frequent association with small cell lung cancer (SCLC), which also expresses VGCC.[90,91,98-100]

LEMS occurs more frequently in men than in women. Approximately 70% of men with LEMS have SCLC, as compared with 20% of women. LEMS may precede the detection of malignancy by up to 3 years. Malignancy is rare in persons younger than 40 years.

Patients present with proximal muscle weakness, increased fatigability, and transient ocular symptoms of ptosis or diplopia. Autonomic symptomatology, with dry mouth, dry eyes, sexual impotence, constipation, and abnormal pupillary reflexes, is frequent. Hyporeflexia is common. A typical sign is an increase in muscle strength and reflexes a few seconds after a sustained maximal effort. The diagnosis is confirmed by repetitive nerve stimulation studies that demonstrate a dramatic increase in the amplitude of the MAP upon tetanic stimulation. Single-fiber EMG shows increased jitter and blocking, which improve with faster stimulation rates. Using radiolabeled peptides from cone snail toxins, antibodies to P-type or Q-type calcium channels are detected in as many as 95% of LEMS patients.[90,91,99,100] Antibodies to N-type channels are seen in as many as 75% of LEMS patients, especially those who have lung cancer. A search for SCLC, especially in men older than 40 years, is an essential part of the patient workup. Antibodies to the P-type or Q-type VGCC are also found in patients with paraneoplastic cerebellar degeneration in both the serum and the CSF. These antibodies may interfere with calcium influx into cerebellar Purkinje cells and may be implicated in the patient's ataxia.

The presynaptic region of the motor end plates in patients with LEMS exhibits marked depletion of the active zone particles that represent the VGCCs. The VGCCs in LEMS are no longer in parallel rows but are aggregated as a result of cross-linking by the specific IgG antibodies. The patient's IgG [$F(ab')_2$ fraction] injected into mice transmits the electrophysiologic and morphologic changes associated with the disease. Complement is not involved in the process. SCLC expresses VGCC of the N, L, or P type. It is believed that tumor cells trigger autoantibodies against surface determinants, which cross-react with similar epitopes at the presynaptic regions of the neuromuscular junctions.

In LEMS associated with SCLC, the primary focus is to treat the tumor because the symptoms of LEMS improve as the cancer regresses. The first drug of choice in LEMS is 3,4-diaminopyridine. This drug prolongs the duration of the presynaptic action potential by blocking the outward K^+ currents; this allows increased Ca^{2+} entry into the nerve terminal and further release of ACh. The drug alleviates fatigue and weakness in LEMS patients, and it is well tolerated in dosages of 40 to 60 mg daily. Sometimes, pyridostigmine is added. Prednisone helps substantially. Azathioprine, plasmapheresis, and intravenous immune globulin are additional therapeutic approaches that are given as steroid-sparing agents or to improve the strength of patients not responding well to 3,4-diaminopyridine and prednisone.

NEUROMYOTONIA WITH K^+ CHANNEL AUTOANTIBODIES (ISAAC SYNDROME)

Isaac syndrome is a rare autoimmune disease presenting as isolated neuromyotonia [*see* Isolated Neuromyotonia (Isaac Disease), *above*] or in association with thymoma, MG, and CNS symptoms, such as limbic encephalitis, personality changes, hallucinations, and sleep disturbances.[74] Patients with neuromyotonia have myokymia, myotonia, and, often, muscle hypertrophy. Myokymic discharges and prolonged motor unit discharges are seen electrophysiologically. Other patients have cramp-fasciculation syndrome and peripheral neuropathy.

An antibody against *o*-dendrotoxin–sensitive K^+ channels is responsible for the disease.[73,74] Affected patients have antibodies against voltage-gated potassium channels (VGKCs). The MAP is generated by the opening of the VGCCs; inactivation of the VGKCs, followed by the opening of the potassium channels, leads to repolarization of the nerve terminal. In patients with antibodies to VGKC, the depolarization is prolonged, prompting the calcium channel to remain open longer, so that more calcium enters the nerve terminal and more quanta are released.

This autoimmune disorder responds to plasma exchange, intravenous immune globulin, or immunosuppressants.

CONGENITAL MYASTHENIC SYNDROMES

The congenital myasthenic syndromes are a heterogeneous group of syndromes that cause a failure of neuromuscular transmission that is not autoimmune, but, rather, is the result of genetic defects in various molecules, enzymes, or channels at the neuromuscular junction.

A congenital myasthenic syndrome is suspected when an infant, a child, or, occasionally, a young adult presents with fluctuating ptosis, fatigability, increased weakness on sustained exertion (common to all the neuromuscular transmission defects), mild or delayed motor milestones, absence of autoimmune MG, and a positive family history.[101]

IV CEREBROVASCULAR DISORDERS

Scott E. Kasner, m.d.
Lewis B. Morgenstern, m.d.

Definitions

Stroke is a sudden neurologic deficit caused by either ischemia (80%) or hemorrhage (20%). Ischemic stroke is classified according to the area of the brain affected and the etiologic mechanism. Hemorrhagic stroke is classified as either subarachnoid (5%) or intracerebral (intraparenchymal) (15%). Transient ischemic attack (TIA) is a sudden vascular-related focal neurologic deficit that resolves completely. TIAs are classically defined as lasting less than 24 hours; they generally last less than 1 hour. A TIA should not be considered a separate entity but, rather, a herald of ischemic stroke and an opportunity to intervene.

Epidemiology

Stroke is the leading cause of disability and the third leading cause of death in the United States. Until 1998, the annual incidence of stroke was estimated to be 550,000 on the basis of studies of homogeneous, predominantly white populations. Results of the Greater Cincinnati/Northern Kentucky Stroke Study suggest that previous reports underestimated stroke incidence by almost 50%. By rigorously counting strokes in all racial and ethnic groups in Cincinnati, the yearly estimate for the United States was revised to 731,100.[1] The explanation for the previous underestimation of stroke incidence is that the incidence is higher in African Americans than in non-Hispanic whites. African Americans in Cincinnati had a twofold to fourfold higher incidence of stroke than did non-Hispanic whites in Rochester, Minnesota, during the same period. In northern Manhattan, African Americans had a 2.4-fold higher incidence of stroke than did non-Hispanic whites.[2]

African Americans also have higher stroke mortality. In Texas, African-American men 45 to 59 years of age had a 306% higher stroke mortality than did non-Hispanic whites. At 75 years of age and older, when stroke mortality is at its highest, the excess mortality for African-American men had diminished to 26% above the mortality for non-Hispanic whites. African-American women in the same age groups had a 222% and a 10% greater stroke mortality, respectively, than that of non-Hispanic whites.[3] The increased burden of stroke in African Americans may be worsening. Between 1992 and 1996, rates of almost all subtypes of stroke had increased among African Americans, and the number of stroke deaths had increased by 8%.[4]

The pathogenesis of stroke in African Americans may also differ somewhat from that in non-Hispanic whites. Extracranial carotid disease and cardioembolism more commonly cause ischemic stroke in non-Hispanic whites, whereas intracranial thromboembolic disease is more common in African Americans.[5] However, the various disease mechanisms can occur in either racial group.

Information on stroke in Hispanic Americans is less readily available. Data from northern Manhattan suggest a twofold higher incidence of stroke in Hispanics than in non-Hispanic whites.[2] In Mexican Americans, the incidence of ischemic stroke and intracerebral hemorrhage is substantially greater than in non-Hispanic whites.[6] As the Mexican-American population grows and ages, targeting of this population for stroke prevention becomes critical.

Women have lower stroke rates than men at all age ranges except 75 years and older, when stroke rates are at their highest. In Texas, 61% of all stroke-related deaths occur in women.[3] Stroke and vascular disease have traditionally been seen as male disorders; this has resulted in a shift in the focus of prevention and acute treatment regimens away from women.

Overall, the decline in stroke-related mortality has inexplicably slowed over the past several decades and almost came to a halt in the 1990s.[4] A lack of emphasis on prevention may have led to an increase in incidence, particularly in some racial and ethnic groups. As people survive other diseases, stroke may become a more common cause of death. Nonetheless, this leveling of the previous downward trend in stroke mortality is cause for alarm.

Approach to the Acute Stroke Patient

Stroke is the quintessential medical emergency. Stroke patients who receive neurologic care within 6 hours of the onset of symptoms have a fourfold greater chance of a good outcome than those treated after this acute period.[7] This observation, which was made before the thrombolytic era, illustrates the crucial link between time and outcome for stroke victims. Patients who receive early treatment to restore cerebral perfusion and to maximize protection of neurons have better outcomes. Physicians can reduce the delay in getting stroke victims to the emergency department by educating at-risk patients and their families about stroke symptoms and encouraging them to call 911 if stroke symptoms occur.[8] Once a stroke patient arrives at the emergency department, triage and treatment are critical in reducing mortality and morbidity [*see Figure 1*]. One clinical instrument for assessing stroke patients is the National Institutes of Health Stroke Scale, which is available online at http://www.ninds.nih.gov/doctors/NIH_Stroke_Scale.pd. Before specific treatment is implemented, however, neuroimaging must be performed.

Neuroimaging of Acute Stroke

The brain should first be imaged with noncontrast computed tomography, which reliably distinguishes acute intracerebral hemorrhage (ICH) from ischemia [*see Figure 2*]. This distinction is critical because the management of hemorrhagic stroke [*see* Hemorrhagic Stroke, *below*] is substantially different from that of ischemic stroke. CT is relatively insensitive to ischemic changes in the first few hours after stroke. Early CT findings may be subtle [*see Figure 2*], but hyperdense vessels (suggestive of acute thrombus), loss of boundaries between gray and white matter, and effacement of cerebral sulci are highly specific for ischemic stroke.[9]

The ability to identify at-risk cerebral tissue has considerable clinical relevance because therapy has the potential to salvage viable tissue.[10] Physiologic imaging may detect the presence of so-called ischemic penumbra (tissue with impaired blood flow but active metabolism) surrounding infarcted tissue [*see Figure 3*]. Aerobic metabolism cannot be sustained in the face of inadequate blood flow, and necrosis ultimately results. The time

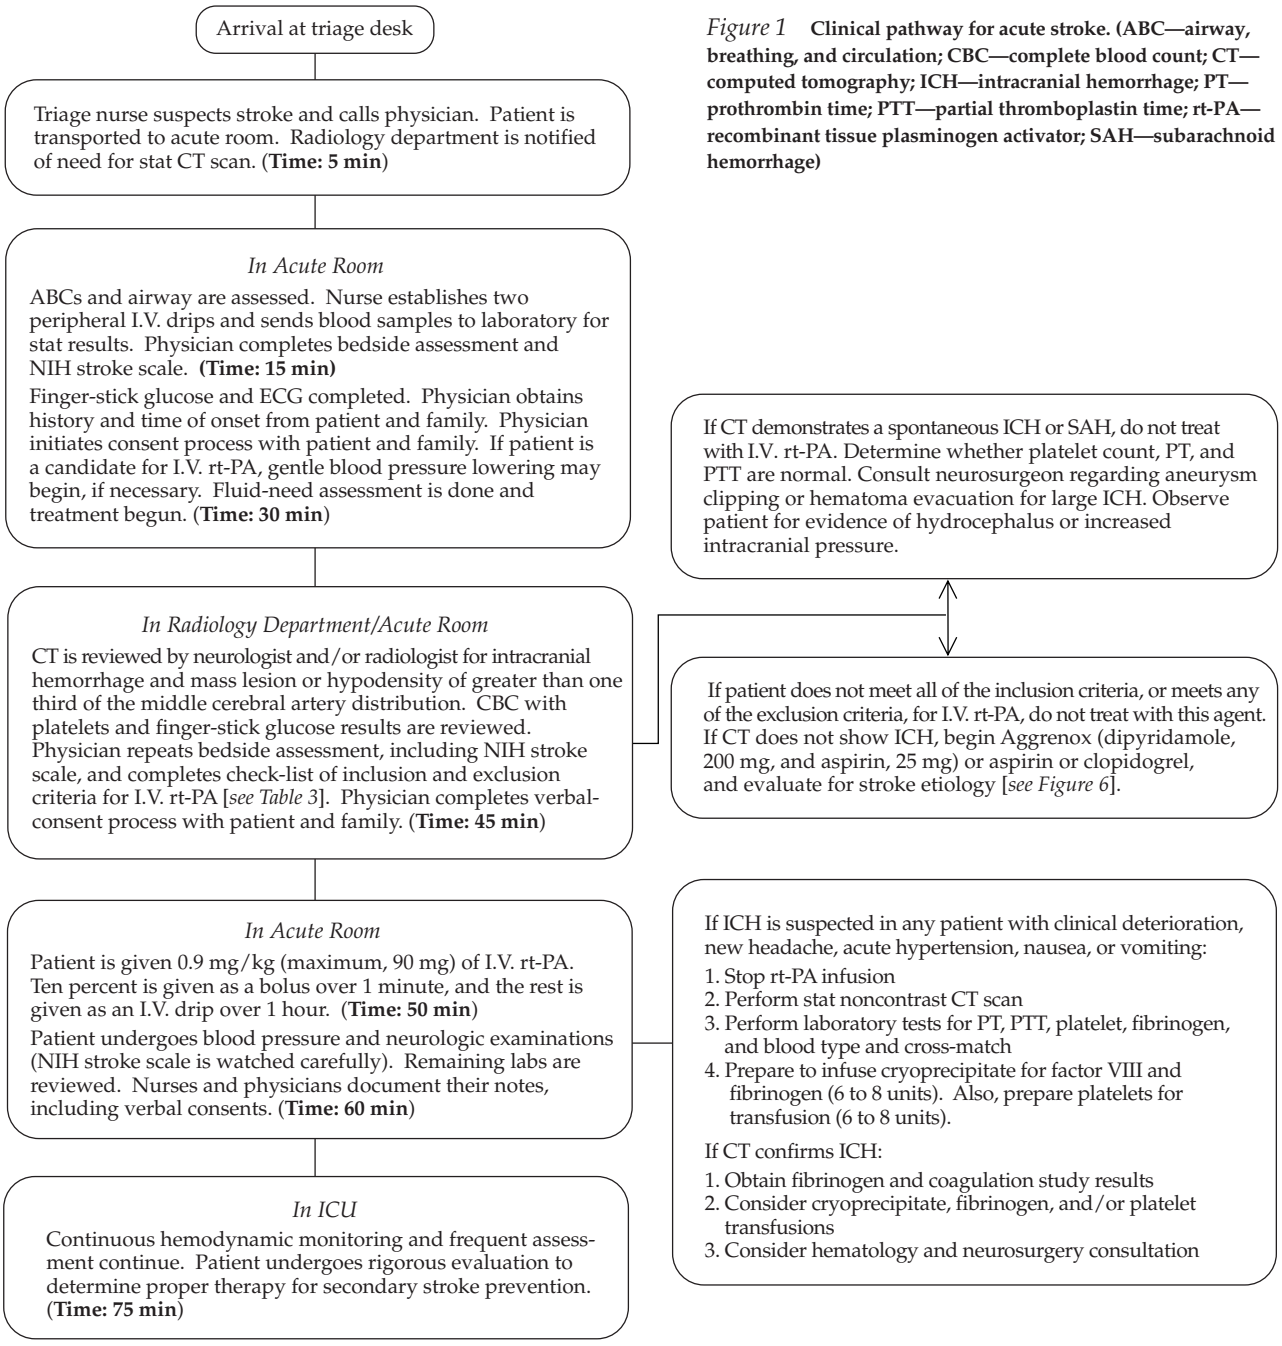

Figure 1 **Clinical pathway for acute stroke. (ABC—airway, breathing, and circulation; CBC—complete blood count; CT—computed tomography; ICH—intracranial hemorrhage; PT—prothrombin time; PTT—partial thromboplastin time; rt-PA—recombinant tissue plasminogen activator; SAH—subarachnoid hemorrhage)**

course of this process is poorly defined, although substantial volumes of brain potentially remain viable for up to 17 hours after stroke. Diffusion-weighted imaging (DWI) reveals changes in infarcted tissue hours before conventional CT or magnetic resonance imaging. Hyperintensity on DWI is predictive of the extent of infarction, and quantitative analysis of the apparent diffusion coefficient may identify areas of cytotoxic edema, suggesting permanently infarcted tissue. Perfusion-weighted imaging (PWI) demonstrates regionally reduced cerebral blood flow. The difference between the perfusion defect and the diffusion defect may represent penumbral tissue, which is the target of acute therapy [*see Figure 3*]. Further, MRI spectroscopy may provide biochemical markers of the extent of ischemic injury. However, these MRI techniques are not available emergently in many centers, which limits their clinical utility at present.

Several imaging techniques may characterize the acute vascular lesion.[10] The gold standard is conventional angiography, which may demonstrate acute occlusion or an embolus lodged at a vascular bifurcation. The vasculature can also be visualized quickly and noninvasively with CT angiography (CTA) and magnetic resonance angiography (MRA). Alternatively, transcranial Doppler ultrasonography can provide indirect evidence of major vascular occlusion and offers the advantage of real-time bedside monitoring in patients who receive thrombolytic therapy.[11]

Ischemic Stroke

Patients who present with neurologic dysfunction of sudden onset or who report neurologic signs and symptoms evolving

over a few minutes to a few hours are most likely experiencing a stroke. In most of these patients, the stroke is ischemic rather than hemorrhagic [*see Table 1*].

ETIOLOGY AND PATHOGENESIS

Classically, ischemic strokes have been categorized as either thrombotic or embolic; clinically, however, strokes resulting from thrombosis may be indistinguishable from those caused by embolism. Ischemic strokes are more reliably categorized as resulting from cardioembolism, large-vessel atherothromboembolism, small-vessel occlusive disease, or other identified mechanism or as cryptogenic (idiopathic).[12] The first three causes account for 70% to 90% of ischemic strokes. The latter two causes are pathophysiologically, diagnostically, and therapeutically distinct, and they are, therefore, are discussed separately [*see* Uncommon Causes of Ischemic Stroke, *below*].

Common Mechanisms

Cardioembolism Cardioembolism most commonly results from atrial fibrillation, mural thrombus, ventricular akinesis after myocardial infarction, dilated cardiomyopathy, and valvular disease [*see Figure 4*]. In each of these disorders, thrombus develops within the heart and embolizes to the brain. Ischemic events may be multiple and may occur in any major vessel. Therefore,

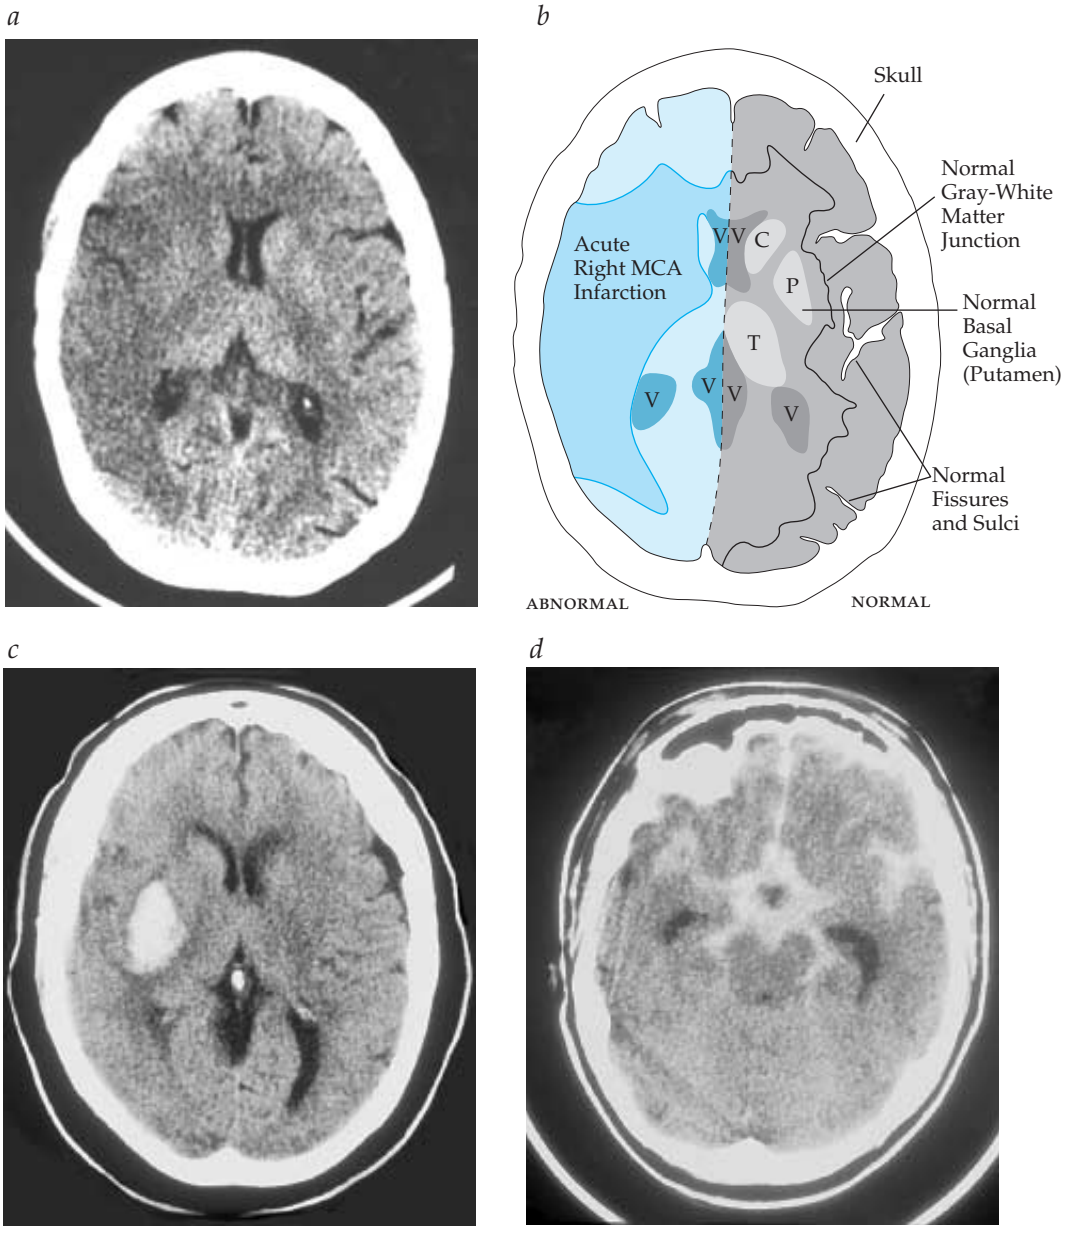

Figure 2 **(*a*) Early computed tomographic findings in acute ischemic stroke. Three hours after onset of left hemiparesis and neglect, this noncontrast CT scan reveals extensive early findings in the right hemisphere, including obscuration of the gray-white junction and the basal ganglia and effacement of the cortical sulci. (*b*) Detail of CT findings shown in panel *a*. (*c*) Noncontrast head CT scan of a right putamenal intracerebral hemorrhage. (*d*) Noncontrast head CT scan of a subarachnoid hemorrhage manifesting the classic star-shaped area of hyperdensity in the basal cisterns. (C—caudate nucleus; P—putamen; T—thalamus; V—ventricles)**

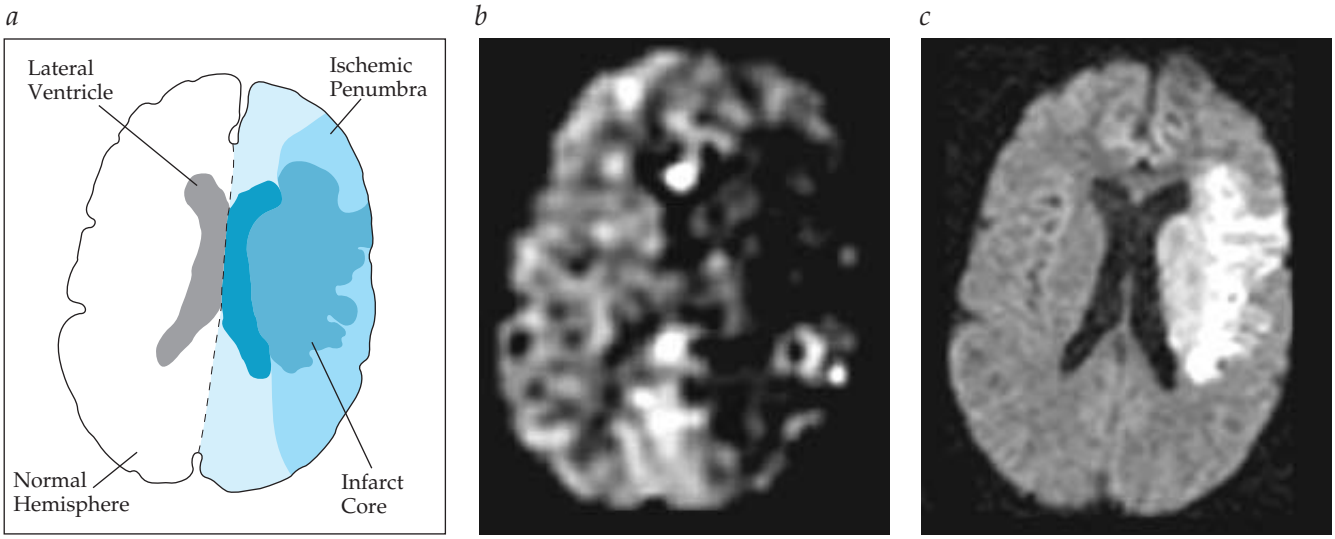

Figure 3 **Magnetic resonance imaging scan showing perfusion-diffusion mismatch in acute ischemic stroke. The mismatch between diffusion and perfusion abnormalities may represent the ischemic penumbra (*a*). This patient presented with right hemiparesis, right-visual-field impairment, right sensory loss, and aphasia. The area of decreased perfusion (*b*) is much larger than the area identified on diffusion imaging (*c*), suggesting that the surrounding tissue may still be salvageable.**

cardioembolism must be considered in nearly every ischemic stroke patient.

Large-vessel atherothromboembolism Atherosclerotic narrowing of the major extracranial or intracranial arteries may cause acute occlusion of the vessel itself, distal artery-to-artery embolic stroke, or focal hypoperfusion [*see Figure 5*]. A hallmark is the recurrence of similar clinical events, as a result of ischemia in the same vascular territory caused by involvement of a single large vessel. In general, atherosclerosis occurs at major arterial branches (e.g., the carotid bifurcation in the neck or intracranial branch points) and at vessel origins (e.g., the origin of the vertebral artery from the subclavian artery).

Small-vessel occlusive disease Small vessels are tiny terminal branches of larger vessels, such as those in the internal capsule, corona radiata, thalamus, and pons. Occlusion of these small vessels is often synonymous with so-called lacunar infarction. The mechanism of the occlusive process is uncertain, but lipohyalinosis, local atherosclerosis, and microthrombosis are possible. The process is most common in patients with long-standing diabetes or hypertension and is characterized by several specific clinical syndromes [*see* Clinical Manifestations and Lesion Localization, *below*]. The diagnosis of small-vessel disease rests on the clinical syndrome and the absence of an alternative etiology.

DIAGNOSIS OF ACUTE ISCHEMIC STROKE

Clinical Manifestations and Lesion Localization

Two pairs of vessels supply blood to the brain: the internal carotid arteries and the vertebral arteries. These vessels, which deliver 20% of the cardiac output, join on the ventral surface of the brain to form the intracranial vessels and the circle of Willis [*see Figure 5*]. The anterior cerebral artery supplies blood to the medial frontal and deep structures. Occlusion of the anterior cerebral artery is characterized by contralateral leg weakness [*see Table 2*], but isolated infarction of the anterior cerebral artery is uncommon.

The middle cerebral artery (MCA) divides into two major trunks, and each trunk divides into five to seven branches that supply blood to the lateral hemisphere. Because the MCA supplies a large territory, MCA occlusion causes a clinical syndrome that includes contralateral hemiparesis and hemisensory deficit (in which the deficit in the face and arm is greater than the deficit in the leg), aphasia (if the dominant hemisphere is affected) or neglect (if the nondominant hemisphere is affected), contralateral visual-field defect, deviation of gaze, dysarthria, and other cortical symptoms.

Table 1 Differential Diagnosis of Acute Ischemic Stroke

Possible Cause	*Comment*
Drugs or other toxins	Unlikely to cause focal neurologic symptoms; exclude by history and toxic screening
Seizure	Can mimic focal neurologic signs; exclude by history
Metabolic derangements	Abnormalities of glucose, calcium, Po_2, Pco_2, and electrolytes and liver and kidney dysfunction can all cause neurologic abnormalities; hypoglycemia and hyperglycemia are notorious for causing focal signs; exclude by laboratory tests
Migraine	Although migraine is a diagnosis of exclusion, it must be considered in patients with stroke; headache can be a prominent component of both ischemic and hemorrhagic stroke; exclude by history and physical examination
Brain tumor	Unlikely to present acutely; exclude by history and CT scan
Intracranial hemorrhage	Subdural, epidural, subarachnoid, and intracerebral hemorrhage can all mimic ischemic stroke; exclude by CT scan
Psychiatric disease	Conversion disorder and malingering can usually be discovered by a careful physical examination and history

CT—computed tomography Pco_2—carbon dioxide tension Po_2—oxygen tension

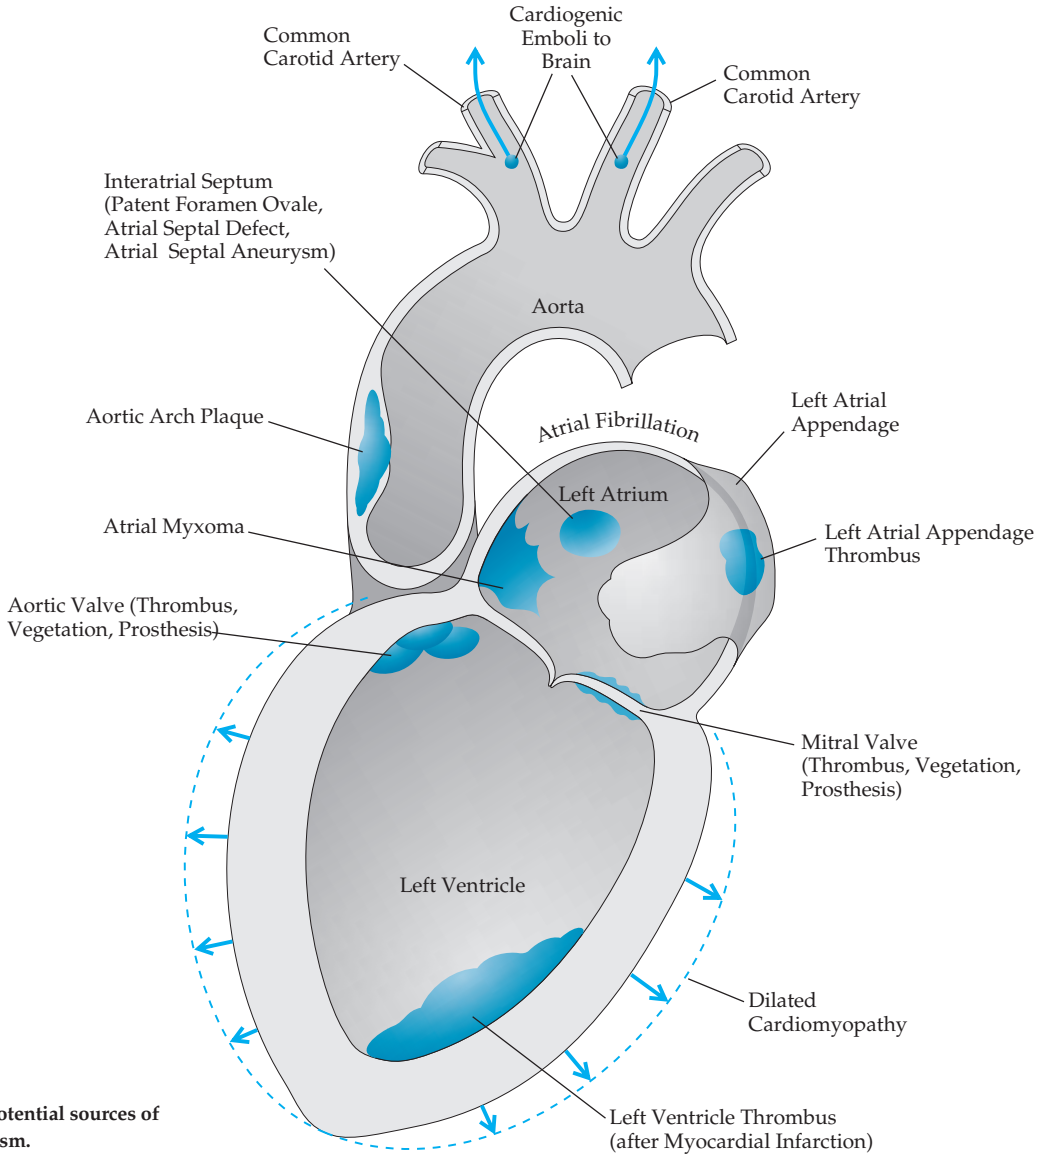

Figure 4 **Potential sources of cardioembolism.**

The two major branches of the vertebral arteries are the anterior spinal artery, which supplies the spinal cord, and the posterior inferior cerebellar artery, which leads to the inferior cerebellum and the lateral medulla. The two vertebral arteries then unite to form the basilar artery. The major branches of the basilar artery are the anterior inferior cerebellar artery and the superior cerebellar artery, which supply parts of the pons and cerebellum. Occlusion of the vertebral arteries or basilar artery leads to a combination of signs and symptoms that depend on the level and extent of infarction. These signs and symptoms include so-called crossed facial sensory and body motor signs, diplopia, facial numbness and weakness, vertigo, nausea and vomiting, tinnitus, hearing loss, ataxia, gait abnormality, hemiparesis, dysphagia, and dysarthria. The basilar artery terminates by dividing into two posterior cerebral arteries that supply the medial temporal lobe, the occipital lobe, and parts of the thalamus. Occlusion of the posterior cerebral artery results in occipital infarction and therefore contralateral visual-field loss. Such occlusion may also cause contralateral hemiparesis and behavioral changes.

After leaving the circle of Willis, the vessels branch repeatedly and ultimately become end arteries. Occlusion of these penetrating vessels typically manifests as pure motor hemiparesis, pure sensory stroke, clumsy hand–dysarthria syndrome, or ataxic hemiparesis.

Diagnostic Evaluation

The highest risk of recurrent stroke occurs within the first month after initial stroke symptoms (and within the first few days after TIA)[13,14]; therefore, an expeditious evaluation of patients presenting with TIA or suspected stroke should be undertaken and prophylactic therapy begun immediately at presentation [*see Figure 6*] (though after initial treatment with thrombolytics, if applicable [*see* Treatment of Acute Ischemic Stroke, *below*]). In a patient with recent cerebral ischemia, the first step is to localize the lesion [*see* Clinical Manifestations and Lesion Localization, *above*]. Patients with anterior circulation strokes should undergo evaluation of the heart, extracranial carotid arteries, and intracranial anterior circulation. Cardiac evaluation [*see Figure 4*] begins with an electrocardiogram, a cardiac history and examination, and either a transthoracic echocardiogram (TTE) or a transesophageal echocardiogram (TEE). If a TTE does not provide an absolute diagnosis but suggests mural throm-

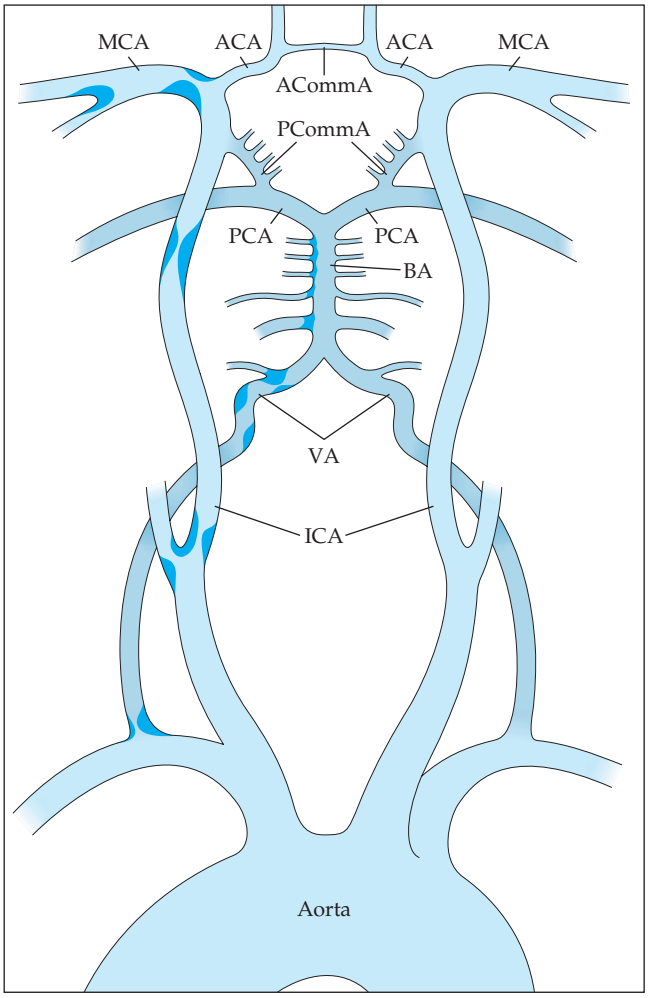

Figure 5 **Cerebrovascular anatomy and common sites of atherosclerosis are shown. The internal carotid artery (ICA) enters the skull, and its first major branch is the ophthalmic artery to the eye. Next are the anterior choroidal artery and the posterior communicating artery (PCommA). The PCommA connects the anterior circulation to the posterior circulation. The ICA then terminates as it divides into the anterior cerebral artery (ACA) and the middle cerebral artery (MCA). The vertebral arteries (VA) enter the skull and merge at the inferior border of the pons to form the basilar artery (BA). The BA then terminates as it divides into the two posterior cerebral arteries (PCA). (ACommA—anterior communicating artery)**

bus, valvular disease, or patent foramen ovale, then a TEE is ordered. A TEE allows visualization of structures not seen on a TTE, including clots in the left atrial appendage and aortic arch. The extracranial carotid circulation and intracranial anterior circulation can be visualized by MRA or CTA. In hospitals where these diagnostic tools are either not available or of poor quality, carotid ultrasonography should be performed. Transcranial Doppler imaging can help detect intracranial stenosis. The gold standard remains conventional cerebral angiography. Because this invasive test has possible complications (1% risk of stroke in most series) and is expensive, it should be reserved for cases in which its results could change treatment decisions. Posterior circulation evaluation involves the same cardiac evaluation. The posterior circulation is visualized by MRA, CTA, or conventional angiography.

Subcortical infarctions, or lacunae, that are greater than 1.5 cm in diameter are usually thromboembolic in nature. The evaluation in these patients is the same as that described above.

Laboratory investigations for all patients include measurement of the fasting lipid level within 48 hours of symptom onset, measurement of the homocysteine level, complete blood count, prothrombin time, partial thromboplastin time, and chemistry panel. If the patient is younger than 45 years or has no stroke risk factor or other identified etiology, the following tests should be considered but are of low yield: anticardiolipin antibody test, lupus anticoagulant profile, erythrocyte sedimentation rate, testing for factor V Leiden, rapid plasmin reagin test, and antinuclear antibody test. Tests for rarer causes of ischemic stroke include assays for protein C and protein S, measurement of antithrombin III, testing for prothrombin gene mutation, testing for HIV, and measurement of lactate level (for mitochondrial disease). Additionally, lumbar puncture and cerebral angiography should be considered if there is suspicion of infection or inflammation of the cerebral blood vessels.

TREATMENT OF ACUTE ISCHEMIC STROKE

Antiplatelet and Antithrombotic Treatment

Aspirin (160 to 325 mg daily) administered within 48 hours of stroke onset has been shown to significantly reduce the risk of recurrent stroke during the first 2 weeks and, possibly, to improve outcome at 6 months.[15,16] Therefore, aspirin is recommended as initial therapy for most acute stroke patients. However, aspirin should be withheld for at least 24 hours after administration of thrombolytics [*see* Intravenous Recombinant Tissue Plasminogen Activator, *below*]. For patients who have a known contraindication to aspirin, other antiplatelet agents may serve as rational, although unproven, alternatives.

Anticoagulation is commonly used in the acute setting to prevent progressive or recurrent thromboembolic events. Nevertheless, the efficacy and safety of anticoagulation for this purpose are not well established, and its role in clinical stroke management is controversial. Many neurologists formerly used heparin, although studies have demonstrated that it offers no appreciable benefit for most patients. The International Stroke Trial was a multicenter clinical trial involving 19,436 patients who were ran-

Table 2 Clinical Features of the Major Cerebrovascular Occlusive Syndromes

Artery	*Major Clinical Features*
Anterior cerebral artery	Contralateral leg weakness
Middle cerebral artery	Contralateral face + arm > leg weakness, sensory loss, visual-field cut, aphasia/neglect
Posterior cerebral artery	Contralateral visual-field cut
Basilar artery	Oculomotor deficits and/or ataxia with "crossed"sensory/motor deficits
Vertebral artery	Lower cranial nerve deficits and/or ataxia with "crossed" sensory deficits
Penetrators	Contralateral motor or sensory deficit without cortical signs*

*Cortical signs include aphasia, apraxia, neglect, and other cognitive abnormalities.

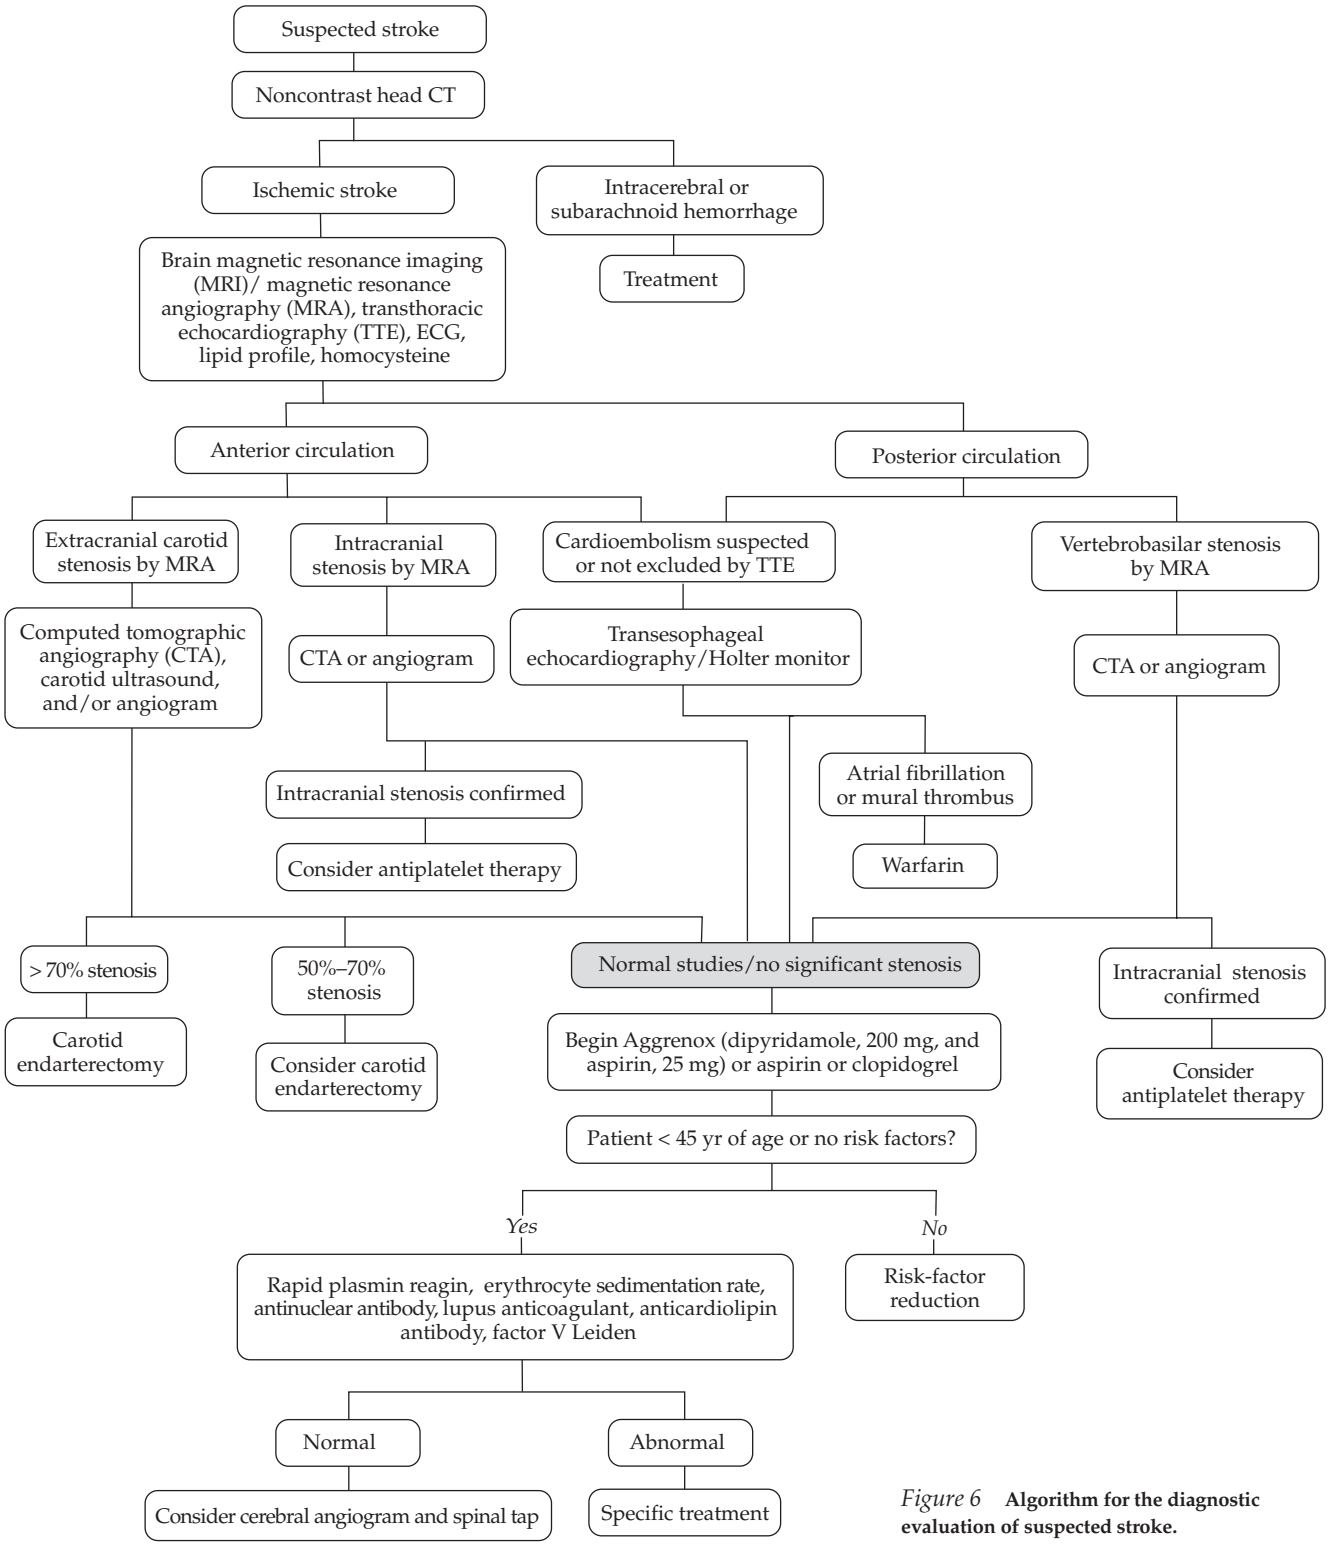

Figure 6 **Algorithm for the diagnostic evaluation of suspected stroke.**

domized within 48 hours of stroke onset into two arms. In the first arm, patients received subcutaneous heparin at a dosage of either 12,500 units or 5,000 units twice daily for 14 days. In the second arm, patients received no heparin.[15] Patients were independently randomized to receive either 300 mg of aspirin daily or no aspirin. The rate of recurrent stroke or death at 14 days was 11.7% in the patients receiving heparin and 12.0% in the nonheparin group—an insignificant difference—and there was no improvement in outcome at 6 months. The reduction in ischemic strokes by heparin was completely counterbalanced by an increase in hemorrhagic strokes. Similarly, in randomized clinical trials, use of low-molecular-weight heparin (LMWH) did not lead to a reduction in recurrent stroke or improvement in outcomes.[17] Therefore, as noted in a scientific statement developed jointly by the American Heart Association and the American Academy of Neurology, most patients with ischemic stroke

should not be treated with anticoagulation.[17] Some neurologists believe that carefully selected patients, such as those with acute basilar thrombosis, may benefit from acute anticoagulation therapy, although there is no clear evidence for or against its use.

Intravenous Recombinant Tissue Plasminogen Activator

Intravenous recombinant tissue plasminogen activator (rt-PA) was approved for use in acute stroke by the Food and Drug Administration in 1996, and consensus statements from the American Academy of Neurology and the American Heart Association support its use.[18] Although the FDA has approved the use of intravenous rt-PA for acute ischemic stroke up to 3 hours after the onset of symptoms, physicians should strive to treat patients as quickly as possible because earlier therapy is associated with better outcomes.[19] In acute stroke patients who meet the criteria for its use [*see Table 3*], rt-PA is given in a dose of 0.9 mg/kg (maximum dose, 90 mg) infused over 1 hour, with 10% of the total dose infused over the first minute. If treatment with rt-PA is suspected of inducing intracranial hemorrhage, the infusion should be suspended.

Two major trials conducted by the National Institute of Neurological Disorders and Stroke led to FDA approval of rt-PA.[19,20] The final outcome measure was return to independent function (i.e., no disability) at 3 months after onset of stroke. These studies together enrolled 624 patients at eight centers across the United States. Intravenous rt-PA was compared with placebo for patients presenting within 3 hours after onset of symptoms. The rate of symptomatic intracranial hemorrhage at 36 hours after administration of intravenous rt-PA was 6.5%, compared with 0.6% in the control group. Mortality from intracranial hemorrhage was 2.9% in the rt-PA group, compared with 0.3% in the placebo group.

Including the risk of intracranial hemorrhage, disability was significantly reduced when measured at 3 months, 6 months, and 1 year.[21] The rt-PA–treated patients were at least 30% more likely to recover to independent function than the placebo-treated patients. Mortality at 1 year was 24% in the rt-PA group and 28% in the placebo group. This benefit was seen in all stroke subtypes regardless of age or patient risk factors. Patients with large strokes were more likely to experience ICH after use of intravenous rt-PA, but this group was also more likely to have severe disability or to die if left untreated.

Only a small proportion of stroke patients are currently treated with rt-PA. Aggressive public and professional education effectively increases this proportion.[22]

Intra-arterial Thrombolysis

Direct infusion of thrombolytic agents into occluded blood vessels is a potential alternative or adjunct to therapy with intravenous rt-PA [*see Figure 7*]. The value of intra-arterial thrombolysis has been demonstrated with the experimental agent prourokinase (Prolyse), which is the highly clot-specific precursor of urokinase. The Prolyse in Acute Cerebral Thromboembolism (ProACT) trial enrolled patients with ischemic stroke caused by middle cerebral artery (MCA) occlusion within 6 hours of onset.[23] Eligibility criteria were similar to those for intravenous rt-PA treatment. Patients underwent emergent angiography; if MCA occlusion was confirmed, either intra-arterial prourokinase (9 mg) or placebo was infused for 2 hours. All patients received concomitant intravenous heparin. Arterial occlusions effectively opened in 67% of patients given prourokinase, whereas only 18% opened in patients given placebo. Three months after stroke, 40% of treated patients were functionally independent, compared with 25% of those given placebo ($P = 0.04$). The drug seemed particularly effective for moderately severe strokes. Symptomatic intracerebral hemorrhage occurred in 10.2% of treated patients, compared with 1.8% of those given placebo.

Because prourokinase is not commercially available, many centers that are capable of performing intra-arterial thrombolysis are using rt-PA, although it is not approved for this purpose. The intra-arterial rt-PA dose is uncertain, though many centers use 0.2 mg/kg (maximum, 20 mg), and all other aspects of the ProACT protocol may be followed.

Table 3 Indications and Contraindications for Intravenous rt-PA Treatment in Acute Ischemic Stroke

Indications	*Contraindications*	
	Absolute	*Relative*
Clinical diagnosis of disabling stroke firmly established	Onset > 3 hr ago or patient not seen normal within previous 3 hr	Glucose < 50 or > 400 mg/dl
Patient > 17 yr	Intracranial mass lesion or hemorrhage on noncontrast head CT	Seizure at stroke onset
Onset of symptoms or last time seen normal < 3 hr ago	Previous stroke or serious head trauma within previous 3 mo	Major surgery within 14 days
Previously independent functional status	Any history of intracranial hemorrhage	Arterial puncture at a noncompressible site or LP within 1 wk
	Current use of anticoagulants with PT > 15 sec or use of heparin within the past 48 hr*	Rapidly improving symptoms suggestive of TIA
	Platelets < 100,000/mm^3	GI or GU hemorrhage within 21 days
	Presenting symptoms suggestive of subarachnoid hemorrhage (worst headache of patient's life)	
	Blood pressure > 185/110 mm Hg unless minimal doses of a smooth-acting I.V. agent such as labetalol were sufficient to lower below this range†	
	Previously known cerebral aneurysm or arteriovenous malformation	

*Partial thromboplastin time and PT results are not needed before therapy unless patient is on anticoagulants.

†Caution: Do not lower blood pressure acutely by more than 10% to 15% and avoid agents that precipitously lower blood pressure. A patient who requires multiple doses should be excluded. After I.V. rt-PA is administered, blood pressure must be kept below 185/110 mm Hg for at least 24 hours.

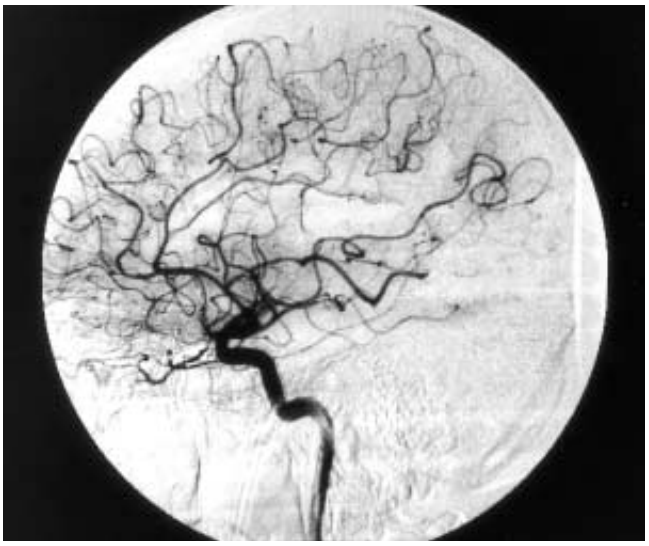

Figure 7 **Intra-arterial thrombolysis for acute ischemic stroke. Four hours after onset of left hemiparesis and neglect, conventional angiography (lateral view shown) revealed acute occlusion of the middle cerebral artery (MCA) (*a*). After treatment with intra-arterial thrombolysis, the MCA recanalized (*b*) and the patient had near-complete recovery from the deficit.**

The role of intra-arterial thrombolysis in other cerebral vessels remains uncertain. Cases of spectacular responses to thrombolytics have been reported in patients with basilar occlusion, even well beyond 6 hours. Although it is claimed that the brain stem may be relatively more tolerant of ischemia and less susceptible to hemorrhage, this hypothesis remains to be proved.

Combinations of intravenous and intra-arterial thrombolysis,[24] as well as mechanical manipulation or retrieval of an acute thrombus, are currently under investigation.

Neuroprotection

Neuroprotective strategies involve interfering with the ischemic cascade, thereby prolonging cellular viability and substantially reducing stroke size. Regrettably, a number of different compounds that seemed effective in animal studies failed in human clinical trials.[25] While several agents are being developed, researchers are attempting to determine how best to simulate stroke in animals so that animal data will be more generalizable to humans.

Supportive Medical Management

Several general medical issues are important for all stroke patients, including management of airway and oxygenation, blood pressure and hemodynamics, blood glucose, and temperature. Medical complications are also common after stroke, and such complications are associated with poor outcomes.[26] Management of these common issues and complications is critically important. Therefore, it is advisable to treat stroke patients in dedicated stroke units to reduce morbidity, mortality, and disability.[27]

Respiration Respiratory function must be evaluated immediately in all stroke patients. Ventilatory drive is usually intact except after medullary or massive hemispheric infarction or hemorrhage. The ability to protect the airway from aspiration may also be impaired, particularly in the acute setting. Intubation and mechanical ventilation may be necessary in these patients.[28] Most stroke patients do not require such aggressive maneuvers, but supplemental oxygen should be provided to maintain oxygen saturation above 95%.[29]

Blood pressure Maintenance of adequate blood pressure is vital for all patients. Cerebral blood flow to ischemic regions is dependent on cerebral perfusion pressure, which in turn is determined by the difference between mean arterial pressure and intracranial pressure (ICP). Elevated blood pressure is common at the time of initial stroke presentation, even in patients without chronic hypertension. Rapid lowering of blood pressure may further impair cerebral blood flow and worsen the ischemic injury.[30] Elevations in blood pressure will often spontaneously and gradually improve during the first few days after stroke.[30]

Antihypertensive therapy is indicated before and during thrombolysis with rt-PA; when infarction converts to hemorrhage; and in patients with myocardial ischemia, aortic dissection, or hypertensive encephalopathy. Candidates for thrombolysis should be treated only with modest measures (e.g., topical nitropaste or small intravenous boluses of labetalol) to maintain blood pressure below 185/110 mm Hg. Definitive treatment—including intravenous infusions of nicardipine, labetalol, or sodium nitroprusside—is appropriate for the other indications.

Fluid volume Careful volume replacement in patients with acute stroke improves cardiac output and cerebral perfusion.[31] Patients should receive isotonic saline to maintain euvolemia. Additional fluid administration (hypervolemic hemodilution) may increase cerebral blood flow while reducing blood viscosity without causing a reduction in oxygen delivery. However, clinical trials of hemodilution have yielded mixed results, with the largest of these trials showing no benefit.[32] Further investigation is required before hemodilution can be advocated.

Temperature Brain and body temperatures play an important role in outcome after stroke. Hypothermia improves outcome after ischemic injury in animals, after cardiac arrest, and after cardiac and neurosurgical procedures in humans, but it has not been adequately studied in acute stroke. Hypothermia may mitigate neurotransmitter toxicity, reduce neuronal metabolic

demands, and improve cerebral edema in acute stroke.[33] On the other hand, fever or even mild hyperthermia is known to be deleterious.[34] An elevation in body temperature dramatically increases the odds of severe disability or death, with risk doubling for each 1° C (1.8° F) above normal.[35] Normothermia should be maintained with antipyretics or cooling blankets, but therapeutic hypothermia must undergo more investigation before it can be recommended for focal ischemia.

Blood glucose levels Hyperglycemia appears to correlate with poor outcome in stroke.[36] Glucose may be metabolized to lactic acid, resulting in acidosis and increased tissue injury. Although the effect of correcting the blood glucose level is unknown, normalization is recommended. The administration of parenteral glucose should be minimized in patients with acute stroke.

Intracranial pressure In the most critically ill stroke patients, cerebral edema and elevations in ICP may complicate the clinical course. The expanding infarction may cause both focal and diffuse effects that typically peak at 2 to 5 days.[37,38] Large hemispheric stroke may result in malignant MCA syndrome, in which the edematous infarcted tissue compresses the anterior and posterior cerebral arteries, resulting in secondary infarctions.[37] Similarly, infarction of the cerebellum may lead to basilar artery compression and brain stem ischemia. Mortality in both malignant MCA syndrome and cerebellar infarction approaches 80% [*see* Intracerebral Hemorrhage, *below*]. Surgical decompression has a potential role in a minority of stroke patients. In acute cerebellar stroke, craniotomy with cerebellar resection is a lifesaving intervention that has become widely accepted.[39] Surgery removes the mass effect and prevents secondary brain stem and vascular compression. Malignant MCA syndrome may be similarly amenable to hemicraniectomy; this controversial approach is under investigation.

Preventive measures Prophylaxis for deep vein thrombosis should be instituted early with heparin (5,000 units given subcutaneously every 12 hours)[15] [*see 1:XVIII Venous Thromboembolism*]. For patients in whom heparin is contraindicated (e.g., patients with acute hemorrhage), pneumatic compression stockings are employed. Similarly, prevention of aspiration pneumonia should be a priority from the initial presentation at the hospital. Early intervention with physical therapy, occupational therapy, and speech therapy is important in recovery and prevention of complications.

PROGNOSIS AND RECOVERY

Initial stroke severity is one of the strongest predictors of outcome,[35] and early evidence of improvement is a good prognostic sign.[40] Recovery also depends on the size and location of the infarction or hemorrhage. Small infarctions, particularly subcortical lacunar strokes, may result in little chronic deficit, whereas large cortical infarctions may cause severe, permanent disability. Comorbid diseases, such as hypertension and diabetes, do not appear to affect recovery, but younger patients have a better prognosis than older patients.[40] Despite these predictors, the marked variability among patients makes early prognostication difficult. In general, recovery is greatest in the first 3 months after stroke.

The mechanisms of recovery after stroke remain poorly understood. Infarcted brain tissue is irreparable, so recovery of function has long been presumed to occur by recruitment of other neurons to serve new or additional roles. In rodents, neurons may be influenced to create new synapses after stroke.[41] Electrical brain mapping in monkeys has demonstrated that the cerebral cortex can be functionally reorganized during recovery after an infarction.[42] Similarly, functional MRI in humans has shown that activity in both hemispheres increases as patients improve, suggesting recruitment of neighboring cortex, as well as recruitment of the corresponding area of the contralateral cortex.[43]

Recovery may be improved by inducing these restorative mechanisms. Physical, occupational, and speech therapy are widely used, but no consensus exists regarding the optimal approach or timing of intervention. Neurotrophic growth factors and amphetamines may stimulate neuronal sprouting and also accelerate recovery by increasing the activity of uninjured neurons.[41] However, these pharmacologic approaches require extensive research before they can be advocated for routine use in stroke rehabilitation.

Table 4 Modifiable Risk Factors for Stroke

Risk Factor	*Prevention*	*Risk-Reduction Potential*	*Clinical Trial Evidence?*
Hypertension	P, S	25%–47%	Yes
Tobacco	P, S	?	No
Hyperlipidemia	P, S	24%–31%	Yes
Diabetes	P	?	No
Alcohol	P	50%	No

ISCHEMIC STROKE PREVENTION

Reduction of Risk Factors

Numerous risk factors for stroke are modifiable. Reduction of factors such as excessive alcohol consumption, tobacco use, hypertension, and diabetes, as well as aggressive lipid control, contributes to stroke prevention [*see Table 4*].

Hypertension Hypertension has the highest population-attributable risk of any of the modifiable risk factors for stroke, and reduction in blood pressure has been shown to dramatically reduce stroke risk.[44] The reduction in risk of first stroke for those treated with antihypertensive agents is 25% to 47%.[45] Both diastolic and systolic hypertension have been linked to excess risk of stroke. Reducing isolated systolic hypertension even in the elderly has been shown to markedly lower stroke rates.[46] Patients who are undertreated with antihypertensive agents still have a higher stroke rate than those who are adequately treated.[47] Recommended actions to reduce the risk of stroke include (1) maintaining blood pressure below 140/90 mm Hg, (2) frequent checking of patients' blood pressure by physicians, and (3) at-home monitoring of blood pressure by patients.[44] Lowering diastolic blood pressure by 5 to 6 mm Hg can reduce stroke risk by 42%[44]; thus, hypertension should be assiduously diagnosed and treated. In the primary prevention of stroke and other major

vascular events, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) showed that the thiazide diuretic chlorthalidone was effective and safe, and it is also inexpensive.[48] Comprehensive discussion about the management of hypertension for primary prevention is provided elsewhere [*see 1:III Hypertension*].

Although many antihypertensive agents can effectively reduce blood pressure, drugs that act upon the renin-angiotensin system appear to have a unique role in both primary and secondary stroke prevention. Two major studies demonstrated that angiotensin-converting enzyme (ACE) inhibitors—specifically, ramipril used alone[49] or perindopril used in combination with the diuretic indapamide[50]—reduce the risk of recurrent stroke by 25% to 30%. Furthermore, patients without a history of hypertension also seemed to benefit from the addition of an ACE inhibitor to their preventive regimen. A similar effect may exist for angiotensin receptor blockers (ARBs). In a trial comparing the beta blocker atenolol with the ARB losartan in patients with hypertension and left ventricular hypertrophy, there was a 25% reduction in the relative risk of a first stroke with the ARB.[51] In these trials, ACE inhibitors and ARBs appeared to decrease the risk of stroke more than would be expected by their relatively modest lowering of blood pressure; this suggests the possibility of an additional beneficial action via an uncertain mechanism.

Tobacco use Daily cigarette smoking has been shown to increase the risk of stroke by 250%.[52] A dose-effect response is seen in most studies. For those who smoke less than one pack a day, quitting reduces their risk to baseline within 5 years. For heavy smokers, the risk is greatly reduced but remains higher than that in individuals who never smoked. Switching from cigarettes to a pipe or cigars does not reduce stroke risk.[53]

Hyperlipidemia Evidence has emerged implicating hyperlipidemia as an independent risk factor for stroke, and studies have demonstrated impressive stroke risk reductions with statin agents. The Medical Research Council/British Heart Foundation Heart Protection Study (HPS), which included over 20,500 persons at high risk for coronary artery disease but who had characteristics that excluded them from previous statin studies, showed that long-term treatment with simvastatin (i.e., 40 mg daily for more than 5 years) reduced all strokes by 27%.[54] The study included patients with total cholesterol levels of 135 mg/dl or more; benefits were apparent even in patients with normal total cholesterol levels.

In an older study of patients who had had a previous myocardial infarction and whose cholesterol level was lower than 240 mg/dl, those given pravastatin had a 31% reduction in the risk of stroke, compared with patients given placebo.[55] In a study involving patients who had a median cholesterol level of 218 mg/dl and who received pravastatin, the relative risk reduction of stroke was 19%.[56] Meta-analyses also suggest that the use of statins reduces the risk of first stroke by 24% to 29%.[57,58] High-density lipoprotein cholesterol may be especially important in the risk of stroke. Statins may also exert their protective effects through mechanisms other than pure regulation of serum lipid concentrations. These effects include the processes involved in inflammation and thrombosis. In addition to pravastatin, simvastatin has an FDA indication for stroke prevention in patients with coronary artery disease and elevated cholesterol levels. Gemfibrozil was found to modestly reduce stroke in patients with coronary artery disease.[59]

Diabetes Although diabetes mellitus is a well-recognized risk factor for stroke, not all features of diabetes appear to contribute equally to that risk. Treatment of elevations in blood pressure and serum lipid levels appears to be more effective in reducing the risk of stroke, whereas treatment of hyperglycemia reduces the risk of microvascular complications.[60] At present, no studies directly link glucose control with reduction in risk of stroke. However, the international Action in Diabetes and Vascular Disease (ADVANCE) study is examining the effects of controlling blood pressure and blood glucose in patients with type 2 diabetes mellitus.[61]

Alcohol consumption In a quadratic model of the risk of stroke, there appears to be a J-shaped relation between alcohol intake and risk. In one report, those who consumed more than six drinks a day were at increased risk for stroke; those who consumed one to two drinks a day appeared to benefit from a protective effect of alcohol that reduced the risk of stroke by almost 50%.[62] There did not appear to be a difference associated with the type of alcoholic beverage consumed (i.e., wine, beer, or liquor). In another report, drinking as little as one alcoholic drink a week reduced the risk of stroke by 22%, compared with drinking no alcohol.[63]

Homocysteine level Elevated homocysteine levels are an independent risk factor for stroke.[64] Trials of high doses of vitamins B_6, B_{12}, and folic acid demonstrated that these agents can reduce homocysteine levels, but their use had no significant impact on stroke risk. Because vitamin supplementation is inexpensive and readily available, some clinicians use this approach empirically, though fortification of the United States food supply with folic acid may obviate this practice.[65]

Exercise Data from the Physician Health Study, a prospective cohort study of 21,823 men, demonstrated that exercise significantly reduced the risk of stroke, most likely by reducing other risk factors, including hypertension, lipid levels, and diabetes.[66]

Infection Infection and inflammation may be the single most important area of stroke research in the next decade. There have been several observations linking infection and inflammation with stroke. People with poor dentition seem to have a higher incidence of stroke. Although this increase may be related to other risk factors and access to care, it may also be related to oral infections. *Chlamydophila* (formerly *Chlamydia*) *pneumoniae* titers may be an independent risk factor for stroke.[67] *Chlamydophila* seems to promote thrombosis through effects on fibrinogen and vascular endothelium.

Therapeutic Measures to Prevent Ischemic Stroke

Management of risk of cardioembolism Disorders in many parts of the heart can potentially lead to stroke [*see Figure 4*]. Cardiac valves affected by bacterial endocarditis can give rise to septic emboli. The therapy for this condition is aggressive administration of antibiotics [*see 7:XVIII Infective Endocarditis*]. Akinetic ventricular segments can cause mural thrombi that in turn act as cardiac emboli. The treatment for this disorder is anticoagulation with warfarin to an international normalized ratio (INR) of 2.0 to 3.0. Similarly, anticoagulation after myocardial infarction is beneficial for patients with concomitant atrial fibrillation, decreased left ventricular function, or left ventricular throm-

bus.[44] Long-term warfarin therapy is necessary for patients with mechanical prosthetic valves. However, bioprosthetic valves require only brief anticoagulation, followed by antiplatelet treatment. Other conditions, such as patent foramen ovale, septal aneurysm, so-called ventricular smoke, and aortic arch atheroma, are more of a therapeutic dilemma. Although these conditions are known to increase stroke risk, there is still uncertainty as to whether antiplatelet or antithrombotic treatment is superior for stroke prevention. Indications for surgical intervention are also uncertain.

The most rigorously studied cardiac condition in terms of stroke prevention is fortunately the one most commonly related to stroke: atrial fibrillation [*see Table 4 and 1:IV Atrial Fibrillation*]. Nonvalvular atrial fibrillation is a common and readily preventable cause of stroke in the elderly.[68]

Lack of treatment of at-risk patients remains a significant public health challenge. The groups at highest risk for stroke include those with hypertension, diabetes mellitus, previous TIA or stroke, or poor left ventricular function and women older than 75 years. These patients should be treated with warfarin if they are appropriate candidates. For patients without risk factors and for those younger than 65 years, the risk of stroke is 1% a year without therapy. Thus, warfarin treatment is not necessary. For those individuals 65 to 75 years of age who are without risk factors, the yearly risk of stroke is 1.1% with warfarin therapy and 1.4% with aspirin therapy. Patients' INRs must be monitored and maintained in the 2.0 to 3.0 range so as to minimize the risk of ischemic stroke or hemorrhage from undertreatment or overtreatment.[69] An oral direct thrombin inhibitor, ximelagatran, has been shown to have efficacy and safety similar to those of warfarin in patients with atrial fibrillation and deep vein thromboembolism.[70,71] Ximelagatran offers several apparent advantages over warfarin, including minimal if any food or drug interactions, a high therapeutic index, rapid onset, and no need for INR monitoring. However, 6% of patients on this agent develop elevations in the transaminase level, which may limit its use.

Management of carotid artery disease Surgical treatment of symptomatic carotid stenosis (i.e., after a TIA or minor stroke) greatly reduces stroke risk.[72] In patients with a stenosis that is greater than 70% of the vessel diameter and who are good surgical candidates, surgery dramatically reduces the risk of stroke occurring within 2 years from 26% to 9%. For patients with 50% to 70% stenosis, the benefit is not as great. In this moderate-stenosis group, surgery reduces the risk of stroke over 5 years from 22% to 16%. This benefit is seen mostly in men, in those with recent stroke symptoms, and in those with hemispheric rather than ocular symptoms. Endarterectomy is most beneficial when it can be performed in the first 2 to 4 weeks after the initial cerebrovascular event.

Asymptomatic patients whose stenosis is less than 60% of the carotid diameter also benefit from surgery, but the risk and the results from surgery are more modest. In the Asymptomatic Carotid Atherosclerosis Study, surgery reduced stroke risk at 5 years from 11% to 5%. A surgical benefit was not seen in subgroup analysis for disabling stroke or death, and no benefit was seen for women.[73] Studies of community practice suggest that the risk of carotid endarterectomy may be higher than that seen in randomized clinical trials.[74] Many endarterectomies are done for asymptomatic patients in low-volume hospitals where perioperative morbidity and mortality are high.[74] For the beneficial effect of carotid endarterectomy in symptomatic patients to be realized, referring physicians should insist that surgeons provide objective evidence of surgical complication rates of no higher than 6%.[74] In asymptomatic carotid stenosis, surgical risk must be less than 3% because the combined risk of angiography and surgery in trials demonstrating surgical benefit was 2.4%.[74]

Carotid angioplasty and stenting (CAS) is being evaluated as an alternative to carotid endarterectomy. For patients who are at high risk for major complications during carotid endarterectomy, such as those with severe cardiac disease or prior carotid endarterectomy, CAS has been associated with better outcomes, both in the short term and long term.[75] However, for patients who would be candidates for carotid endarterectomy, there are no data from randomized clinical trials to support CAS except as part of a research protocol with appropriate informed consent from the patient.

Antiplatelet and antithrombotic treatment Inhibition of platelet activation can be achieved with several agents, including aspirin, dipyridamole, ticlopidine, and clopidogrel [*see Table 5*]. The role of aspirin in the primary prevention of stroke is uncertain, although it prevents myocardial infarction in high-risk patients.[76] However, aspirin is clearly indicated for secondary prevention of stroke in patients who have already experienced TIA or stroke. Numerous trials of antiplatelet therapy demonstrated that aspirin reduced the risk of nonfatal stroke by about 30%.[77] The ideal aspirin dose is controversial, and there is significant variability in patient responses. For the majority of patients, 50 to 325 mg a day (the dose range recommended by the FDA) appears to maximize the prophylactic effect and minimize the bleeding risk.

Other antiplatelet drugs offer modest additional preventive benefit, compared with aspirin, but at a greater cost and with more potential adverse effects. These medications are recommended for patients who are unable to tolerate aspirin or who have recurrent vascular events while on aspirin. Ticlopidine and clopidogrel reduce the risk of stroke by approximately 21%[78] and 7.3%,[79] respectively, compared with aspirin. Ticlopidine may cause significant neutropenia and thrombocytopenia and therefore requires complete blood count monitoring every 2 weeks for the first 3 months. Although early studies suggested a possible specific benefit for ticlopidine, as compared with aspirin, in African Americans, this was refuted by a large randomized trial.[80] Clopidogrel is associated with a lower frequency of neutropenia than ticlopidine, but thrombotic thrombocytopenic purpura has been reported.[81] Dipyridamole inhibits platelet phosphodiesterase activity and increases the availability of adenosine. Although early trials failed to demonstrate any benefit of dipyridamole, the European Stroke Prevention Study–2 compared regimens consisting of aspirin (50 mg), dipyridamole (extended release, 200 mg), both drugs in combination, and placebo and found a relative risk reduction with the combination of aspirin and dipyridamole of 23% when compared with aspirin alone.[82]

Oral anticoagulation with warfarin is used to inhibit the coagulation cascade and the formation of red blood cell thrombi, and it is appropriate for prevention in patients with high-risk sources of cardioembolism (see above). Warfarin was sometimes used empirically for patients with recurrent cerebrovascular events while on antiplatelet therapy, but in this setting warfarin may not be warranted. The Warfarin Aspirin Recurrent Stroke Study (WARSS) compared warfarin with aspirin in 2,000 patients with noncardioembolic strokes, most of which were lacunar strokes.

Table 5 Comparison of Antiplatelet Therapies for Prevention of Ischemic Stroke

Antiplatelet Drug	*Relative Risk Reduction**	*Major Side Effects*
Aspirin	(Reference drug)	Gastritis Peptic ulcer disease
Ticlopidine	21%	Neutropenia Diarrhea Rash
Clopidogrel	7.3%	Rash Diarrhea Thrombotic thrombocytopenic purpura
Dipyridamole + aspirin	23%	Headache

*Relative risk reduction for stroke.

The risk of recurrent stroke was the same in the two treatment arms, although the risk of hemorrhage tended to be slightly higher in the warfarin group.[83] Consequently, the role of warfarin in noncardioembolic strokes has become somewhat dubious. Further, in the randomized Warfarin versus Aspirin for Symptomatic Intracranial Disease (WASID) trial, both drugs had similar impact on the risk of recurrent stroke or death in patients with large-vessel intracranial stenosis, but the use of warfarin was associated with an increased risk of major bleeding complications.[84] Together, WARSS and WASID show that aspirin is at least as effective as warfarin, and in real-world practice, it is likely safer. Some stroke specialists use warfarin for acute internal carotid artery occlusion and arterial dissection, although controlled trials are lacking.

Contraindications to warfarin include pregnancy, poor compliance, alcohol abuse, and risk of falling. Long-term anticoagulation therapy is associated with a risk of major hemorrhage, which occurs at a rate of 1% to 3% a year.[85]

UNCOMMON CAUSES OF ISCHEMIC STROKE

Mechanisms other than cardioembolism, large-vessel atherothromboembolism, and small-vessel occlusive disease account for only a minority of all ischemic strokes, but they have specific diagnostic and therapeutic implications. Moreover, these unusual causes are disproportionately represented in young stroke victims, accounting for nearly one third of strokes in patients younger than 45 years.[86]

Atherosclerosis of the extracranial and intracranial arteries is a common cause of stroke, but several nonatherosclerotic disorders may also cause stroke. These disorders include inflammatory arteriopathies such as collagen vascular diseases, Takayasu disease, and neurovascular syphilis, as well as noninflammatory arteriopathies such as arterial dissection, fibromuscular dysplasia, moyamoya disease, CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), radiation vasculopathy, and vasospasm after subarachnoid hemorrhage (SAH).

Arterial Dissection

Dissection of the internal carotid artery and vertebral artery can occur after head and neck trauma but may also occur spontaneously. Some connective tissue disorders may be risk factors, including fibromuscular dysplasia, Marfan syndrome, and Ehlers-Danlos syndrome. Arterial wall dissection causes vascular stenosis, occlusion, or a dissecting aneurysm. Clinical features include neck pain, headache, Horner syndrome, TIA or ischemic stroke, and tinnitus or audible bruits. Conventional angiography is the diagnostic gold standard and reveals the string sign, tapered stenosis or occlusion, dissecting aneurysm, intimal flap, distal pouch formation, and an underlying arteriopathy. Dissection may be diagnosed noninvasively with ultrasonography, CTA, MRI, or MRA, but each modality has potential limitations.

Prevention of stroke secondary to extracranial arterial dissection consists primarily of antithrombotic therapy. Heparin should be considered early because stroke risk is greatest in the first few days after the initial vascular injury. If anticoagulation is contraindicated, aspirin is recommended. Antithrombotic therapy should be continued until serial imaging demonstrates recanalization or stabilization of the dissected vessel.[87]

Inflammatory Arteriopathy

Inflammatory arteriopathies, or vasculitides, are a heterogeneous group of disorders in which vascular inflammation results in cerebral ischemia.[88] Vasculitis may be primary (e.g., isolated angiitis of the central nervous system) or secondary to infections (e.g., syphilis, tuberculosis, or varicella-zoster virus), toxins (e.g., cocaine, amphetamines, or LSD), neoplasms, or systemic inflammatory disorders (e.g., polyarteritis nodosa, Churg-Strauss angiitis, Wegener granulomatosis, giant cell arteritis, systemic lupus erythematosus, or rheumatoid arthritis). Symptoms may include headache, seizures, focal neurologic deficits, and multifocal encephalopathy. Clinical and serologic features of the vasculitides vary, but angiographic findings tend to be similar and nonspecific, showing segmental narrowing and dilatation ("beading"). Brain biopsy may confirm the diagnosis. Treatment should be directed at any underlying systemic disorder. Immunosuppressive regimens with corticosteroids and other agents are often used empirically.

Prothrombotic States

Ischemic stroke may be associated with hereditary and acquired prothrombotic states, including abnormalities of red cell or platelet function, of coagulation factors, or of endogenous fibrinolysis. Such disorders are uncommon but should be considered when no alternative etiology is identified.[86,89]

Cerebral Vein Thrombosis

Cerebral vein thrombosis (CVT) is a rare but important cause of stroke that is often missed or discovered late in diagnosis. Infection is the most common cause of CVT in children; in adults, most cases are associated with pregnancy. Infrequent etiologies include severe dehydration, sickle cell anemia, malignancy, and hypercoagulable states. Oral contraceptive agents have also been implicated. Severe headache, nausea, and vomiting are nonspecific but common symptoms. Papilledema, if present, may be the only abnormality on initial examination. Fluctuating focal neurologic deficits, such as unilateral weakness, numbness, or seizures, may appear. Lumbar puncture may demonstrate elevated protein levels, the presence of red blood cells, or xanthochromia. Noncontrast CT can determine whether acute hemorrhage or mass effect is present. Contrast CT may demonstrate a so-called empty delta sign in the sagittal sinus. MRI and MR venogram (MRV) have better sensitivity for detection of CVT; conventional cerebral angiography remains the diagnostic gold

standard. A small randomized trial demonstrated safety and efficacy of intravenous heparin in CVT, even in patients with preexisting hemorrhage.[90] Consequently, acute anticoagulation is recommended for most patients with CVT. Thrombolysis may be considered, but its role remains unconfirmed, and it should be reserved for patients whose condition declines despite adequate anticoagulation.[91,92] After the acute period, oral anticoagulation is typically used for several months until MRI or MRV demonstrates sinus patency. Mortality from CVT is estimated to be 5% to 30%, but survivors have a good prognosis with little residual deficit.[91]

Idiopathic Stroke

Cryptogenic (idiopathic) stroke is diagnosed when all indicated studies fail to identify the likely stroke mechanism. About half of strokes in young patients are diagnosed as cryptogenic.[86] In general, the risk of recurrent stroke in this context is believed to be relatively low.

Hemorrhagic Stroke

INTRACEREBRAL HEMORRHAGE

ICH accounts for 11% of stroke deaths. Prevalence among African Americans is notably higher than in the general population.[93] ICH cannot be reliably distinguished from ischemic stroke by clinical criteria alone. Noncontrast CT imaging establishes the diagnosis and is required to detect the presence of blood. The volume of ICH and the level of consciousness are the two most powerful predictors of outcome [*see Figure 2*]. Specific therapy for ICH remains largely an enigma. Patients with ICH frequently deteriorate as edema worsens over the first 24 to 48 hours. Late hematoma evacuation is ineffective in reducing mortality or improving outcome. Early surgical evacuation remains controversial. Theoretically, early hematoma evacuation may reduce surrounding ischemic injury and prevent edema formation and consequent herniation. Pilot studies of surgery within 12 hours[94] and 24 hours[95] suggested that early surgery is feasible and may be beneficial. In contrast, a trial comparing surgical evacuation with medical management for patients with ICH who appeared to be clinically stable (i.e., whose condition was not declining or who did not show signs of herniation) up to 48 hours after onset showed no difference in mortality or functional outcomes.[96]

Besides surgery, other strategies may be used to control ICP [*see Table 6*]. Intraventricular hemorrhage is a particularly bad complication of ICH. Prompt ventricular drainage should be performed if there are any signs of hydrocephalus. Ventricular drainage may reduce ICP without obvious hydrocephalus. Sedation with or without chemical neuromuscular paralysis is often helpful in controlling ICP in intubated patients. Propofol is an especially useful agent because of its short half-life. An ICP monitor should be used in all sedated patients and in patients who are obtunded (i.e., those whose Glasgow Coma Scale score is less than 9) to follow ICP. Osmotic diuretics are often useful in the short term before a definitive procedure such as hematoma evacuation is performed. The benefit of osmotic diuretics dissipates after 12 to 24 hours, but rebound elevations in ICP can occur. The same is true of hyperventilation, which lowers ICP by reducing cerebral blood flow through vasoconstriction. Although use of hyperventilation to reduce carbon dioxide tension (P_{CO_2}) to 30 to 35 mm Hg may transiently lower ICP, the effect is short-lived (6 to 12 hours), and rebound elevations in ICP are a serious problem if normocapnia is not slowly restored. Steroids are not recommended.

Table 6 Management Strategies for Elevated Intracranial Pressure

Strategy	*Comment*
Ventricular drainage	Most useful in hydrocephalus
Osmotic diuresis	Mannitol load, 0.5–1.0 g/kg I.V.; maintenance dose, 0.25–1.0 g q. 6 hr; titrate to keep serum osmolality 300 to 310 mOsm/kg H_2O
Hyperventilation	Titrate to keep P_{CO_2} 30–35 mm Hg; wean slowly
Sedation	Consider propofol or other benzodiazepine drip
Neuromuscular blockade	Always combine with sedation
Barbiturate coma	Rarely indicated

Blood pressure management in ICH also remains controversial. Observations suggest that about one third of ICHs expand during the first 24 hours.[97] Some investigators have therefore concluded that blood pressure should be lowered in patients with acute ICH. No trial has demonstrated that this action is necessary, and the concern about reducing cerebral perfusion pressure in patients with elevated ICP remains. The American Heart Association guidelines recommend only that mean arterial blood pressure be kept lower than 130 mm Hg in patients with a history of hypertension.[98]

A novel approach to preventing ICH expansion involves the use of procoagulants, and activated factor VII is currently under investigation. This approach may increase the risk of thromboembolic events, which are common complications in patients with ICH, so extreme caution is warranted until further data become available.

Further supportive care should probably be similar to those for patients with ischemic stroke [*see* Supportive Medical Management, *above*]. Premature withdrawal of these measures may worsen outcome.[99]

SUBARACHNOID HEMORRHAGE

Spontaneous SAH most commonly results from aneurysms of the circle of Willis. Aneurysms of the anterior and posterior communicating arteries are most frequently responsible [*see Figure 5*]. Hypertension and cigarette smoking are clear risk factors for aneurysmal rupture. A family history of SAH associated with ruptured intracranial aneurysms in first-degree relatives of patients with SAH is also a risk factor for aneurysm (unruptured aneurysms are detected in about 4% of such patients), but routine screening is not recommended.[100] The risk of rupture depends on aneurysm size. For patients with no history of SAH, the risk of rupture of aneurysms less than 7 mm in diameter is 0.05% a year. For aneurysms greater than 10 mm in diameter, the risk is slightly less than 1% a year. For aneurysms at least 25 mm in diameter, the risk jumps to 6% in the first year.[101]

Diagnosis

Up to 50% of patients with SAH present with a so-called warning leak or sentinel hemorrhage. Establishing the diagnosis early and consequent prompt aneurysm clipping can reduce long-term morbidity and mortality. Modern head CT imaging [*see Figure 2*] can establish the diagnosis in 97% of patients presenting to the emergency department with "the worst headache

of my life." In the remaining small percentage of patients, lumbar puncture and examination of the cerebrospinal fluid for xanthochromia are necessary.[102] In addition to severe headache, the following all suggest SAH and should prompt a thorough evaluation: rapid onset, photophobia, stiff neck, decreased level of consciousness, and focal neurologic signs.

Treatment

The treatment of SAH involves localizing the aneurysm with cerebral angiography and securing it to prevent subsequent bleeding. Traditionally, surgical clipping within 72 hours of onset has been recommended, although in patients with severe symptoms (coma), surgery is often delayed.[103] In a randomized trial involving 2,143 patients with ruptured intracranial aneurysms for whom both surgery or endovascular coiling were technically feasible, disability-free survival at 1 year was better with coiling.[104] However, these patients were very carefully selected, and there is considerable debate about how widely these results can be generalized. In practice, evaluations by both a neurosurgeon and an endovascular interventionalist are recommended.

Before aneurysm clipping or coiling, patients are kept mildly sedated in a quiet room and given stool softeners to reduce the risk of rebleeding. Anticonvulsants should be given at the first sign of seizure. Blood pressure is gently controlled. Although hypertension is related to rebleeding, some investigators believe that blood pressure works to tamponade the bleeding, and drastic reductions in blood pressure should be avoided.

Hydrocephalus is common after SAH and is very treatable with ventricular drainage. Any change in mental status should prompt the performance of an emergency CT scan to look for signs of hydrocephalus. Because it has been shown to improve outcome, nimodipine, a calcium channel blocker, is begun on the first day and continued for 21 days. After aneurysm clipping, the goal is to prevent vasospasm. Daily transcranial Doppler examinations are warranted. Patients should be well hydrated, and blood pressure should be slightly high. At the first clinical or transcranial Doppler sign of vasospasm, so-called triple H (hypertensive, hypervolemic, and hemodilution) therapy should be initiated to maximize cerebral blood flow, but only in patients with secured (i.e., clipped or coiled) aneurysms. Both colloid and crystalloid therapy are employed, and frequently, pressor support is needed.

V TRAUMATIC BRAIN INJURY

Andres M. Salazar, m.d.

Traumatic brain injury (TBI) is the leading cause of death and disability in young adults in the United States; the total national cost of TBI is more than $39 billion a year.[1] Elucidation of the pathophysiology of brain injury is an important challenge for physicians who care for TBI patients. Equally important are prevention and a better scientific understanding of recovery and rehabilitation.

TBI is now generally viewed as a multidimensional, dynamic process. It is not unusual for a patient with TBI who initially is relatively stable and awake or in a light coma to deteriorate rapidly. Delayed hematoma or expanding contusions that are amenable to surgery account for many such cases. Others are related to uncontrolled brain swelling that may not respond to conventional management. Delayed secondary injury at the cellular level is also a major contributor to brain swelling and tissue loss after TBI. The ultimate pathologic picture thus evolves during the first few hours and days after trauma, and the physiologic, clinical, and behavioral aspects of recovery can continue for years. For these reasons, therapy should be predicated on an understanding of the multidimensional pathology of TBI and its evolution.

TBI is traditionally classified by its severity [*see Table 1*], though the current definitions are imperfect and distinctions between mild, moderate, and severe head injury can be difficult to make in the acute period. For example, acute management of an unconscious patient with a moderate head injury may differ little from that of a comatose patient with a more severe head injury; or a patient with little or no initial loss of consciousness may harbor a more serious and even life-threatening pathology, such as a delayed hematoma. Nevertheless, the distinctions are generally useful in guiding the approach to the patient.

Etiology

Brain injury may be caused by any of several types of head trauma, including the more typical closed head injury (in which rapid acceleration or deceleration causes the brain to strike the inside of the skull), direct impact to the head, or penetration by a missile or other foreign object. Although some details of the pathology of these types of trauma may differ, acute and long-term management are similar in most cases.

Pathogenesis

The pathologic changes that occur in TBI may result less from the injury itself than from an uncontrolled vicious circle of biochemical and physiologic events set in motion by the trauma. These biochemical events include changes in arachidonic acid metabolites (e.g., the prostaglandins); the formation of oxygen free radicals and lipid peroxidation; and changes in electrolytes (e.g., calcium and magnesium) in excitotoxic neurotransmitters (e.g., glutamate) and changes in various kinins and cytokines.[2] These events can result in progressive injury to otherwise viable brain tissue by altering vascular reactivity and producing further ischemia, by producing brain swelling (hyperemia, edema, or both), by injuring neurons and glia directly, or by activating macrophages that cause neuronal and glial injury. The patient with severe TBI also often has multiple systemic abnormalities—such as changes in nutrition, cardiopulmonary status,[3] circulating catecholamines, and coagulation[4]—that may be directly related to the brain injury and may have a profound impact on treatment.

At least five parallel components of the pathology of closed head injury have been identified: (1) focal hematomas and contusions, (2) diffuse axonal injury, (3) diffuse microvascular injury with loss of autoregulation and acute brain swelling, (4) hypoxia-ischemia, and (5) selective neuronal loss (especially of thalamic reticular, hippocampal, and cerebellar neurons), possibly caused by excitotoxins. In addition, recent electrophysiologic evidence suggests that a diffuse neuronal (gray matter) dysfunction may be the most subtle and sensitive measure of mild TBI and concussion [*see* Diffuse Gray Matter Dysfunction, *below*]. Each component may have a different effect on the patient, depending on the patient's premorbid status, the severity of the injury, the treatment given, and the time that has elapsed since injury.

Some of these pathologic processes, such as focal hematomas and microvascular injury with brain swelling, can result in the death of the patient soon after injury; others, such as diffuse axonal injury and excitotoxic injury, may result principally in the death of neuronal groups and thus have implications for long-term function. Evaluation of the clinical efficacy of specific therapies therefore depends on the particular pathology targeted by the treatment. For example, survival after TBI may be a good outcome measure of the efficacy of agents designed to limit subacute brain swelling, but it may not be a good measure for evaluating potentially neuron-sparing agents, such as certain glutamate antagonists and neurotrophins.

Focal Injury

Focal injuries include intracerebral and extracerebral hematomas and focal contusions. Hematomas are most common after the rapid acceleration or deceleration that occurs as

Table 1 Severity of Traumatic Brain Injury

Severity	*Admission GCS Score*	*Duration of Unconsciousness*	*Duration of Posttraumatic Amnesia*	*CT/MRI*
Uncomplicated mild	13–15	0–20 min	< 24 hr	Normal
Complicated mild	13–15	0–20 min	< 24 hr	Abnormal
Moderate	9–12	< 24 hr	> 24 hr	Usually abnormal
Severe	3–8	> 24 hr	Weeks	Abnormal

GCS—Glasgow Coma Scale

the result of a fall or another form of impact, especially in the elderly. Delayed hematomas, which can occur in patients who are initially at low risk but whose condition deteriorates rapidly, are particularly important. Small hematomas can be treated conservatively, but delaying the surgical removal of large hematomas for longer than 4 hours after injury significantly increases mortality and morbidity.

Focal contusions may occur under the site of impact, but by far the most common locations after acceleration-deceleration injury are in the orbitofrontal and anterior temporal lobes, where the brain abuts the base of the skull. The most troubling clinical sequelae are usually behavioral and cognitive abnormalities referable to these areas of the brain. Contusions can undergo secondary expansion or result in delayed hematomas. Patients with such injuries require particularly close observation in the acute period. Both hematomas and contusions are also significant risk factors for the development of posttraumatic epilepsy [*see 11:XII Epilepsy*].

DIFFUSE AXONAL INJURY

Diffuse axonal injury—a shearing injury of axons in the hemispheric white matter, corpus callosum, and brain stem[5]—is a significant cause of persistent, severe neurologic deficits in closed-head injury. When severe, the injury is manifested clinically by immediate and prolonged loss of consciousness. Petechial hemorrhages in the white matter or blurring of the gray matter–white matter junction is best seen on magnetic resonance imaging, especially in coronal slices. However, the only early abnormality may be microscopic focal cytoskeletal disruption. These changes lead to disturbance of axonal flow and the subsequent severing of axons, with the typical light microscopic picture appearing 12 to 24 hours later. If severe enough, such axonal injury can lead to wallerian degeneration and diffuse target deafferentation.[6,7] It is possible that medical treatments can prevent total axonal disruption. Certain neurotrophins, such as brain-derived neurotrophic factor and perhaps insulinlike growth factor, may attenuate it.[8]

Such axonal injury may also occur even after mild TBI (MTBI) and in the absence of morphopathologic change in any other vascular, neural, or glial element. Some of the cognitive changes seen after MTBI may relate to diffuse axonal injury.

DIFFUSE MICROVASCULAR DAMAGE

Diffuse microvascular damage is a major component of both closed and penetrating TBI. Depending on the severity of the injury, early changes may include loss of cerebrovascular autoregulation, with decreased responses to changes in carbon dioxide and perfusion pressure, and transient systemic hypertension. The loss of autoregulation makes the brain particularly susceptible to fluctuations in systemic blood pressure; otherwise tolerable hypotension can thus result in cerebral ischemic damage in the patient with TBI. In addition, altered vascular sensitivity to circulating catecholamines can lead to vasoconstriction and further focal ischemia or reperfusion injury. The microvascular pathology includes an endothelial change that probably involves oxygen free radical–induced decreases in endothelial nitric oxide, with a concomitant vasoconstriction, and an initial hyperglycolysis with a dissociation of cerebral blood flow and metabolism.[9] Positron emission tomography has demonstrated these metabolic changes even in patients with MTBI.

Free radicals, including the superoxide radical peroxynitrite, and the process of lipid peroxidation play a critical role in secondary injury, not only by their effect on the microvasculature but also by their direct effects on tissue. The pharmacologic agents used to reduce the formation of free radicals or to scavenge those already formed include steroids to inhibit lipid peroxidation; α-tocopherol (vitamin E) and its analogues; α-lipoic acid; iron chelators, such as deferoxamine; and enzymes such as superoxide dismutase. However, in phase III clinical studies, two such compounds—the 21-aminosteroid tirilazad mesylate and a polyethylene glycol–conjugated superoxide dismutase—failed to provide clear benefit to patients with acute, severe TBI.[10,11]

HYPOXIA-ISCHEMIA

The classic pathology of hypoxia-ischemia primarily involves the hippocampus and the vascular border zones of the brain. It is often superimposed on other, more specific pathologies of TBI. The traumatized brain is particularly sensitive to hypoxia-ischemia, possibly because of the metabolic demands already placed on neurons by the trauma itself[12] or by increasing vascular permeability.[13] The most significant improvements in the survival of patients with TBI have resulted from recognition of the importance of this component and its prevention, largely through training of paramedics, the development of emergency transport systems, and immediate resuscitation protocols.[14]

SELECTIVE NEURONAL VULNERABILITY, EXCITOTOXIC INJURY, AND NEURONAL ENERGY FAILURE

Selective vulnerability of certain neuronal groups, including hippocampal and thalamic reticular neurons that receive glutaminergic afferents from the orbitofrontal cortex, occurs after head injury and appears to be caused by glutamate excitotoxicity.[15] It also occurs after mild head injury in animal models and may be a cause of the fatigue, attention, and memory problems often seen in postconcussion syndrome in humans.

Excitotoxic injury may be one of the most important mechanisms of neuronal death after traumatic or ischemic injury. Excessive release of glutamate and other neurotransmitters unleashes a chain of cellular events that deplete neuronal energy stores, damage mitochondria, and result in cell death or apoptosis. Thus, glutamate antagonists or other neuroprotectants, such as dextrorphan, riluzole, memantine, and magnesium, may play a role in the acute treatment of TBI. However, because of the importance of glutamate in the brain, receptor blockade is usually accompanied by intolerable side effects; a number of clinical trials with such agents have failed to show a clear benefit.[16] Alternatively, therapies that prevent depletion of neuronal metabolic stores or that enhance neuronal stores have also been shown to protect cells in models of glutamate toxicity. One related neuroprotective strategy that reduces glutamate release and appears to protect cellular energy metabolism is moderate systemic hypothermia. A controlled pilot study showed long-term benefit from treatment with hypothermia for patients surviving severe TBI.[17] However, a larger multicenter study failed to confirm these findings.[18]

A more direct approach may be to use agents that enhance neuronal energy metabolism and mitochondrial function after injury. Because it addresses a "final common path" in neuronal dysfunction, death, or both, this approach may protect against various stressors, including excitotoxic, oxidative, or calcium-induced injury.[19] Depletion of neuronal energy can result because of the increased demands placed on neurons and their membrane pumps by the injury and because of a failure of adenosine triphosphate (ATP) production.

Mitochondrial dysfunction has been demonstrated after brain injury. One mechanism of mitochondrial dysfunction is the fail-

ure of the mitochondrial membrane, with consequent release of cytochrome-c into the cytoplasm and the subsequent activation of caspases and the apoptotic cascade. Similarly, it has been postulated that mitochondrial failure, including failure of the pyruvate dehydrogenase pathways, may underlie the demonstrated uncoupling of blood flow and metabolism after TBI.[19]

Cyclosporine has been demonstrated to have a neuroprotective effect, which is achieved through stabilization of the mitochondrial membrane.[20,21] Both creatine and the three-carbon sugar pyruvate have been shown to have marked neuroprotective effects in animal models of TBI. As with cyclosporine, this effect is achieved through stabilization of the mitochondrial membrane.[22,23] Pyruvate is not only the primary energy substrate in neuronal mitochondria but also a good scavenger of oxygen free radicals. Both pyruvate and creatine are inexpensive and nontoxic; they are in early clinical trials for the treatment of brain injury.

DIFFUSE GRAY MATTER DYSFUNCTION

In addition to selective neuronal vulnerability, recent evidence from quantitative electroencephalograhic and quantitative MRI studies suggests that a very common effect of TBI may be a diffuse gray matter dysfunction that manifests itself primarily through changes in brain electrical activity, as measured by EEG coherence, phase, and power.[24-27] These alterations may, in turn, reflect a relative loss of neuronal membrane electrical efficiency, probably as a consequence of the failure of neuronal energy metabolism and the ATP-driven neuronal ion pumps. Such failure would not be unexpected in the face of a probable diffuse excitotoxic challenge or other challenges in the early period after TBI. These alterations may be the only physiologic or pathologic evidence of MTBI or concussion. Although the pathology of this dysfunction is likely to be very subtle, there is a strong correlation between these changes and changes in the T_2-weighted MRI signal in the gray matter, which in turn is thought to reflect the functional integrity of neuronal membranes (T_2 refers to spin-spin, or transverse, relaxation time). These EEG changes have also been demonstrated to correlate with neuropsychological performance, suggesting that they could also be responsible for some of the cognitive changes that occur after MTBI. Restoration of neuronal energy metabolism might be expected to ameliorate these cognitive changes.

Mild Traumatic Brain Injury

With an incidence of 180 per 100,000 people, MTBI is more common than any other neurologic diagnosis except migraine. MTBI is variably defined as any TBI/concussion with loss of consciousness of 0 to 30 minutes, a Glasgow Coma Scale (GCS) score of 13 to 15 on admission [*see Table 2*], posttraumatic amnesia or confusion lasting less than 24 hours, and no evidence of contusion or hematoma on CT. Concussion can be further divided into grades I, II, and III. Grade I concussion is characterized by transient mental changes lasting longer than 15 minutes, with no loss of consciousness; in grade II concussion, transient mental changes last longer than 15 minutes, and there is no loss of consciousness; and grade III concussion is characterized by brief loss of consciousness. Although these distinctions, especially the distinction between grade I and grade II concussion, can be relatively subtle, they can serve as a useful guide for return to normal activity, especially in athletes or other active individuals.[28] In any case, MTBI, even without loss of consciousness, has been repeatedly associated with measurable abnormalities in cognition, attention, and behavior, as well as documented quantitative EEG and neuropathologic changes.[24,29] Abnormalities seen on assessments of cognitive task have been repeatedly documented after MTBI; these abnormalities usually include disturbances of attention, information processing, and memory.[30-33] As might be expected, MTBI also has a significant psychosocial impact.

Over 75% of MTBI patients report some somatic or cognitive symptoms over the first several weeks after injury; these can have important functional, social, and economic implications. Symptoms include headache, dizziness or vertigo, blurred vision, fatigue, sleep disturbance, irritability, depression, anxiety, and poor memory and concentration. Typically, these symptoms improve steadily and are largely cleared after the first 3 months after injury. However, some symptoms, especially the emotional symptoms, can persist longer. The term postconcussion syndrome is often applied when this complex of symptoms is persistent.[30]

There has been increasing attention paid to MTBI in sports.[34] The study of MTBI in athletes offers several advantages, including the generally high preinjury health and motivation of athletes, the ability to conduct preinjury testing, and the relative predictability of the time of the injury. In one study, college football players were examined before and after injury; significant attention deficits were found to persist for as long as 5 days after a minor "ding" that was not associated with loss of consciousness.[35] Similar findings have been reported in soccer players.[36]

PATHOGENESIS

The pathology associated with MTBI or concussion is still unclear, but some evidence suggests that these injuries may be associated with a diffuse cortical neuronal dysfunction; selective vulnerability of certain neurons and a modest amount of diffuse axonal injury may also be factors. Microvascular injury with alterations in autoregulation and uncoupling of blood flow and metabolism has also been described in MTBI, especially with repeated MTBI—the so-called second impact syndrome—in pediatric and adolescent patients.[9,37,38] Finally, hematomas occur with some frequency in patients who might otherwise be classified as having MTBI.[39-41]

Table 2 Glasgow Coma Scale[92]

(*b*) Positron emission tomography confirms decreased metabolism in the left temporal lobe.**

EVALUATION AND ACUTE MANAGEMENT

Although the emergency department evaluation and management of MTBI is controversial, the principal concern is with identifying evolving surgical lesions such as hematomas and contusions. The cause of injury can be a factor in management; for example, motor vehicle accidents involving large forces or impact to the head may raise the likelihood of hematomas, as do falls in older patients, especially if the patient is taking anticoagulants or aspirin. Documentation of the history of the injury, as well as the length of the period of unconsciousness, mental confusion, or both, can be very helpful in both acute and long-term management. In the past, many patients with traumatic loss of consciousness were admitted to the hospital for overnight observation, especially if there was no responsible adult to be with the patient at home. However, changes in managed care over the past several decades and the increased availability of computed tomography have led to a marked decrease in such admissions.[42]

In addition to history and examination, CT has become the mainstay of evaluation, to the exclusion of skull x-ray. Prolonged or deteriorating mental status or the presence of neurologic signs or other risk factors are still clear indications for CT scanning, observation, or both after MTBI. For example, MTBI patients whose GCS scores are 13 or 14 on admission have a much higher incidence (up to 28%) of abnormal findings on CT scanning than do patients with a GCS score of 15.[43] In addition, on rare occasions, even MTBI patients whose initial CT scans are negative may develop surgical complications after discharge; repeat CT scanning should thus be considered in patients who return with severe, persistent symptoms or new neurologic signs.

The diagnosis of contusion is also important for its longer-term prognostic value. Patients with MTBI complicated by cerebral contusion have a 6-month outcome that is more consistent with that of patients with moderate head injury[39] and are thus candidates for more intensive, longer-term observation and management.

In the postacute period, MRI, single-photon emission computed tomography (SPECT), and quantitative EEG can provide additional documentation and localization of brain injury that can be very valuable in guiding nonsurgical management [*see Figure 1*]. For example, MRI can help provide a presumptive diagnosis of diffuse axonal injury and subtle brain contusions that might have been be missed on CT. Standard neuropsychological testing is usually not indicated in the MTBI patient, but some brief, specialized cognitive batteries that have been developed for this population can be very helpful in diagnosis and follow-up. These include the Sideline Assessment of Concussion (SAC) and the Automated Neuropsychological Assessment Metric (ANAM).[28,29,44-46]

MANAGEMENT OF MTBI

Postconcussive symptoms, which include headache, dizziness, fatigue, and documented deficits in cognition, can be seen even after mild injuries without loss of consciousness. In general, the prognosis for recovery is very good, with most cognitive and somatic sequelae improving markedly by 3 months; 85% of patients experience no disabling symptoms 1 year after injury.[40,47] In the small percentage of patients who have postconcussive complaints and disability over periods exceeding 1 year, psychogenic factors can often contribute to the persistence of symptoms. Patients who have persistent symptoms of anxiety, depression, or both need appropriate diagnosis and treatment, preferably by a psychiatrist who has experience with TBI.

Probably the most important element in the longer-term management of patients with MTBI is the clinician's recognition that the postconcussive symptoms in these patients have a structural cause and that the patients usually recover. Attention deficits and fatigue appear to be especially common and troubling, and there is nothing more disconcerting to the intelligent but symptomatic MTBI patient than to be told by his physician, family, or employer that there is nothing wrong. Early symptomatic management and counseling as to what to expect can help avoid the all too common delayed emotional symptoms of anxiety and depression, especially in patients who may be at risk because of underlying psychopathology. Recognition that the concussed patient is not always able to understand oral counseling in the emergency department has led some physicians to use information booklets that expand and reinforce initial recommendations. Recent controlled studies have convincingly demonstrated that the use of such booklets significantly reduces long-term morbidity, particularly with regard to emotional symptoms.[48]

Moderate and Severe Head Injury

INITIAL EVALUATION AND RESUSCITATION

An organized team approach to the acute management of the unconscious patient with TBI is essential and includes prehospital, intensive care unit, and post-ICU care. A cornerstone of early evaluation and care is recognition of deterioration in patient status through the sequential use of a standardized measure such as the GCS score [*see Figure 2*], along with checks of lateralized deficits in neurologic function and careful attention to pupillary responses. The history should be obtained from witnesses, particularly with regard to the onset of coma. For example, if a patient who is comatose had an initial interval of lucidity or semilucidity, an expanding mass lesion may be present, and severe diffuse axonal injury is less likely.[49]

The importance of cardiopulmonary resuscitation in patients with acute TBI cannot be overstated.[50] Airway and shock management should be the first priority in all trauma patients. The loss of cerebrovascular autoregulation places the brain at increased risk for cerebral ischemia from systemic hypotension, and levels of hypercapnia tolerated by the normal brain can lead to critical marginal increases in intracranial pressure (ICP) in the patient with head injury. Most prehospital deaths after TBI are probably caused by vascular and respiratory failure. This is supported by the marked improvements in outcome achieved by emergency care systems with early prehospital intubation and resuscitation.

Shock is usually caused by hemorrhage elsewhere in the body, not in the head. Cerebral perfusion pressure should be maintained above 70 mm Hg by vigorous management of hypotension. Fluid resuscitation with normal saline or lactated Ringer solution is generally recommended, but patients with TBI should not receive excessive hydration, and central venous pressure should be monitored. Glucose administration should be avoided because it has been linked to poor outcome, possibly through increased lactic acidosis.[51]

Comatose patients with TBI are often hypoxic or hypercapnic, even though ventilation may appear to be normal. Patients who are in a coma (i.e., those with a GCS score < 8) should undergo gentle hyperventilation, via intubation if necessary, until a carbon dioxide tension (P_{CO_2}) of about 35 mm Hg is achieved. Short-term hyperventilation to levels of about 25 mm Hg can be lifesaving in the patient with impending tentorial herniation. However, the recommended standard is that chronic hyperventilation be maintained at a P_{CO_2} no lower than 25 mm Hg, because lower levels reduce cerebral blood flow and have a negative impact on outcome. Sedation or pharmacologic paralysis should be used when necessary to control acute agitation. The head should be elevated and immobilized in the plane of the body for airway maintenance and facilitation of cranial venous return.

Finally, the special nutritional requirements of the TBI patient also need particular attention, from coma through subacute recovery. Early nutritional support (often parenteral) may be associated with improved survival and decreased disability.[52]

Radiologic Examination

CT has revolutionized the diagnosis and management of mass lesions in patients with head trauma; it should be performed in all patients with a GCS score of less than 15 and in those who have focal signs or posttraumatic amnesia. Comatose patients must be accompanied by trained personnel on the way to the CT suite because patients who are assumed to be stabilized may suffer respiratory arrest or irreversible brain damage as a result of simple airway problems en route.

The principal role of CT is in the diagnosis and management of acute surgical lesions. Hemorrhage can occur in the subarachnoid, subdural, epidural, and intraventricular spaces or in the brain parenchyma. Subdural and epidural hematomas should

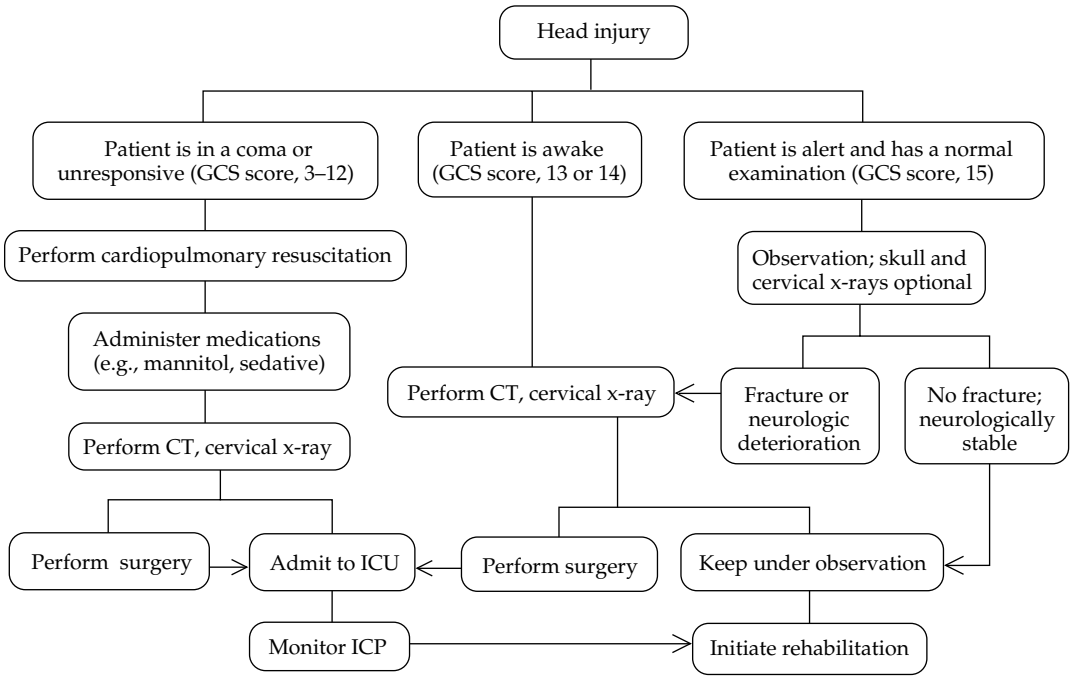

Figure 2 **Management algorithm for patients with traumatic brain injury. (GCS—Glasgow Coma Scale; ICP—intracranial pressure)**

Figure 3 **CT in a 19-year-old man with a history of head injury and recent occipital injury shows the old lesion, the resulting midline distortion, and an epidural hematoma (arrow) resulting from the recent injury.**

be evacuated promptly when associated with a significant mass effect, because it has been shown that there is a significantly poorer outcome with surgical delays of greater than 4 hours.[53,54] However, surgical management of intraparenchymal hemorrhage will vary, depending on the size, mass effect, location, and neurologic status. Intraventricular hemorrhage will generally require ventricular drainage, and it has also been associated with a worse prognosis. Obliteration of the basilar cisterns from mass effect also portends a worse outcome, as does diffuse hypodensity typical of cerebral hypoxia.[49]

CT has made the skull x-ray all but obsolete, and the latter rarely affects management.[55] Normal findings on initial skull x-ray or CT should not lull the clinician into ignoring the possibility that a delayed hematoma may develop, although this is fortunately relatively rare [*see Figure 3*]. Whether in the hospital or at home with a responsible adult, observation remains a critical element of care, even for patients with MTBI.

MRI promises to be very useful in the long-term management of moderate and severe TBI as well as in the documentation of brain pathology in patients with milder injury. However, it is often impractical and not cost-effective in the acutely comatose patient and is not as good as CT for diagnosis of acute hematomas.

Laboratory tests should include a complete blood count; measurements of electrolytes, glucose, arterial blood gases, and blood alcohol; liver and kidney function tests; and a toxicology screen. In addition, because coagulopathies frequently occur after TBI, other tests may be indicated. Such tests include a platelet count; prothrombin, partial thromboplastin, and thrombin times; and an evaluation of fibrinogen and fibrinogen degradation products.

ACUTE MANAGEMENT

Acute management of severe head trauma is aimed at minimizing the progression or the effects of secondary injury. Although there are no specific treatments targeting the biochemical events discussed (see above), much progress has been made in early resuscitation and the management of elevated ICP. Evidence-based guidelines and standards for management of patients with severe acute TBI, as well as options for the care of such patients, have been updated by the Joint Section on Neurotrauma and Critical Care and the American Association of Neurological Surgeons, under sponsorship of the Brain Trauma Foundation.[56] These guidelines are also available through the Brain Trauma Foundation Web site (www.braintrauma.org). They represent a major advance in standardization of the management of severe TBI and should be consulted by anyone involved in the care of these patients.

Aspects of care described in the guidelines include early resuscitation; ICP monitoring; ICP treatment threshold and methods; and the use of mannitol, barbiturates, nutrition, hyperventilation, corticosteroids, and prophylactic anticonvulsants. It is important to note that even guidelines that are presented as options for care are very valuable, because such options represent the consensus of experts in areas where studies documenting more definitive levels of certainty are not available or are not possible [*see Table 3*]. The guidelines currently support a standard recommendation against the routine use of aggressive hyperventilation, corticosteroids, and prophylactic anticonvulsants.

The Intensive Care Unit, Intracranial Pressure Monitoring, and Cerebral Perfusion Pressure

After a mass lesion has been surgically treated or excluded, the comatose patient should be managed in the ICU. Preventing secondary insults to the brain remains the principal goal of therapy. In general, the same principles of care that are applied in earlier stages of treatment (see above) are applied at this stage, but better monitoring is available in the ICU. Organization, training, and adherence to relatively simple principles are the mainstay of care.

ICP and cerebral perfusion pressure (CPP) are probably the most sensitive measures for monitoring the patient with severe TBI, and the results of these assessments correlate significantly with outcome.[57-59] The current guideline recommends that ICP be monitored in comatose patients in whom CT yields abnormal results and in those in whom CT is normal but who have two or more of the following risk factors: age greater than 40 years, motor posturing, or a systolic blood pressure of less than 90 mm Hg. The particular monitoring technique to be used is determined by the neurosurgeon and the facilities available. An intraventricular catheter is recommended, because it can also be used for ventricular drainage as needed, though fiberoptic epidural or subdural transducers can also be used.[60]

The current standard measures for control of elevated ICP include sedation, paralysis, controlled hyperventilation, use of mannitol and other osmotics, ventricular drainage, and barbiturate coma [*see Table 4*]; these interventions are usually undertaken in that sequence to maintain an ICP of lower than 20 mm Hg.[58,61] It is recommended as a guideline that mannitol be given in intermittent boluses of 0.25 to 1.0 g/kg every 4 hours as needed, but serum osmolarity should be kept below 320 mOsm/L because of concerns about renal failure. Use of a Foley catheter is strongly recommended to monitor urine output and help maintain euvolemia through adequate fluid replacement. Barbiturate coma significantly improves outcome in patients younger than 45 years with otherwise uncontrolled ICP. This is the last step recommended as a guideline in the nonsurgical control of ICP.

Barbiturate coma is induced with pentobarbital at an initial loading dose of 10 mg/kg I.V. over 30 minutes, and serum levels should then be maintained at 3 to 4 mg/dl with dosages of about 1 mg/kg/hr. The literature supports a standard recommendation that corticosteroids not be used for neuroprotection or control of ICP in patients with severe TBI.[62] Finally, progressive elevations in ICP may be caused by lesions that require surgery, such as delayed hematoma or hydrocephalus. Similarly, seizures, hyponatremia, and airway problems will raise ICP.

MANAGEMENT OF AGITATION

Patients with TBI often experience agitation during the immediate recovery period. Nonpharmacologic interventions, including limiting environmental stimuli and providing gentle interaction with the patient, are of great importance in early management and should typically be the first line of therapy. When ICU patients require chemical restraint for their own safety and the safety of staff, propofol may be given intravenously to manage agitation; the recovery time with propofol is quicker than with benzodiazepines such as midazolam.

After the patient has left the ICU, benzodiazepines (e.g., lorazepam, 0.5 to 2.0 mg p.o. or I.M., or clonazepam, 0.5 to 2.0 mg p.o.) may be the first choice, either alone or in combination with carbamazepine or valproate. However, benzodiazepines may cause disinhibition in some patients with brain injury. Neuroleptics (e.g., molindone, 10 mg p.o., b.i.d., or haloperidol, 0.5 to 2.5 mg p.o., b.i.d.) are less desirable because they may cause extrapyramidal effects, akathisia (a subjective sense of restlessness that may prolong agitation), or both. Some newer agents, such as olanzapine, 2.5 to 5.0 mg/day orally, may have fewer side ef-

Table 3 Evidence-Based Guidelines for the Management of Severe Head Injury[62]

Subject	*Certainty Level**	*Recommendations*
Trauma systems	Guideline	All regions in the United States should have an organized trauma care system
Resuscitation	Guideline	Systolic BP < 90 mm Hg or hypoxia must be scrupulously avoided or corrected immediately
	Option	Mean arterial pressure should be kept above 90 mm Hg
Integration of brain-specific treatments into initial resuscitation	Option	When clear signs of transtentorial herniation are present, the herniation should be treated aggressively; hyperventilation should be performed rapidly (mannitol is desirable with adequate volume resuscitation); sedation and short-acting neuromuscular blockade can be used but may interfere with the neurologic examination
ICP monitoring	Guideline	Admission GCS 3–8 plus abnormal CT scan, *or* GCS 3–8 and normal CT plus age > 40 years, *or* motor posturing, *or* systolic BP < 90 mm Hg
ICP treatment threshold	Guideline	ICP > 20–25 mm Hg
	Option	ICP treatment should be corroborated by frequent clinical examination and cerebral perfusion pressure data
ICP treatment critical pathway	Option	[*See* text, Table 4, and reference 47]
CPP	Option	Maintain CPP above 70 mm Hg
Hyperventilation	Standard	In the absence of increased ICP, chronic prolonged hyperventilation (P_aco_2 < 25 mm Hg) should be avoided
	Guideline	Prophylactic hyperventilation (P_aco_2 < 35 mm Hg) should be avoided during the first 24 hr after severe TBI because it can compromise CPP when cerebral blood flow is reduced
	Option	Hyperventilation therapy may be necessary for brief periods when there is neurologic deterioration or when ICP elevations are refractory to other treatment
Mannitol	Guideline	Mannitol is effective for ICP control; intermittent boluses (0.25 to 1.0 g/kg) may be more effective than continuous infusion
	Options	Indications for mannitol before ICP monitoring are progressive neurologic deterioration or transtentorial herniation not attributable to systemic pathology
		Maintain serum osmolality < 320 mOsm
		Maintain euvolemia by adequate fluid replacement; use Foley catheter
Barbiturates	Guideline	High-dose barbiturates may be used in hemodynamically stable severe TBI patients with ICP elevations refractory to maximal medical and surgical therapy
Glucocorticoids	Standard	Glucocorticoids are not recommended for ICP control or improving outcome in severe TBI patients
Nutritional support	Guideline	Replace 140% of resting metabolic expenditure (100% in paralyzed patients) by using enteral or parenteral formulas, with at least 15% of calories as protein
	Option	Feeding by gastrojejunostomy is preferred
Antiseizure prophylaxis	Standard	Prophylactic use of phenytoin, carbamazepine, or phenobarbital is not recommended for preventing late posttraumatic seizures
	Option	Short-term (1 wk) phenytoin or carbamazepine is recommended to prevent early posttraumatic seizures in high-risk patients after head injury

Note: This table should not be used alone as a guide to therapy. Clinicians are referred to the full guideline document (see text).
*For determining certainty level, studies that are controlled and randomized rank highest, and expert opinion ranks lowest. The highest level of certainty is represented by standards; the next highest, by guidelines; and the lowest, by options for care.
BP—blood pressure CPP—cerebral perfusion pressure GCS—Glasgow Coma Scale ICP—intracranial pressure P_aco_2—arterial carbon dioxide tension TBI—traumatic brain injury

Table 4 Management of Intracranial Pressure

Treatment	*Dosage*
Sedation (with morphine)	As needed
Paralysis (with pancuronium)	As needed
Ventricular drainage	As needed
Mannitol	0.25–1.0 g/kg q. 4 hr
Hyperventilation	To a Pco_2 of 35 mm Hg (25 mm Hg only for brief periods, if needed for transtentorial herniation)
Barbiturate coma (pentobarbital)	Loading dose of 10 mg/kg, then 1 mg/kg/hr

Pco_2—carbon dioxide tension

fects. Animal models suggest that neuroleptics have a negative long-term effect on recovery.[63] Dopamine agonists such as amantadine and bromocriptine have also been successfully used for postcoma agitation caused by impairment of dopaminergic and other ascending monoaminergic pathways.

A recent survey of rehabilitation physicians suggests that those who are more experienced in caring for patients with brain injury tend to use carbamazepine and beta blockers in preference to neuroleptics for management of agitation. In all cases of prolonged confusion or agitation, however, other causes must also be considered, such as the side effects of medication, infection, electrolyte imbalance, hypoxia, and late intracranial complications.

TREATMENT OF NEUROPSYCHIATRIC SEQUELAE

The neuropsychiatric sequelae of brain injury, both socially and in the workplace, are well appreciated. Verbalizations and behavior can be striking, especially when the patient has a reduced ability to self-monitor and is unconcerned.[64,65] Neurologic abnormalities may not be as distressing to the patient and his or her family as personality changes and inappropriate behavior. Suitable treatment of neurobehavioral sequelae will often decrease patient and caregiver distress and markedly improve overall outcome.[66]

Intellectual impairments increase as the duration of posttraumatic amnesia rises from less than 1 hour to longer than 7 days. Inappropriate behavior associated with frontal, temporal, and limbic connections (e.g., poor social judgment, increased irritability, and poor impulse control) is particularly common, even in patients in whom imaging studies show no focal pathology. Frontal-thalamic reticular circuit damage may also cause fatigue and frequent sleep disturbances.

Depression

Studies consistently show a 25% to 50% incidence of depression after TBI. In one study, of the 75% of TBI patients who were not depressed at the initial interview, 25% developed depression during the first year of follow-up; the mean duration of depression was 4 to 5 months for the total sample.[67] Patients frequently complain of hopelessness, a loss of interest in usual activities, self-deprecation, a lack of energy, and a lack of self-confidence. Anxiety symptoms may be prominent, especially within 6 months after injury.

Many reports suggest that the depression associated with stroke and TBI has a neurologic basis. Acutely depressed patients with TBI frequently have left anterior lesions, whereas patients with mixed anxiety and depression are more likely to have right-hemisphere lesions, a longer duration of depression, and poorer psychosocial outcome.[67] The incidence of depression, its duration, and its associated symptoms, such as anxiety, may therefore be related to the location and laterality of cerebral pathology.

Antidepressants are indicated in the treatment of depression and of mixed anxiety and depression in TBI [*see 13:VIII Anxiety Disorders*]. The selective serotonin reuptake inhibitors (SSRIs) fluoxetine, sertraline, and paroxetine are favored because they are safe and easy to administer and do not cause unwanted anticholinergic side effects. Tricyclic antidepressants may also be used; desipramine and nortriptyline have the fewest anticholinergic and antihistaminic properties. The antidepressant venlafaxine is both serotoninergic and dopaminergic. Although stimulants such as methylphenidate and dextroamphetamine have primarily been used in TBI patients to treat attention difficulties, they can also be used to treat depression or to augment antidepressant treatment with SSRIs or tricyclic antidepressants. Bupropion should be given only with caution to patients with brain injury, because it can lower the seizure threshold.

Anxiety

Anxiety disorders, alone or in combination with depression, occur in patients with TBI and are treated with SSRIs, tricyclic antidepressants, benzodiazepines, or buspirone. As with antidepressants, buspirone has a 2- to 3-week latency period until it reaches full therapeutic effect. Patients with phobic avoidance are best treated with a combination of cognitive-behavioral therapy and benzodiazepines. Symptoms of posttraumatic stress disorder (PTSD) may occur and are more common in patients with MTBI than in patients with more severe TBI. Longer periods of posttraumatic amnesia, in which an explicit memory of the upsetting events is not established, may protect against the development of nightmares and intrusive thoughts about the trauma.[68] The development of PTSD symptoms probably entails implicit memory by a mechanism similar to negative conditioning and thus may not require explicit memory of the event.[69]

Irritability and Aggression

Irritability occurs in more than 50% of patients with moderate or severe traumatic head injury during the first 6 months after injury. Aggressive outbursts in brain-injured patients tend to be verbal and brief and are precipitated by seemingly trivial provocations. Patients may be remorseful and apologetic afterward but seem to be unable to curtail subsequent outbursts. Irritability and aggression may occur in patients without a history of such behavior; disinhibition caused by frontal system dysfunction and possible injury to limbic and hypothalamic structures is implicated.[70] Impaired serotonin transmission may also be involved, because low levels of 5-hydroxyindoleacetic acid (5-HIAA) have been noted in the cerebrospinal fluid of impulsive, violent patients. Anticonvulsants, lithium, buspirone, beta blockers, SSRIs, and stimulants have been variously reported to be of use in decreasing the amount of aggression.[71]

Attention Deficits

The stimulants dextroamphetamine and methylphenidate may improve attention and concentration and are often used in the clinic in selected patients. A randomized, controlled study of methylphenidate in adults with moderate TBI found a more

rapid rate of recovery of attention and improved scores on motor and disability tests but no change in ultimate overall outcome through the use of methylphenidate.[72] Findings of a recent controlled crossover study on the use of methylphenidate in children suggested that there is no difference in behavior, attention, memory, or processing speed between persons receiving medication and those given placebo.[73] Clear guidelines on the use of stimulants to treat attention deficits in TBI await additional studies.

TREATMENT OF POSTTRAUMATIC EPILEPSY

The risk of epilepsy in patients with closed-head injury is relatively small: 2% to 5% in all patients and about 10% to 20% in patients with severe closed-head injury.[74] Some studies have shown a higher incidence of seizures in patients with depressed skull fractures (15%), hematomas (31%), and penetrating brain wounds (50%).[75,76] In all cases, the risk decreases markedly with time. Although the relative risk of developing epilepsy 10 to 15 years after penetrating head injury is still 25 times higher than in the normal age-matched population, 95% of patients with penetrating head injury will remain seizure-free if they have no seizures during the first 3 years after injury.[77]

Because most patients who develop posttraumatic epilepsy in the first week after injury will have recurrent seizures for some time, anticonvulsant therapy is indicated in documented cases.[78] Controlled, randomized studies have shown that the use of phenytoin, phenobarbital, carbamazepine, or valproate does not prevent the development of posttraumatic epilepsy beyond the first week after injury. It is now recommended as a standard of care that these medications not be used to prevent posttraumatic epilepsy in patients who have not had a seizure.[79] In light of the sensitivity of the acutely traumatized brain to the secondary insult of a grand mal seizure, I recommend routine short-term use (for 1 to 2 weeks after injury) of phenytoin or carbamazepine in high-risk patients with acute TBI. Carbamazepine may be preferable because it helps control agitation in some patients.

Evidence suggests that iron-catalyzed lipid peroxidation may partly mediate the development of posttraumatic epilepsy; inhibitors of lipid peroxidation, such as methylprednisolone and α-tocopherol, can prevent iron-induced epilepsy in animals, but no well-controlled clinical trials have explored this avenue.[80]

Long-term Outcome

The young-adult brain has a remarkable capacity to compensate for many aspects of injury naturally. Although disabilities such as hemiparesis, seizures, and certain language disorders may initially appear more dramatic, the most devastating long-term impairments are the cognitive defects, attention deficits, and, in particular, behavioral changes that often persist after TBI.[81]

Prognosis for full recovery must be more guarded in the elderly, who have been reported to have about twice the mortality of younger TBI patients. Likewise, seemingly less severe injuries often result in worse functional outcomes in older patients.[82]

Measurement of outcome from TBI remains a challenge. Functional measurement instruments include the Glasgow Outcome Score, the Disability Rating Scale, the Rancho Los Amigos Score, the Functional Independence Measure, and various neuropsychological, behavioral, and quality-of-life measures. However, return to gainful employment is probably the best overall measure of long-term outcome.[83] About 50% of patients who survive severe TBI eventually return to work. In recent studies, return to work was also the single best correlate of perceived quality of life.[84,85]

Accurate predictors of outcome are also important to patients, their families, and caregivers in understanding recovery and planning for care. Early predictors of good outcome include a higher preinjury intelligence, youth, and a lower severity of injury.[49] Certain genotypes, such as the *ApoE4* allele, may affect recovery and outcome.[86,87] In a large multidisciplinary study of survivors of penetrating head injury, the presence of seven factors were significantly predictive of unemployment: hemiparesis, epilepsy, visual field loss, verbal memory loss, visual memory loss, psychological problems, and violent behavior. These factors represent different domains of brain function and were relatively equipotent in the model (i.e., it was the number of impaired domains, not impairment in any one particular domain, that was predictive of unemployment). The brain may thus compensate for injury by utilizing whichever functional domains are still available to it.[88]

Traumatic Brain Injury Rehabilitation

In the 1990s, the field of TBI rehabilitation blossomed. A profusion of therapies, including coma stimulation, cognitive rehabilitation, speech therapy, occupational therapy, and recreational therapy, are now available. Their use is largely empirical, and these sometimes expensive interventions have not been subjected to a high level of scientific scrutiny for efficacy and cost-effectiveness. Nevertheless, a growing body of animal and clinical literature supports the beneficial effects of training on the brain and on performance after injury.

The goals of therapy should be recovery of the patient's independence and his or her reintegration into the community. The prevention of maladaptive behaviors is an important secondary goal. However, patients with scarce economic resources can find those resources depleted in the early phases of recovery by the evaluation of and therapy for specific neurologic or cognitive deficits that may resolve even without therapy or may ultimately be of marginal importance to the patient's achieving the goal of independence. Interventions that may be more cost-effective, such as training in decision-making or other community reintegration skills and certain forms of behavioral management, may ultimately be omitted for lack of resources.

Although there is consensus about the benefits of some forms of rehabilitation for patients with TBI, the type, intensity, and duration of rehabilitation that are best for a given patient remain hotly debated.[89,90] For example, a recent large prospective, randomized, controlled trial compared an intensive in-hospital program of cognitive rehabilitation with a limited (and much less expensive) home rehabilitation program in soldiers recovering from moderate to severe TBI.[91] At 1 year after injury, there was no difference between the two groups with regard to return to work, fitness for military duty, or behavioral, neuropsychological, or quality-of-life measures. However, in a subset analysis of patients who were unconscious for longer than 1 hour after suffering TBI, there was a higher return-to-work rate for the patients who underwent hospital rehabilitation than for those who underwent home rehabilitation, suggesting the differential value of these approaches for selected patients. Thus, a fundamental challenge for rehabilitation is to distinguish the effect of the brain's natural processes of recovery from the effects of treatment in patients with varying prognostic risk factors for long-term function. Clear

resolution of these issues will require further properly designed, prospective, controlled, randomized trials.

Additional Information

Additional information on TBI can be obtained from the American Academy of Neurology (http://www.aan.com), the Brain Injury Association (http://www.biausa.org), and the Brain Trauma Foundation (http://www.braintrauma.org).

VI NEOPLASTIC DISORDERS

Jerome B. Posner, m.d.

Neoplasms can damage the nervous system in three ways: cells within the central nervous system or peripheral nervous system can become neoplastic[1]; tumors located outside the nervous system (i.e., systemic cancers) can metastasize to neural structures[2,3]; and systemic cancers can cause neural dysfunction indirectly [*see Table 1*].[2,4] This chapter focuses on primary and metastatic tumors of the CNS. Strictly speaking, meningiomas, pituitary tumors, and pineal region tumors are not brain tumors; however, because they arise within the intracranial cavity, they are considered here. Some nonmetastatic effects of cancer on the nervous system are also discussed.

Primary Nervous System Tumors—General Principles

EPIDEMIOLOGY

Neoplasms can develop in the brain and spinal cord, especially from glial cells or their precursors; neoplasms can also develop from intracranial structures outside of the brain and spinal cord, such as the meninges and the pituitary and pineal glands. Brain tumors of neuronal origin are uncommon.[5] The American Cancer Society (http://www.cancer.org) estimates that in 2004, 18,400 new cases of brain cancer and other CNS cancers developed (10,540 in males and 7,860 in females) and 12,690 patients died of CNS cancer.[6]

Although the incidence of brain tumor increases with age and thus most brain tumors are encountered in the elderly, brain tumors are the most common solid tumor of childhood and are the second most common cause of cancer death, after leukemia, in males under the age of 40 and in females under the age of 20.[6] Brain tumors affect both sexes and all races. Meningiomas and pituitary adenomas are more common in women and African Americans, whereas gliomas are more common in men and whites. Meningiomas and pituitary tumors[7] are quite common. Low-grade gliomas, such as astrocytomas, are more common in the young; high-grade gliomas, such as anaplastic astrocytomas and glioblastomas multiforme, are more common in the elderly. The incidence of glioma may actually decrease in the very old (i.e., persons 75 to 80 years of age or older).[8] The apparent incidence of CNS cancers increased during the late 1970s and 1980s as a result of better diagnosis, but the overall rate now is stable.[8] However, the incidence of primary CNS lymphoma (PCNSL) in immunocompetent persons (e.g., those who are not infected with HIV) continues to increase.[9] Although once rare, PCNSL is now an important consideration in the diagnosis and treatment of brain tumors, particularly because the tumor is sometimes curable.[10]

CLASSIFICATION

The World Health Organization (http://www.who.int) classifies CNS and peripheral nervous system tumors by their presumed cell of origin [*see Table 2*].[5] Most parenchymal brain and spinal cord tumors are of neuroepithelial origin—glial cells (astrocytes or oligodendroglia) or their precursors. Oligodendroglial tumors constitute 5% to 10% of glial tumors. Glial tumors are classified as either high grade or low grade; nuclear atypia, mitotic figures, microvascular proliferation, and necrosis indicate high-grade tumors. If three or all four of these features are present, the prognosis is poor.

Although often used, the terms benign and malignant have less meaning in tumors of brain and spinal cord parenchyma than in other cancers. Brain and spinal cord tumors are seldom truly benign because surgery rarely cures; they are not truly malignant in the usual sense because they seldom metastasize to other organs. Surgery fails because even histologically benign intrinsic brain tumors (e.g., gliomas) infiltrate normal tissue, thereby preventing total resection and allowing tumor recurrence. Certain tumors, such as medulloblastoma, ependymoma, glioblastoma, and PCNSL, may seed the leptomeninges or spread to distant sites within the neuraxis, but they rarely spread outside the CNS.

ETIOLOGY

Environmental Risk Factors

Immunosuppression—either congenital or acquired—and exposure to ionizing radiation are the only well-established environmental risk factors for brain tumors.[11] Low-dose irradiation of the scalp, once a treatment of tinea capitis, has been shown to cause a 10-fold increase in the incidence of meningiomas, many of which are anaplastic or malignant, and a threefold increase in the incidence of glial tumors. High-dose irradiation for intracranial or extracranial cancers, including prophylactic irradiation for leukemia,[12] increases the incidence of glioma, meningioma, and sarcoma. Dental radiography is probably not a risk factor.

Numerous other conditions and environmental exposures have been suggested as possible risk factors for brain tumors [*see Table 3*]; however, evidence to support a causal relationship is weak.[11] Head trauma may be a risk factor for the development of

Table 1 How Neoplasms Damage the Nervous System

Means of Damage	*Examples*
Primary tumors	Brain, spinal cord, and meninges Gliomas Meningiomas Cranial and peripheral nerves Schwannomas (neurilemomas) Neurofibromas Other intracranial structures Pituitary Pineal region
Metastatic tumors	Intracranial structures (usually brain) Spinal cord (usually epidural) Leptomeninges Peripheral nerves
Nonmetastatic effects	Vascular disorders Infections Metabolic and nutritional disorders Side effects of therapy Paraneoplastic syndromes

glial and other brain tumors.[13,14] HIV infection and other immunosuppressive disorders constitute risk factors for the development of PCNSL, probably glioma, and possibly leiosarcoma.[15,16] Exposure to electromagnetic radiation (including cellular telephones),[17-19] hair dyes, aspartame, pesticides, formaldehyde, or other industrial or occupational substances have not been proved to be causes of brain tumors.[11] If these are indeed risk factors, they cause only a small percentage of brain tumors.

Genetic Risk Factors

Most CNS tumors are sporadic, but some run in families [*see Table 4*].[20,21] Gliomas develop in as many as 14% of patients with neurofibromatosis type 1 (NF-1, or von Recklinghausen disease). Schwannomas, meningiomas, and, less commonly, ependymomas are found in patients with neurofibromatosis type 2 (NF-2). Both NF-1 and NF-2 tumor suppressor genes have been cloned, as have the genes responsible for other familial CNS tumors.[22] However, the low concordance of brain tumors in monozygotic twins indicates that inherited factors are a minor cause of brain tumor.[23]

Acquired (i.e., nonfamilial) genetic abnormalities are associated with CNS tumors [*see Table 5*]. These abnormalities include the loss or mutation of a tumor suppressor gene, such as *p53* or the retinoblastoma gene, and the amplification and rearrangement of oncogenes.[22] Many oncogenes code for growth factors or growth factor receptors that can self-stimulate tumor cells (i.e., autocrine stimulation) or stimulate cells nearby (i.e., paracrine stimulation). The two most common abnormalities identified in patients with glial tumors are mutations in *p53,* which occur in 40% of patients with astrocytoma and with approximately equal frequency in patients with anaplastic astrocytoma or glioblastoma multiforme, and overexpression of the epidermal growth factor receptor, in either normal or mutated form, which occurs in approximately 40% of patients with glioblastoma multiforme. Platelet-derived growth factor and its receptor have also been implicated. A sequence of genetic abnormalities can be identified in the progression of some tumors from low grade (astrocytoma or oligodendroglioma) to high grade (anaplastic glioma or glioblastoma multiforme).[5] However, glioblastoma multiforme can also arise de novo. Mutations in *p53* are rare in patients with glioblastomas who are younger than 18 years; they are common in patients between the ages of 18 and 45 years and are less common in patients older than 45 years. This suggests that glioblastomas in the young and elderly may arise via a different pathway or pathways than those that arise in midlife.

PATHOPHYSIOLOGY

The pathophysiology of CNS tumors explains why even relatively small growths often cause symptoms, whereas small systemic tumors usually do not.[1,2] First, small, strategically located tumors (e.g., tumors of the brain stem) damage vital pathways of the brain and spinal cord, thereby causing severe dysfunction.

Similar lesions in more homogeneous organs, such as the lung or liver, must destroy large areas of these organs before symptoms appear. Second, because the brain and spinal cord are encased in unyielding dura and bone, there is little room for a neoplasm to grow without compressing normal tissue [*see Figure 1*]. Third, tumor vessels do not possess a normal blood-brain barrier. Because these neovessels leak, proteins and other potentially noxious substances can enter the tumor and diffuse into the surrounding normal tissue, causing edema and further compressing normal structures [*see Figure 1*]. Edema removal is slow because the brain itself lacks lymphatics, although lymphatics around cranial nerves empty into cervical lymph nodes.[24] Tumors create their own vascular supply by secreting angiogenesis factors such as vascular endothelial growth factor. Angiogenesis factors are now targets for brain tumor therapy.[25]

Although small tumors often cause symptoms, exceptions do occur. Slowly growing tumors, especially those in the so-called silent brain areas (e.g., the frontal pole), may not cause symptoms until they become very large. Even glioblastoma multiforme sometimes causes fewer symptoms than might be expected from the size of the lesion and the degree of shift seen on imaging studies.

CNS symptoms are caused by three mechanisms:

1. The tumor invades, irritates, and replaces normal tissue. This mechanism is characteristic of infiltrating low-grade gliomas but rarely occurs in metastatic tumors or meningiomas.
2. Both the tumor and the edema compress normal tissue and its blood vessels, causing ischemia.
3. Tumors that compress or grow in the third or fourth ventricle (e.g., ependymomas) or the leptomeninges obstruct cerebrospinal fluid pathways, causing hydrocephalus.

The effects of tumor invasion, peritumoral edema, and hydrocephalus combine to cause herniation in normal cerebral structures under the falx cerebri, through the tentorium cerebelli, or through the foramen magnum [*see Figure 1*], thus causing symptoms at a distance from the tumor site.

Table 3 Possible Risk Factors for Primary Brain Tumors of Neuroepithelial, Meningeal, or Lymphocytic Origin[11]

Hereditary syndromes [*see Table 4*]
Ionizing radiation: therapeutic, diagnostic, and other sources
Family history of brain tumors
Immunosuppression
Constitutive polymorphisms
Lymphocyte mutagen sensitivity to gamma radiation
Prior cancers
Infectious agents or immunologic response: viruses, *Toxoplasma gondii*
Allergies
Head trauma
Epilepsy, seizures, or convulsions
Drugs and medications
Diet and vitamins: nitrosamine/nitrosamide/nitrate/nitrite consumption
Tobacco smoke exposure (women)
Alcohol use
Coffee use
Hair dyes and sprays
Traffic-related air pollution
Occupations and industries: synthetic rubber manufacturing, vinyl chloride, petroleum refining/production work, licensed pesticide applicators, agricultural work, and others
Cellular telephone use
Exposure to radio waves
Exposure to electromagnetic fields associated with power lines
Left-handedness (fewer gliomas in left-handed persons)
Sociodemographic status (more low-grade tumors in affluent; more high-grade tumors in Medicaid patients)

SYMPTOMS AND SIGNS

Patients with brain tumors may have generalized symptoms caused by diffuse intracranial pressure, focal symptoms caused by ischemia and compression at the site of the brain tumor, or false localizing symptoms caused by shifts of cerebral or spinal structures.[1] Generalized or false localizing symptoms are probably caused by slowly growing tumors in silent areas, whereas focal symptoms occur with even small tumors in more functionally important areas of the brain, such as the motor cortex and brain stem, or in the spinal cord.

Generalized Symptoms and Signs

Headache, the most common symptom of increased intracranial pressure, is the first symptom in about 40% of patients with a brain tumor.[26] It is more frequently the first symptom of brain tumor in those who have a history of headache than in those who have no such history. Most of the headaches associated with brain tumors are nonspecific. A brain tumor should be suspected when headache is present on awakening from sleep but disappears within 1 hour, when headaches begin in a middle-aged or an older person who has not previously experienced them, or when the character or severity of headache suddenly changes in a chronic headache sufferer. Localized headache is a reliable indicator of the side of the head that contains the tumor but does not mark the precise location of the tumor. For example, a right frontal headache indicates that the tumor is on the right side but does not indicate that the tumor is frontal; it could be occipital or even cerebellar.

Vomiting that is or is not preceded by nausea—particularly vomiting that occurs on awakening—is a common symptom of brain tumor in children but is less common in adults. Acute headache that is immediately followed by vomiting is characteristic of a brain tumor and indicates increased intracranial pressure. In contrast, a headache that is followed by vomiting several hours later is characteristic of migraine. Papilledema is a sign of increased intracranial pressure; it commonly occurs in children but is less common in the elderly. Papilledema is usually asymptomatic but may cause transient episodes of blindness.

The mental changes associated with a brain tumor begin with irritability and progress to apathy. All activities are performed more slowly. Patients sleep longer, seem preoccupied when awake, and often fail to initiate activity, including conversation. However, if spoken to, they usually respond appropriately. Psychiatric consultation for the treatment of what is thought to be depression is often obtained before a brain tumor is suspected.

Brain tumors may be associated with episodic symptoms such as headache, visual loss, altered consciousness, and sometimes transient weakness of the extremities. These episodes are often precipitated by rising from a recumbent position, cough-

Table 4 Familial CNS Tumor Syndromes

Disorders	*CNS Tumors*	*Tumors of Other Organs and Tissues*	*Skin Lesions*	*Genes*	*Chromosomes*

PNET—primitive neuroectodermal tumor

ing, or sneezing and are associated with plateau waves—abrupt increases in an already elevated intracranial pressure that last for 5 to 20 minutes.[1] These symptoms are not seizures; they respond to a decrease in the intracranial pressure but do not respond to anticonvulsant therapy.[27]

Focal Symptoms and Signs

Seizures are the most common focal sign of a brain tumor. Focal seizures are particularly common in patients who have tumors that compress the cortex, such as meningiomas, or that arise in or near the motor cortex or temporal lobe (both the motor cortex and the temporal cortex are epileptogenic areas). Focal seizures caused by frontal or temporal tumors often cause behavioral or emotional symptoms that are sometimes confused with panic attacks or psychological disorders. Focal seizures may progress to generalized convulsions, or a generalized seizure may arise from an asymptomatic focal discharge. Depending on the growth rate of the tumor, seizures may be present for months to years before other symptoms develop. Any patient with focal or generalized seizures that begin in adulthood should undergo diagnostic evaluation for a brain tumor.[28]

Other focal symptoms and signs of a brain tumor depend on the site of the lesion. These focal symptoms and signs (e.g., hemiparesis, aphasia, and visual field defect) are the same as

Table 5 Molecular and Cytogenetic Abnormalities Associated with Common Primary Brain Tumors

Tumor	*Abnormalities*	*Prevalence (%)*	*Gene*

*Only 30% of 10q loss is attributed to *PTEN*.

those of CNS infection, stroke, or other structural diseases of the brain or spinal cord.[1]

False Localizing Symptoms and Signs

False localizing symptoms are caused by shifts of cerebral structures. Diplopia may result from displacement or compression of the sixth cranial nerve at the base of the brain. Hemianopsia may be caused by tentorial herniation that compresses the posterior cerebral artery. A number of other cranial nerve palsies associated with shifts of brain stem structures may also occur.[1]

DIAGNOSIS

A CNS neoplasm should be suspected in all adults with new-onset seizures and all patients with papilledema or new focal motor or sensory signs. Such patients warrant magnetic resonance imaging with the injection of contrast material (e.g., gadolinium) to determine whether the blood-brain barrier has been disrupted and, if so, where.[29] Patients with behavioral or personality changes should be evaluated by MRI if drowsiness, apathy, or memory loss accompanies the psychiatric symptoms or if the psychiatric symptoms are atypical. Patients whose only symptom is headache require MRI only if the headache began recently, has changed in character, or fails to respond to headache therapy [*see 11:VIII Headache*]. A negative MRI almost always rules out a tumor as the cause of the patient's symptoms or signs.

MRI identifies tumors that computed tomography misses and distinguishes tumors from vascular lesions. With the exception of biopsy, other laboratory tests are unnecessary. MRI may also suggest the histology of the tumor. Low-grade gliomas often fail to exhibit contrast enhancement; their presence is indicated by a hyperintense T_2-weighted image in conjunction with a normal or hypointense T_1-weighted image. The hyperintense area on the T_2-weighted image includes both the tumor and its

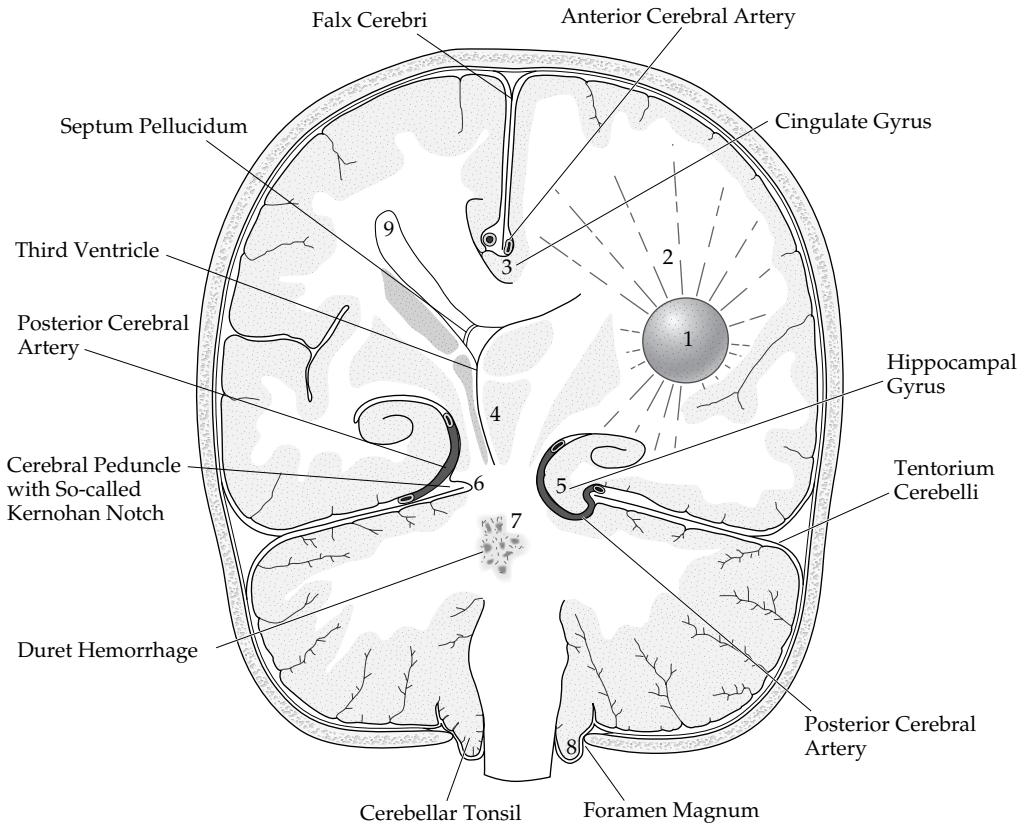

Figure 1 **This schematic drawing illustrates a brain tumor in the cerebral hemisphere (1), the surrounding edema (2), and several areas of herniation (3 through 8), which occur because of the increasing mass effect. Also illustrated is ventricular enlargement on the contralateral side caused by obstruction of the third ventricle (9).**

associated edema. High-grade gliomas usually exhibit contrast enhancement, with the T_1-weighted image showing an enhanced rim of irregular shape and thickness that surrounds a hypointense center [*see Figure 2a*]. The T_2-weighted image shows only hyperintensity. Although the enhancement does not encompass the entire infiltrating margin, it allows a clinically useful approximation of tumor volume to be made. A metastasis usually has a more regular, spherical enhancing rim than does a glioma [*see Figure 2b*]. Some low-grade tumors (e.g., meningiomas and pilocytic astrocytomas) also exhibit contrast enhancement. Metastases are more likely than gliomas to be multiple.

About 75% to 80% of patients with metastases have multiple lesions, whereas only 5% of gliomas appear at more than one site. Of patients with PCNSL, 40% have multiple tumors; these are located periventricularly, usually exhibit diffuse contrast enhancement, have poorly circumscribed margins compared with gliomas and metastases, and are usually surrounded by less edema than those tumors [*see Figure 2*].

Although MRI may suggest the histologic diagnosis, only biopsy is definitive. An exception to this rule occurs in PCNSL, in which lumbar puncture or, if the eyes are involved, vitrectomy may yield malignant cells. In other tumors, lumbar puncture poses a risk of cerebral herniation that outweighs any likely benefit.

Positron emission tomography (PET) with positron-emitting radionuclides, single-photon emission computed tomography (SPECT),[30] magnetic resonance spectroscopy (MRS), and perfusion-weighted images may prove to be useful noninvasive methods for determining the histologic type and degree of malignancy of a brain tumor.[31]

TREATMENT

The treatment of patients with CNS neoplasms depends on the nature and location of the neoplasm and the general condition of the patient. Treatments of specific tumors are detailed in the sections on individual tumors; certain principles that apply to all cases of CNS neoplasms are considered in this section.[32] Survival rates for patients with brain tumors have increased since the 1970s as a result of better diagnosis and therapy.[33]

Corticosteroids

Corticosteroids dramatically relieve the symptoms of most brain and spinal cord tumors by decreasing intracranial pressure and reducing the edema surrounding the lesions.[2] Symptomatic improvement may begin within minutes, and patients often become asymptomatic within 24 to 48 hours after administration. The mechanisms by which corticosteroids exert these effects are poorly understood. Corticosteroids decrease the flux of water-soluble agents across the disrupted blood-brain barrier, thus providing one mechanism for decreasing edema. Corticosteroids may also have the unintended effect of inhibiting the entry of chemotherapeutic agents into the tumor.

Corticosteroids are indicated in all symptomatic patients with brain and spinal cord tumors, with the exception of patients with PCNSL. Because of their lympholytic effects, cortico-

steroids may cause tumor necrosis, precluding definitive diagnosis of PCNSL. Therefore, when PCNSL is suspected, corticosteroids should be withheld until a biopsy is performed to establish the diagnosis.

Dexamethasone at a dosage of 16 mg/day is usually administered. Once treatment has begun, a corticosteroid is taken until the patient's symptoms are relieved and intracranial pressure is diminished. The drug is then tapered to the lowest dose commensurate with good neurologic function; it can often be completely discontinued.

Surgery

For intracranial tumors that arise outside the brain, such as meningiomas, schwannomas, and pituitary adenomas, surgery is often curative. Surgery for tumors that arise within the brain or spinal cord is rarely curative, although pilocytic astrocytomas and ependymomas are exceptions. Nevertheless, surgery is the most important treatment in patients with accessible tumors other than PCNSL. Surgery establishes the diagnosis, relieves intracranial pressure, and improves symptoms and seizure control.[34] With modern surgical techniques[35] and corticosteroid therapy to prevent postoperative swelling, the risk of worsening neurologic function is reduced. Even areas once thought surgically unapproachable, such as the insula and the corpus callosum, are now accessible through an operative approach.[36,37] Most studies indicate that more complete surgical removal of the gliomas improves both the duration of survival and quality of life.[38,39] If the tumor exhibits contrast enhancement before surgery, a postoperative contrast-enhanced MRI obtained within 3 days after resection accurately predicts the extent of residual tumor and thereby helps establish the prognosis; surgeons' estimates of the extent of resection are often inaccurate.

Radiation Therapy

Postoperative radiation therapy increases survival and improves the quality of life in patients with high-grade tumors (i.e., anaplastic astrocytomas or gliomas). However, its role in patients with low-grade tumors, particularly those that are asymptomatic, is uncertain.[40] After total resection of pilocytic astrocytomas, radiation therapy is not required. In patients with low-grade astrocytomas or oligodendrogliomas whose only symptoms are well-controlled seizures, radiation therapy may safely be deferred until symptoms develop.[40] High-grade gliomas should be treated with high doses of radiation (5,500 to 6,000 cGy in fractions of 180 to 200 cGy) delivered to a limited field that encompasses the tumor and its immediate surroundings.[34] New techniques of conformal field radiation planning, such as intensity-modulated radiotherapy (IMRT), decrease treatment-related morbidity and may enhance tumor control.[41] Stereotactic radiosurgery, in which high doses of ionizing radiation in multiple narrow beams are directed to a precise intracranial location by stereotaxy, is used in some centers to treat metastases, schwannomas, meningiomas, and some pituitary tumors and to boost conventional radiation for gliomas; its efficacy for gliomas has not been established.[42]

Chemotherapy

With the exception of oligodendrogliomas, germ cell tumors, and medulloblastomas, the response of most brain tumors to chemotherapy is limited; the addition of nitrosoureas or temozolomide to radiation therapy increases the survival of some patients with high-grade gliomas.[43,44] It is not possible to determine, in advance, which patients will respond to chemotherapy. Therefore, all patients with high-grade gliomas should be treated with a combination of radiation therapy and a nitrosourea or another lipid-soluble chemotherapeutic agent such as temozolomide.[45] Whether to give chemotherapy during radiation therapy, perhaps enhancing the effect of the radiation, or to begin chemotherapy after radiation therapy is open to debate. There is no evidence that chemotherapy given concurrently with radiation therapy enhances survival over chemotherapy administered after radiation therapy, nor is there any evidence that combination chemotherapy is superior to single-agent chemotherapy.

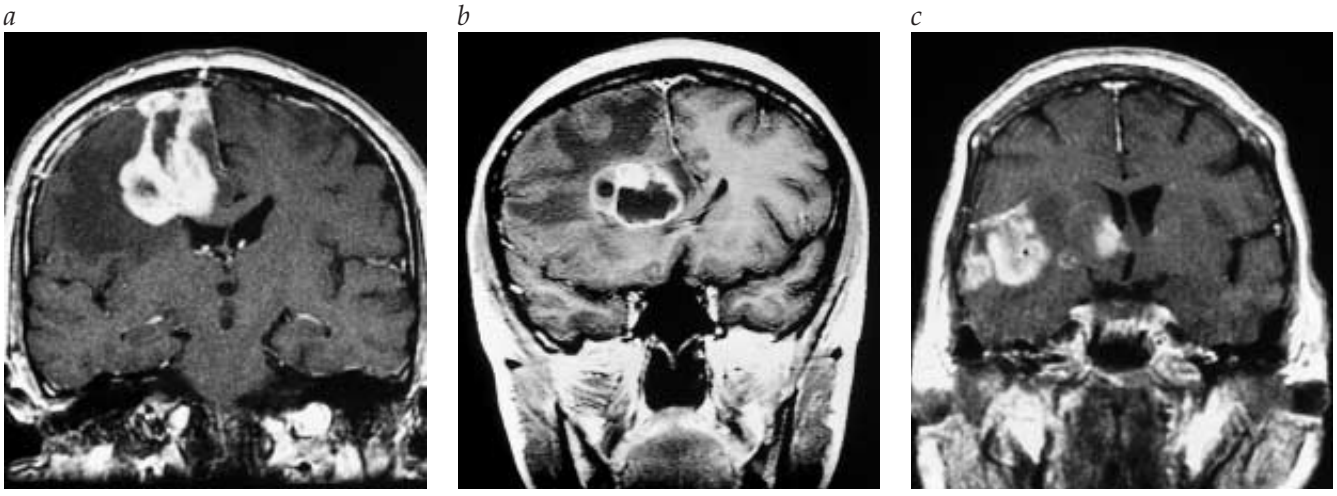

Figure 2 **(*a*) Magnetic resonance imaging of a frontal section shows the characteristics of a high-grade glioma. The tumor is irregular in shape, and the rim of contrast enhancement is thick and irregular in shape. The rim is surrounded by edema, as illustrated by the hypointensity around the area of contrast enhancement. (*b*) On MRI, the characteristics of a metastatic tumor are different from those of a high-grade glioma. The tumor is more spherical, and the contrasting edge is relatively thin and regular in shape. The thick area at the top of the tumor is a hemorrhage, not contrast enhancement. White-matter edema, as illustrated by the hypointensity surrounding the tumor, is massive. (*c*) MRI of a primary central nervous system lymphoma displays multiple lesions—with one in the periventricular area—that uniformly exhibit contrast enhancement. There is little surrounding edema. The edges of the tumor are less well defined than those of a high-grade glioma or a metastatic tumor.**

Experimental Therapies

Several new therapeutic approaches show promise in the treatment of brain tumors.[46] These include new delivery systems that use liposomes to enhance entry into the brain or that infuse or implant chemotherapy directly into the tumor bed. Other techniques include gene therapy, immunotherapy, and small molecules targeted to inhibit pathways necessary for tumor growth. None of these approaches have yet proved to be superior to conventional therapy.

PROGNOSIS

Histologic grade is an important prognostic factor for patients with primary brain tumors.[47] For example, the median survival of patients with glioblastoma multiforme is a little longer than 1 year, and the 5-year survival rate is less than 10%. Patients with anaplastic astrocytoma have a median survival of 2 to 3 years; for those with astrocytoma, median survival is 5 to 10 years. Patients with a pilocytic astrocytoma often have a normal life span. Many patients with meningiomas[48] and pituitary tumors[7] remain asymptomatic; in such patients, the tumor is often discovered incidentally when a brain image is done for another reason or at autopsy after the patient dies of another disease. Age is an important determinant of prognosis; younger patients survive longer than older patients despite having tumors of similar histology. Gene expression profiles may prove to be a better prognostic factor than histology.[49]

Primary Nervous System Tumors—Specific Diagnoses

ASTROCYTOMAS

Tumors believed to arise from astrocytes or their precursors are classified by the World Health Organization into four grades: pilocytic astrocytomas (grade I), diffuse astrocytomas (grade II), anaplastic astrocytomas (grade III), and glioblastomas multiforme (grade IV). The classification is made on histologic criteria.[5]

Pilocytic astrocytomas, which usually occur during childhood, are characterized by low cellularity and the presence of microcystic areas and eosinophilic intracytoplasmic masses called Rosenthal fibers. The tumors are well circumscribed on MRI and frequently exhibit contrast enhancement.

Diffuse astrocytomas are either isointense or hypointense on T_1-weighted MRI. They usually do not show contrast enhancement.

Anaplastic astrocytomas are characterized by nuclear atypia and mitotic activity. They may or may not show contrast enhancement.

Glioblastomas are characterized by nuclear atypia, mitosis, endothelial proliferation, and, sometimes, necrosis. They are poorly circumscribed and usually exhibit contrast enhancement.

Grade I

Pilocytic astrocytomas, which often occur in the cerebellum, are generally tumors of children. Whenever possible, they are treated surgically. Postoperative radiation therapy is usually unnecessary unless the tumor recurs. It has not been determined whether chemotherapy has any effect on pilocytic astrocytomas. The prognosis is excellent.

Grade II

Diffuse astrocytomas are tumors of young adults. Patients usually present with seizures; with time, other neurologic symptoms and signs may develop. Tumors preferentially occur in areas such as the insula and supplementary motor area, which are difficult sites to approach surgically.[50] For surgically accessible lesions, a maximally feasible resection is indicated.

Postoperative radiation therapy decreases tumor growth and may cause some shrinkage. Although radiation therapy of asymptomatic patients increases the time to development of symptoms, it does not increase survival.[51] Accordingly, it makes no difference in long-term prognosis whether the patient receives radiation therapy when the tumor is first discovered or later, after the tumor causes neurologic signs and symptoms. Because radiation therapy can cause neurotoxicity—particularly neurotoxicity affecting cognitive function—many authors recommend deferring radiation therapy in patients who have no symptoms or signs other than seizures that are controllable by anticonvulsants until such time as neurologic signs and symptoms develop. It has not been determined whether chemotherapy has any significant effect on these tumors.

Grade II astrocytomas often progress to grade III or IV tumors. The short-term prognosis is good; however, even if the tumor remains of low grade, it continues to grow at a steady rate, and the median survival is only a few years.[52]

Grades III and IV

Anaplastic astrocytomas and glioblastomas multiforme (malignant gliomas) are treated with a combination of surgery, radiation therapy, and chemotherapy.[45] A neurosurgeon skilled in the management of brain tumors should attempt to remove all grossly visible tumor. Surgical resection should be followed by radiation therapy to the tumor bed and to an area 2 to 3 cm around the tumor. There is no evidence that a radiosurgical boost to the tumor bed improves survival. Radiation therapy should be followed by chemotherapy. A number of chemotherapeutic agents have proved to have some modest effect. Most physicians use either lomustine or temozolomide.

Despite treatment, the prognosis is poor. Most such tumors recur within 1 to 2 years. The median survival for patients with glioblastomas is about 1 year; for patients with anaplastic astrocytomas, median survival is slightly longer. Age is a major prognostic factor, with younger patients having a better prognosis than older patients.

OLIGODENDROGLIOMAS

Oligodendrogliomas are believed to arise from precursors of oligodendroglial cells—cells that are responsible for the production of myelin within the CNS. Oligodendrogliomas are often difficult to distinguish histologically from astrocytomas, but they are genetically different. Most oligodendrogliomas have deletions of the short arm of chromosome 1 (1p deletion) and the long arm of chromosome 19 (19q deletion).[49] These deletions are associated with chemosensitivity and longer survival.[49] Histologically, oligodendrogliomas are characterized by cells that have round, homogeneous nuclei; on paraffin sections, cells are seen to have a swollen, clear cytoplasm (i.e., a fried-egg appearance). Lesions may be calcified and contain a dense network of delicate, branching capillaries. Unless calcification is present, oligodendrogliomas appear no different from astrocytomas on MRI. Sometimes, hemorrhage can be identified within the tumor. Hemorrhage is more likely to occur with oligodendrogliomas than with astrocytomas.

Patients who are asymptomatic, including those with large low-grade oligodendrogliomas, may not require treatment. Pa-

tients with anaplastic oligodendrogliomas and patients with low-grade tumors who are symptomatic should be treated. The treatment of choice for initial therapy is surgical resection; the resection should be as extensive as possible. Patients with a 1p/19q deletion usually respond to chemotherapy.

The established chemotherapeutic regimen is combination therapy with procarbazine, vincristine, and carmustine. Other chemotherapeutic agents, particularly temozolomide, may be equally efficacious.[53] It has not been determined, especially for oligodendrogliomas of lower grade, whether chemotherapy alone suffices or whether chemotherapy should be followed by radiation therapy. In patients without a 1p deletion, postoperative radiation therapy is probably the treatment of choice.

With oligodendrogliomas of all grades, the prognosis is substantially better than that for patients with comparable astrocytic tumors.

MENINGIOMAS

Meningiomas arise from the dura and the arachnoid villi of the intracranial and spinal spaces. They are found along the dorsal surface and base of the brain, the falx cerebri, and the sphenoid ridge, as well as in the lateral ventricles and the thoracic spinal canal. More common in women than in men, meningiomas possess progesterone receptors; some also express estrogen receptors.[54] The incidence of meningiomas is increased in women with breast cancer.

The most frequent genetic abnormality is allelic loss of chromosome 22q12. Atypical and anaplastic tumors may have losses of 1p, 9q, 10q, 14q, and 17p.[55] Meningiomas may be multiple and often grow slowly, or sometimes not at all.[56]

Meningiomas cause symptoms by brain compression, not by invasion. The common presenting symptoms of patients with brain meningiomas are seizures and cranial nerve palsies; for patients with spinal cord meningiomas, the most common presenting symptom is a gradual and sometimes painless paraparesis.

Meningiomas can be easily diagnosed with contrast-enhanced MRI; they are of the same intensity as brain tissue on T_1-weighted MRI. They exhibit uniform and intense contrast enhancement and are clearly outside the brain or spinal cord. An elongated dural attachment (i.e., a dural tail) can sometimes be identified. Occasionally, meningiomas appear en plaque, causing widespread thickening of the dura.

Patients with meningiomas can often be cured by complete surgical removal of the tumor or tumors. However, many meningiomas, particularly those in the cavernous sinus and at the base of the brain, cannot be completely resected. In addition, a few meningiomas, especially those that are anaplastic, recur despite apparently complete resection. Radiation therapy may control their regrowth.[57] Radiosurgery may control small lesions.[57] Chemotherapeutic and hormonal agents have not yet demonstrated benefit. Because meningiomas have a slow rate of growth, patients with small or asymptomatic meningiomas can usually be managed with follow-up examinations rather than resection; this is particularly the case with elderly patients.

If histology shows the meningioma to be benign, total resection is usually curative. Patients with partially resected meningiomas or those with anaplastic or malignant meningiomas may benefit from postoperative radiation therapy. In any event, patients who have undergone total resection should receive follow-up examinations because even after complete resection, some tumors recur.

SCHWANNOMAS

Schwannomas (also called Schwann cell tumors or neurilemomas) occur in the cranium or along peripheral nerves, both within and outside the spinal canal. Vestibular schwannomas, also called acoustic neuromas, arise from the vestibular portion of the eighth cranial nerve near or in the internal auditory canal where Schwann cells replace oligodendroglia as myelin producers.

Schwannomas usually grow slowly, and some do not grow at all.[58] Initially, they cause asymptomatic unilateral vestibular failure; later, symptomatic unilateral hearing loss occurs. Untreated tumors may grow large, compressing the nearby trigeminal and facial nerves and the cerebellum. The tumors are often associated with loss of the *NF2* tumor suppressor gene on chromosome 22q. Bilateral vestibular schwannomas are virtually pathognomonic for NF-2. Patients with unexplained unilateral hearing loss, tinnitus, or vertigo should undergo further evaluation by MRI. MRI is especially indicated if the caloric test (i.e., stimulation of the semicircular canal on the ipsilateral side through alteration of the temperature of the eardrum by use of warm and cold water) fails to elicit nystagmus; such a finding indicates vestibular nerve failure.

Early diagnosis with auditory testing and MRI enables the surgeon to remove the tumors by microsurgery, which preserves facial nerve function and sometimes hearing. Some investigators advocate the use of stereotactic radiosurgery in patients with small vestibular schwannomas. Patients with small, asymptomatic lesions may choose a course of watchful waiting in lieu of undergoing treatment.[59]

If the tumors are treated early with either surgery or radiosurgery, the prognosis is excellent. Although larger tumors can be treated successfully, treatment may result in complete deafness and facial paralysis. Headaches are a common complication of surgery for vestibular schwannomas[60]; however, CSF leaks are uncommon.[61]

PITUITARY ADENOMAS

When pituitary adenomas are symptomatic, patients usually present with endocrine symptoms. Headache, another common symptom (70% prevalence in one series), is unrelated to tumor size.[62] Macroadenomas (tumors > 1 cm in diameter) may breach the diaphragma sellae and compress the optic chiasm, causing bitemporal hemianopsia. The mass may extend laterally into the cavernous sinus, causing diplopia by compressing the ocular nerves. Visual loss and diplopia occur acutely when the tumor bleeds or infarction develops (a condition known as pituitary apoplexy).

Patients with pituitary tumors can be treated with transsphenoidal resection,[63] radiation therapy,[64] or radiosurgery[65]; patients with prolactinomas, and perhaps thyrotropin-secreting tumors,[66] can be effectively treated with bromocriptine or related dopamine agonists.[67] Pharmacologic therapy is also effective in some patients with growth hormone–secreting tumors.[68] Most patients with tumors that compress the optic chiasm are treated surgically. With appropriate treatment, most patients with pituitary adenomas are cured.

PINEAL REGION TUMORS

Tumors of the pineal region compress the upper brain stem, causing paresis of upward gaze (Parinaud syndrome), pupillary dysfunction, and hydrocephalus through compression of the aqueduct of Sylvius. Patients first complain of headache, and they may develop papilledema from increased intracranial pres-

sure caused by the hydrocephalus. Double vision and ataxia from compression of the upper brain stem may also be presenting symptoms.

Pineal parenchymal tumors may be low grade (pineocytoma), high grade (pineoblastoma), or intermediate grade. The more malignant varieties usually occur in children and often seed the leptomeninges.[69] Surgery often cures pineocytomas and establishes the diagnosis for patients with the more malignant varieties. For pineocytomas that are only partially resected and for the more malignant tumors, postoperative radiation with or without chemotherapy is indicated.[70-72]

Tumors of the pineal region also arise from germ cell structures and include germinomas, yolk sac tumors, and choriocarcinomas. Some germ cell tumors spill biochemical markers into the CSF, making noninvasive diagnosis possible (especially in choriocarcinomas releasing β–human chorionic gonadotropin and in yolk sac tumors releasing α-fetoprotein). Patients with germinomas can be cured by radiation therapy[73] or by a combination of chemotherapy and radiation therapy.[74,75] Most other germ cell tumors are incurable.[76]

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

PCNSL arises from B cells that are believed to enter the CNS from the bloodstream either by routine trafficking of B cells across the blood-brain barrier or in response to tissue injury.[77] It is not known whether the B cells that enter the brain are already malignant or are transformed in the brain. PCNSL differs from systemic lymphoma in several respects. Although PCNSL is localized, it is less likely to be cured than systemic lymphoma.[78] Furthermore, when systemic lymphoma metastasizes to the CNS, it usually seeds the leptomeninges, whereas PCNSL usually presents as a brain mass. Less commonly, PCNSL begins in the eye, spinal cord, or leptomeninges.

Headache and hydrocephalus may result from leptomeningeal tumors. If the eyes are affected, visual difficulties that suggest uveitis or vitreitis may be the first complaint. Because the mass lesions in the brain are generally deep, patients often present with behavioral and personality change rather than the seizures that characterize gliomas. PCNSL grows rapidly and spreads widely throughout the brain and spinal cord but rarely metastasizes outside the CNS. Multiple lesions are common.

Diagnosis of PCNSL can be made by vitrectomy (in cases of eye involvement), CSF examination (in cases of leptomeningeal tumor), or needle biopsy of the brain. In all cases, diagnosis is made by identification of malignant lymphocytes (usually B cells), most of which are of the cleaved, large cell, or immunoblastic type. Untreated patients die within several months after diagnosis.

Treatment consists of high-dose, methotrexate-based systemic chemotherapy with or without subsequent radiation therapy.[78] Compared with radiation therapy alone, chemotherapy increases the median time to relapse; for some patients, this treatment is curative. HIV-positive patients with PCNSL are also treated with this regimen. Treatment with highly active antiretroviral therapy (HAART) has been effective in some patients with AIDS.

MEDULLOBLASTOMAS

Medulloblastomas are highly aggressive tumors that occur most often in children[79]; they arise from primitive neuroectodermal cells in the vermis of the cerebellum. Early symptoms include truncal ataxia, headache, nausea, and vomiting. Headache, nausea, and vomiting may be secondary to early hydrocephalus. In both adults and children, the tumors often seed the leptomeninges. Treatment consists of surgical removal followed by whole neuraxis irradiation and adjuvant chemotherapy.[79,80] Cure is effected in over 70% of patients with medulloblastomas. Unfortunately, despite cure of the tumor, many patients suffer cognitive defects and growth failure as a result of the neuraxial radiation.[81]

SPINAL CORD TUMORS

Spinal cord tumors can be epidural, subdural but extramedullary, or intramedullary.[82] The site usually cannot be determined clinically but is easily established by MRI. Spinal cord tumors are characterized by myelopathy, which usually consists of paraparesis or quadriparesis, hyperactive reflexes, Babinski signs, and loss of sensation below the lesion. Local pain and sometimes radicular pain appear weeks or months before the myelopathy develops. Bladder and bowel functions are usually spared until late in the course of disease.

Epidural tumors are usually metastases. Subdural tumors are usually benign meningiomas or schwannomas. Occasionally, leptomeningeal metastases grow large enough to cause a subdural mass. The signs and symptoms of subdural meningiomas and schwannomas develop slowly; pain may be absent, particularly in patients with meningiomas. The treatment of meningiomas and schwannomas is surgery.

Intramedullary tumors include ependymomas, astrocytomas, and metastases. Patients with ependymomas of the spinal cord are often cured by surgical removal of the tumor.[83] Patients with ependymomas that arise below the spinal cord in the filum terminale can also be cured if the tumor can be totally removed by surgery; partial resections should be followed by radiation therapy.[84] Astrocytomas of the spinal cord cannot be totally resected. Patients with these tumors are treated with postoperative radiation therapy.[85] There is no evidence that chemotherapy is beneficial.

Metastases to the Nervous System

Metastases to the nervous system are far more common than primary CNS tumors.[86] Symptomatic CNS metastases often considerably decrease the quality of life of patients who are otherwise functional, despite having cancer. Early diagnosis of CNS metastases and vigorous treatment often lead to amelioration of CNS symptoms and improvement in the patient's quality of life, even though survival may not be prolonged. With the development of more effective treatment for tumors outside the nervous system, CNS metastases, which are protected by the blood-brain barrier, are becoming increasingly more common. Metastases affect the brain by hematogenous spread to brain parenchyma and affect the spinal cord by epidural compression. Cranial and spinal nerves are affected by leptomeningeal seeding or by direct compression by bone or lymph node metastases. Brain metastases may be the presenting symptom in as many as 10% of patients with lung cancer who are otherwise asymptomatic. Routine brain scans of patients with newly diagnosed lung cancer show asymptomatic metastases in 5% to 10% of these patients. Epidural spinal cord compression is the presenting sign of cancer in about 20% of patients.[87]

Tumors that commonly metastasize to the brain include lung and breast cancers and malignant melanoma. Uterine, ovarian, and prostate cancers rarely cause brain metastases. Epidural spinal cord compression is a common complication of cancers of the prostate, breast, and lung. Leptomeningeal metastases com-

plicate breast cancer, leukemia and lymphoma, melanoma, and small cell lung cancer.

BRAIN METASTASES

The signs and symptoms of brain metastases are the same as those of primary brain tumors.[2] MRI characteristically identifies one or more spherical lesions within the white matter that exhibit contrast enhancement and are surrounded by edema. With small lesions, the contrast enhancement may be uniform. With larger lesions, a symmetrical rim of contrast enhancement surrounds a central nonenhanced area. MRI cannot unequivocally distinguish these lesions from brain abscesses or primary tumors. Dura-based metastases appear similar to meningiomas but usually cause more brain edema. In certain clinical settings (e.g., in a patient with multiple lesions in the brain or in a patient with one lesion who is known to have active cancer), MRI is diagnostic. If the image is atypical or if the patient is not known to have cancer, biopsy may be required. In one series of presumed single-brain metastasis, biopsy revealed an 11% error rate; several of the lesions were benign.[88]

Use of corticosteroids in the treatment of brain metastases is the same as in the treatment of primary brain tumors. In a patient whose systemic cancer is controlled, single, surgically accessible brain metastases should be excised,[89] especially if they are greater than 3 cm in diameter and are therefore too large for radiosurgery. Randomized trials indicate that whole brain irradiation after surgical excision decreases recurrence.[90,91] Patients with multiple or surgically inaccessible metastatic tumors are treated with whole brain irradiation to eradicate both the visible tumor and micrometastases that may be present elsewhere in the brain. Stereotactic radiosurgery may control metastases smaller than 3 cm in diameter and has been used to treat multiple lesions.[92] Metastatic brain tumors that disrupt the blood-brain barrier often respond as well to chemotherapy, as does the primary tumor.[93,94] Such tumors can be identified on contrast-enhanced MRI. Thus, when dealing with small, relatively asymptomatic tumors in a patient requiring chemotherapy for tumors outside the CNS, it may be worthwhile to treat the brain metastasis with chemotherapy before initiating radiation therapy. The brain acts as a sanctuary for small, nonenhancing metastases; however, disruption of the blood-brain barrier caused by larger tumors allows even water-soluble chemotherapeutic agents to enter the brain. The brain sanctuary explains the frequent occurrence of isolated CNS relapse in patients with peripherally controlled breast cancer.

SPINAL CORD METASTASES

Metastases to vertebral bodies cause symptoms by compressing the spinal cord.[95] Epidural spinal cord compression by a metastatic tumor is a neurologic emergency. At our institution, treatment consists of high-dose dexamethasone, 100 mg by I.V. bolus, followed by 100 mg/day in divided doses for 3 days; the drug is then rapidly tapered. Other institutions use smaller doses. Definitive therapy entails irradiation with or without surgical decompression. A study by Patchell and colleagues indicated that patients treated with radical decompressive surgery plus postoperative radiation therapy regain the ability to walk more often and maintain it longer than patients treated with radiation alone.[96] Surgical procedures include laminectomy or removal of a vertebral body.[97,98] Patients who are ambulatory when treated usually remain so after treatment.[95] Those who are not ambulatory may regain the ability to walk; those who are paraplegic rarely do so.

LEPTOMENINGEAL METASTASES

The diagnosis of leptomeningeal metastases is established by cytologic identification of malignant cells in the CSF, by contrast enhancement of the brain or spinal leptomeninges on MRI,[99,100] or by the presence of tumor markers in CSF when compared with serum. Tumors that metastasize from non-Hodgkin lymphoma or leukemia usually respond to the intrathecal administration of drugs such as methotrexate or cytarabine. Administration of radiation therapy to symptomatic areas often affords significant palliation; many solid tumors also respond. Systemic chemotherapy using drugs that produce therapeutic levels in the CNS may be equally efficacious. Disruption of the blood-CSF barrier by neovascularization of the tumor may allow water-soluble chemotherapeutic agents to cross the blood-brain barrier. Nevertheless, with the exception of some patients with leptomeningeal metastases from breast cancer and patients with meningeal lymphoma or leukemia, the prognosis is poor, whatever therapy is applied.

Nonmetastatic Complications of Cancer

Cancer may profoundly affect the nervous system even when it does not metastasize [*see Table 1*]. The nonmetastatic complications of cancer discussed here include paraneoplastic syndromes and the side effects of anticancer therapy.

PARANEOPLASTIC SYNDROMES

Paraneoplastic syndromes involve remote effects of cancer on the nervous system.[4] Paraneoplastic syndromes are caused by cancer, but the symptoms cannot be ascribed to metastases or identifiable infectious, vascular, nutritional, toxic, or metabolic disorders. Most paraneoplastic syndromes are believed to result from an immune attack mounted against an antigen that is expressed by both the cancer and the nervous system.[4] The immune response often controls growth of the cancer but damages the part of the nervous system that expresses the same or similar antigens. The best example of this mechanism occurs in the Lambert-Eaton myasthenic syndrome (LEMS), in which a humoral immune response develops against calcium channel proteins in small cell lung cancer cells. The antibody binds to calcium channels on the presynaptic side of the cholinergic synapse, blocking the calcium uptake necessary for acetylcholine release, resulting in muscle weakness.

Paraneoplastic syndromes can affect any nervous system structure. They cause symptoms that mimick similar, presumably autoimmune, syndromes not associated with cancer. The neurologic symptoms usually precede identification of a cancer that may be too small to be detected. Several clinical characteristics suggest a paraneoplastic syndrome.[2,4]

1. The neurologic disorder usually has a rapid course that evolves over weeks or months and then stabilizes.
2. The incidence of certain clinical syndromes (e.g., LEMS) is substantially higher in cancer patients than in the general population. For example, in 60% of patients presenting with LEMS, cancer—usually small cell lung cancer—is the cause. In about 50% of patients presenting with a subacute onset of pancerebellar degeneration, the disorder is paraneoplastic.
3. In some patients with a given clinical syndrome, specific serum antibodies react against both the nervous system and the cancer. The presence of these autoantibodies identifies the clinical disorder as paraneoplastic and suggests the type of

neoplasm involved [*see Table 6*]. These autoantibodies include anti-Yo antibodies found in patients with the paraneoplastic cerebellar degeneration associated with gynecologic cancers; antimyelin-associated glycoprotein antibodies (anti-MAG) found in patients with the peripheral neuropathy associated with lymphoma and Waldenström disease; anti-Hu antibodies found in patients with the sensory neuropathy or encephalomyelitis associated with small cell lung cancer; and antibodies to the cancer-associated retinopathy antigen. Tests for many of these antibodies are commercially available.

Paraneoplastic Cerebellar Degeneration

Paraneoplastic cerebellar degeneration is characterized by the rapid development of bilateral, usually symmetrical, cerebellar dysfunction, including arm and leg ataxia and severe dysarthria. Vertigo, diplopia, and nystagmus are common. CSF findings include pleocytosis and elevated protein and IgG concentrations. The disease, which may be associated with any cancer, usually precedes discovery of the neoplasm by a few weeks to 3 years. MRI, particularly when performed several months after the illness begins, shows cerebellar atrophy. Anti-Purkinje cell antibodies are found in the serum of some patients, especially patients with ovarian cancer.[101] Pathologic changes are often restricted to loss of Purkinje cells throughout the cerebellum. Lymphocytic cuffs may be encountered around blood vessels, particularly in deep cerebellar nuclei.

Clinically, paraneoplastic cerebellar degeneration can be distinguished from cerebellar metastases by the symmetry of its signs and the absence of increased intracranial pressure. It differs from alcoholic cerebellar degeneration in that dysarthria and ataxia of the upper extremities are prominent features of the paraneoplastic form but are usually mild or absent in the alcoholic form. It differs from the hereditary types of cerebellar degeneration in that the latter rarely have as rapid a course.

Paraneoplastic cerebellar degeneration runs its course over weeks to months, usually rendering the patient severely disabled. In rare instances, the disorder improves with successful treatment of the tumor.

Paraneoplastic Opsoclonus

Paraneoplastic opsoclonus (spontaneous, conjugate, chaotic, and uncontrollable eye movements) is associated with cerebellar ataxia and myoclonus of the trunk and extremities. It occurs most commonly in children as a remote effect of neuroblastoma. It also occurs in adults with various cancers.[101] In children, the neurologic symptoms respond to treatment with corticosteroids and antitumor therapy.

Paraneoplastic Sensory Neuronopathy

Paraneoplastic sensory neuronopathy is marked by loss of sensation with relative preservation of motor power. The illness usually precedes the appearance of cancer—typically, small cell lung cancer (in which case it is known as the anti-Hu syndrome)[101]—and progresses over a few months, leaving the patient moderately or severely disabled. CSF pleocytosis is common at onset but resolves in a few weeks. Pathologic findings include destruction of the dorsal root ganglia and the posterior columns of the spinal cord; perivascular lymphocytic cuffing;

Table 6 Antineuronal Antibody Associated Paraneoplastic Disorders

Antibody	*Neuronal Reactivity*	*Protein Antigens*	*Cloned Genes*	*Tumor*	*Paraneoplastic Symptoms*
Anti-Hu (ANNA1)	Nucleus/cytoplasm (all neurons)	35-40 kd	*HuD, HuC Hel-N1*	SCLC, neuroblastoma, prostate,	PEM, PSN, PCD, autonomic dysfunction
Anti-Yo (PCA-1)	Cytoplasm Purkinje cells	34, 62 kd	*CDR34, CDR62*	Ovary, breast, lung	PCD
Anti-Ri	Nucleus/cytoplasm (CNS neurons)	55, 80	Nova	Breast, gyn, lung, bladder	Ataxia/opsoclonus
Anti-Tr	Cytoplasm Purkinje cells	?	—	Hodgkin	PCD
Anti-VGCC	Presynaptic NMJ	VGCC 64 kd	P/Q type *MysB*	VGCC, SCLC	LEMS
Antiretinal	Photoreceptor, ganglion cells	23, 65, 145, 205 kd	Recoverin	SCLC, melanoma, gyn	CAR, MAR
Anti-amphiphysin	Presynaptic NMJ	128 kd	Amphiphysin	Breast, SCLC	Stiff-person syndrome PEM
Anti-CRMP5 (Anti-CV2)	Oligodendrocytes, neurons, cytoplasm	66 kd	*CRMP5 (POP66)*	SCLC, thymoma	PEM, PCD chorea, sensory neuropathy

*Common causes of complications.
I.V.—intravenous I.T.—intrathecal I.A.—intra-arterial

and wallerian degeneration of sensory nerves. Many patients also have inflammatory and degenerative changes in the brain and spinal cord. In some patients, sensory neuronopathy improves when the tumor is treated; in a few patients, the neuronopathy improves spontaneously or responds to immunosuppression (e.g., plasma exchange or intravenous gamma globulin). However, in most patients, the neuronopathy does not improve, even after the tumor is cured.

Lambert-Eaton Myasthenic Syndrome

LEMS is characterized by proximal muscle weakness with ptosis, dry mouth, and, in men, impotence.[101] Physical examination reveals that the patient has greater strength than would be expected given the patient's complaints, and that when the patient makes a sustained effort, strength increases over several seconds. Deep tendon reflexes at the knees and ankles are usually absent but sometimes return transiently with exercise. The diagnosis is made by electrical studies. In patients with LEMS, neuromuscular transmission increases with repetitive stimulation—the opposite of what occurs in patients with myasthenia gravis. Antibodies against P/Q-type calcium channels are found in the patient's serum. Successful treatments are plasma exchange and eradication of the underlying cancer.

NEUROTOXICITY CAUSED BY CHEMOTHERAPEUTIC AGENTS

Anticancer chemotherapy can cause a number of neurotoxic side effects [*see Table 7*], the most prominent being peripheral neuropathy and encephalopathy.[102,103] When neurologic dysfunction occurs in patients who are undergoing chemotherapy, even in those who are taking drugs that are usually not considered neurotoxic, the presence of drug-related neurotoxicity should be considered and standard references consulted for precedents.

Peripheral Neuropathy and Myopathy

The vinca alkaloids, particularly vincristine, affect the microtubules, causing a sensorimotor peripheral neuropathy.[102,103] Virtually all patients treated with vincristine complain of paresthesias in the fingertips and sometimes in the toes. Ankle reflexes disappear early. Occasionally, patients develop motor weakness that occurs in a diffuse distal distribution or in individual cranial or peripheral nerves. Autonomic neuropathy may also occur. These symptoms are reversible.

Cisplatin causes a large-fiber sensory neuropathy by damaging dorsal root ganglia. This dose-related disorder occurs in patients who receive more than 450 mg/m^2. Symptoms often begin several weeks after completion of cisplatin therapy and progress for several months. Loss of proprioceptive sensation may be severe enough to prevent the patient from walking and effectively using his or her hands. Pinprick and temperature sensations are normal, and motor power is spared; some patients recover. In addition to sensory neuropathy, oxaliplatin can cause the acute onset of reversible symptoms consisting of paresthesias, cold hypersensitivity, jaw and eye pain, ptosis, leg cramps, and vision and voice changes. Carboplatinum rarely causes neurotoxicity. Platinum-induced neurotoxicity may be somewhat ameliorated by administration of amifostine.[102]

Doses of paclitaxel greater than 250 mg/m^2 cause a predominantly sensory neuropathy, characterized by paresthesias in the

Table 8 Radiation Injury to the Nervous System

Time after Radiation Therapy	*Organ Affected*	*Clinical Findings*
Primary injury		
Acute (minutes to hours)	Brain	Acute encephalopathy
Early delayed (6–16 wk)	Brain	Somnolence, focal signs
	Spinal cord	Lhermitte sign
Late delayed (months to years)	Brain	Dementia, focal signs
	Spinal cord	Transverse myelopathy
	Peripheral nerves	Paralysis, sensory loss
Secondary injury (years)	CNS, peripheral nervous system	Brain, cranial, or peripheral nerve sheath tumors
	Arteries (atherosclerosis)	Cerebral infarction
	Endocrine organs	Hypothyroidism, hypopituitarism

hands and feet. It may be accompanied by a sensory ataxia. Proximal muscle weakness may complicate the disorder. The neuropathy may resolve even with continuation of therapy and is rarely a disabling problem. Docetaxel is less neurotoxic.

Standard dosages of corticosteroids (prednisone or its equivalent at 60 to 100 mg/day) cause myopathy characterized by weakness of neck flexors and of the proximal extremities. The first sign of this neurotoxicity is difficulty in rising from low chairs or the toilet seat without pushing down with the arms; difficulty in climbing stairs subsequently occurs. Respiratory muscles may be affected.[104] The myopathy usually resolves when the drug is discontinued.

Encephalopathy

Many chemotherapeutic agents cause encephalopathy [*see Table 7*].[102,103] High-dose cyclophosphamide is sometimes associated with acute delirium; reversible acute encephalopathy is more common with ifosfamide. High-dose cytarabine may cause acute delirium or acute cerebellar degeneration, both of which are usually reversible. High-dose intravenous methotrexate or standard doses of intrathecal drugs can cause reversible acute encephalopathy. However, prolonged use of methotrexate, particularly in conjunction with radiation therapy, can lead to chronic encephalopathy that is characterized by progressive dementia.

NEUROTOXICITY CAUSED BY RADIATION THERAPY

The neurotoxic effects of radiation therapy may involve any portion of the CNS or peripheral nervous system and may occur acutely or be delayed for weeks to years after irradiation[105] [*see Table 8*]. The extent of neurotoxicity is determined by the total dose of radiation, the size of each fraction, the total time over which the dose is received, the volume of nervous system tissue that is irradiated, and the time that has elapsed since treatment. Other factors, such as underlying nervous system disease (e.g., a brain tumor or cerebral edema), previous surgery, concomitant use of chemotherapeutic agents, and individual susceptibility (especially to methotrexate), make it impossible to determine precisely the safe dose for a given person. However, guidelines exist that allow the radiation oncologist to calculate doses that are generally safe.

Acute Encephalopathy

Acute encephalopathy occurs in patients who have increased intracranial pressure, particularly in those who are given large fractional doses of radiation without corticosteroid prophylaxis. It is believed to occur when radiation-induced alteration of the blood-brain barrier causes brain edema that increases intracranial pressure. Acute worsening of neurologic symptoms does not occur after spinal cord irradiation.

Immediately after the first treatment, susceptible patients experience headache, nausea and vomiting, somnolence, fever, and, occasionally, worsening of neurologic signs. In rare instances, cerebral herniation and death occur. Acute encephalopathy responds to corticosteroids.

Early Delayed Encephalopathy or Myelopathy

Early delayed encephalopathy or myelopathy appears 4 to 16 weeks after therapy and persists for days to weeks. These early delayed irradiation syndromes are believed to result from demyelination, which may be caused by radiation-induced damage to oligodendroglia.

In children, early delayed encephalopathy, also called the postirradiation somnolence syndrome, commonly occurs after prophylactic irradiation of the brain for leukemia. The disorder is characterized by somnolence that is often associated with headache, nausea, and vomiting and is sometimes associated with fever. Electroencephalography may show slow waves, but focal signs are absent.

In adults, the syndrome usually occurs after cranial irradiation for brain tumors and is characterized by lethargy and worsening of focal neurologic signs. MRIs may also indicate transient worsening, suggesting that the tumor is not responding. In both adults and children, the disorder usually responds to corticosteroids; if it goes untreated, it usually resolves spontaneously.

Early delayed myelopathy occurs after radiation therapy to the neck or upper thorax. It is characterized by the Lhermitte sign, an electric shock–like sensation that radiates into various parts of the body when the neck is flexed. The symptoms resolve spontaneously.

Late Delayed Radiation Injury

Late delayed radiation injury appears months to years after radiation therapy and may affect any part of the nervous system. In the brain, two clinical syndromes occur: diffuse injury and focal radiation damage. Diffuse injury may be caused by whole brain irradiation, either in patients who do not have brain tumors (i.e., in those who receive prophylactic irradiation for small cell lung cancer) or in some patients with primary or metastatic brain tumors. The disorder is characterized by dementia, sometimes with gait apraxia and incontinence. MRI shows cerebral atrophy or hydrocephalus; pathologic changes are nonspecific. Some patients respond temporarily to ventricular shunting.[106]

Focal radiation damage affects patients who receive either focal brain irradiation for the treatment of extracranial neoplasms or whole brain irradiation for the treatment of intracranial neoplasms. Neurologic signs suggest that a mass is present and include headache, focal or generalized seizures, and hemiparesis. MRI reveals a hypointense mass that sometimes exhibits contrast enhancement. Neuropathologic features are coagulative necrosis in the white matter, vascular abnormalities (i.e., telangiectasia, fibrinoid necrosis, and thrombus formation), and glial proliferation with bizarre, multinucleated astrocytes. The clinical and MRI findings in patients with focal radiation damage cannot be distinguished from those in patients with brain tumors; diagnosis can be made only by biopsy. Corticosteroids may ameliorate symptoms. If they fail, treatment consists of surgical removal of the mass.

Late Delayed Myelopathy or Neuropathy

Late delayed myelopathy often begins with the Brown-Séquard syndrome (weakness and loss of proprioception in the extremities of one side and loss of pain and temperature sensations on the other) and is subsequently characterized by progressive paralysis, sensory changes, and sometimes pain. Occasionally, patients transiently respond to corticosteroids, and the disorder may stop progressing. Generally, however, paraplegia or quadriplegia develops. Pathologic changes include necrosis of the spinal cord.

Late delayed neuropathy may affect any cranial or peripheral nerve. Common disorders are blindness, caused by optic neuropathy, and paralysis of an upper extremity, caused by brachial plexopathy after therapy for lung or breast cancer. The pathogenetic mechanisms are probably fibrosis and ischemia of the plexus. There is no therapy for patients with these disorders.

Radiation-Induced Tumors

Meningiomas,[107] sarcomas, or, less commonly, gliomas may appear years to decades after cranial irradiation and may be associated with even low-dose radiation therapy. Malignant or atypical nerve sheath tumors may develop after irradiation of the brachial, cervical, or lumbar plexus. The CNS may also be damaged when radiation alters extraneural structures.

Other CNS Syndromes

Radiation therapy accelerates atherosclerosis, and cerebral infarction associated with carotid artery occlusion may occur many years after neck irradiation. Endocrinologic dysfunction (involving the pituitary, thyroid, or parathyroid) may be caused by radiation therapy and may be associated with neurologic signs. Hypothyroidism that results from irradiation may also cause encephalopathy.

Additional Information

The National Cancer Institute of the National Institutes of Health provides continually updated information on CNS neoplasms on their Web site CancerNet (http://cancernet.nci.nih.gov). CancerNet provides information on clinical trials; summaries on cancer treatment, screening, prevention, and supportive care; and publications of the National Cancer Institute.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VII ANOXIC, METABOLIC, AND TOXIC ENCEPHALOPATHIES

MICHAEL J. AMINOFF, M.D., D.SC.

The term encephalopathy is generally used to designate diffuse cerebral dysfunction. Such dysfunction is typically manifested by alterations in cortical function and disturbances of consciousness, ranging from mild confusional states (i.e., obtundation) to coma.[1] Abnormalities of consciousness reflect dysfunction of both cerebral hemispheres or of the reticular activating system in the brain stem. Encephalopathies may also be characterized by focal deficits, reflecting more localized cerebral dysfunction. In general, however, the cause is usually a systemic disorder that affects the brain diffusely, though some regions are more severely affected than others. A variety of mechanisms may contribute to encephalopathies, but anoxic, metabolic, and toxic factors are often significant and can lead to secondary structural abnormalities of the brain. Because of the risk of brain damage or death, diagnostic evaluation in patients with an encephalopathy of uncertain cause should proceed concurrently with stabilization and, in patients with acute coma of unknown cause, empirical treatment for common precipitating factors [*see Table 1*].

Clinical Evaluation

Metabolic and toxic encephalopathies cannot be distinguished with confidence from those caused by a mass lesion, but certain general points can be made. Onset is often insidious except when an acute event, such as cardiac arrest or drug overdose, is responsible. In general, the neurologic findings are symmetrical or multifocal in distribution, and tremor, asterixis, and myoclonus are common. Asterixis (sometimes referred to as a flapping tremor) consists of brief lapses of a sustained muscular contraction, as when the arms are held outstretched against gravity. Focal or lateralizing signs are absent or inconsistent; when present, they sometimes alternate from one side to the other. With some exceptions, preserved pupillary responses in the context of impaired brain stem function are strongly suggestive of metabolic or toxic disorders.

HISTORY

Evaluation requires an accurate history to determine the cause of the encephalopathy and the prognosis for recovery. It is important to determine whether the neurologic symptoms came on abruptly (as with vascular pathology) or gradually, whether the symptoms have progressed since their onset, and whether they were preceded by other symptoms and signs that may suggest the cause of the dysfunction. Generalized seizures occur in drug and alcohol withdrawal states, with various other toxic and metabolic encephalopathies, and in the presence of structural lesions of the brain. Partial seizures are more suggestive of focal pathology but may occur in certain metabolic disorders, especially when the disorder is superimposed on a preexisting focal structural lesion, such as an old stroke. Similarly, the past medical history should be reviewed in detail. A history or clinical features indicative of diabetes mellitus suggest that the obtundation is associated with iatrogenic hypoglycemia or a nonketotic hyperosmolar state, whereas the cause of obtundation in an alcoholic patient may be a metabolic disorder (e.g., hepatic disease or thiamine deficiency), toxicity (e.g., ethanol intoxication or withdrawal), an infection, or trauma.

PHYSICAL EXAMINATION

The general physical examination of encephalopathic patients is important. Jaundice, petechial hemorrhages, gastrointestinal bleeding, ascites, or hypothermia may indicate hepatic dysfunction. A coarse facies, dry hair, or bradycardia suggests hypothyroidism. Acne, obesity, and hypertension are common in Cushing syndrome. Needle tracks in the skin raise the possibility of a toxic encephalopathy. Hypertension suggests that the encephalopathy is caused by a metabolic disorder (e.g., a renal or endocrinologic disorder) or an ischemic disorder (e.g., a cerebrovascular or cardiovascular condition), and hypothermia suggests a metabolic or toxic cause. Individual signs may be misleading, however, and must be evaluated within their clinical context; for example, fever and tachycardia are common signs of infection but also occur in drug and alcohol withdrawal states.

NEUROLOGIC EXAMINATION

The neurologic examination should characterize the nature and severity of the encephalopathy and should exclude a primary disorder of the central nervous system. An encephalopathy associated with signs of meningeal irritation suggests meningitis or subarachnoid hemorrhage, whereas a focal neurologic deficit or evidence of increased intracranial pressure mandates exclusion of an intracranial mass lesion. In metabolic or toxic en-

Table 1 Immediate Management of Patients with an Encephalopathy of Uncertain Cause

- Maintain adequacy of respiration and circulation
- Obtain blood samples for determination of the following:
  - Serum glucose and electrolytes
  - Complete blood count and sedimentation rate
  - Liver and kidney function studies
  - Toxicity screen
- Obtain urine for toxicity screen
- For coma of acute onset and unknown cause, administer the following:
  - Dextrose, 25 g I.V. (to treat possible hypoglycemia)
  - Thiamine, 100 mg I.V. (to prevent or treat Wernicke encephalopathy)
  - Naloxone, 1 mg I.V. (to treat possible opiate overdose)
- General clinical and neurologic examination
- Computed tomographic scanning of the head (if focal intracranial lesion is suspected)
- Lumbar puncture (if meningitis or subarachnoid hemorrhage is suspected)
- Arterial blood gas determinations (to distinguish between different causes of metabolic encephalopathy)
- Chest radiography
- Further investigation and treatment, depending on results of initial studies

cephalopathies, focal or lateralizing neurologic signs are often absent, but their presence does not exclude such disorders.

In determining the nature and severity of an encephalopathy, the mental status is evaluated with particular regard to the level of consciousness as judged by the attention span and response to verbal or painful stimuli [*see Table 2*]. Orientation, behavior, language function, mood and affect, thought content, and memory should also be assessed, if possible. Brief examination of the CNS requires evaluation of the cranial nerves, especially the pupillary responses, and of sensorimotor functions in the limbs, including tendon reflexes and plantar responses.

Although pupillary responses to light are often normal in persons with metabolic and toxic encephalopathies, a variety of pupillary abnormalities may occur. For example, fixed dilated or poorly responsive pupils often result from acute cerebral anoxia or intoxication with anticholinergic or sympathomimetic agents; depending on the circumstances in which they are encountered, such pupillary responses should also raise concern about a herniating intracranial mass lesion. Pinpoint pupils are a feature of opioid toxicity, organophosphate poisoning, or the use of miotic eyedrops; they are also a common sequela of pontine damage, as from a stroke. Abnormal asymmetry of pupil size or responsiveness suggests that a structural brain stem (or cranial nerve) lesion is responsible; such symptoms are unlikely in metabolic and toxic encephalopathies. Reflex ocular movements should also be assessed. In comatose patients, loss of oculovestibular responses may occur with either a structural pontine lesion or sedative intoxication. By contrast, downward deviation of one or both eyes with unilateral cold-water stimulation strongly suggests sedative intoxication.

As an encephalopathy becomes progressively more severe, patients become comatose. The depth of coma is best characterized by the response to external stimulation [*see Table 2*]. Lateralized responses suggest a structural lesion, whereas bilaterally symmetrical responses occur with either structural or metabolic-toxic pathology. In cases of expanding or progressive structural lesions causing downward transtentorial herniation, loss of cortical function may occur in a rostrocaudal sequence [*see Table 2*].

Table 2 Evaluation of Level of Consciousness

Level of Consciousness	*Characteristics*
Confusional state	Patient is disoriented, is irritable, and has a poor attention span Hallucinations and delusions may occur
Stupor	Patient is inattentive, drowsy, and unresponsive but can be aroused by vigorous stimuli for short periods
Coma	Patient is unresponsive and unarousable In patients with downward transtentorial herniation, the level of dysfunction is further characterized (below)
Diencephalic level	Reactive pupils Preserved oculocephalic responses
Early	Purposive response to pain
Late	Decorticate response to pain
Midbrain level	Fixed and midsized pupils Abnormal oculocephalic responses Decerebrate response to pain
Lower brain stem level	Fixed and midsized pupils Abnormal oculocephalic responses No response of upper limbs to pain

Anoxic Encephalopathies

CARDIAC DISORDERS

Circulatory Arrest

Transient circulatory arrest may lead to global cerebral ischemia and thus to syncope, which is sometimes preceded by nonspecific premonitory symptoms such as paresthesias, lightheadedness, palpitations, and a graying-out of vision. Syncope is associated with pallor and loss of muscle tone, but prolonged ischemia results in tonic posturing, sometimes accompanied by irregular jerking movements that resemble seizures. If postictal confusion occurs, it clears within 1 minute. In elderly patients, syncope may present simply as unexplained falls. Syncope may be related to cardiac pathology, dysautonomia, postural hypotension, endocrinopathies, and metabolic disorders. Neurocardiogenic (vasovagal) syncope, however, is the most common variety [*see 1:1 Approach to the Cardiovascular Patient*].

Depending on its duration, ventricular fibrillation or asystole may cause irreversible anoxic-ischemic brain damage. The prognosis varies with the patient's age, the duration of circulatory arrest, and the interval before cardiopulmonary resuscitation and defibrillating procedures were undertaken. Circulatory arrest from ventricular fibrillation has a better prognosis than that from asystole. The neurologic consequences of the arrest may relate to the accumulation of intracellular calcium, increased extracellular concentrations of glutamate and aspartate, and increased levels of free radicals.

In the mature nervous system, gray matter is generally more vulnerable to ischemia than white matter, and the cerebral cortex is more sensitive than the brain stem. So-called watershed areas bordering the zones supplied by major arteries are especially vulnerable.

Circulatory arrest of less than 5 minutes' duration leads to transient confusion or temporary loss of consciousness and impaired cognitive function. Complete recovery is usual, but in rare instances, the circulatory arrest is followed after 7 to 10 days by a demyelinating encephalopathy, with increasing cognitive dysfunction and pyramidal or extrapyramidal deficits that may have a fatal outcome. In such cases, patients regain consciousness several hours after the circulatory arrest but then develop progressive neurologic deficits, such as intellectual deterioration; personality changes; seizures; cortical blindness; amnestic syndromes; or, less commonly, the locked-in syndrome (characterized by quadriplegia and mutism), extrapyramidal syndromes, bibrachial paresis, or intention (action) myoclonus. Spinal cord dysfunction may occur but is unusual.

Circulatory arrest of longer than 5 minutes' duration may cause widespread and irreversible brain damage, resulting in prolonged coma. Prognosis for survival or useful recovery is poor, especially when brain stem reflexes (most notably the pupillary responses to light) are lost. In particular, loss of pupillary reactivity for more than 24 hours or persistence of coma for more than 4 days indicates a poor prognosis. In one study, comatose survivors of cardiac arrest who continued to have nonreactive pupils, failed to open their eyes in response to pain, or had absent or reflex motor responses 3 days after onset of coma generally failed to survive or to regain useful independent function [*see Table 3*].[2] In this study, the most accurate sin-

gle predictor of poor outcome immediately after restoration of spontaneous circulation was the absence of pupillary response to light: Outcome was poor (i.e., either death or a persistent vegetative state) in 73 of 89 patients (82%) with absent pupillary responses.[2]

In the first several days after the onset of ischemic encephalopathy, diffusion-weighted magnetic resonance imaging may be useful in determining prognosis; hyperintense cortical lesions are associated with a poor outcome.[3,4]

Evoked potential studies can also have prognostic utility. In a systematic review of somatosensory evoked potentials performed early after onset of coma, rates of awakening in adults with hypoxic-ischemic encephalopathy ranged from 0% when somatosensory evoked potentials were absent to 52% when somatosensory evoked potentials were normal.[5] In a prospective study of 346 comatose patients, pupillary reflex was the strongest prognostic variable for awakening. The probability of awakening was higher when late auditory evoked potentials were also present, and it was higher still when middle-latency evoked potentials were present. No patient with cognitive potentials became permanently vegetative.[6]

Even if consciousness is regained, focal or multifocal neurologic signs may lead to significant disability from focal motor deficits, extrapyramidal disturbances (e.g., parkinsonism), sensory loss, seizures, myoclonus, and disturbances of higher cortical function from which recovery is usually delayed and incomplete. Intention (action) myoclonus is particularly characteristic in such circumstances; it is often activated by startle or various sensory stimuli and is responsive only occasionally to clonazepam, valproate, piracetam, or 5-hydroxytryptophan. The last two medications are not commercially available in the United States.

Some patients do not fully regain consciousness after circulatory arrest. These patients may be in one of three states: the minimally conscious state, the persistent vegetative state, or brain death.[7,8]

The minimally conscious state, which is characterized by inconsistent but clearly discernible behavior of consciousness, can be distinguished from coma and a vegetative state by the presence of behavioral conditions not found in either of those two conditions, including intermittent behavioral evidence of awareness of self or environment; although these patients are unable to follow simple instructions or communicate reliably, functional MRI studies suggest that some of them may retain widely distributed cortical systems with potential for cognitive and sensory function.[9] Identification of the minimally conscious state is important because these patients appear to have a better outcome than do patients in a persistent vegetative state. The minimally conscious state may be transient or permanent.[10]

The persistent vegetative state is characterized by the return of sleep-wake cycles and of various reflex activities, but wakefulness is without awareness.[11,12]

Brain death is defined as the loss of all cerebral activity, including activity of the cerebral cortex and brain stem, for at least 6 hours if confirmed by electroencephalographic evidence of electrocerebral inactivity or for 24 hours without a confirmatory electroencephalogram. A useful clinical test in patients with suspected brain death is the apnea test. This test involves evaluation of the respiratory response of the brain stem by allowing the carbon dioxide tension (P_{CO_2}) to rise to 60 mm Hg while 100% oxygen is given through the endotracheal tube. Brain-dead patients have no ventilatory response to the apnea test.

Brain death may be simulated clinically by extreme hypothermia, sedative overdose, and neuromuscular blockade. Such conditions must always be excluded, especially when no clear history of circulatory arrest can be obtained.

Table 3 Clinical Evaluation of Prognosis in Comatose Survivors of Cardiac Arrest

Sign	*Patients with Poor Outcome (%)*		
	Immediate	*Day 3*	*Day 7*
Lack of response to pain			
No opening of the eyes	69	100	100
No motor response	75	100	100
Lack of response to verbal stimuli	67	94	100
Lack of pupillary response	83	100	100

Disorders Associated with Cardiac Procedures

Cardiac catheterization or percutaneous transluminal coronary angioplasty sometimes causes cerebral emboli that may lead to focal neurologic deficits or an encephalopathy manifested by a behavioral disturbance. Encephalopathy, seizures, and cerebral infarction after cardiac surgery usually result from hypoxia or emboli. Postoperative encephalopathies may also be caused by metabolic disturbances, medication, infection (especially in immunosuppressed patients), or multiple organ dysfunction syndrome (MODS). Postoperative seizures may result from focal or generalized cerebral ischemia, electrolyte or metabolic disturbances, or MODS. Recognition of the precise cause of encephalopathy in such cases can be difficult. After cardiopulmonary bypass is performed, intracranial hemorrhage may result because of diminished platelet adhesiveness and reduced levels of coagulation factors.

Coronary angioplasty leads to cerebral emboli in approximately 1% of cases; however, when undertaken after acute myocardial infarction, it is associated with a higher risk of stroke and anoxic encephalopathy.[13]

An encephalopathy may occur soon after cardiac transplantation as a side effect of an immunosuppressive agent or as the result of an infection (e.g., meningitis, meningoencephalitis, or cerebral abscess) related to immunosuppressive therapy. Infecting organisms include *Aspergillus, Toxoplasma, Cryptococcus, Candida, Nocardia,* and viruses. In patients on long-term immunosuppressive agents, an encephalopathy may develop from a primary CNS lymphoma [*see 11: VI Neoplastic Disorders*].

The occurrence of an encephalopathy after coronary artery bypass surgery may be caused by stroke, which develops in about 2% to 4% of bypass patients[14]; it is either embolic or, less commonly, the result of watershed infarction from hypoperfusion. Risk factors include advanced age, proximal aortic atherosclerosis, hypertension, previous stroke or transient ischemic attack (TIA), and diabetes.[15] A carotid bruit or radiologic evidence of atherosclerosis of the carotid artery does not clearly increase the risk of stroke, and carotid endarterectomy before cardiac surgery is of questionable utility.[16]

In rare cases, patients do not recover consciousness after surgery, and no specific metabolic cause can be identified. This encephalopathy is probably the result of diffuse cerebral ischemia or hypoxia. Hemispheric or multifocal infarction is sometimes responsible.

RESPIRATORY DISEASES

Hypoxia and Hypercapnia

The pathogenesis of neurologic abnormalities related to hypoxia and hypercapnia is not fully understood, because hypoxia is often associated with acid-base imbalance and leads to hematologic and biochemical changes that affect cerebral function. Moreover, both hypercapnia and hypoxemia can result from impaired ventilation, and their neurologic sequelae are not easily differentiated.

Chronic pulmonary insufficiency leads to an encephalopathy characterized by headache, confusion, disorientation, and impaired cognitive function. Examination may also reveal a postural tremor, myoclonus, asterixis, and hyperreflexia; papilledema is sometimes present. These findings are not only the result of cerebral hypoxia but also the result of hypercapnia, which produces cerebral vasodilatation, increased cerebrospinal fluid pressure, and an altered pH of the CSF.

High-altitude sickness can lead to an encephalopathy characterized by headache, fatigue, anorexia, nausea, poor concentration, and sleep disturbances.[17] Symptoms of high-altitude sickness begin within hours or days of ascent to altitudes above 10,000 ft. In severe cases or at higher altitudes, consciousness is impaired and coma may occur—sometimes with a fatal outcome. Cerebral edema causes papilledema, retinal hemorrhages, cranial neuropathies, a variety of sensorimotor deficits, and behavioral disturbances. High-altitude cerebral edema arises because the low barometric pressure encountered at high altitudes causes a reduction in the partial pressure of oxygen (P_{O_2}); the condition often follows acute mountain sickness and may be an extreme form of that disorder. Acetazolamide (250 mg once or twice a day) or dexamethasone (2 mg every 6 to 8 hours) may prevent acute mountain sickness. High-altitude cerebral edema is treated with prompt descent to a lower altitude and administration of oxygen and dexamethasone (8 mg, then 4 mg every 6 hours).[17]

Hypocapnia

Hypocapnia, which results from hyperventilation, causes cerebral vasoconstriction, a decline in the peripheral availability of oxygen, and an altered ionic balance of calcium. The resultant encephalopathy leads to light-headedness, paresthesias, visual disturbances, headache, unsteadiness, tremor, nausea, palpitations, and loss of consciousness. Muscle cramps and carpopedal spasms also occur. The many causes of hyperventilation include hepatic coma, brain stem lesions, and certain cardiopulmonary diseases, but in many instances, no specific cause can be found.

SEPSIS

A diffuse encephalopathy with progressive obtundation may complicate sepsis, especially in patients with acute respiratory distress syndrome. The cause of sepsis-related encephalopathies is uncertain but may relate to cerebral edema, hypoxia, disruption of the blood-brain barrier, direct cerebral infection, toxins produced by organisms infecting other tissues, alterations in the cerebral microcirculation, metabolic disturbances, and the effects of medications.[18] Sepsis-related encephalopathy tends to be worse at night; it is associated with marked EEG abnormalities and often clears spontaneously. Overt infection should be treated vigorously; in addition, metabolic abnormalities should be corrected, and medication requirements should be reviewed.

LIVER DISEASE

Portosystemic Encephalopathy

Encephalopathy can result from chronic liver disease and sometimes precedes systemic features of hepatic dysfunction [*see 4:IX Cirrhosis of the Liver*]. It may be precipitated by GI hemorrhage, a high protein intake, use of certain sedatives and diuretics, or sepsis. Portosystemic encephalopathy is characterized by a fluctuatingly abnormal mental status, often with an insidious onset that delays clinical recognition of the disorder. Somnolence, obtundation, and agitation can occur and may progress to coma. Ocular reflexes are preserved, but disconjugate eye movements or tonic ocular deviation (downward) may be found in rare instances. A flapping tremor (asterixis) is often conspicuous; in severe cases, decerebrate or decorticate posturing, hyperreflexia, and bilateral extensor plantar responses may be present. Routine liver function tests may not correlate with the severity of the encephalopathy. The fasting arterial ammonia concentration and EEG findings of diffuse slow activity with associated triphasic waves are more helpful in determining severity. Respiratory alkalosis is commonly present. The CSF often shows nonspecific abnormalities, but an increase in the glutamine level is strongly supportive of hepatic encephalopathy. Abnormal signal intensities may be found in the basal ganglia on T_1-weighted MRI.

The pathogenesis of hepatic encephalopathy is multifactorial. A critical element is altered brain-energy metabolism and increased permeability of the blood-brain barrier, which facilitates the passage of neurotoxins.[19] Treatment consists of reduction of hyperammonemia; restriction of dietary protein intake; control of GI bleeding; management of portal hypertension; removal of blood from the GI tract; administration of lactulose or neomycin; correction of associated electrolyte, biochemical, and hematologic disturbances; and general supportive measures[20] [*see 4:XIII Enteral and Parenteral Nutrition*].

Chronic Non-Wilsonian Hepatocerebral Degeneration

Some patients with chronic liver disease develop a permanent neurologic deficit resembling that of Wilson disease, with action (intention) tremor, ataxia, dysarthria, and choreoathetosis. Severity correlates best with the fasting arterial ammonia level. Neuroimaging studies may be abnormal. There is no specific treatment.

Liver Transplantation

An encephalopathy that worsens soon after liver transplantation suggests organ rejection, cerebral anoxia, or a complication of immunosuppressive agents, especially cyclosporine. Seizures often occur, suggesting metabolic disturbances, cerebrovascular disease, infections, or medication complications. Encephalopathies occurring weeks or months after liver transplantation are usually caused by infections or malignancies involving the nervous system.

PANCREATIC ENCEPHALOPATHY

Acute pancreatitis has been associated with a transient encephalopathy, but its symptoms are nonspecific and resemble those of other metabolic encephalopathies. Diagnosis, therefore, hinges on exclusion of other metabolic causes.

GASTROINTESTINAL DISEASES

Nutritional deficiency is the usual cause of any neurologic complication of GI disorders, but it is usually impossible to determine the responsible nutrient. Neurologic complications oc-

cur in up to 15% of patients who undergo gastric resection. Vitamin B_{12} absorption is impaired because of loss of gastric intrinsic factor; impaired vitamin B_{12} absorption can lead to a variety of disturbances [*see 5:III Anemia: Production Defects*]. Gastric plication has been associated with a nonspecific encephalopathy, myelopathy, polyneuropathy, Wernicke encephalopathy, and a nutritional amblyopia, but the responsible nutritional deficiencies are unknown. Chronic gluten enteropathy causes a progressive and sometimes fatal CNS disorder, with some combination of encephalopathy, myelopathy, cerebellar disturbances, and peripheral neuropathy.

RENAL FAILURE

Encephalopathy can result from uremia or its treatment.[21] Uremic encephalopathy clinically resembles other metabolic encephalopathies, and its severity cannot be related to any single laboratory abnormality. Its pathophysiologic basis remains uncertain, but it is usually attributed to the accumulation of toxic organic acids in the CNS or to the direct toxic effects of parathyroid hormone.

Dialysis Disequilibrium Syndrome

The dialysis disequilibrium syndrome consists of an encephalopathy characterized by headache, irritability, agitation, somnolence, seizures, muscle cramps, and nausea. It occurs during or after hemodialysis or peritoneal dialysis and has been related to shifting of water to the brain. Other features of dialysis disequilibrium syndrome include exophthalmos, increased intraocular and intracranial pressure, and papilledema.

Dialysis Dementia

In some patients who have undergone dialysis for more than a year, a fatal encephalopathy called dialysis dementia has developed. The cause of this condition is uncertain, although aluminum intoxication has been suggested as the cause, for two reasons: (1) increased cerebral concentrations of aluminum are found at postmortem examination and (2) dialysis dementia has become rare since aluminum was removed from dialysates.[22] A characteristic early feature is hesitancy of speech, followed by speech arrest. As the disorder advances, intellectual function declines, and hallucination, delusions, seizures, myoclonus, asterixis, gait disturbances, and other neurologic abnormalities develop. Death usually occurs within 1 year after onset. Deferoxamine, a chelating agent that binds aluminum, is often prescribed, but the optimal duration of treatment is unknown. Deferoxamine therapy may exacerbate encephalopathy in patients with high serum aluminum levels and may provoke visual and auditory disturbances.[23,24]

Renal Transplantation

The long-term immunosuppressive treatment of patients who undergo renal transplantation can lead to encephalopathic complications.[21]

ELECTROLYTE DISTURBANCES

Sodium

Hyponatremia and hypernatremia have several causes [*see 10:I Renal Function and Disorders of Water and Sodium Balance*]. Rapid changes in serum sodium concentration can cause encephalopathy because the osmotic equilibrium between the CSF and other body fluids is altered. Disturbances of cognition and arousal occur and may lead to coma. Associated features include myoclonus, asterixis, tremulousness, and seizures. Seizures are often poorly responsive to anticonvulsant medication unless the associated metabolic disturbance has been corrected. Focal motor deficits (e.g., hemiparesis) can occur with hyponatremia in the absence of any structural lesion or with hypernatremia as a result of intracerebral or subdural hemorrhage related to osmotically caused brain shrinkage, with secondary tearing of blood vessels.

In patients with acute brain syndromes, such as subarachnoid hemorrhage, hyponatremia is often erroneously attributed to the syndrome of inappropriate antidiuretic hormone secretion (SIADH). In such patients, hyponatremia is more often caused by salt wasting than by SIADH; because plasma volume is reduced, fluid restriction exacerbates hypovolemia and can result in cerebral ischemia. Hyponatremia should be corrected at a rate not exceeding 12 mEq/L/day, because rapid correction of hyponatremia leads to central pontine myelinolysis [*see* Nutritional Deficiencies, *below*].[25] Central pontine myelinolysis may obscure or follow improvement in hyponatremic encephalopathy. When severe, it leads to obtundation, a spastic or flaccid quadriparesis, and pseudobulbar palsy; in mild cases, clinical deficits are minimal, though conspicuous abnormalities may be detectable on MRI.

Potassium

Alterations of serum potassium concentration can have several causes [*see 10:II Disorders of Acid-Base and Potassium Balance*]. Hyperkalemia usually causes disturbances of cardiac rhythm before affecting neurologic function, but occasionally the arrhythmia is accompanied by burning paresthesias, progressive flaccid paralysis, depressed tendon reflexes, and mental changes. Treatment depends on the underlying cause, the severity of the electrolyte disturbance, and the electrocardiographic findings. Hypokalemia usually causes reversible neuromuscular dysfunction rather than an encephalopathy.

Calcium

The main CNS complication of hypercalcemia is an encephalopathy characterized by an impaired level of consciousness, headache, apathy or agitation, and, in rare cases, seizures. Neuromuscular complications (e.g., muscle weakness and fatigability) result from involvement of the peripheral nervous system.

Tetany is a widely recognized manifestation of hypocalcemia, but focal or generalized seizures can also occur, as can an encephalopathy characterized by confusion, hallucinations, delusions, psychosis, disturbances of consciousness, and cognitive impairment. The seizures are resistant to anticonvulsant drugs until the hypocalcemia is corrected. Other CNS complications include parkinsonism and chorea that clear with correction of the serum calcium level; increased intracranial pressure and a myelopathy may also occur with hypocalcemia.

Magnesium

Hypomagnesemia may coexist with hypocalcemia and has similar neurologic complications. Hypermagnesemia leads to an encephalopathy with drowsiness, confusion, diminished responsiveness, and depressed or absent tendon reflexes. Hypotension, respiratory depression, and weakness from impaired neuromuscular transmission may also be present. In severe cases, coma ensues, with the possibility of a fatal outcome.

PITUITARY DISEASE

Encephalopathy is common in Cushing disease, which leads to a variety of symptoms, including anxiety, agitation, insomnia,

depression, euphoria, excitement, and psychosis. Intracranial hypertension, with its attendant effects on cerebral function, may complicate Cushing syndrome; it occurs particularly after resection of the pituitary adenoma.

Hypopituitarism leads to apathy and intellectual decline, but the specific hormonal basis of these symptoms is uncertain because several hormones are affected concurrently.

Diabetes insipidus leads to an encephalopathy that ranges in severity from irritability to somnolence to coma. Patients are hypotensive and hyperthermic. Vasopressin or a long-acting vasopressin analogue is the usual therapeutic approach.

THYROID DISEASE

Hyperthyroidism

An encephalopathy that is common in hyperthyroidism takes the form of anxiety, restlessness, tremulousness, irritability, emotional lability, poor concentration, headaches, and insomnia. Depression and lethargy may be conspicuous in elderly patients (i.e., apathetic hyperthyroidism). Seizures can occur. Examination commonly reveals a postural tremor and generalized hyperreflexia. Chorea and paroxysmal choreoathetosis have also been described.

A more severe encephalopathic disturbance characterizes thyrotoxic crisis, with confusion and agitation progressing to coma. Thyrotoxic crisis is often associated with fever, cardiac arrhythmias, and other systemic disturbances. It is treated with hydrating and cooling agents, beta blockers, glucocorticoids, and, occasionally, plasmapheresis [*see 3:I Thyroid*].

Hypothyroidism

Mental changes are often seen in cases of hypothyroidism. Apathy, somnolence, and poor concentration are often attributed to depression. Cognitive function may decline. Confusion, delirium, and psychosis also occur. Symptoms reverse with correction of the thyroid disorder. Severe hypothyroidism may lead to impairment of consciousness accompanied by hypotension, hypothermia, respiratory failure, hypoglycemia, and other metabolic abnormalities. If treatment is delayed, the encephalopathy progresses to coma, sometimes with a fatal outcome.

Hashimoto Thyroiditis

A relapsing encephalopathy manifested by confusion, alterations in consciousness, seizures, tremulousness, and myoclonus may develop in patients with Hashimoto disease and high serum antithyroid antibody concentrations; the condition is termed Hashimoto encephalopathy.[26,27] Strokelike episodes of deterioration are common. Investigations reveal a diffusely abnormal EEG and an increased CSF protein concentration without associated pleocytosis, but neuroimaging studies show no abnormalities other than a patchy uptake on isotope brain scan. The disorder is treated with glucocorticoids and is associated with a good long-term prognosis.[27]

DIABETES MELLITUS

An encephalopathy may occur in diabetic patients as a consequence of metabolic derangements directly related to the diabetes or its treatment or to complications of the disease, such as renal failure (see above). It may also be related to cerebrovascular disease, which is relatively common in diabetic patients, who have an increased incidence of hypertension and atherosclerosis.

Diabetic ketoacidosis may be the presenting feature of previously unrecognized diabetes. The condition presents as an encephalopathy, manifested by an altered state of consciousness that progresses from mild confusion to coma. If the patient has no underlying structural disease of the brain, there are usually no focal or lateralizing signs. The encephalopathy is probably multifactorial. Serum hyperosmolality, acidosis, and disseminated intravascular coagulation (DIC) are likely contributing factors of importance; other metabolic derangements, infection, vascular occlusive phenomena, and cerebral edema may also be involved. Treatment is with fluid and electrolyte replacement and I.V. insulin (10 to 20 units given as a bolus, followed by continuous infusion of 10 to 15 U/hr in normal saline, with the dose being lowered as the blood glucose level declines) [*see 9:VI Diabetes Mellitus*].

Nonketotic hyperosmolar coma typically occurs in elderly patients with mild diabetes [*see 9:VI Diabetes Mellitus*]. Progressive obtundation is the predominant clinical manifestation, sometimes accompanied by seizures and focal deficits. Hypotension and evidence of dehydration may be present. Treatment involves fluid replacement with hypotonic (one-half normal) saline, correction of hyperglycemia with I.V. insulin, and correction of other biochemical derangements.

HYPOGLYCEMIA

Hypoglycemia causes an acute metabolic encephalopathy that can lead to irreversible brain damage if treatment is delayed. The most common cause of the hypoglycemia is insulin administration in diabetic patients [*see 9:VI Diabetes Mellitus*]; other causes include hepatic disease, alcoholism, and various tumors [*see 3:IX Hypoglycemia*]. Hypoglycemia leads initially to sweating, tachycardia, dilated pupils, tremulousness, and mental changes, which, depending on the level of the hypoglycemia, may include anxiety, confusion, stupor, or coma. The warning signs of sympathetic overactivity may not be evident in patients with autonomic dysfunction. As the depth of coma increases, the plantar responses become extensor, and decorticate or decerebrate posturing occurs. Brain stem dysfunction (including abnormal pupillary responses) and transitory focal neurologic deficits—sometimes alternating from side to side—may also occur. In some patients, seizures may be the only manifestation of hypoglycemia. Depressed respiration, heart rate, and tendon reflexes presage the development of irreversible brain damage. Administration of glucose improves or reverses symptoms and signs within a few minutes and should not be delayed for laboratory confirmation of hypoglycemia. All patients presenting with an encephalopathy of uncertain cause should therefore immediately receive 50 ml of 50% dextrose I.V.

NUTRITIONAL DEFICIENCIES

Wernicke Encephalopathy

Wernicke encephalopathy is common in alcoholic patients. It also occurs in malnourished patients (especially when glucose or oral hypoglycemic agents are administered), in patients on kidney dialysis, in obese patients treated with gastroplasty, and in patients who vomit persistently. Thiamine (vitamin B_1) deficiency is responsible for the hallmark features of Wernicke encephalopathy, which include ophthalmoplegia (i.e., nystagmus, extraocular palsies, gaze palsies, and, in rare cases, internuclear ophthalmoplegia), gait ataxia, and fluctuating confusional states. Pathologic changes occur in characteristic regions of the brain stem, especially in the mamillary bodies and thalamus. Diffusion-weighted MRI may show signal changes in these character-

istic midline locations.[28] A polyneuropathy is often present, and hypothalamic involvement may lead to hypotension and hypothermia. The prognosis depends on the rapid initiation of effective therapy. Treatment is with thiamine replacement (100 mg I.V. daily for 1 week, followed by daily oral supplementation). Improvement of the ophthalmoplegia commences within a day or so, and improvement of the encephalopathy is seen in days to weeks, but residual deficits are common.

Korsakoff Encephalopathy

As with Wernicke encephalopathy, Korsakoff encephalopathy is attributed to thiamine deficiency, though the precise pathophysiology is unknown. Selective disturbance of memory is the predominant clinical abnormality, but thiamine replacement therapy rarely leads to improvement. There is marked impairment of recent memory and difficulty in incorporating new memories, though immediate recall is intact. Patients are unaware of any deficit and often confabulate. Other cognitive abnormalities are found less often. The disorder is common in persons with chronic alcoholism, often occurring in association with Wernicke encephalopathy (Wernicke-Korsakoff syndrome). The pathologic changes are similar in distribution to those in Wernicke encephalopathy (see above).

Subacute Necrotizing Encephalomyelopathy

Subacute necrotizing encephalomyelopathy occurs as an autosomal recessive disorder in children (rarely in adults). The distribution of pathologic changes of this disorder resembles that of Wernicke disease, suggesting that the disorder relates to a disturbance of thiamine metabolism. Thiamine supplementation is sometimes helpful, but the encephalomyelopathy is not caused by nutritional deficiencies alone, and its precise pathophysiologic basis is unclear. Symptoms and signs include cognitive decline, seizures, flaccid weakness, optic atrophy, nystagmus, ataxia, vomiting, and irregular respirations. Death often results within a few months. There is no specific treatment.

Pellagra

Deficiency of niacin (nicotinic acid) leads to an encephalopathy, as well as cutaneous lesions, glossitis, anemia, and GI disturbances (e.g., anorexia, nausea, and diarrhea). Poor concentration, irritability, and affective complaints are followed by confusion, hallucinations, delusions, and pyramidal and extrapyramidal deficits (e.g., tremor and rigidity). A polyneuropathy may also occur. Pathologic changes are widespread in the CNS but most commonly involve Betz cells in the motor cortex. The response to treatment with niacin is usually disappointing, which suggests that other nutritional deficiencies may be involved.[29]

Central Pontine Myelinolysis

Central pontine myelinolysis is manifested clinically by confusion or more marked impairment of consciousness; pseudobulbar palsy; pyramidal deficits in the lower extremities or all extremities; and extensor plantar responses. Symptoms and signs progress over days to weeks; locked-in syndrome or coma may occur in advanced cases. The pathologic hallmark of the disorder is a breakdown and loss of myelin in the anterior pons and other brain stem regions, which may be visualized by MRI.[30] The disorder is associated with alcoholism, electrolyte disturbances, malignant disease, and malnutrition. It relates particularly to the rapid correction of hyponatremia; for this reason, hyponatremia should generally be corrected by no more than 12 mEq/L/day [*see* Electrolyte Disturbances, *above*].

Vitamin B_{12} Deficiency

Encephalopathy is a well-recognized complication of vitamin B_{12} deficiency. It may be accompanied by myelopathy, optic neuropathy, or peripheral neuropathy, or any combination of these conditions. The neurologic complications do not reflect the presence or the severity of any associated megaloblastic anemia. Folic acid masks the hematologic abnormality and fails to prevent the neurologic complications. Although cereal grains have been fortified with folic acid since 1994 in the United States, a 2003 Veterans Affairs study found that since fortification began, there has been no evidence of an increase in the incidence of vitamin B_{12} deficiency in persons who are not anemic.[31]

Treatment with vitamin B_{12} arrests and may reverse the neurologic disorder; the extent of any residual deficit relates to the severity and duration of symptoms before initiation of treatment[32] [*see 5:III Anemia: Production Defects*].

Hyperalimentation

An encephalopathy may occur in patients receiving parenteral hyperalimentation, usually because of metabolic abnormalities such as hypophosphatemia, hyperammonemia, or hyperosmolarity. A malignant form of Wernicke encephalopathy (see above) may develop if thiamine supplementation is not provided to patients who are being supported parenterally for prolonged periods.

Toxic Encephalopathies

IATROGENIC DISORDERS

Many toxic encephalopathies are iatrogenic in origin.[33] The CNS is affected by many drugs in a variety of ways, but the resultant disturbances of CNS function generally reverse with withdrawal of the offending medication. Attention here is directed at those medications that cause diffuse disturbances of cerebral function manifested particularly by alterations in the level of consciousness. Iatrogenic encephalopathies commonly manifest themselves primarily as seizures or as focal neurologic deficits, such as extrapyramidal and cerebellar syndromes.

Coma is a common sequela of overdosage with various drugs, including hypnotics, sedatives, neuroleptics, antidepressants, anticonvulsants, and analgesics [*see 8:I Management of Poisoning and Drug Overdose*]. On clinical examination, pupillary responses are generally found to be intact, though pinpoint pupils are found in cases of opioid poisoning, and dilated, sluggish pupils occur in cases of barbiturate or glutethimide overdose. Spontaneous and reflex ocular movements are typically impaired, even at an early stage, in barbiturate and phenytoin intoxication. Depending on the depth of coma, the corneal reflex may be lost, and painful stimuli to the trunk or extremities may lead to purposive movements, decorticate or decerebrate posturing, or an absence of motor response. Flaccidity and hyporeflexia of the limbs are common, but spasticity, hyperreflexia, and extensor plantar responses are sometimes found.

A fluctuating level of consciousness—with confusion, delirium, hallucinations, and a poor attention span—may occur, especially in the elderly, in reaction to many medications, including various antimicrobials, CNS depressants, antiparkinsonian drugs, anticonvulsants, and cardiovascular agents. Nonspecific

behavioral changes—such as restlessness, irritability, sleep disturbances, affective changes, and nightmares—often occur initially, but their significance may not be recognized. Examination often reveals tremor, asterixis, and myoclonus in addition to mental disturbances. Nystagmus may also be present, particularly when CNS depressants or anticonvulsants have been taken. A similar clinical disturbance may result from the withdrawal of certain medications, such as benzodiazepines and barbiturates.

Some encephalopathies may be related to the infectious and neoplastic complications associated with immunosuppressive and chemotherapeutic agents. Such agents and other drugs causing encephalopathies include (but are not limited to) cisplatin,[34] paclitaxel,[35] valproate,[36] vigabatrin,[37] cyclosporine,[33,38] methotrexate,[39,40] and cefuroxime.[41] Encephalopathies have been associated with transcatheter embolization[42] and allogeneic bone marrow transplantation.[43] Treatment with glucocorticoids can cause encephalopathies characterized by behavioral disturbances and psychoses.[44] Among other medications prescribed for the treatment of cardiac disorders, lidocaine and related agents may cause seizures, tremor, paresthesias, and confusional states. Calcium channel blockers, beta blockers, digoxin, and thiazide diuretics can also cause encephalopathies.

ALCOHOL-RELATED DISORDERS

Alcohol intoxication leads initially to behavioral changes (e.g., disinhibition, irritability, euphoria), dysarthria, ataxia, nystagmus, tachycardia, and cutaneous flushing. Increased alcohol intake may cause obtundation, coma, hyporeflexia, respiratory depression, and death. Level of tolerance to alcohol may influence the behavioral response to a particular blood level of alcohol.

Acute withdrawal from alcohol after a period of regular consumption can lead initially to postural tremor and signs of autonomic hyperactivity. Seizures may also occur, especially within the first 48 hours after withdrawal. The seizures are usually generalized tonic-clonic convulsions that are self-limited and rarely require anticonvulsant drug treatment. Delirium tremens may develop 2 to 7 days after withdrawal; it is characterized by marked agitation, excitement, hallucinations, hyperthermia, dehydration, and hypotension. Treatment is with benzodiazepines, fluid and electrolyte replacement, and general supportive measures [*see 13:III Alcohol Abuse and Dependency*].

Various encephalopathies can occur in alcoholics as a result of nutritional deficiencies (see above).

Miscellaneous Encephalopathies

DISSEMINATED INTRAVASCULAR COAGULATION

DIC may occur in patients with diseases of the brain and other organs; septicemia; immune-mediated disorders; diabetic ketoacidosis; neoplastic disease; or obstetric complications [*see 5:XV Coagulation Disorders*]. The clinical manifestations of DIC, including the predominance of thrombosis or hemorrhage, are influenced by its cause, rate of onset, and severity. Encephalopathy is a common manifestation, ranging in severity from mild confusion to coma. Even comatose patients may recover fully; they therefore require continuing support.

CONNECTIVE TISSUE DISEASES AND VASCULITIDES

Connective tissue diseases are characterized by an autoimmune inflammatory response and vasculitis. The common direct CNS manifestations are encephalopathy with cognitive or behavioral changes and focal neurologic deficits. An encephalopathy may also result from metabolic disturbances related to the involvement of other organs or to treatment with glucocorticoids or immunosuppressive agents.

Common features of direct CNS involvement in polyarteritis nodosa, allergic granulomatous angiitis (Churg-Strauss syndrome), and overlap syndrome include headache (sometimes indicative of an aseptic meningitis) and behavioral disturbances, such as cognitive decline, acute confusion, and affective or psychotic disorders. The EEG may be diffusely slow; neuroimaging studies are sometimes abnormal. Focal CNS deficits, which are uncommon, are usually caused by infarction or hemorrhage. Angiography may not reveal the vasculopathy.

Headache is the most common initial complaint of patients with giant cell (temporal) arteritis [*see 15:VIII Systemic Vasculitis Syndromes*]. Other features of giant cell arteritis include masticatory claudication and acute unilateral or bilateral blindness, which may be permanent. Other CNS complications are rare, but encephalopathy with neuropsychiatric disturbances, strokes, seizures, and other manifestations sometimes occurs in these patients.

In Wegener granulomatosis, cerebral involvement results from vasculitis or extension of granulomas from the upper respiratory tract.[45] The resulting encephalopathy may be caused by basilar meningitis with associated cranial neuropathies, temporal lobe dysfunction, cerebral infarction, or venous sinus obstruction.

Headache, cognitive deficits, behavioral and neuropsychiatric disturbances, and focal or multifocal deficits from small infarcts are usual presenting features of isolated angiitis of the CNS. Consciousness becomes depressed as the disease advances. The CSF exhibits a lymphocytic pleocytosis and increased protein concentration. Focal ischemic changes may be detected by computed tomography or MRI; angiography sometimes shows beading of vessels. Meningeal and brain biopsies are usually necessary to make a definitive diagnosis.

Rheumatoid arthritis, the most common of the connective tissue diseases, rarely causes encephalopathy unless involvement of the upper cervical spine or atlantoaxial dislocation causes headaches or hydrocephalus or leads to brain stem deficits from direct medullary compression or vertebral artery involvement.

In most patients with systemic lupus erythematosus, neurologic complications ultimately develop, often during the first year. Episodic affective or psychotic disorders are common and are often difficult to distinguish from corticosteroid-related mental disturbances. Alterations in consciousness sometimes occur. Focal neurologic deficits may be manifestations of strokes related to cardiac valvular disease, the presence of antiphospholipid antibodies, or cerebral vasculitis.[46] Generalized or partial seizures sometimes occur; they probably result from microinfarcts, metabolic disturbances, and systemic infections.

Uncommonly, patients with Sjögren syndrome may experience encephalopathies that are characterized by behavioral and psychiatric disturbances; these encephalopathies may result from aseptic meningitis, meningoencephalitis, or focal neurologic dysfunction. About 20% of patients with Behçet syndrome develop an aseptic meningitis or meningoencephalitis that leads to an encephalopathy. Focal or multifocal deficits may also result from cerebral ischemia. The CSF is commonly abnormal, with a mild pleocytosis and increased protein concentration.

Antiphospholipid antibodies (i.e., the lupus anticoagulant and anticardiolipin antibodies) are found especially in patients with certain connective tissue diseases,[47] in patients taking various

medications, in patients with infections and obstetric complications, and as an incidental finding [*see 5:XIV Thrombotic Disorders*]. An acute ischemic encephalopathy, manifested by confusion, obtundation, quadriparesis, and bilateral pyramidal signs, has been described in patients with antiphospholipid antibodies.[48]

The pathogenesis of the thrombotic tendency associated with the presence of these antibodies is unclear. Immunosuppressive therapy is not indicated. Cerebral thrombosis is managed as it is in other contexts.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VIII HEADACHE

Randolph W. Evans, m.d.

Headaches are a near-universal experience, with a 1-year prevalence of 90% and a lifetime prevalence of 99%. Each year in the United States, 9% of adults see physicians for headaches and 83% self-medicate. Headaches are one of the most common complaints of patients seen by primary care physicians and account for 20% of outpatient visits to neurologists.

The differential diagnosis of headaches is one of the longest in medicine, with over 300 different types and causes. Although most headaches are of benign (and still poorly understood) origin, some headaches can have serious and even potentially life-threatening causes. Thus, it is critical for the physician to diagnose headaches as precisely as possible.

The International Headache Society (IHS) criteria,[1] which were introduced in 1988 and updated in 2004, are the worldwide standard for headache classification. IHS criteria categorize headaches as primary or secondary. Primary headaches—those with no other underlying cause—account for 90% of headaches. This category includes migraine, tension, cluster, and miscellaneous headaches, such as primary exertional headaches. There are a large number of secondary headaches, which are classified according to their causes [*see Table 1*].

A careful history, examination, and, in some cases, diagnostic testing will usually provide the accurate diagnosis of a headache, although a precise diagnosis is not always possible. For example, some benign headaches have both migraine and tension-type features. Chronic daily headaches may also be difficult to classify.

This chapter reviews pain-sensitive structures in the head, the history and examination in patients with headache, and many of the primary and secondary headaches. The interested reader may wish to refer to a headache textbook for more comprehensive information (see the reference list at the end of the chapter).[2-5]

Pain-Sensitive Structures

Similar headaches can have different causes because there are a limited number of pain-sensitive structures in the head. Although all pain is registered in the brain, the brain parenchyma itself is not pain sensitive. The arachnoid, ependyma, and dura (except portions near blood vessels) are also insensitive to pain. The following are sensitive to pain: cranial nerves V, VII, IX, and X; the circle of Willis and proximal continuations; meningeal arteries; large veins in the brain and dura; and structures external to the skull (including scalp and neck muscles, cutaneous nerves and skin, the mucosa of paranasal sinuses, teeth, cervical nerves and roots, and the external carotid arteries and branches).

Headache pain may be felt at its source (e.g., cheek or forehead pain from maxillary or frontal sinusitis) or be referred from another site. For example, supratentorial structures are innervated by the ophthalmic division of the trigeminal nerve, whereas infratentorial and posterior fossa structures are supplied by C_2 and C_3. Thus, a cerebellar hemisphere lesion generally refers pain posteriorly and an occipital lobe lesion refers pain anteriorly. The caudal nucleus of the trigeminal nerve, which is located from the midpons to the third cervical segment, receives pain messages from the upper cervical roots and the trigeminal nerve. Thus, pain from the upper cervical spine or posterior fossa can also be referred to the front of the head.

Headache History

The headache history is usually essential to establishing the diagnosis.[6] Key elements of the history include not only the features of the headache but also the patient's own diagnosis, past history, psychosocial history, and family history [*see Table 2*]. In gathering the key elements, both open-ended ("What are your headaches like?") and closed-ended ("Do you have nausea with the headache?") questions are necessary [*see Table 3*]. Often, it is helpful to ask about a history of mild headaches and bad headaches. Some patients are not able to clearly remember or articulate features of the headache ("It's just a headache, doc."). With patients who have chronic headaches, it may be necessary to provide a headache diary or have them record features of their headaches and then return for a later appointment.

Table 1 Major Categories of Headache Disorders[1]

Primary Headaches
Migraine
Tension-type headache
Cluster headache and chronic paroxysmal hemicrania
Miscellaneous headaches unassociated with structural lesion: idiopathic stabbing, external compression, cold stimulus, benign cough, benign exertional, associated with sexual activity
Secondary Headaches
Headache associated with head trauma
Headache associated with vascular disorder: acute ischemic cerebrovascular disorder, intracranial, hematoma, subarachnoid hemorrhage, unruptured vascular malformation, arteritis, carotid or vertebral artery pain, venous thrombosis, arterial hypertension, associated with other vascular disorder
Headache associated with nonvascular intracranial disorder: high and low cerebrospinal fluid pressure, intracranial infection, intracranial sarcoidosis and other noninfectious inflammatory disease, related to intrathecal injections, intracranial neoplasm, associated with other intracranial disorder
Headache associated with substances or their withdrawal: acute and long-term substance use or exposure, withdrawal after acute and long-term use, associated with substances with uncertain mechanism
Headache associated with noncephalic infection: viral infection, bacterial infection, other infection
Headache associated with metabolic disorder: hypoxia, hypercapnia, mixed hypoxia and hypercapnia, hypoglycemia, dialysis, other metabolic abnormality
Headache or facial pain associated with disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
Cranial neuralgias, nerve trunk pain, and deafferentation pain
Persistent pain of cranial nerve origin, trigeminal neuralgia, glossopharyngeal neuralgia, nervus intermedius neuralgia, superior laryngeal neuralgia, occipital neuralgia, central causes of head and facial pain other than tic douloureux

Table 2 Key Elements of the Headache History

Element	*Examples*
Temporal profile	
Age of onset	Migraine, usually ≤ 40 yr; temporal arteritis after age 50
Time to maximum intensity	Gradual in migraine; immediate in thunderclap headache
Frequency	Eight per day with cluster; a few in a lifetime with migraine
Time of day	Cluster or migraine on awakening; tension in the afternoon
Duration	Migraine, 4–72 hr; cluster, 15 min to 3 hr
Recurrence	Migraines recur about 30% of the time after relief with a triptan
Headache features	
Location	Cluster always unilateral; migraine unilateral or bilateral
Quality of pain	Migraine, throbbing; tension, pressure; cluster, boring
Severity of pain	Most severe headaches are migraine or cluster
Associated symptoms and signs	
Before headache	Migraine aura or prodrome, fever before meningitis
During headache	Nausea/vomiting in migraine, eye redness and tearing in cluster
After headache	Mental dullness after migraine
Aggravating or precipitating factors	
Trauma	Migraine, subdural hematoma
Medical conditions	Obesity in pseudotumor cerebri
Triggers	Present in 85% of migraineurs; stress in tension type
Trigger zones	Trigeminal neuralgia
Activity	Exertional headache, benign orgasmic cephalalgia
Pharmacologic	Oral contraceptives, rebound headaches
Relieving factors	
Nonpharmacologic	Sleep for migraine, relaxation for tension type
Pharmacologic	Prescription and over-the-counter drugs, herbs, and vitamins
Previous evaluation and treatment	Obtain medical records as appropriate
Psychosocial history	
Substance use	Rebound headaches from too much caffeine
Occupational and personal life	Stress, occupational toxin exposures
Psychological history	Depression, anxiety
Sleep history	Deprivation causing headaches; sleep apnea
Impact of headache	Missed school, work, family activities
Patient's own diagnosis	May incorrectly self-diagnose as brain tumor, sinus headache, aneurysm
Family history	70% of migraineurs have a first-degree relative with migraine
Complete medical and surgical history	Asthma as a contraindication to beta blockers for migraine

Physical Examination

A directed physical examination may be informative. Examples of significant abnormal findings include hypertension, fever, cervical lymphadenopathy in infectious mononucleosis, cervical trigger points in tension-type headache, and maxillary sinus tenderness in sinusitis. Every patient seen for headaches should have, at the least, a screening neurologic examination; this takes only a few minutes to perform. Although the results of this examination are usually normal, the examination can point to significant underlying disease by revealing abnormalities such as papilledema, a mild lateral rectus paresis, unequal pupils, a mild hemiparesis, or a Babinski sign.

Clinical Classification

In most cases, the findings on history and physical examination will point the clinician toward the diagnosis of primary headache. The three most common primary headaches are migraine, episodic tension type, and cluster headache [*see Table 4*]. Much less often, the clinical features suggest secondary headache [*see Table 5*].

Diagnostic Testing

The vast majority of headaches require no diagnostic testing at all; they can be diagnosed accurately on the basis of a detailed history and a physical examination.[7,8] For example, patients who meet IHS criteria for migraine rarely have abnormal neuroimaging findings to explain the headache. In patients with headache of any type and a normal neurologic examination, the yield of a computed tomographic or magnetic resonance imaging scan is only about 2% or less. However, certain clinical features, patient characteristics, and associated symptoms and signs justify neuroimaging for headaches [*see Table 6*].

Although a CT scan of the head will detect most pathologic conditions that cause headaches and it is the preferred study for acute head trauma and subarachnoid hemorrhage (SAH), an MRI scan is generally preferred for evaluation of headaches. An MRI may demonstrate pathology not seen on a standard CT scan, including abnormalities of the paranasal sinuses, pituitary, posterior fossa, cortical veins (e.g., superior sagittal sinus thrombosis), cervicomedullary junction (e.g., Chiari I malformation), intracranial aneurysms, carotid dissection, infarcts, white-matter abnormalities, congenital abnormalities, and neoplasms.

Electroencephalography (EEG) is not useful for the routine evaluation of patients with headache. However, EEG may be helpful if the patient has headaches and symptoms suggesting a seizure disorder or alteration of consciousness.

Blood tests are generally not helpful for the diagnosis of headaches, but specific tests are indicated when certain conditions are suspected. Such conditions, along with their indicated tests, include arteritis (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP] in temporal arteritis); infection (tests for infectious mononucleosis, Lyme disease, and HIV); and antiphospholipid antibody syndrome, which should be considered in patients with white-matter lesions on MRI. Complete blood counts and metabolic studies are indicated in suspected anemia, renal failure, or hypercalcemia; and endocrine studies are indicated in suspected hypothyroidism or pituitary tumors. Blood studies are also valuable as a baseline for monitoring adverse effects of certain medications for preventing headache (e.g., valproic acid and carbamazepine).

Lumbar puncture can be helpful in diagnosing meningitis, encephalitis, meningeal carcinomatosis, lymphomatosis, SAH, high cerebrospinal fluid pressure (e.g., pseudotumor cerebri), and low CSF pressure. MRI or CT scanning is always performed before a lumbar puncture for the evaluation of headaches, to rule out mass lesions, except in some cases in which acute meningitis is suspected. Lumbar puncture is often indicated for the first or worst headache, to exclude SAH [*see* First or Worst and Thunderclap Headaches, *below*]; headache with fever or other findings that suggest an infectious cause; a subacute or progressive headache in a patient with HIV infection or carcinoma; and an atypical chronic headache (e.g., to rule out pseudotumor cerebri in an obese woman without papilledema).

Migraine

EPIDEMIOLOGY

The 1-year prevalence of migraine is 18% in women, 6% in men, and 5% in children (both boys and girls). In the United States, 28 million persons have migraine each year.[9,10] The lifetime prevalence is 25% for women and 8% for men. Migraine begins before the age of 20 in 50% of cases and after the age of 50 in 2%; the highest prevalence is from 25 to 50 years of age. About 70% of migraineurs have a positive family history in a first-degree relative. The mode of transmission of susceptibility to migraine remains unclear; there is probably genetic heterogeneity. Interestingly, there is a high prevalence in neurologists (lifetime of 47% in males and 63% in females).[11]

The frequency of migraine can range from once in a lifetime to almost daily. The frequency of attacks in migraineurs is as follows: one to 12 a year, 38%; one to three a month, 37%; one a week, 11%; and two to six a week, 14%. Half of migraineurs do not know that they have migraine, with 42% of undiagnosed patients self-diagnosing themselves with so-called sinus headache and 43% having received a diagnosis of sinus headache from a physician.[10]

There are many disorders with a greater-than-coincidental association (comorbidity) with migraine, including stroke, epilepsy, systemic lupus erythematosus, Raynaud syndrome, multiple sclerosis, and essential tremor.[12] Psychiatric disorders comorbid with migraine include bipolar disorder, major depression, generalized anxiety disorder, panic disorder, and simple and social phobia. Migraine may also be associated with hypertension, mitral valve prolapse, and patent foramen ovale.[13]

Table 3 Helpful Questions to Ask for the Headache History[6]

Do you have different types of headaches or just one?
Where does the headache hurt?
When did you first start having these headaches?
What were you doing when the headache started?
How long before the headache reaches maximal intensity?
How long does the headache last?
Does the headache recur? If so, how often?
What is the pain like? Is it a pressure, throbbing, pounding, aching, or stabbing pain?
Is the pain mild, moderate, or severe?
On a scale of 1 to 10, with 10 the worst and 1 the least, how would you rate the headache?
Do you have trouble with your vision before or during the headache?
Do you have other symptoms (e.g., nausea, vomiting, light sensitivity, noise sensitivity, discomfort with eye movement) with the headache?
Are there signs present (e.g., fever, ptosis, miosis)?
Do you have triggers of your headaches (e.g., menses, stress, foods, beverages, lack of sleep, oversleeping, strong odors, trigger zones)?
What makes the headache worse (e.g., coughing, bending over, physical activity)?
What makes the headache better (e.g., sleep, lying down in a quiet room)?
Do your headaches have any impact on your life?
Do you take over-the-counter medications, vitamins, or herbs for your headaches? If so, how much and how often?
Do you drink caffeinated beverages? If so, what types and how many?
What prescription drugs have you tried and with what effect?
What doctors have you seen in the past for your headaches?
What other treatments have you tried and with what success (e.g., acupuncture, chiropractic, biofeedback, stress management, massage)?
Have you been under much stress lately?
Have you been depressed?
Do you have any parents or siblings with a history of migraines or bad headaches?

ETIOLOGY AND PATHOPHYSIOLOGY

Although the mechanism of migraine remains incompletely understood, there is growing evidence that migraine is a neurovascular disorder.[14] The aura that precedes some migraines is a slow march of visual or other neurologic symptoms associated with changes in neuronal activity that result in spreading neural depression from the occipital cortex. Excitatory changes produce increased blood flow, followed by reduced blood flow caused by neuronal inhibition.

The trigeminal nerve and the blood vessels it innervates may constitute the anatomic substrate for migraine pain. Input from the pain-sensitive cranial nerves and dura passes through the ophthalmic division of the trigeminal ganglion to the trigeminocervical complex (the trigeminal nucleus caudalis and dorsal horns of C_1 and C_2) that produces referred pain in the head (especially the ophthalmic division) and upper posterior neck. When the peripheral branches of the trigeminal nerve are activated during migraine, pain results from neurogenic inflammation that is produced by the antidromic release of calcitonin gene–related peptide by trigeminal nerve endings and that is associated with the release of other pain substances from plasma, platelets, and mast cells (e.g., histamine, prostaglandin, and serotonin). These substances induce vasodilatation and extravasation of plasma proteins and the sensitization of trigeminal nociceptive nerve endings. Throbbing pain and exacerbation by activities such as bending over, head movement, coughing, and walking may reflect mechanical hypersensitivity of meningeal C-fiber nociceptors. Nitric oxide released from blood vessels, perivascular nerve endings, or brain tissue can be a trigger for migraine pain.

Pain signals in the trigeminocervical complex undergo central processing, with second-order neurons receiving input and projecting rostrally to the contralateral thalamus (ventrobasal complex and medial nuclei) and then to the activating cortex (anterior cingulate, insular, and frontal), the periaqueductal gray matter (dorsal raphe nuclei), and the locus coeruleus. Aminergic areas in the periaqueductal gray matter and locus coeruleus influence the incoming pain and cortical blood flow. A continuous

Table 4 Features of Selected Primary Headaches[6]

Feature	*Migraine*	*Episodic Tension-Type*	*Episodic Cluster*
Female-to-male ratio	1:1 before puberty, 3:1 after	5:4	1:5
Family history	First-degree relatives affected in 80% of cases	Frequent	Rare
Typical age at onset (yr)	92% before age 40, 2% after age 50	20–40	20–40
Visual aura	20% of cases	No	Occasional
Location	Unilateral 60%, bilateral 40%	Bilateral > unilateral; anywhere on the head, posterior neck, face	Unilateral, especially orbital, periorbital, frontotemporal
Quality	Pulsatile or throbbing in 85%	Pressure, aching, tight, squeezing	Boring, burning, or stabbing
Severity	Mild to severe (moderate to severe [untreated] in 80%)	Mild to moderate	Severe
Triggers	Present in 85%; numerous	Stress, lack of sleep	Alcohol, nitrates
Duration	4–72 hr; duration > 24 hr (untreated) in 62%; may be < 1 hr in children	Hours to days	15 min to 3 hr
Frequency	Rare to frequent	Rare to frequent	1–8 a day during clusters
Periodicity	Menstrual migraine	No	Yes; average bout, 4–8 wk; average 1 or 2 bouts yearly
Associated features	Nausea in 80%, vomiting in 30%, light and noise sensitivity in 80%	Occasional nausea	Ipsilateral conjunctival injection, tearing, and nasal congestion or drainage; ptosis and miosis in 30%
Behavior during headache	Still, quiet, tries to sleep	No change	Often paces, agitated
Awakens patient from sleep	Can occur	Rare	Frequently

discharge in this pain-control system may occur from stimulation from the cortex or hypothalamus caused by stress or by excessive afferent input from the special senses or from cerebral or extracranial vessels. The migraine prodrome may originate in the hypothalamus.

CLINICAL FEATURES

Migraine can occur with or without an aura [*see* Migraine Aura, *below*]. Migraine without aura (formerly referred to as common migraine) occurs in 80% of migraineurs, and migraine with aura (formerly referred to as classic migraine) occurs in 20%. Most patients who have migraine with aura also have migraine without aura.

According to the IHS criteria for migraine without aura, the duration of untreated or unsuccessfully treated episodes ranges from 4 to 72 hours. The headaches are associated with at least two of the following pain characteristics: unilateral location; pulsating quality; moderate or severe intensity; and aggravation by, or resultant avoidance of, routine physical activity (e.g., walking or climbing stairs). The pain is accompanied by nausea, vomiting, or both, as well as by sensitivity to light (photophobia) and sound (phonophobia). Also, the patient has a history of at least five previous attacks that meet these criteria. If there are no indications that other primary etiologies may be responsible for the headaches, a diagnosis of migraine without aura can be reasonably established.[1]

Although the IHS criteria have been very useful for research purposes, most clinicians recognize migraine through familiarity with the general features [*see Table 4*]. Migraine pain is unilateral in 60% of cases and bilateral in 40%. About 15% of migraineurs report so-called side-locked headaches, with migraine always occurring on the same side. The pain will often be more intense in the frontotemporal and ocular regions before spreading to the parietal and occipital areas. Any region of the head or face may be affected, including the parietal region, the upper or lower jaw or teeth, the malar eminence, and the upper anterior neck. Throbbing pain is present in 85% of episodes of migraine, although up to 50% of patients describe nonthrobbing pain during some attacks. Along with having head pain, up to 75% of migraineurs report having unilateral or bilateral tightness, stiffness, or throbbing pain in the posterior neck. The neck pain can occur during the migraine prodrome, the attack itself, or the postdrome and is typically relieved by migraine medication such as a triptan.

Migraine persisting for more than 72 hours is termed status migrainosus. Without treatment, 80% of patients have moderate to severe pain and 20% have mild pain. The pain, which is usually increased by physical activity or movement, is associated with nausea in about 80% of episodes, vomiting in about 30%, photophobia in about 90%, and phonophobia in about 80%.[10] In children, migraine pain is bilateral in 60% and unilateral in 40%. The duration of the untreated headache in children can be 1 hour or more, much shorter than that in adults.

During an attack, 45% of migraineurs have at least one autonomic symptom (i.e., lacrimation, eye redness, ptosis, eyelid edema, nasal congestion, or rhinorrhea). These symptoms are caused by parasympathetic activation of the sphenopalantine ganglion, which innervates the tear ducts and sinuses, and these symptoms can lead to confusion of migraine with so-called sinus headaches.[15] Of patients with autonomic symptoms, 45% have both nasal and ocular symptoms, 21% have nasal symptoms only, and 34% have ocular symptoms only.

Prodromal symptoms (premonitory phenomena) may be present in about 10% of cases and precede the migraine attack by hours or by up to 1 or 2 days. Prodromal symptoms include changes in mental state such as depression, hyperactivity, euphoria, talkativeness, irritability, drowsiness, and restlessness. Neurologic symptoms may include photophobia, difficulty concentrating, phonophobia, dysphasia, hyperosmia, and yawning. General symptoms may include stiff neck, food cravings, feeling cold, anorexia, sluggishness, diarrhea or constipation, thirst, and fluid retention.

Triggers

Migraines are often triggered by environmental or other factors; 85% of migraineurs report triggers. Patients typically have multiple triggers, with a mean of three.[16] Up to 50% of migraineurs report that a change of weather is a trigger. Other environmental triggers are heat, high humidity, and high altitude. There are numerous additional triggers, including stress (reported by about 50% of patients), letdown after stress, vacations, and crying. Missing a meal (40%), lack of sleep, oversleeping, and fatigue are also commonly reported as triggers. Sensory triggers include bright lights, glare, flickering lights, loud noise, and strong smells such as perfume or cigarette

Table 5 Features of Selected Secondary Headaches[6]

Headache Type	*Epidemiology*	*Age of Onset*	*Location*	*Quality and Severity*	*Frequency*	*Associated Features*	*Comments*
Trigeminal neuralgia	4.3/100,000/yr; male-to-female ratio, 1.6:1	Usually > 40 yr; if < 40 yr, consider multiple sclerosis	Unilateral, 96%; second or third trigeminal division more often than first	Stabbing; electrical bursts; burning; lasts few seconds to < 2 min	Few to many a day	Trigger zone present in > 90% of cases	Usually due to vascular compression of CN V; scan needed to exclude occasional tumor
Brain tumor	Persons/yr: 24,000 primary, 170,000 metastatic	Any age	Often bifrontal; unilateral or bilateral; any location	Can be pressure or throbbing, mild to severe	Occasional to daily; usually progressive	Papilledema in 40%; at time of diagnosis, headache present in 30%–70%	Primaries in adults: lung, 64%; breast, 14%; unknown, 8%; melanoma, 4%; colorectal, 3%; hypernephroma, 2%
Pseudotumor cerebri	1/100,000/yr; 90% are female; 90% are obese	Mean of 30 yr	Often bifrontotemporal but can occur in other locations and unilaterally	Pulsatile; moderate to severe	Daily	Papilledema in 95%; transient visual obscurations in 70%; intracranial noises in 60%; CN VI palsy in 20%	MRI scan preferred to better exclude cortical venous thrombosis and posterior fossa lesions
Subarachnoid hemorrhage	30,000/yr caused by saccular aneurysm	Mean of 50 yr	Usually bilateral; any location	Usually severe but can be mild and gradually increasing	Paroxysmal	Often with nausea, vomiting, stiff neck, focal findings, syncope; stiff neck absent in 36%	CT scan abnormal on first day in 95%; third day, 74%; 1 wk, 50%; lumbar puncture may be essential for diagnosis
Temporal arteritis	In age > 50 yr, annual incidence of 18/100,000; male-to-female ratio, 3:1	Rare before 50 yr; mean age of 70 yr	Variable, unilateral, or bilateral; often temporofrontal	Often throbbing; may be sharp, dull, burning, or lancinating; mild to severe	Intermittent to continuous	50% have PMR; jaw claudication in 38%; 50% have absent pulse or tender STA	ESR WNL in up to 36%; CRP usually elevated; STA biopsy false negative in up to 44%
Acute paranasal sinusitis	More common in children (in whom frontal and sphenoid sinusitis are rare) than in adults	Any age	Frontal (forehead), maxillary (cheek), ethmoid (between eyes), sphenoid (variable)	Dull, aching; can be severe	Acute lasts from 1 day to 3 wk	Fever in about 50%; nasal congestion and purulent nasal drainage usually present (less often in sphenoid)	Well visualized on routine MRI but not on routine head CT scan; sinus CT is the best study
Subdural hematoma	Occurs in 1% after mild head injury; in chronic cases, up to 50% without history of head injury	Any age	Unilateral or bilateral	Mild to severe; may be aching, dull, or throbbing	Paroxysmal to constant	Normal neurologic exam in 50%; alteration in consciousness and focal findings may be present	MRI may detect the occasional isodense subdural hematoma, which can be missed on CT scan

CN—cranial nerve CRP—C-reactive protein ESR—erythrocyte sedimentation rate MRI—magnetic resonance imaging PMR—polymyalgia rheumatica STA—superficial temporal artery WNL—within normal limits

Table 6 Reasons to Consider Neuroimaging for Headaches[6]

Temporal and clinical features	First or worst headache Subacute headaches with increasing frequency or severity A progressive or new daily persistent headache Chronic daily headache Headaches always on the same side Headaches not responding to treatment
Patient characteristics	New-onset headaches in patients with cancer or HIV infection New-onset headaches after age 50
Associated symptoms and signs	Fever, stiff neck, nausea, and vomiting Aura and focal neurologic symptoms or signs in nonmigraine headache Papilledema, cognitive impairment, or personality change Seizures

smoke. Up to 50% of patients report alcohol as a trigger; this can be all forms of alcohol or only one type, such as red wine or beer. Up to 45% report food triggers such as chocolate, dairy products (particularly cheese), citrus fruits, fried foods, and nitrates and nitrites in cured meats or fish (e.g., frankfurters, bacon, and smoked salmon). Other triggers include minor head trauma, exertion, and nitroglycerin.

There are triggers unique to women. Half of women with migraine report menses as a trigger, and 14% have migraines associated only with their menses. During pregnancy, the frequency of migraines decreases (especially during the second and third trimesters) in 60%, remains the same in 20%, and increases in 20%. Migraines may occur for the first time when women start using oral contraceptives (OCs). Low-estrogen OCs usually have no effect on migraine or may even improve it, although frequency can increase. Of patients with new-onset migraine or increased frequency of migraine associated with OCs, 30% to 40% may improve when OCs are discontinued, although improvement may not occur for up to 1 year. Two thirds of women with prior migraine improve with physiologic menopause. Surgical menopause results in worsening of migraine in two thirds of cases.

Migraine Aura

The migraine aura has a total duration of usually less than 1 hour and frequently less than 30 minutes. An aura lasting more than 1 hour but less than 1 week is termed migraine with prolonged aura, or complicated migraine. The most common aura is a vision-related one, which is present in 99% of cases. There are two types: (1) positive visual phenomena, with hallucinations, and (2) negative visual phenomona, or scotomas, with either an incomplete or a complete loss of vision in a portion or all of the visual field. Most visual auras have a hemianoptic distribution. Photopsias consist of small spots, dots, stars, unformed flashes or streaks of light, or simple geometric forms and patterns that typically flicker or sparkle.

A scintillating scotoma, also called a fortification spectrum (because of its resemblance to a medieval fortified town as viewed from above) or teichopsia (seeing fortifications), is present in about 10% of cases. The scotoma, which is frequently semicircular or horseshoe shaped, usually begins in the center of the visual field and then slowly extends laterally. The scotomatous arc or band is a shimmering or glittering, bright, zigzag border. Most visual auras consist of flickering, colored or uncolored, unilateral or bilateral zigzag lines or patterns, semicircular or arcuate patterns, wavy lines, or irregular patterns. Rare visual auras include metamorphopsia (objects appear to change in size and shape), macropsia, micropsia, telescopic vision (objects appear larger than normal), teleopsia (objects appear to be far away), mosaic vision, Alice in Wonderland syndrome (distorted body image), and multiple images. Headaches, when unilateral, usually occur on the side contralateral to the visual symptoms but can occasionally be ipsilateral.

A sensory aura, which is present in about 30% of episodes of migraine with aura, consists of numbness, tingling, or a pins-and-needles sensation. The aura, which is usually unilateral, commonly affects the hand and then the face, or it may affect either one alone. Paresthesias of one side of the tongue is typical. Less often, the leg and trunk may be involved. A true motor aura is rare, but sensory ataxia or a heavy feeling is often misinterpreted as weakness.

Speech and language disturbances may occur in up to 20% of cases. Patients often report a speech disturbance when the spreading paresthesias reach the face or tongue. Slurred speech may be present. With involvement of the dominant hemisphere, paraphasic errors and other types of impaired language production and comprehension may occur. Rarely, other aura symptoms may be described, including déjà vu and olfactory and gustatory hallucinations.

Although visual symptoms frequently occur by themselves, combinations of aura symptoms can occur. Sensory, speech, and motor symptoms are usually associated with visual symptoms or with one or more other symptoms. When two or more aura symptoms are present, they almost always occur in succession rather than simultaneously.

Migraine aura can occur without headache (acephalgic migraine), often in patients whose migraine episodes typically involve headache (with or without aura). A visual aura is the most common in such cases. Another type of acephalgic migraine is episodic vertigo without a headache, auditory disturbances, or other neurologic symptoms, lasting minutes to days.[17] In older persons, the aura—termed late-life migraine accompaniment—can be confused with a transient ischemic attack [*see* Geriatric Headache, *below*]. Rarely, migraineurs have persistent visual aura. This usually consists of simple, unformed hallucinations in the entire visual field of both eyes, including innumerable dots, television static, clouds, heat waves, flashing or flickering lights, lines of ants, a rainlike or snowlike pattern, squiggles, bubbles, and grainy vision. Occasionally, palinopsia (the persistence of visual images), micropsia, or formed hallucinations occur.

Migraine Variants

Migraine variants include familial hemiplegic; basilar-type; benign paroxysmal vertigo of childhood; abdominal; confusional; so-called footballer's; benign episodic mydriasis; and retinal. Familial hemiplegic migraine is a rare variant of migraine with aura accompanied by hemiplegia or hemiparesis. Attacks may occur on the same side as previous episodes or on another side and typically feature a slow spread of paresis involving the face, arm, and leg. Alteration of consciousness, ranging from confusion to coma and aphasia, may be present. Familial hemiplegic migraine type I is caused by an autosomal dominant mutation in a brain-specific P/Q-type calcium channel subunit on chromosome 19.

Basilar-type migraine is a rare disorder that most often occurs in children and rarely occurs in patients older than 50 years.[18] According to IHS criteria, attacks are marked by two or more of the following fully reversible aura symptoms: dysarthria, vertigo, tinnitus, hypacusia, diplopia, visual symptoms simultaneously in the temporal and nasal fields of the two eyes, ataxia, decreased level of consciousness, and simultaneous bilateral paresthesias. These symptoms, which originate from the brain stem or both occipital lobes, are not accompanied by motor weakness. There is also at least one of the following: bilateral paresthesias; gradual development of at least one aura symptom over 5 minutes or longer, the occurrence of different aura symptoms in succession over 5 minutes or longer, or both; or persistence of each aura symptom for 5 to 60 minutes. Patients with basilar-type migraine may also have other types of migraine. Visual symptoms—which usually take the form of blurred vision, shimmering colored lights accompanied by blank spots in the visual field, scintillating scotoma, and graying of vision—may start in one visual field and then spread to become bilateral. Diplopia occurs in up to 16% of cases. Vertigo may be present, either alone or accompanied by various combinations of tinnitus, dysarthria, gait ataxia, and paresthesias (usually bilateral but sometimes affecting alternate sides in successive episodes). Impairment of consciousness is common and may include obtundation, amnesia, syncope, and, rarely, prolonged coma. A severe throbbing headache, typically with a bilateral occipital location, is present in 96% of cases. Nausea and vomiting typically occur, with light and noise sensitivity in up to 50% of cases.

Benign paroxysmal vertigo of childhood presents as episodes of vertigo without headache. Abdominal migraine also occurs in children and features recurring episodes of abdominal pain without headache that may be associated with nausea, vomiting, pallor, and flushing. Confusional migraine presents with a headache, which can be minimal, associated with a confusional state that can last from 10 minutes to 2 days. Agitation and impaired memory may be present. The patient may exhibit inattention, distractibility, and difficulty maintaining coherent speech or action. So-called footballer's migraine (originally described in soccer players) refers to the triggering of migraine by acute minor head trauma in children or adolescents.

Benign episodic mydriasis is a transient, isolated mydriasis. This disorder typically occurs in young adults or children. Patients have normal vision and pupillary reactivity to light that may occasionally accompany migraine headaches. The episodes last 15 minutes to 24 hours, are often associated with blurred vision, and can average two or three a month. Eyelid or ocular motility abnormalities are absent. Angle-closure glaucoma should be excluded. Dilatation of the pupil is secondary either to parasympathetic insufficiency of the iris sphincter or to sympathetic hyperactivity of the iris dilator. Retinal migraine, a rare diagnosis of exclusion, produces episodes of transient monocular visual loss lasting minutes to hours, which may or may not be associated with headache.

ACUTE TREATMENT

Certain general principles apply to the use of medications for acute (symptomatic) treatment of migraine. Early treatment, when the headache is mild, is much more effective than later treatment, when the migraine is moderate or severe in intensity. Frequent use of acute-treatment medications can lead to rebound headache; for that reason, acute therapy should be restricted to a maximum of 2 or 3 days a week. Different patients may respond to different medications at different times. Patients benefit from stratified care.[19] Treatment is based on characteristics of the patient's episodes (including peak intensity, time to peak intensity, associated symptoms, and disability) and is tailored to specific patient needs. Nasal, parenteral, or rectal administration of medication should be used in patients with significant nausea or vomiting or gastroparesis. Antinausea medications such as promethazine and prochlorperazine may help in such cases. Many migraineurs respond to over-the-counter medications for acute symptoms [*see Table 7*]. Over-the-counter drugs are often more effective if taken when the pain is mild rather than when it has become more intense.

Patients who do not respond or who respond incompletely to over-the-counter medications may require a prescription medication. The combination of isometheptene mucate, dichloralphenazone, and acetaminophen (Midrin) can be highly effective, especially for mild to moderate headache.[20] Combination medications that include butalbital (e.g., Fiorinal) may also be effective. Surprisingly, despite their common use, the butalbital combinations have not been studied in a placebo-controlled trial.[21] Oral and intranasal opiates may also be effective. Butorphanol nasal spray (Stadol) may be very effective for some patients who have severe migraine with nausea or vomiting and cannot keep an oral medication down, do not respond to triptans, or require a rescue medication when the usual medication is ineffective. Side effects include dizziness, nausea, vomiting, and drowsiness. However, frequent use of medications such as

Table 7 Efficacy of Selected Over-the-Counter Medications for Relief of Moderate to Severe Migraine Pain[75-78]

Medication and Dose	*Percentage of Responders at 2 Hr (Percentage Placebo)*		*Percentage of Responders at 6 Hr (Percentage Placebo)*	
	Mild or No Pain	*No Pain*	*Mild or No Pain*	*No Pain*
Ibuprofen, 400 mg	42 (28)	15 (8)	49 (32)	31 (20)
Acetaminophen, 1,000 mg	58 (39)	22 (11)	77 (46)	46 (28)
Acetaminophen, 500 mg, plus aspirin, 500 mg, plus caffeine, 130 mg	59 (33)	22 (7)	79 (52)	51 (23)
Aspirin, effervescent, 1,000 mg	55 (37)	29 (17)	Not assessed	

Note: Percentages are rounded.

butalbital and opiates can lead to rebound headaches and habituation.

Triptans

The introduction of the triptans has dramatically improved the acute treatment of migraine. Triptan medications are selective 5-hydroxytryptamine ($5\text{-}HT_{1B/1D}$) receptor agonists that share a basic indole ring structure with different side chains. Triptans have three potential mechanisms of action: cranial vasoconstriction, peripheral neuronal inhibition, and inhibition of transmission through second-order neurons of the trigeminocervical complex. These mechanisms inhibit the effects of activated nociceptive trigeminal afferents and control acute migraine attacks.[14]

Over the past decade, seven triptans have become available in the United States: sumatriptan, zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan [*see Table 8*].[22] In migraineurs who take oral triptans when their pain is moderate to severe in intensity, the 2-hour response rate (i.e., no pain or mild pain) is about 45% for naratriptan and frovatriptan and about 65% to 70% for the others. With all of the triptans, the 2-hour pain-free response rates are much higher if the drug is taken when the headache is mild; depending on the drug, the response rate may exceed 70%.

The oral triptans may not be equally effective for all patients. If a patient has an unsatisfactory or inconsistent response, unpleasant side effects, or tachyphylaxis with one triptan, a different triptan may prove to be effective and tolerable. Patients who have prominent vomiting or nausea or who desire the quickest relief may benefit from subcutaneous sumatriptan (at 2 hours, 79% of patients show a response and 60% are pain free) or intranasal sumatriptan or zolmitriptan.

Patients may experience a recurrence, which is defined as the return of headache (usually of moderate or severe intensity) within 24 hours after an initial response to acute treatment. When taken for moderate to severe pain, naratriptan, frovatriptan, almotriptan, and eletriptan have the lowest recurrence rates (about 20% to 25%). The recurrence rates for the other triptans are about 31% with zolmitriptan, 33% with sumatriptan, and 40% with rizatriptan. The time to recurrence is generally about 12 hours.[23]

Triptans can stimulate $5\text{-}HT_{1B}$ receptors on coronary arteries and result in constriction, which may become clinically significant in patients with coronary artery stenosis or vasospastic disease.[24] For example, in a study of patients undergoing cardiac catheterization, 6 mg of subcutaneously administered sumatriptan resulted in a 14% reduction in coronary artery diameter.[25] Consequently, triptans as a class are contraindicated in patients with known or suspected ischemic heart disease, Prinzmetal angina, or uncontrolled hypertension. Data on cardiac risk have been derived from the use of sumatriptan because sumatriptan has been the most widely used triptan and has the largest reported studies; however, all the triptans have a similar cardiac risk. The common triptan side effects—tightness, heaviness, pressure, or pain in the chest, neck, or throat—are not associated with electrocardiogram changes and are not caused by coronary vasoconstriction.[26]

The estimated chance of a myocardial infarction occurring within 24 hours of oral or subcutaneous use of sumatriptan is small but not negligible. Between 1991 and December 1996, 19 cardiac-related deaths occurring within 24 hours after the last sumatriptan dose were reported worldwide in five million migraineurs treating more than 100 million attacks.[26] In addition, there have been seven reported cases of atrial fibrillation triggered by sumatriptan,[27] possibly caused by transient elevations in atrial pressure.[28] In a prospective study of 23,339 migraineurs who used 6 mg of sumatriptan subcutaneously for up to 12 months, a total of 185,579 migraine attacks occurred.[29] There were a total of 13 cardiac events (three myocardial infarctions, six anginal episodes, and four cases of dysrhythmia) occurring 24 hours or more after the administration of sumatriptan. Subcutaneously administered sumatriptan is eliminated from the body within 10 hours, so the late cardiac events were probably unrelated to the drug. However, only about 15% of the patients in this study were older than 50 years and only a small percentage were older than 60 years.

In view of the potential adverse cardiovascular events associated with triptans, a cardiac evaluation is recommended for patients at risk for unrecognized coronary artery disease. The evaluation can be done before or during the use of triptans. Patients at risk include men older than 40 years, women older than 50 years, and those with cardiac risk factors. There is no consensus, however, on what constitutes an appropriate cardiac evaluation.[30]

INTRACTABLE MIGRAINE AND MIGRAINE STATUS

Intravenous fluids and electrolyte replacement may be necessary for patients with intractable vomiting associated with migraine. Medication options include the following:

1. Sumatriptan, 6 mg subcutaneously.
2. Dihydroergotamine (DHE), 0.5 to 1 mg by slow intravenous push, perhaps combined with an antiemetic such as metoclopramide, because DHE may cause nausea (DHE and triptans should not be used within 24 hours of each other).
3. Prochlorperazine, 5 to 10 mg intravenously.
4. Ketorolac, 30 to 60 mg intramuscularly.
5. Corticosteroids (a single or rapidly tapering dose of prednisone, starting at 80 mg a day, or dexamethasone, 6 mg orally or I.V.).

Table 8 Triptans Available in the United States

Drug (Brand Name)	*Formulation*	*Strengths (mg)*
Almotriptan (Axert)	Tablets	12.5
Eletriptan (Relpax)	Tablets	20, 40
Frovatriptan (Frova)	Tablets	2.5
Naratriptan (Amerge)	Tablets	1, 2.5
Rizatriptan (Maxalt)	Tablets Orally disintegrating preparation* (Maxalt MLT)	5, 10
Sumatriptan (Imitrex)	Subcutaneous injection Tablets Nasal spray	6 25, 50, 100 5, 20
Zolmitriptan (Zomig)	Tablets Orally disintegrating preparation* (Zomig ZMT)	2.5, 5

*Dissolves on the tongue; can be taken without water (efficacy similar to that of tablet form).

Table 9 Preventive Medications for Migraine

Drug Class	*Agent*	*Dosage*	*Typical Side Effects*
Beta blockers	Propranolol*	40–120 mg b.i.d.	Hypotension, tiredness, exacerbation of asthma
	Propranolol long acting*	60–160 mg/day	
	Metoprolol	50–200 mg/day	
	Nadolol	40–160 mg/day	
	Atenolol	50–100 mg/day	
	Timolol	10–30 mg/day	
Antidepressants	Amitriptyline*	25–150 mg h.s.	Drowsiness, dry mouth, weight gain, constipation
	Nortriptyline	25–150 mg h.s.	
	Venlafaxine	37.5–225 mg/day	Nausea and vomiting
Anticonvulsants	Divalproex sodium*	500–1,000 mg/day	Nausea, tremor, drowsiness, weight gain, alopecia, hematologic and liver abnormalities, fetal abnormalities
	Topiramate*	25–300 mg h.s.	Weight loss, paresthesias, cognitive disturbances, kidney stones
	Gabapentin	300–800 mg t.i.d.	Dizziness, fatigue, drowsiness

*Class I evidence indicates that these are the most effective medications for migraine prevention.

6. Parenteral narcotics such as meperidine, which may be combined with promethazine.
7. Valproate sodium (500 mg diluted in 50 ml of saline, administered intravenously over 5 to 10 minutes and repeated every 8 hours, if necessary).
8. Droperidol (2.5 mg I.M. or I.V.).
9. Intravenous metoclopramide.

There is a very small risk of torsade de pointes with the use of neuroleptics such as prochlorperazine and droperidol.

PREVENTIVE TREATMENT

A number of factors may justify daily preventive medication for patients with migraines [*see Table 9*].[31] Indications for preventive treatment are as follows:

1. The headaches significantly interfere with the patient's daily routine, despite acute treatment.
2. Acute medications are contraindicated, ineffective, or overused or have intolerable side effects.
3. Frequent migraines (two or more attacks a week).
4. Uncommon migraine types (hemiplegic, basilar, prolonged aura, or migrainous infarction).
5. The cost of acute medications is significantly greater than the cost of preventive medication.
6. Patient preference (i.e., the patient is willing to risk the possibility of side effects from the preventive medication to reduce the frequency of headaches).

Several general principles apply to the use of preventive medications[31]:

1. The clinician should start with a low dose of medication and increase it slowly, depending on the response and whether side effects occur.
2. Each medication should be given a trial of 2 to 3 months at adequate doses.
3. Overused medications that may be causing rebound headache and may decrease the efficacy of preventive treatment should be discontinued or tapered (depending on the drug).
4. The patient should keep a headache diary to monitor his or her headaches.
5. The clinician should educate the patient about the rationale for treatment and possible side effects and should address the patient's expectations for treatment. Many patients want a complete cure, and although this is certainly understandable, it is usually not possible.

Coexistent or comorbid conditions should be considered. Some medications may be effective against both migraine and another disorder. Other disorders, along with the migraine medications that may be effective against them, include epilepsy (divalproex sodium, topiramate, and gabapentin), hypertension (beta blockers), depression (tricyclic antidepressants), bipolar disorder (divalproex sodium or topiramate), insomnia (tricyclic antidepressants), essential tremor (beta blockers and topirimate), and overweight or obesity (topiramate). On the other hand, coexistent diseases such as depression or asthma may be relative contraindications to the use of beta blockers. In a woman who is pregnant or may become pregnant, the potential for teratogenesis should be considered. Patients who have mild responses to one preventive agent may benefit from the addition of a second agent. Finally, if a medication does not work or has significant side effects, withdrawal of the agent may need to be done slowly, especially if the patient has been receiving moderate or high doses of the drug. This is particularly true of tricyclic antidepressants and beta blockers.

Class I evidence indicates that the beta blocker propranolol, the tricyclic antidepressant amitriptyline, and the antiseizure medications divalproex sodium and topiramate are the most effective preventive medications, reducing the frequency of migraines by more than 50% in about 50% of patients. In general, preventive medications are more effective when patients are placed on a titration schedule with a minimum target dose. Titration schedules and minimum target doses are as follows:

propranolol (either regular or long acting), 40 mg daily, increased weekly by 40 mg to a maximum daily dose of 120 to 160 mg; amitriptyline, 10 mg at bedtime, increased weekly by 10 mg to a maximum daily dose of 50 mg; divalproex sodium (either regular or extended release), 500 mg daily for 1 week and then 1,000 mg daily; and topiramate, 25 mg daily for the first week, increased by 25 mg/wk in divided doses, to a maximum daily dose of 100 mg administered at a dosage of 50 mg twice daily.[32]

In addition to propranolol, other beta blockers may be effective [*see Table 9*]. Regarding the tricyclic antidepressants, the quality of evidence for nortriptyline is not as good as that for amitriptyline, but nortriptyline has been shown to have similar efficacy with less sedation. Venlafaxine may be as effective as amitriptyline with fewer side effects.[33,34] Selective serotonin reuptake inhibitors (SSRIs) are probably not effective for migraine prevention, and verapamil and gabapentin are only modestly effective.[31]

There are natural products that may be beneficial for migraine prevention, including the herb feverfew (*Tanacetum parthenium*); extract from the butterbur plant, *Petasites hybridus* (Petadolex, 75 mg twice daily); riboflavin (400 mg a day); coenzyme Q10 (100 mg three times daily[35]); and oral magnesium supplements. Botulinum toxin injections may also be of benefit, especially in intractable cases. The relative benefit of these treatments may become clearer with additional studies, but for now, some migraineurs may prefer them because they have few if any side effects.

For many migraineurs, the avoidance of triggers may be useful. Examples include adequate sleep at set hours, routine exercise, regular meals, avoiding triggering foods and beverages, and wearing sunglasses in bright sunlight or glare. Some patients may benefit from biofeedback, relaxation training, and psychotherapy.

WOMEN AND MIGRAINE

There are issues specific to treatment of female migraineurs.[36] Menstrual migraine is treated with the same acute-treatment medications as other migraines (see above). Interval or short-term preventive treatment of menstrual migraine, starting 2 or 3 days before menses and continuing during the menses, may be helpful for some women with regular menses and migraines that are poorly responsive to symptomatic medications. Potentially effective medications include the following: amitriptyline or nortriptyline, 25 mg at bedtime; long-acting propranolol, 60 to 80 mg daily, or nadolol, 40 mg daily; nonsteroidal anti-inflammatory drugs (NSAIDS) such as naproxen sodium, 550 mg twice daily; ergotamine, 1 mg once or twice a day, or DHE, 1 mg subcutaneously or intramuscularly; naratriptan, 1 mg orally twice daily, or frovatriptan, 2.5 mg twice daily, for 6 days perimenstrually; transdermal estradiol, 100 µg applied 3 days before the expected start of menses and replaced after 3 days; continuous combined OC use, with a lower estrogen dose given during the menses; and extended-duration OC use.

Although there is controversy regarding whether low-estrogen OCs increase the risk of stroke, most women who have migraine without aura can safely take low-estrogen OCs if they have no other contraindications or risk factors. When taking low-estrogen OCs, women younger than 35 years who have migraine with aura (e.g., visual symptoms lasting less than 1 hour) have a risk of ischemic stroke of about 30 per 100,000 annually, which is twice the risk of those women who have migraine without aura.[37] An IHS task force concluded that OCs may be contraindicated in women with migraine who have additional risk factors that cannot easily be controlled, including migraine with aura, because of a possible increase in the risk of ischemic stroke, and that these risks must be assessed and evaluated on an individual basis.[38] Women with aura symptoms such as hemiparesis or aphasia or prolonged focal neurologic symptoms and signs lasting more than 1 hour should avoid starting low-estrogen OCs and should stop the medication if they are already taking it. Progestin-only OCs and the many other contraceptive options can be considered, as appropriate. Cigarette smoking should be strongly discouraged, because female migraineurs who smoke one or more packs of cigarettes a day raise their risk of ischemic stroke by a factor of about 10.

Estrogen replacement therapy has a variable effect on migraine: 45% of patients show improvement, 46% show worsening of migraine, and 9% show no effect. If migraines increase when a patient starts estrogen replacement, the following strategies may be beneficial:

1. Reduce the estrogen dose.
2. Change the estrogen type to one less likely to promote migraine. From most to least likely to promote migraine, these are, in order, conjugated estrogens (Premarin), pure estradiol (Estrace), synthetic estrogen (Estinyl), and pure estrogen (Ogen).
3. Convert from interrupted to continuous dosing in the case of estrogen-withdrawal migraine.
4. Convert from oral to parenteral administration (e.g., a transdermal patch).
5. Add androgens.

Management of migraine during pregnancy and breastfeeding[39] is beyond the scope of this chapter.

Tension-Type Headaches

The 1-year prevalence of tension-type headaches has been variably reported as being from 30% to 90%. The lifetime prevalence is 78% (63% in males and 86% in females; the male-to-female ratio is about 1:1.3). The prevalence peaks in the fourth decade of life.

CLINICAL FEATURES

Tension-type headache may be episodic or chronic. The IHS criteria for episodic tension-type headache are as follows: at least 10 previous headache episodes fulfilling the criteria; number of days with the headache being less than 180 a year or 15 a month; and headache lasting from 30 minutes to 7 days. At least two of the following pain characteristics should be present: pressing/tightening (nonpulsating quality); mild or moderate severity; bilateral location; and no aggravation of headache by walking up and down stairs or performing similar types of routine physical activity. There should be no nausea or vomiting (anorexia may occur); and either photophobia or phonophobia may be present, but not both.

The pain is variably described as pressure, soreness, tightness, a band or cap on the head, or a weight on the head. During severe episodes, a pulsating sensation is occasionally present. Although 90% of episodic tension-type headaches are bilateral, these headaches can be unilateral in patients with trigger points or oromandibular dysfunction.

In chronic tension-type headache, according to IHS criteria,

the average headache frequency is 15 days or more a month for at least 6 months, or 180 days or more a year. The pain characteristics are the same as for episodic tension-type. There should be no concomitant vomiting, and no more than one of the following features should be present: nausea, photophobia, or phonophobia. Some patients may have continuous headaches for years. Secondary causes of episodic and chronic tension-type headaches should be excluded, as appropriate.

TREATMENT

Acute headaches may respond to the following: aspirin or acetaminophen, alone or in combination with caffeine; NSAIDs; isometheptene in combination with other agents; and butalbital with other agents. Overuse of any of these medications, however, may lead to rebound headaches. Frequent butalbital use can also result in dependency. The muscle relaxants baclofen and tizanidine may also be effective and are not habituating, whereas the muscle relaxant carisoprodol can be habituating. Tizanidine is an α_2-adrenergic agonist that inhibits the release and effectiveness of norepinephrine both at central sites (e.g., the locus coeruleus) and at the spinal cord. It has central muscle relaxant and antinociceptive effects. Tizanidine can be given at a dosage of 2 mg three times a day, or it can be started as 2 mg at bedtime and titrated upward to the maximum tolerated dose or a maximum dosage of 18 mg in three divided doses daily, depending on the response. Because about 5% of patients on tizanidine develop abnormally elevated transaminase levels, which reverse after discontinuance of the drug, baseline measures and periodic monitoring of liver function for the first 6 months are recommended. Tizanidine may be effective for chronic tension-type and chronic daily headaches.

Frequent headaches may require preventive medications. Tricyclic antidepressants are generally more effective than SSRIs. Other migraine preventive agents (see above) may be helpful, especially when tension-type headache and migraine are both present.

Chronic Daily Headache

Chronic daily headache (CDH) has a frequency of 15 or more days a month. The 1-year prevalence of CDH in adults is about 3% in males and 5% in females; it is about 1% in adolescents of both sexes. Severe CHD affects 0.5% of the population of the United States.

HEADACHE TYPES IN CDH

CDH includes four different headache types: chronic, or transformed, migraine (35% of patients with CDH); chronic tension-type headache, occurring in more than 50% of patients with CDH; hemicrania continua; and new daily persistent headache.

Chronic migraine, or transformed migraine, is a complication of intermittent migraine that usually occurs by 20 to 30 years of age. It may occur with or without medication overuse. In 70% of patients, there is a gradual transformation from episodic migraine to CDH that may be associated with analgesic overuse, psychological factors (e.g., depression, anxiety, abnormal personality profile, and home or work stress), and obesity. In 30% of patients, there is a sudden transformation that may be triggered by head or neck trauma, flulike illness, aseptic meningitis, surgery, or medical illness. Migraine characteristics are present to a significant degree, intermittently or continuously.

Chronic tension-type headache, with or without medication overuse, occurs 15 days a month for at least 6 months or occurs at least 180 days a year [*see* Tension-Type Headaches, *above*]. Hemicrania continua, with or without medication overuse, is a rare entity with constant, unilateral pain of variable intensity that responds dramatically to indomethacin. Painful exacerbations are associated with ptosis, lacrimation, and nasal congestion. New daily persistent headache, with or without medication overuse, involves a fairly rapid onset of a daily persistent headache in a patient with no past history of increasingly frequent migraine or tension-type headache.[40] This is probably a heterogeneous disorder of uncertain cause, which in some cases may be triggered by a viral infection.

TREATMENT

If medication-overuse or rebound headaches (see below) are a possibility, medications that may be responsible should be tapered. Some acute-treatment medications that may be effective are longer-acting NSAIDs (e.g., naproxen sodium), baclofen, tizanidine, and hydroxyzine (50 mg p.o., t.i.d., p.r.n.), which are not associated with rebound. Triptans may be used as appropriate but should be limited to 2 or 3 days a week because of the risk of rebound.

For prevention of CDH, the same medications are used as for chronic tension-type headache and migraine. Combination therapy may be helpful in some cases. The effect of treatment may not be apparent for weeks. Treatment may not be effective until rebound is eliminated.

For detoxification or if there is significant medical or psychiatric comorbidity, inpatient treatment may be indicated if outpatient therapy fails. Options include intravenous DHE (0.5 to 1.0 mg I.V.), usually given with an antiemetic (e.g., metoclopramide, 5 to 10 mg I.V.) every 8 hours. DHE may be combined with other medications, such as NSAIDs, oral or intravenous corticosteroids, intravenous prochlorperazine, and intravenous valproate sodium [*see* Intractable Migraine and Migraine Status, *above*]. One or more of these treatments can be used in patients who cannot tolerate DHE or patients in whom DHE is contraindicated.

Behavioral therapy and psychological or psychiatric referral may be beneficial. Physical therapy may be useful if there is a myofascial contribution to the headaches. Trigger-point injections and occipital nerve blocks may be worthwhile in some cases.

Even with optimal therapy, about one third of patients who show improvement will experience recurrence of their daily headache and medication-overuse pattern. Some patients have intractable CDH that is resistant to all treatments.

Medication-Overuse Headaches

Migraineurs are particularly susceptible to medication-overuse or rebound headaches, which can occur with frequent use of symptomatic medications, including acetaminophen, aspirin, caffeine, NSAIDs with short half-lives (e.g., ibuprofen), butalbital, ergotamine, opiate agonists, and triptans.[41] Frequent use of symptomatic medications may also result in tolerance (the decreased effectiveness of the same dose of an analgesic, often leading to the use of higher doses to achieve the same degree of effectiveness) and in habituation and dependence (respectively, the psychological and physical need to repeatedly use drugs).

Rebound headache is a retrospective diagnosis made when headache frequency decreases after the patient stops or reduces

the medication suspected of causing the headache. The best evidence is from a prospective study of caffeine-withdrawal headache in persons with low to moderate caffeine intake (the equivalent of about 2.5 cups of coffee daily). In this study, 50% of persons given placebo had a headache by day 2, compared with 6% of those given caffeine.[42] Withdrawal was also associated with nausea, depression, and flulike symptoms.

Because it would be unethical to conduct prospective studies on rebound headache from medication withdrawal, only limited information is available regarding the percentage of migraineurs who are susceptible to rebound, the dosage limits, and the time required for rebound to develop. Medication overuse may occur when simple analgesics are taken 15 or more days a month for 3 months; when triptans are taken 10 or more days a month; when combination analgesics containing simple analgesics plus opioids, butalbital, or caffeine (alone or together) are taken for 10 or more days a month for 3 months; and when opioids are used 10 or more days a month.[43]

In the treatment of suspected rebound headache, the medications acetaminophen, aspirin, NSAIDs with short half-lives, and triptans can be stopped abruptly. Caffeine use should be tapered off, to avoid withdrawal symptoms. Opiates and butalbital should be tapered because of the risk of a serious withdrawal syndrome. If butalbital is abruptly discontinued, phenobarbital can be substituted to prevent withdrawal; the phenobarbital is tapered down from 60 mg to 15 mg at night over 1 week.[44] After medication withdrawal, the duration of rebound headaches from triptans is about 4 days and from other analgesics is about 9 days.[45] A migraine preventive medication can also be started, but it may not be effective when patients are overusing symptomatic medications.

Two outpatient transitional strategies have been suggested to reduce the headaches during the withdrawal period. One approach is the use of prednisone: 60 mg/day for 2 days, 40 mg/day for 2 days, and then 20 mg/day for 2 days.[46] Alternatively, the combination of tizanidine and a long-acting NSAID such as naproxen may be effective.[47] Inpatient treatment is the same as for CDH (see above).

Drug-Induced Headache

Many drugs can induce acute headache, including nitroglycerin, antihypertensive agents (beta blockers, calcium channel blockers, angiotensin-converting enzyme inhibitors, and methyldopa), dipyridamole, hydralazine, phosphodiesterase-5 inhibitors (e.g., sildenafil), histamine receptor antagonists (e.g., cimetidine and ranitidine), NSAIDs (especially indomethacin), cyclosporine, and antibiotics (especially amphotericin, griseofulvin, tetracycline, and sulfonamides).

Drug-induced aseptic meningitis, a rare occurrence, has numerous possible causes, including NSAIDs, antibiotics (e.g., trimethoprim-sulfamethoxazole, sulfasalazine, cephalosporins, ciprofloxacin, isoniazid, and penicillin), intrathecal drugs and diagnostics (e.g., antineoplastic agents such as methotrexate and cytarabine; gentamicin; corticosteroids; spinal anesthesia; baclofen; repeated iophendylate for myelography; and radiolabeled albumin); intraventricular chemotherapy; intravenous immunoglobulin; vaccines (polio; measles, mumps, and rubella; and hepatitis B); and other drugs, such as carbamazepine, muromonab-CD3, and ranitidine.[48]

The clinical presentation of drug-induced aseptic meningitis is the same as that of viral meningitis. CSF findings are the same as those in viral meningitis, except for a neutrophil predominance; however, in cases induced by intravenous immunoglobulin, eosinophils are present.

Cluster Headaches

Cluster headaches are an uncommon headache type, occurring in only about 0.4% of the general population. Cluster headaches are five times more common in men than in women. The headaches can occur at any age, including childhood and adolescence (although they are rare in children younger than 10 years), but usually begin in the third or fourth decade of life. As the name denotes, this condition is marked by periods of recurrent headaches (one to eight a day) interspersed with periods of remission. In 90% of patients, the clusters occur episodically. In the remaining 10%, the clusters are chronic, with cluster periods lasting for more than 1 year without remission or with remission lasting less than 14 days.

CLINICAL FEATURES

Cluster headaches are one sided and severe. The most common types of pain, in order of decreasing frequency, are orbital, retro-orbital, temporal, supraorbital, and infraorbital. The headache may alternate sides between cluster periods or, rarely, within the same period. The pain is described as constant, boring, pressing, burning, or stabbing; about 30% of patients describe throbbing or pulsating pain. Cluster headaches have a rapid onset, with peak intensity in 5 to 10 minutes, and usually a short duration of 30 to 45 minutes, although a minority of patients may have pain persisting up to 3 hours (rarely longer). During attacks, most patients prefer to walk, sit, kneel, stand, or jog in place. Many find it difficult to lie down, and they feel restless and agitated.

Autonomic symptoms are present in over 97% of cases. Lacrimation and conjunctival injection are each present in about 80% of cases, and ipsilateral nasal congestion or clear drainage is present in 75%.[49] A partial Horner syndrome with a slight ipsilateral ptosis or miosis or a combination of both is present in about 65% of cases and, in some patients, may persist between attacks in later stages of the disorder. Increased forehead sweating may occur in some patients during attacks. Erythema of the eyelid or a circumscribed area of the face or forehead may be present. Nausea and sensitivity to light and noise accompany the headache in some patients. An aura, usually visual, occasionally precedes the headache. Small quantities of alcohol, nitroglycerin, and histamine can trigger attacks during cluster periods but not during remission.

DIAGNOSTIC TESTING

Cluster headaches can usually be diagnosed on the basis of the clinical criteria alone. Neuroimaging, preferably MRI, may be considered in cases with the following features: a pattern of clusterlike headache that does not conform to the clinical criteria; onset of cluster headache after age 40; a progressive pattern of headaches; chronic cluster headache; and any focal neurologic deficit other than Horner syndrome.

Symptomatic or secondary cluster headache can result from head trauma or iatrogenic trauma (e.g., orbital enucleation or dental extraction). A variety of pathologic conditions have been associated with clusterlike headaches, including arteriovenous malformations, aneurysms, sphenoid sinusitis, parasellar tumors, upper cervical cord meningioma and infarction, subdur-

al hematoma, cerebral metastases, and temporal arteritis. These headaches are usually atypical in their lack of periodicity or response to medications or their accompaniment with abnormal neurologic signs.

TREATMENT

For acute attacks of cluster headache, inhalation of 100% oxygen at a rate of 7 to 10 L/min for 15 to 20 minutes with a nonrebreathing face mask is effective in about 60% of cases.[50] Sumatriptan, 6 mg subcutaneously, is effective in about 75% of all cluster headache patients, with no tachyphylaxis or rebound effect in most patients. Intranasal sumatriptan or oral triptans are less efficacious. Intravenous DHE, 1 mg, may provide relief in less than 10 minutes; onset is slower with intramuscular or intranasal administration. Triptans and DHE should not be used within 24 hours of each other. Ergotamine may also be effective. Topical lidocaine 4%, administered as nosedrops, may be effective in at least one third of patients. To administer the drops, the patient lies supine with the head tilted backward 30° and turned to the side of the headache. A nasal dropper may be used. The dose (1 ml) may be repeated once after 15 minutes. Butorphanol nasal spray may be tried if other treatments are not effective or are contraindicated, but this medication has a significant potential for habituation and addiction.[51]

Transitional treatments are medications that may induce rapid suppression of attacks before a preventive medication takes effect. Transitional treatments include prednisone, 60 mg daily for 3 days, followed by 10 mg decrements every 3 days (the drug is given in the morning to prevent interference with sleep); ergotamine tartrate, 1 mg orally twice a day, including a bedtime dose if nocturnal attacks occur (the drug is contraindicated in patients with peripheral vascular and cardiovascular disease; ergotamine and triptans should not be used within 24 hours of each other); DHE, 0.5 to 1.0 mg subcutaneously or intramuscularly every 8 to 12 hours; and a greater occipital nerve block on the side ipsilateral to the attacks, using 120 mg of methylprednisolone and 3 ml of 1% lidocaine.

A number of medications may be effective for prevention of cluster headaches. Verapamil is the drug of choice for both episodic and chronic types. It is started at 120 to 240 mg a day and slowly increased (up to 80 mg increase every 3 days) to 480 mg if necessary.[50] The drug can be given in both a regular formulation three times daily and an extended-release formulation once a day. In some cases of chronic cluster headache, a daily dose of more than 720 mg may be necessary. With daily doses of 240 mg or higher, baseline and serial electrocardiograms are indicated to monitor for the development of heart block. Methysergide may be effective for younger patients with episodic cluster headache who have no contraindications for its use. Methysergide is started at 2 mg three times a day and increased to 12 mg daily if necessary. It may be best to avoid combining methysergide with ergotamine, DHE, or triptans because of the potential for additive vasoconstrictor effect. However, methysergide has limited availability in the United States. Other medications that may be effective include topiramate (50 to 125 mg daily); divalproex sodium (500 to 2,000 mg daily); lithium carbonate (150 to 300 mg t.i.d. with monitoring of blood levels), especially for chronic rather than episodic cluster; baclofen (10 mg t.i.d.); and melatonin, 10 mg at bedtime. Topical capsaicin cream 0.025% may be effective; it is applied with a cotton-tipped applicator 0.5 in. up the nostril on the same side as the headache three times daily for 7 days. For chronic or intractable cases, combination therapy can be used.

Surgical treatment may be useful for patients with total resistance to medical treatment and strictly unilateral pain. Options include percutaneous radiofrequency retrogasserian rhizotomy, gamma-knife radiosurgery to ablate the trigeminal nerve root, and percutaneous retrogasserian glycerol rhizolysis.

Geriatric Headache

Older persons have fewer headaches than younger ones. The prevalence of headaches at different ages in women and men, respectively, is as follows: 21 to 34 years, 92% and 74%; 55 to 74 years, 66% and 53%; and after age 75, 55% and 22%.[52] Although 90% of headaches in younger patients are of the primary type, only 66% of headaches in the elderly are primary.[53] There is a decreasing prevalence of migraine with older age. Past the age of 70 years, only 5% of women and 2% of men still have migraine. There are many causes of new-onset headaches in the elderly, some of which can be particularly worrisome.[54] The risk of serious secondary disorders in persons older than 65 years is 10 times higher than that in younger persons.[55]

LATE-LIFE MIGRAINE ACCOMPANIMENTS

Late-life migraine accompaniments are transient visual, sensory, motor, or behavioral neurologic manifestations that are similar or identical to migraine aura.[56] Headache is associated with only 50% of cases and may be mild. These accompaniments occur more often in men than in women. From most to least common, migraine accompaniments consist of visual symptoms (transient blindness, homonymous hemianopsia, and blurring of vision); paresthesias (numbness, tingling, pins-and-needles sensation, or a heavy feeling of an extremity); brain stem and cerebellar dysfunction (ataxia, clumsiness, hearing loss, tinnitus, vertigo, and syncope); and disturbances of speech (dysarthria or dysphasia).

Other causes of transient cerebral ischemia should be considered, especially when the patient is seen after the first episode or if the case has unusual aspects. The usual diagnostic evaluation for transient ischemic attacks (TIAs) or seizures is performed [*see 11:IV Cerebrovascular Disorders and 11:XII Epilepsy*].

Features that help distinguish migraine accompaniments from TIAs include a gradual buildup of sensory symptoms; a march of sensory paresthesias; serial progression from one accompaniment to another; longer duration (90% of TIAs last for less than 15 minutes); and multiple stereotypical episodes.

If the episodes are frequent, preventive treatment can be considered with medications such as verapamil, topiramate, divalproex sodium, and aspirin. Beta blockers should be avoided because of the potential for worsening of vasospasm. For acute treatment, ergotamine, DHE, and triptans should be avoided because of the risk of increasing cerebral vasospasm.

CEREBROVASCULAR DISEASE

Headaches commonly accompany stroke. In a prospective study of 163 patients with stroke, headache occurred in 29% with bland infarcts, 57% with parenchymal hemorrhage, 36% with TIAs, and 17% with lacunar infarcts.[57] Women and patients with a history of recurrent throbbing headaches were more likely to have headaches associated with stroke. The headache began before the stroke in 60% of cases and at its onset in 25%. The quality, onset, and duration of stroke-associated headaches vary widely. The headaches are equally likely to be abrupt and to be gradual in onset. In patients presenting with

what they consider to be the worst headaches of their lives, SAH should be excluded.

Headache accompanying stroke is usually unilateral, focal, and of mild to moderate severity, although up to 46% of patients may have an incapacitating headache. The headache may be throbbing or nonthrobbing and, in rare cases, may be stabbing. The headache is more often ipsilateral than contralateral to the side of the cerebral ischemia. Headache is more common in ischemia of the posterior circulation than of the anterior circulation and more common in cortical than in subcortical events. The headache is of longest duration in cardioembolic infarcts and thrombotic infarcts, of medium duration in lacunar infarction, and of shortest duration in TIAs.

HEAD TRAUMA

Although there are numerous causes of head trauma, falls are of particular concern in the elderly. Approximately 30% of all persons older than 65 years fall at least once a year. Subdural hematomas follow approximately 1% of mild head injuries, even those involving no loss of consciousness, such as a bump on the head or riding a roller coaster. Chronic subdural hematomas occur more often in the elderly because of brain atrophy that causes stretching of the parasagittal bridging veins and a predisposition to tearing. The atrophy in an older person also permits hematomas to accumulate without symptoms for a longer period of time than it does in a younger person. Other risk factors include use of aspirin or warfarin[58] and alcoholism.

Headaches are present in up to 90% of patients with head trauma. The headaches are nonspecific; they can range from mild to severe and from paroxysmal to constant and can be bilateral or unilateral. They may be exacerbated by coughing, straining, or exercise and may be associated with vomiting or nausea. About 50% of patients with chronic subdural hematomas will have altered mental status. A strokelike presentation with a transient or persistent hemiparesis can also occur. Only about 50% of patients with a chronic subdural hematoma will have a history of a head injury. The history may also be inaccurate in patients with dementia.

TEMPORAL ARTERITIS

Temporal (giant cell) arteritis (TA) is a systemic panarteritis that selectively involves arterial walls with significant amounts of elastin. Approximately 50% of patients with TA have polymyalgia rheumatica, and about 15% of patients with polymyalgia rheumatica have TA. Both conditions occur almost exclusively in patients older than 50 years, with a mean age of onset of about 70. The ratio of women to men with TA is 3 to 1. The annual incidence is about 18 per 100,000 population in persons older than 50 years.

Headaches are the most common symptom of TA, reported by 60% to 90% of TA patients.[59] The pain is most often throbbing, although many patients describe a sharp, dull, burning, or lancinating pain. The pain may be intermittent or continuous and is more often severe than moderate or slight. For some patients, the pain may be worse at night when lying on a pillow, while combing the hair, or when washing the face. Tenderness or decreased pulsation of the superficial temporal arteries is present on physical examination in about half of all patients with TA. The location of the headache is variable and may be unilateral or bilateral. Intermittent jaw claudication occurs in 38% of cases.

The diagnosis of TA is based on clinical suspicion, which is usually but not always confirmed by laboratory testing.[60] The three best tests are the Westergren ESR, the CRP level, and temporal artery biopsy. For elderly patients, the ESR range of normal may vary from less than 20 mm/hr to 40 mm/hr. Elevation of the ESR is not specific for TA; elevation of the ESR can be seen in any infectious, inflammatory, or rheumatic disease. TA with a normal ESR has been reported in 10% to 36% of patients. When abnormal, the ESR averages 70 to 80 mm/hr and may reach 120 or even 130 mm/hr. If the ESR is elevated at the time of diagnosis, it can be followed to help guide the corticosteroid dosage.

CRP is an acute-phase plasma protein from the liver. As with the ESR, elevation of CRP levels is nonspecific and can be seen with numerous disorders. The CRP level is not influenced by various hematologic factors or age and is more sensitive than the ESR for the detection of TA. The combination of ESR and CRP levels gives the best specificity (97%).

The diagnosis of TA is made with certainty when a superficial temporal artery biopsy demonstrates necrotizing arteritis characterized by a predominance of mononuclear cell infiltrates or a granulomatous process with multinucleated giant cells. The false negative rate of temporal artery biopsies ranges from 5% to 44%.

In patients without contraindications, treatment of TA is typically started with prednisone at a dosage of 40 to 80 mg a day. The headache will often improve within 24 hours. The initial dose is maintained for about 4 weeks and then slowly reduced over many months, depending on the clinical effect, the ESR, and the occurrence of side effects. Long-term treatment is often required.

TRIGEMINAL NEURALGIA

Trigeminal neuralgia begins after the age of 40 in 90% of cases. About 80% of cases result from vascular compression of the trigeminal nerve at the root entry zone; most commonly, such compression is caused by a branch of the superior cerebellar artery. About 5% of cases are caused by tumors. The pain is a severe, sharp, shooting, or electric shock–like sensation lasting seconds to 2 minutes. It is usually in a unilateral maxillary or mandibular trigeminal distribution and uncommonly in the ophthalmic division.[61]

In about 90% of cases of trigeminal neuralgia, the patient has trigger zones, usually in the central part of the face around the nose and lips. Normally nonpainful stimuli in these zones can trigger pain. Stimuli can include talking, chewing, washing the face, brushing the teeth, shaving, facial movement, and cold air. After a paroxysm of pain, there is a refractory period lasting up to several minutes during which stimulation of the trigger zone will not trigger pain. Facial grimacing or spasm may accompany the pain (tic douloureux). Between painful paroxysms, the patient is usually pain free, although dull aching may persist for a few minutes after attacks of long duration or multiple clustered attacks. Multiple attacks may occur for weeks or months. About 50% of patients with trigeminal neuralgia will have spontaneous remissions for at least 6 months. Physical examination is usually normal except for trigger zones, although up to 25% of patients will have sensory loss.

Medications that may be effective against trigeminal neuralgia, alone or sometimes in combination, include carbamazepine, oxcarbazepine, baclofen, phenytoin, clonazepam, divalproex sodium, topiramate, lamotrigine, gabapentin, and pimozide. About 30% of patients do not respond to medical treatment but may respond to one of the many surgical approaches available.

POSTHERPETIC NEURALGIA

Although herpes zoster most commonly occurs in the thoracic region, the second most commonly involved area is a trigeminal distribution, usually in the ophthalmic division (herpes zoster ophthalmicus), which occurs in 23% of cases. The zoster is almost always unilateral. The incidence of postherpetic neuralgia (PHN) (i.e., the persistence of pain for more than 1 month after the initial outbreak) greatly increases with older age, to about 1,000 per 100,000 population for those who are 80 years of age or older. PHN develops in 50% of persons older than 50 years and in 80% of those older than 80 years. Zoster involving the face nearly doubles the risk of developing facial PHN, which lasts longer than PHN in other locations.

Typically, the vesicles crust, the skin heals, and the pain resolves within 3 to 4 weeks after the onset of the rash of herpes zoster. PHN involves three types of pain: a constant burning or deep aching; an intermittent spontaneous pain with a jabbing or lancinating quality; and a superficial, sharp, or radiating pain or itching provoked by light touch (allodynia), which is present in 90% of persons with PHN and often interferes with sleep.[62] The type of pain experienced varies from patient to patient.

Treatment with oral corticosteroids (e.g., prednisone, starting at 60 mg/day and tapering off over 2 weeks) may reduce acute pain in herpes zoster but does not lower the risk of PHN. One week of therapy with famciclovir (500 mg every 8 hours) or valacyclovir (1,000 mg every 8 hours), ideally started within 72 hours after onset of acute zoster, mildly reduces the risk and duration of PHN.[63] Numerous treatments of varying efficacy are available for PHN, including tricyclic antidepressants (amitriptyline, nortriptyline, and desipramine), duloxetine, gabapentin, pregabalin, topical agents (capsaicin, lidocaine, aspirin, and NSAIDs), opioids, and tramadol. Unfortunately, PHN persists for 1 year or more in over 20% of patients.

CARDIAC ISCHEMIA

In rare cases, cardiac ischemia can cause a unilateral or bilateral headache brought on by exercise and relieved by rest.[64] The headache can occur alone or can be accompanied by chest pain. Angina is generally believed to be caused by afferent impulses that traverse cervicothoracic sympathetic ganglia, enter the spinal cord via the first to the fifth thoracic dorsal roots, and produce the characteristic pain in the chest or inner aspects of the arms. Cardiac vagal afferents, which mediate anginal pain in a minority of patients, join the tractus solitarius. A potential pathway for referral of cardiac pain to the head would be convergence with craniovascular afferents.[65]

HYPNIC HEADACHE

Hypnic headache is a rare disorder that occurs more often in the elderly (but with a range of 36 to 83 years of age) and predominantly in women.[66] The headache occurs only during sleep and awakens the sufferer at a consistent time. Nausea is infrequent, and autonomic symptoms are rare. The headache can be unilateral or bilateral, throbbing or nonthrobbing, and mild to severe in intensity. The headaches can last 15 minutes to 3 hours and can occur frequently, as often as nightly, for many years. Medications reported to be effective include caffeine (one or two cups of caffeinated coffee or a 40 to 60 mg caffeine tablet before bedtime), lithium carbonate (300 mg at bedtime), indomethacin, atenolol, melatonin, cyclobenzaprine, prednisone, and flunarizine (not available in the United States).

The diagnosis of hypnic headache is one of exclusion. Secondary causes of nocturnal headaches that must be ruled out include drug withdrawal, temporal arteritis, sleep apnea, oxygen desaturation, pheochromocytoma, primary and secondary neoplasms, communicating hydrocephalus, subdural hematoma, and vascular lesions.[67] Migraine, cluster, and chronic paroxysmal hemicrania are other primary headaches that can cause awakening from sleep. Migraine typically has associated symptoms and very uncommonly occurs only during sleep. Cluster headaches have autonomic symptoms and may occur during the day as well as during sleep. Chronic paroxysmal hemicrania occurs both during the day and at night, lasts for less than 30 minutes, and occurs 10 to 30 times a day.

Other Headaches

Numerous other types of headache have been identified. The more common of these are briefly discussed.

FIRST OR WORST AND THUNDERCLAP HEADACHES

The term first or worst refers to severe headache of a type the patient has never experienced before, which may be the first episode of a primary headache such as migraine or cluster, or to the worst headache the patient has ever had, which can be caused by numerous primary and secondary disorders [*see Table 10*].[6]

Headache in Subarachnoid Hemorrhage

Headache is present in 90% of cases of subarachnoid hemorrhage, or SAH.[68] The classic headache is sudden, severe, and continuous, often with nausea, vomiting, meningismus, focal neurologic findings, and loss of consciousness [*see 11:IV Cerebrovascular Disorders*].

Thunderclap Headache

A sudden severe headache with maximal onset within 1 minute without evidence of SAH is termed a thunderclap headache.[69] A small percentage of patients with thunderclap headache will have unruptured aneurysms, cerebral vasospasm, cerebral venous thrombosis, carotid artery or vertebral artery dissections, pituitary apoplexy, occipital neuralgia, and possibly Erve virus infection. Most cases of thunderclap headache are primary disorders: primary thunderclap headache, so-called crash migraine, and primary orgasmic headache.

COUGH, EXERTIONAL, AND SEXUAL HEADACHES

Primary cough, exertional, and sexual headache have lifetime prevalence rates of 1% each. All three types occur more often in men.[70]

Primary cough headache is a bilateral headache of sudden onset that is precipitated by coughing and lasts less than 1 minute. About 25% of patients have the onset after a respiratory infection with cough. This is an infrequent type of headache, with patients having a mean age of onset of 55 years. The diagnosis is one of exclusion. Patients should undergo neuroimaging to exclude pathology such as Chiari malformation, platybasia, basilar impression, brain tumors, cerebral aneurysm, carotid stenosis, and vertebrobasilar disease. Treatments that may be effective include indomethacin, a single lumbar puncture, and methysergide. Some patients have an abrupt recovery after extraction of abscessed teeth.

Table 10 Differential Diagnosis of the Acute, Severe New-Onset Headache

- Primary headache disorders
  - Migraine
  - Cluster
  - Primary exertional headache
  - Primary orgasmic cephalalgia
- Posttraumatic
  - Associated with vascular disorders
    - Acute ischemic cerebrovascular disease
    - Subdural and epidural hematomas
    - Parenchymal hemorrhage
    - Unruptured saccular aneurysm
    - Subarachnoid hemorrhage
    - Systemic lupus erythematosus
    - Temporal arteritis
    - Internal carotid and vertebral artery dissection
    - Cerebral venous thrombosis
    - Acute hypertension
      - Pressor response
      - Pheochromocytoma
      - Preeclampsia
  - Associated with nonvascular intracranial disorders
    - Intermittent hydrocephalus
    - Benign intracranial hypertension
    - Post–lumbar puncture
    - Related to intrathecal injections
    - Intracranial neoplasm
    - Pituitary apoplexy
  - Acute intoxications
  - Associated with noncephalic infection
    - Acute febrile illness
    - Acute pyelonephritis
  - Cephalic infection
    - Meningoencephalitis
    - Acute sinusitis
  - Acute mountain sickness
  - Disorders of eyes
    - Acute optic neuritis
    - Acute glaucoma
  - Cervicogenic
    - Greater occipital neuralgia
    - Cervical myositis
  - Trigeminal neuralgia

Primary cough headache also includes headache brought on by sneezing, blowing the nose, laughing, crying, weightlifting, bending, stooping, or straining with a bowel movement. Weightlifting can also produce a benign acute bilateral nuchal-occipital or nuchal-occipital-parietal headache that can persist as a residual ache for days or weeks. SAH should be considered as a cause with the initial presentation.

Primary exertional headache is a bilateral, usually throbbing, headache brought on by physical activity and lasting from 5 minutes to 24 hours. Some of the activities that can cause this headache are running, rowing, tennis, and swimming. In some persons, the headache may be precipitated by one activity but not others. Exercise can trigger a migraine in migraineurs. Depending on the clinical scenario and number of headaches, secondary causes may need to be excluded, such as SAH, sinusitis, brain tumors, pheochromocytoma, cardiac ischemia (anginal headache), and intracranial arterial dissection. The headaches may be prevented by a warm-up period or by avoiding particular activities. Indomethacin may be preventive. Migraineurs with exertional headache may respond to migraine preventive medications.

The IHS criteria describe two types of primary headache precipitated by sexual activity in the absence of any intracranial disorder. Both are usually bilateral and may be prevented or eased by stopping sexual activity before orgasm. The preorgasmic type is a dull ache in the head or neck that intensifies as sexual excitement increases and is probably caused by muscle contraction. The orgasmic type is a sudden severe headache occurring at orgasm; the headache may remain severe for minutes to 4 hours and then fade to a milder headache lasting up to 48 hours. Forty percent of patients with the explosive type of headache also have exertional headache. A postural headache similar to a post–lumbar puncture headache can occur after sexual activity, presumably because of a dural tear and CSF leak triggered by the activity.

Sexual headache occurs more often when a person tries to have repeated orgasms in close succession. A personal or family history of migraine is common. SAH should be excluded, especially when patients present with their first sexual headache, because sexual activity is a precipitant of up to 12% of ruptured saccular aneurysms. Rarely, pheochromocytoma is a cause. Phosphodiesterase-5 inhibitors for erectile dysfunction can cause headaches in about 15% of users.

In some patients, primary orgasmic headaches can be prevented by weight loss, an exercise program, a more passive role during intercourse, variation in posture, and limitation of additional sexual activity on a single day. The headache may also be prevented by taking medication (e.g., indomethacin, ergotamine, or a triptan) 30 to 60 minutes before engaging in sexual activity.[71] Patients with frequent sexual headaches may respond to migraine preventive medications, such as a beta blocker or verapamil.

HEADACHE IN PSEUDOTUMOR CEREBRI

Pseudotumor cerebri, also known as idiopathic intracranial hypertension, is a disorder of unknown etiology, with an incidence of one per 100,000 population and an onset usually in persons between the ages of 11 and 58 (mean age, 31 years). Ninety percent of patients are young, obese women. Headache is present in 75% or more of patients, papilledema in 95%, a cranial nerve VI palsy in 25%, transient visual obscurations in 70%, visual loss in 30%, and roaring noises in 70%. The headaches, which are usually pulsatile, daily, and continuous, can be unilateral or bilateral, with a bifrontotemporal location being the most common. Nausea is present in about 60% of cases, and vomiting is present in 40%.

The diagnosis of pseudotumor cerebri is one of exclusion, because there are many other causes of papilledema [*see Table 11*]. Testing includes a scan of the brain. MRI is more sensitive than CT, and magnetic resonance venography will exclude cerebral venous thrombosis. If the brain scan is negative, a lumbar puncture should be done. The opening pressure is usually elevated and the CSF analysis is normal, except for a low CSF protein level in some cases.

Treatments include weight loss and diuretics to decrease CSF production. Diuretics used in pseudotumor cerebri include acetazolamide, starting with a dosage of 500 mg twice daily and increasing to as much as 1 g twice daily, if necessary, and furosemide, starting at 20 mg twice daily and increasing to as much as 40 mg three times daily. Patients taking furosemide

should also receive potassium supplementation. Migraine preventive medications can be useful for persistent headache. Topiramate is especially useful because weight loss is a side effect.[72] Funduscopic exam, visual acuity, and visual fields should be closely monitored to help prevent visual loss. Corticosteroids can be used for emergency treatment of impending visual loss. Surgery may be considered for patients who do not respond to medical treatment and are experiencing progressive visual loss. Surgical options are optic nerve sheath fenestration and lumboperitoneal shunting.

HEADACHE IN BRAIN TUMORS

Up to 70% of persons with brain tumors report headaches.[73] The headaches are usually similar to tension-type headaches but can mimic migraine and cluster headaches. The headaches are usually bilateral but can be unilateral. The neurologic examination can be normal. Suspicion of a brain tumor should be raised when a patient has new-onset or progressive headaches or headaches associated with other problems, such as a seizure, confusion, prolonged nausea and vomiting, hemiparesis, or other focal findings. Headaches that are worst on arising in the morning account for less than 20% of brain tumor headaches.

HEADACHE IN PARANASAL SINUSITIS

Acute sinusitis lasts from 1 day to 4 weeks, and subacute sinusitis lasts from 4 to 12 weeks. Nasal congestion, purulent nasal drainage, and facial tenderness and pain are common. Fever is present in 50% of patients. Anosmia, pain on mastication, and halitosis may also be present. Maxillary sinusitis usually causes pain in the cheek, gums, and maxillary teeth; less often, it causes pain in the periorbital, supraorbital, or temporal areas. The pain decreases when the patient is supine and increases when the head is upright. The maxillary sinus is tender to palpation. Frontal sinusitis causes severe frontal headaches with tenderness to percussion or palpation over the frontal sinus. The pain is less when the head is upright and worse when the patient is supine. Complications include brain abscess, meningitis, subdural or epidural abscess, osteomyelitis, subperiosteal abscess, orbital edema, orbital cellulitis, and orbital abscess.[74]

The headache of sphenoid sinusitis, which accounts for 3% of all cases of acute sinusitis and is usually associated with pansinusitis, may be frontal, occipital, or temporal (alone or in combination) and periorbital. The pain is less when the person is upright and increases when the person is supine, standing, walking, bending, or coughing. Nausea and vomiting are common. Photophobia and eye tearing may be present. Nasal discharge and drainage are present in 30% of cases, and fever occurs in more than 50%. Sphenoid sinusitis may be misdiagnosed as migraine, meningitis, trigeminal neuralgia, or brain tumor. Complications include bacterial meningitis, cavernous sinus thrombosis, subdural abscess, cortical vein thrombosis, ophthalmoplegia, and pituitary insufficiency. A parameningeal focus may cause an aseptic meningitis.

Ethmoid sinusitis produces pain in the periorbital, retro-orbital, temporal, or inner canthal area or between the eyes, and it is usually associated with rhinitis. Coughing, straining, or lying supine can worsen the pain, whereas keeping the head upright lessens it. Complications include meningitis, orbital cellulitis, cavernous sinus thrombosis, and cortical vein thrombosis.

Chronic sinusitis has a duration longer than 12 weeks and can produce a usually low-grade and diffuse headache often accompanied by nasal obstruction, congestion, and fullness. The symptoms often increase during the day.

Plain sinus radiographs can be used to diagnose acute maxillary or frontal sinusitis but are often inadequate for ethmoid or sphenoid disease. CT of the sinuses in the coronal plane is highly sensitive for the detection of nasal and paranasal sinus disease. However, a routine CT scan of the head may inadequately cover these areas. An MRI scan of the brain routinely visualizes the paranasal sinuses. Radiographic evidence of sinusitis is present as an incidental finding in 40% of adults without symptoms.

Treatment of paranasal sinusitis is discussed in detail elsewhere [*see 7:XIX Bacterial Infections of the Upper Respiratory Tract*].

HYPERTENSION

Although mild or moderate hypertension does not usually cause headache, severe hypertension from the following conditions can cause headache: acute pressor response to exogenous agents; pheochromocytoma; malignant hypertension; and preeclampsia and eclampsia. Headaches from severe hypertension are usually bioccipital and throbbing but can be generalized or involve frontal throbbing. The headache is often present on awakening in the morning. The diastolic blood pressure is usually elevated to 120 mm Hg or higher. Hypertensive encephalopathy can present as headache, nausea, and vomiting, which may be associated with visual symptoms. Papilledema, focal neurologic deficits, seizures, and decreased levels of consciousness may be present.

Table 11 Etiologies of Papilledema and Headache[79]

- Intracranial mass
- Obstruction or deformity of the ventricular system
- Cerebral venous thrombosis
- Extracranial venous obstruction
  - Radical neck dissection
  - Cardiac failure
  - Chronic respiratory disease
- Hypertensive encephalopathy
- Preeclampsia and eclampsia
- Meningitis/encephalitis
- Meningeal carcinomatosis
- Elevated CSF protein concentration
  - Guillain-Barré syndrome
  - Systemic lupus erythematosus
  - Spinal tumors, especially oligodendroglioma
- Large arteriovenous malformations
- Optic neuritis (usually unilateral)
- Central retinal venous thrombosis (usually unilateral)
- Lead toxicity (in children)
- Lyme disease (in children)
- Parameningeal infection (in children)
- Head trauma
- Medications
  - Vitamin A and derivatives (isotretinoin, etretinate)
  - Minocycline and tetracycline
  - Anabolic steroids
  - Steroid withdrawal
  - Nalidixic acid
- Other medical conditions
  - Renal disease
  - Hypoparathyroidism
  - Hypercoagulable states

A sudden severe headache can reflect an acute pressor response caused when patients receiving monoamine oxidase inhibitors ingest wine or foods with a high tyramine level. Illicit drugs with sympathomimetic actions, such as cocaine, methamphetamine, and methylenedioxymethamphetamine (ecstasy), can also cause acute hypertension and stroke [*see 8:I Management of Poisoning and Drug Overdose*].

OCCIPITAL NEURALGIA

The term occipital neuralgia is in some ways a misnomer, because the pain is not necessarily from the occipital nerve and does not usually have a neuralgic quality. Greater occipital neuralgia is a common type of posttraumatic headache but frequently is also seen in patients without injury. The aching, pressure, stabbing, or throbbing pain may be in a nuchal-occipital, parietal, temporal, frontal, periorbital, or retro-orbital distribution. Occasionally, a true neuralgia may be present, with paroxysmal shooting pain. The headache may last for minutes or hours to days and can be unilateral or bilateral. Lesser occipital neuralgia tends to be similar but with pain generally referred more laterally over the head.

The headache may result from an entrapment of the greater occipital nerve in the aponeurosis of the superior trapezius or semispinalis capitis muscle or may instead be referred pain without nerve compression from trigger points in these or other suboccipital muscles. Digital pressure over the greater occipital nerve at the midsuperior nuchal line (halfway between the posterior mastoid and the occipital protuberance) reproduces the headache. However, pain referred from the C2-C3 facet joint or other area of the upper cervical spine and posterior fossa pathology may produce a similar headache.

Occipital neuralgia may improve with local anesthetic nerve blocks, which can be combined with an injectable corticosteroid (e.g., 3 ml of 1% lidocaine or 2.5 ml of 1% lidocaine and 3 mg of betamethasone). Before giving the injection, the physician should perform aspiration to avoid inadvertent injection into the occipital or vertebral artery. NSAIDs and muscle relaxants may also be of benefit. If the patient has a true occipital neuralgia with paroxysmal lancinating pain, treatment with baclofen, carbamazepine, or gabapentin may help. Physical therapy and transcutaneous nerve stimulators may help some patients.

IX DEMYELINATING DISEASES

J. William Lindsey, M.D.
Jerry S. Wolinsky, M.D.

In both the central and the peripheral nervous systems, large-diameter axons are myelinated. Myelin is formed and maintained by oligodendrocytes within the central nervous system and by Schwann cells in the peripheral nervous system (PNS). Myelin both insulates the invested axons and organizes surface membrane constituents of the axon—functions that are critical for the rapid transfer of signals necessary for coordinated motor activity, proper integration and interpretation of sensory stimuli, and facile cognition. Diseases that affect the integrity of the oligodendrocyte and its ability to produce and maintain myelin and diseases that directly damage the myelin sheath disturb conduction in myelinated white-matter pathways and produce a broad array of motor, sensory, and cognitive dysfunctions [*see Figure 1*].

Demyelinating diseases disturb the integrity of myelin, but the axons are relatively spared [*see Table 1*]. These diseases primarily affect oligodendroglial survival (e.g., progressive multifocal leukoencephalopathy), oligodendroglial metabolism (e.g., vitamin B_{12} deficiency), and the myelin sheath with secondary effects on the oligodendrocytes (e.g., multiple sclerosis [MS]).

Immune-mediated demyelinating diseases include recurrent or chronically progressive demyelinating diseases (MS and its variants) and monophasic demyelinating diseases (optic neuritis, acute disseminated encephalomyelitis, and transverse myelitis). Monophasic demyelination may be the first clinical sign of MS.

Multiple Sclerosis

MS is characterized clinically by recurrent or chronically progressive neurologic dysfunction caused by lesions in the CNS. Pathologically, the lesions are multiple areas of demyelination that affect the brain, optic nerves, and spinal cord.

EPIDEMIOLOGY

Approximately 250,000 to 350,000 people in the United States have MS; the prevalence is about 85 cases per 100,000 population.[1] MS is more common in women than men, with a ratio of 2:1. MS occurs in all major racial groups but is most common in whites, less common in blacks, and rare in Asians. The onset of disease usually occurs between 20 and 50 years of age, with a peak at 30 years of age. The prevalence of MS varies widely with location; the highest prevalence is found at higher latitudes in northern Europe and northern North America. The geographic variation suggests that MS may in part be caused by the action of some environmental factor that is more common at high latitudes.[2] To some extent, this idea is supported by studies of migrants. Moving from a high-risk to a low-risk area early in life tends to lower the risk of MS, whereas moving from a low-risk to a high-risk area tends to increase the risk. Much of the state-by-state variation in MS risk in the United States, however, correlates with Scandinavian ancestry, which suggests that geographic variation may be a reflection of the geographic distribution of susceptible ethnic groups.

ETIOLOGY

Although the etiology of MS is unknown, the importance of genetic factors has been firmly established by studies of familial MS. The contribution of nongenetic factors is demonstrated by the lack of concordance for disease in most identical twins and by the effect of migration on risk of disease. The underlying disease process is unknown, but most authorities accept that MS is at least partly an autoimmune or immune-mediated disease. The evidence for this conclusion includes pathologic findings (i.e., immune components within acute and chronic plaques), an in-

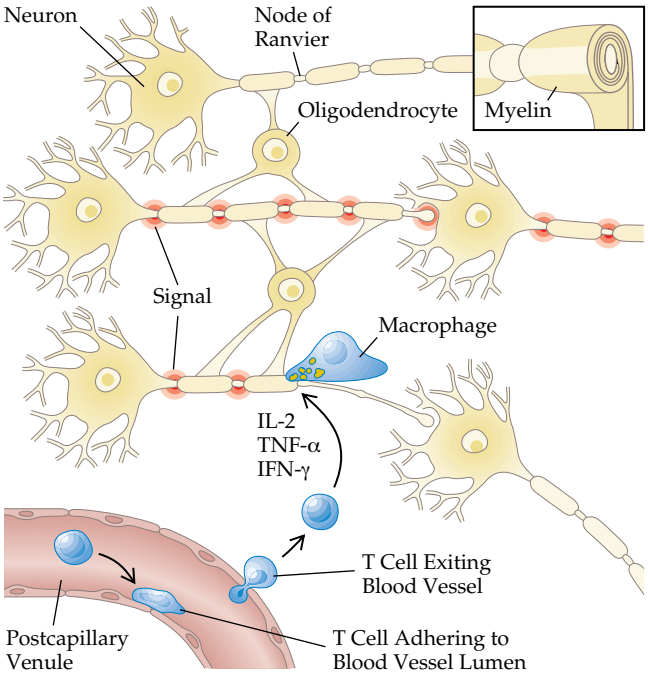

Figure 1 **A single oligodendrocyte may support myelin internodes for 60 or more neighboring axons. A major consequence of myelination is organization of the microenvironment of the larger-diameter axons. Sodium channels are clustered at segments of the axon between myelin segments (the nodes of Ranvier), and potassium channels are diffusely distributed under the myelin-invested segments of the axons. This arrangement allows myelinated axons to rapidly propagate action potentials from the axonal cell body distally to its synapse by saltatory conduction.[93] Depolarization of the nodes of Ranvier in sequential fashion results in rapid propagation of the neural impulses in the largest-diameter nerve fibers at rates in excess of 100 m/sec.**
The upper part of the figure depicts a neuron with a myelinated axon. At the right corner, the neuron is magnified and cut in cross section, demonstrating the concentric lamellar structure of myelin. The middle of the figure shows a neuron with a myelinated axon forming a synapse with another neuron. Two oligodendrocytes are shown; each cell myelinates multiple segments of more than one axon. The bottom neuron has been partially demyelinated, and it is surrounded by T cells, which secrete inflammatory cytokines (interleukin-2 [IL-2], interferon gamma [IFN-γ], and tumor necrosis factor–α [TNF-α]), and by macrophages, which are stripping myelin from the axon. The macrophages contain myelin debris in phagocytic vacuoles. Conduction in the demyelinated axon is blocked. A blood vessel in cross section shows T cells adhering to the lumen and crossing from the vessel into the brain.

crease in the synthesis of IgG in the cerebrospinal fluid, and a variety of in vitro abnormalities of leukocyte function. The autoimmune response could be either the primary cause of disease or an epiphenomenon of another disease process. The popular molecular mimicry model postulates that an infectious organism that contains a protein similar to a myelin protein precipitates the autoimmune attack on myelin. The infection elicits a vigorous immune response from lymphocytes that recognize the cross-reactive protein; in the process of eliminating the organism, the activated lymphocytes damage myelin. The plausibility of this theory has been demonstrated in elegant transgenic experiments in mice,[3] but the relevance of this model in MS remains unproved. Other processes or mechanisms, such as a persistent CNS infection or a biochemical defect in myelin, may cause MS.

GENETICS

The suspicion that susceptibility to MS is at least partly familial has been confirmed in extensive studies. The risk of MS occurring in a monozygotic twin of an MS patient has been found to be 25.3%, whereas the risk of MS occurring in a dizygotic twin has been determined to be about 5%.[4] The risk for a sibling or parent of an affected person is 2% to 5%, compared with a risk in the general population of only 0.1%.[5] Further studies in adopted siblings and half-siblings demonstrated that this increased familial risk is entirely attributable to genetic rather than environmental factors.[6] These findings imply that several interacting genes influence susceptibility to MS.[7]

The genetic factors that confer susceptibility to MS are only partly known. The only locus reproducibly shown to be associated with MS is human leukocyte antigen (HLA) class II; the DRB1*1501 extended haplotype is associated with MS in white patients.[8,9] In an attempt to identify additional loci that contribute to MS, independent research groups conducted genome-wide screens on large groups of families with multiplex MS but found no genome regions with particularly strong linkage to MS.[10]

PATHOLOGY

Plaques, which consist of varying amounts of perivenular mononuclear cell inflammation, demyelination with relative axonal sparing, loss of oligodendrocytes, and astrocyte proliferation with resultant gliosis, are the hallmark of MS.[11] Within the CNS, plaques can appear wherever there are myelinated fibers. The majority of plaques congregate along periventricular draining veins, but plaques also commonly occur within the spinal cord, optic nerves, brain stem, and white matter of the cerebral hemispheres and cerebellum. Plaques can also occur in the connecting pathways of subcortical white matter. Demyelination in gray matter may account for a large fraction of the lesion burden.[12]

The histopathologic appearance of plaques varies over time. Acute, newly formed lesions are dominated by perivenular cellular infiltrates of T cells and macrophages. Blood-brain barrier function is regionally disrupted; this disruption is associated with vasogenic edema. There is immunocytochemical and cytochemical evidence of local endothelial cell activation by cytokines, activation of T cells, and activation of macrophages.[13] Longer-standing lesions are characterized by a total loss of myelin and oligodendrocytes, an intense astrogliosis, variable degrees of axonal loss, and a scant residual infiltrate of mononuclear cells, some of which are immunoglobulin-secreting B cells. Axonal transection is common in many MS lesions, particularly those that appear as areas of persistent low-signal intensity on T_1-weighted magnetic resonance imaging, and axonal transection may be the cause of fixed neurologic deficits.[14-16] Careful pathologic studies of autopsy and biopsy material have defined different types of MS lesions; lesion types differ with regard to the pattern of demyelination, the occurrence of apoptosis in oligodendrocytes, and the activation of complement. This suggests that the underlying pathogenesis of MS may be heterogeneous.[17,18]

Table 1 Demyelinating Diseases of the Central Nervous System

Type	*Disease*
Immune-mediated	Recurrent Multiple sclerosis Monophasic Optic neuritis Transverse myelitis Acute disseminated encephalomyelitis
Inherited	Adrenoleukodystrophy Metachromatic leukodystrophy
Metabolic	Vitamin B_{12} deficiency Central pontine myelinolysis
Infectious	Progressive multifocal leukoencephalopathy Subacute sclerosing panencephalitis

DIAGNOSIS

The diagnosis of MS is made on the basis of the clinical signs and symptoms; MRI and other laboratory tests play a supporting role. The diagnosis of MS requires evidence of the dissemination of lesions in the body over time and the careful exclusion of other causes. The patient should have had more than one episode of neurologic dysfunction and should have evidence of white-matter lesions in more than one part of the CNS. Because there is no pathognomonic sign or symptom or definitive laboratory test result, diagnosis requires careful clinical judgment and should be made only by an experienced neurologist.

The most current version of the recommended diagnostic criteria for MS utilizes both clinical and laboratory data [*see Table 2*].[19] The criteria require the objective demonstration of dissemination of lesions in space and time. This can be achieved with clinical evidence alone or with a combination of clinical and laboratory evidence. The types of laboratory evidence considered are MRI, CSF examination, and evoked responses.

Clinical Features

Almost any neurologic deficit can occur in MS, but there are several signs and symptoms that are characteristic. Although no findings are pathognomonic for MS, the presence of certain signs and symptoms should suggest MS as a possible diagnosis, particularly in young adults.

The typical findings include optic neuritis, internuclear ophthalmoplegia, heat sensitivity, and Lhermitte symptom. Optic neuritis is the initial symptom in about 20% of patients with MS and ultimately develops in more than half of all MS patients. In patients with optic neuritis, vision disturbances are restricted to one eye. These disturbances characteristically occur with central scotoma. There is usually retro-orbital pain that is accentuated with movement of the globe. Results of funduscopic examination are usually normal, but there may be papillitis or pallor of the disk from previous attacks. Symptoms generally evolve over

several days before maximal deficits are reached. A second typical symptom is diplopia caused by an internuclear ophthalmoplegia. On examination, there is failure of adduction on lateral gaze but preservation of adduction with convergence. Internuclear ophthalmoplegia is caused by a lesion in the medial longitudinal fasciculus and is suggestive of MS.

Sensitivity to heat is a characteristic complaint in MS. Exercise, fever, a hot bath, or other activities that raise body temperature may cause the appearance of new symptoms or the recurrence of old symptoms. These events occur as a result of temperature-induced conduction block across partially demyelinated fibers. The symptoms resolve when body temperature returns to normal. Patients with the Lhermitte symptom experience paresthesias that radiate down the spine and into the extremities on neck flexion. This symptom may be reproduced on clinical examination and indicates the presence of a lesion in the cervical spine.

There are a number of other symptoms that are extremely common in MS but also occur in many other disease processes. These symptoms include weakness, sensory loss, ataxia, and bowel and bladder symptoms. All these symptoms develop in the majority of patients during the course of MS [*see Table 3*]. The weakness associated with MS is of the upper motor neuron type and is accompanied by spasticity and increased reflexes. Weakness may occur in any pattern, including paraparesis, hemiparesis, and monoparesis. In established disease, the lower extremities are usually more affected than the upper extremities. Sensory symptoms are also frequent and can occur in different patterns. Patients may note either paresthesias or loss of sensation. Again, the lower extremities tend to be more severely affected. The loss of vibration sense is often most prominent. Ataxia is uncommon at the onset of MS, but it occurs to some degree in most patients. Difficulties with bladder control are frequent and can be extremely distressing. Most commonly, patients have urinary urgency, frequency, and urge incontinence consistent with a spastic bladder, but hesitancy, retention, overflow incontinence, and dyssynergia also occur. Constipation is the most common bowel complaint.

Although almost any deficit can occur in MS, some are extremely rare. These include seizures, aphasia, movement disorders, and muscle atrophy, which reflect primary involvement of gray matter or peripheral nerves. Although these symptoms can occur in MS, their presence is unusual and should prompt reevaluation of the diagnosis.

Table 2 Diagnostic Criteria for Multiple Sclerosis[19]

Clinical Presentation	*Additional Data Needed for MS Diagnosis*
Two or more attacks; objective clinical evidence of two or more lesions	None
Two or more attacks; objective clinical evidence of one lesion	Dissemination in space demonstrated on MRI *or* Two or more MRI lesions plus positive cerebrospinal fluid *or* Await further clinical attack in different site
One attack; objective clinical evidence of two or more lesions	Dissemination in time demonstrated on MRI *or* Second clinical attack
One attack; objective clinical evidence of one lesion	Dissemination in space demonstrated on MRI *or* Two or more MRI lesions plus positive CSF plus dissemination in time demonstrated on MRI *or* Second clinical attack
Insidious progression suggestive of MS	Positive CSF *and* Dissemination in space demonstrated by MRI or MRI and visual evoked response (VER) *and* Dissemination in time demonstrated by MRI or continued progression for 1 yr

Note: a pocket card with current diagnostic criteria and explanation of their use can be obtained from http://www.nationalmssociety.org.

Clinical Course

The clinical course of MS varies greatly among patients. MS typically has a relapsing-remitting pattern, with acute exacerbations followed by partial or complete resolution. New neurologic deficits develop over the course of several hours or days, remain stable for a period of a few days to a few weeks, and then gradually improve. Early in the course of the disease, the symptoms may resolve with minimal residua. With repeated exacerbations, permanent neurologic deficits tend to develop. Patients usually have symptom-free intervals of months or years between attacks.

Symptoms may also occur in a progressive manner, with steady accumulation of neurologic deficits in the absence of clearly defined exacerbations. Patients who initially have relapsing-remitting disease and who then enter a progressive phase are said to have secondary progressive disease, whereas those whose symptoms are progressive from onset are said to have primary progressive disease. About 15% of patients have primary progressive disease; of those who initially have relapsing-remitting disease, 30% to 50% will experience progressive symptoms in the first 10 years.[20] Radiologic and pathologic studies suggest that the primary progressive group may be distinct from the relapsing-remitting and secondary progressive group.[21]

Laboratory Tests

Magnetic resonance imaging MRI is the single most useful laboratory test in the diagnosis of MS. Most patients with MS have abnormalities that can be seen with MRI, and the superb

Table 3 Approximate Distribution of Neurologic Deficits at Onset of MS and after 5 to 10 Years of Disease[94,95]

Deficits	*At Onset (%)*	*5 to 10 Years after Onset (%)*
Cognitive deficits	< 5	30
Visual deficits	20–30	50
Diplopia	10–20	35
Weakness	40	80
Ataxia	5–20	65
Sensory deficits	40	80
Bowel or bladder symptoms	5–10	55

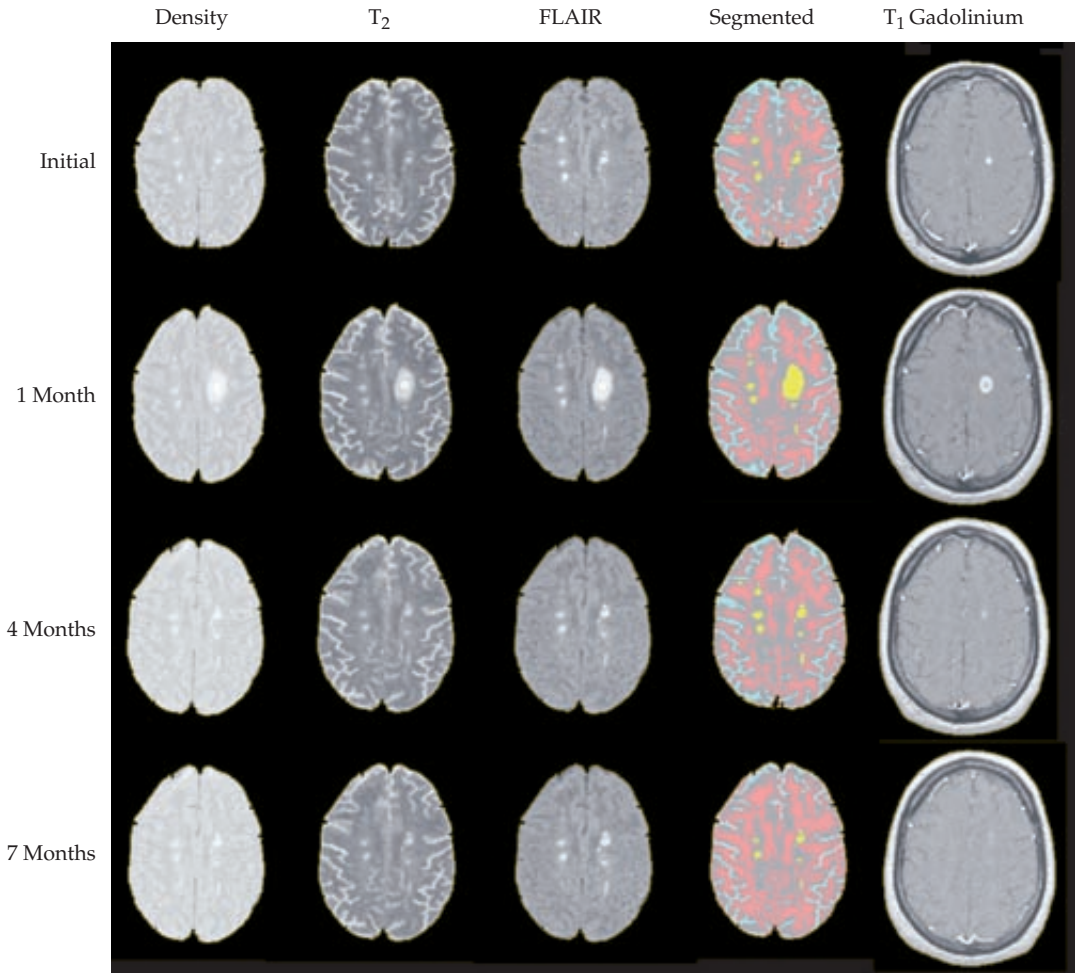

Figure 2 **The composite shows some of the changes captured by serial MRI that are characteristic of the dynamic nature of the underlying pathologic disease activity in multiple sclerosis. The patient was evaluated serially by high-resolution MRI, and the images were quantified automatically. The more conventional appearing images were made using fast spin-echo pulse sequences to produce density-weighted and T_2-weighted images and a fast FLAIR (fluid-attenuated inversion recovery) sequence with magnetization contrast pulse to improve identification of the lesions and suppress signals from the cerebrospinal fluid. The gadolinium-enhanced T_1-weighted image also incorporates a magnetization transfer contrast pulse to amplify the enhancement effects. All images are from the same region of the brain and are 3 mm thick. The segmented images were computer generated through the use of an algorithm that incorporates information from the multiple images. In the segmented images, gray matter is rendered gray, white matter is pink, cerebrospinal fluid appears blue, and the lesions are shown in yellow. The total lesion load in the entire brain varied from 16.71 to 26.98 ml to 16.98 to 21.52 ml at the intervals shown. The total enhanced tissue volume varied from 0.99 to 2.99 ml to 0.33 to 0.04 ml at the same intervals. The patient had no clinically defined change in his neurologic symptoms or findings during this 7-month interval despite the significant activity demonstrated by MRI.**

anatomic resolution of MRI permits the exclusion of many diseases that mimic MS. MS lesions are hyperintense on T_2-weighted or proton-density imaging and are hypointense or isointense on T_1-weighted imaging [*see Figure 2*]. Typical MS lesions are ovoid and periventricular, with their long axis perpendicular to the ventricle, but lesions may appear anywhere in the white matter. Some lesions may be enhanced by the administration of gadolinium chelates; enhancement by gadolinium chelates indicates a breakdown in the blood-brain barrier. Even in early MS, several lesions are usually present, although they may not produce obvious symptoms.

Although MRI is extremely sensitive in detecting white-matter lesions in patients with MS, it is not very specific. Many other diseases produce multiple white-matter lesions; thus, MRI findings should never be used as the sole basis for the diagnosis. MRI findings supportive of the diagnosis of MS include the presence of three or more white-matter lesions, lesions that abut the body of the lateral ventricles, juxtacortical lesions, infratentorial lesions, lesions that are greater than 5 mm, and lesions that show gadolinium enhancement.

The changes that occur in MS lesions over time have been investigated with serial MRI. The size and number of T_2-weighted hyperintense lesions fluctuate, but new lesions tend to accumulate, and the total lesion burden tends to increase.[22] In studies of patients with relapsing-remitting disease who were treated only with short courses of corticosteroids for clinical attacks, the total T_2-weighted lesion burden increased at a rate of 6% to 8% a year.[23,24] Gadolinium enhancement is a transient phenomenon

that usually lasts less than 8 weeks and usually occurs when a new lesion first appears. Gadolinium-enhanced lesions correspond to areas of acute inflammation on pathologic examination, whereas nonenhanced lesions correspond to more chronic disease.[25] Stable, hypointense lesions on T_1-weighted imaging that are not enhanced by gadolinium appear to reflect extensive tissue disruption, including axonal loss. These lesions are highly correlated with clinical measures of neurologic dysfunction.[26] Cerebral atrophy is often present on MRI images. Quantitative computed analysis has demonstrated that the amount of atrophy increases over time[27] and correlates well with clinical disability and disease duration.[28]

The use of serial MRI to study MS has led to fundamental changes in neurologists' concept of the disease process. Disease activity as measured by the appearance of new hyperintense lesions on T_2-weighted images or the appearance of contrast-enhanced lesions on T_1-weighted images greatly exceeds the severity of disease as evidenced by clinical symptoms. Disease activity as assessed by MRI is still episodic but occurs 10 to 20 times more often than clinical symptoms, which suggests that MS is much more of an ongoing and active process, rather than the intermittent process suggested by clinical activity.

Current clinical studies of new therapies for MS include MRI assessment of disease activity as one of the end points. To facilitate the use of MRI in large trials, several groups have developed automated methods for measuring lesion burden and other parameters of interest.[29] Newer sequences, such as magnetization transfer imaging, fluid-attenuated inversion recovery (FLAIR), diffusion tensor imaging, and combinations of these, are being developed to show more subtle changes and greater pathology [*see Figure 2*].[30] Similarly, magnetic resonance spectroscopic imaging (MRSI) [*see Figure 3*] provides additional information on the extent of axonal loss within lesions[31,32] and more directly measures lipid release during active demyelination[33] and in the cortex.[34] MRI may also provide insights into the pathogenesis of the MS lesion. Serial MRI studies demonstrate that a decrease in the magnetization transfer ratio on MRI or the presence of lipid peaks on MRSI in normal-appearing white matter may precede the development of contrast-enhanced lesions, which suggests that the inflammatory response is a secondary factor in the development of a new lesion.[35,36]

Cerebrospinal fluid Most CSF constituents are minimally affected in MS. A mild mononuclear cell pleocytosis can be found during acute relapses, but total cell counts greater than 50 cells/mm^3 are uncommon. The CSF protein level may be mildly

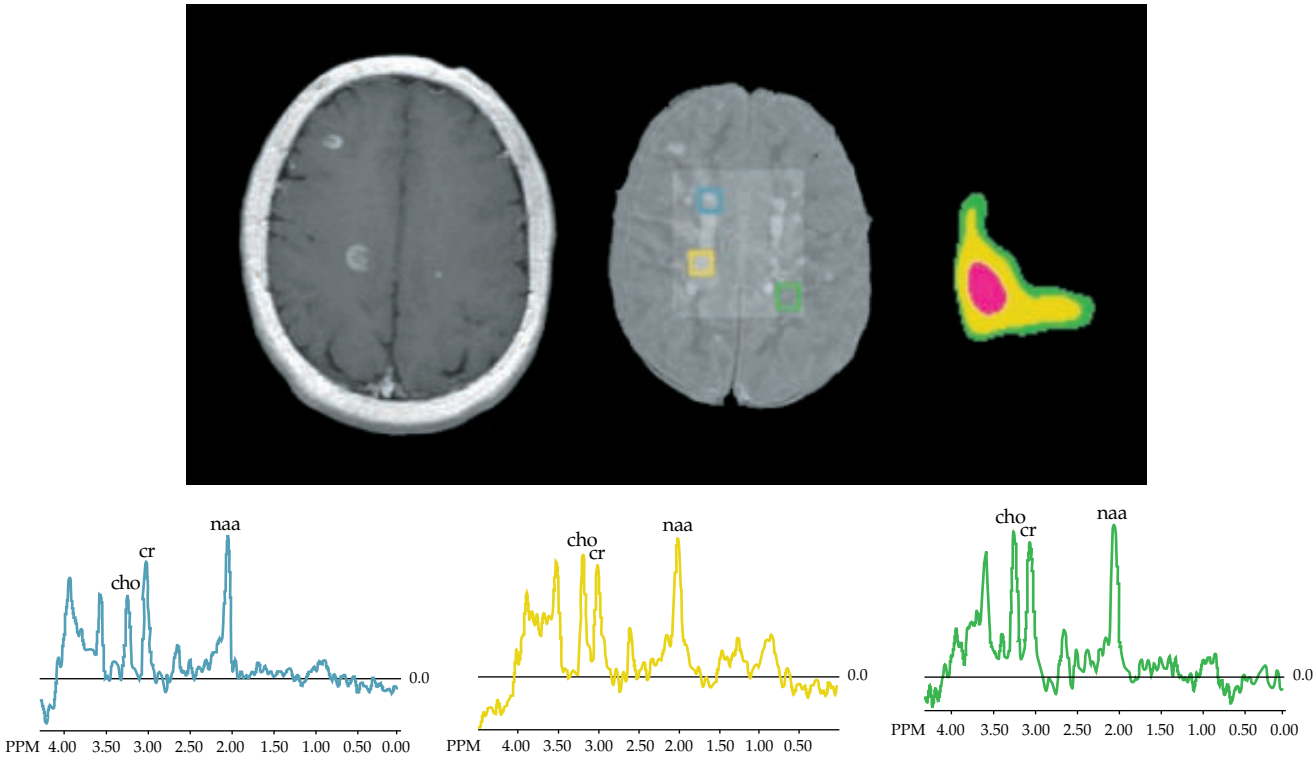

Figure 3 **Two-dimensional proton magnetic resonance spectroscopic imaging (MRSI) was used to investigate an asymptomatic woman with relapsing multiple sclerosis. The central figure is a composite of five 3 mm thick spin density–weighted images through the corpus callosum. A number of scattered lesions are seen, and the rectangular region selected for MRSI is highlighted. To the right is a composite of the same region studied by gadolinium-enhanced T_1-weighted imaging. Three enhancements are seen. The largest enhanced lesion corresponds to the lesion contained within the yellow box in the central spin density image. The blue box in this image contains an unenhanced lesion, and the green box contains an area of normal-appearing white matter. The MRSI is shown next to the spin density image. Here, the maximal regional intensity of resonances attributed to mobile lipids is depicted in red, which corresponds to the region of the enhanced lesion. Relatively less resonance intensity is shown in colors ranging from yellow to green and, finally, to black, indicating the normal lack of lipid resonances from intact white matter. Spectra from individual MRSI voxels that contain the largest enhanced lesion (yellow spectrum), the unenhanced lesion (blue spectrum), and the area of normal-appearing white matter (green spectrum) are shown for comparative detail. The major metabolites that give rise to well-defined spectral peaks include choline (cho), creatine (cr), and *N*-acetyl aspartate (naa). Characteristic paired lipid peaks are seen to the right of the naa peak only in the yellow spectrum. These findings are consistent with active myelin breakdown in association with the enhanced lesion.**

elevated but rarely exceeds 100 mg/dl. During acute attacks, especially those involving the spinal cord and brain stem, the CSF may contain measurable amounts of myelin basic protein. The most characteristic abnormality in MS is intrathecal synthesis of immunoglobulins of restricted heterogeneity. The presence of this abnormality is best determined by comparative electrophoresis of serum and concentrated CSF, which shows oligoclonal immunoglobulin bands specific to CSF. For optimal sensitivity, the paired samples should be analyzed with isoelectric focusing followed by immunofixation. Quantitative measures of immunoglobulin content in CSF, such as the IgG index and the rate of IgG synthesis, are also quite sensitive and useful in clinical practice. Oligoclonal bands or abnormal immunoglobulin synthesis is found in about 90% of patients with clinically definite MS; although not specific to MS, these findings support the diagnosis of MS in equivocal cases. CNS infections or diseases that cause chronic CNS inflammation may also stimulate abnormal immunoglobulin synthesis.

Evoked response The slowing of conduction over demyelinated segments of axons or over incompletely remyelinated pathways provides a useful marker for identifying additional subclinical lesions in sensory pathways. Conduction can be measured along visual, auditory, and somatosensory pathways by use of summated cortical evoked responses. In these tests, a time-locked recording of the electroencephalogram over the afferent cortex of interest is obtained after repeated visual, auditory, or sensory stimulation. If demyelination is significant, conduction over central pathways will be delayed. Evoked responses may be used in MS to reveal evidence of demyelination in a particular sensory pathway when none is clinically evident or to confirm symptomatic pathway involvement in the absence of convincing clinical signs. In general, visual evoked responses provide the most useful information.[37]

MS VARIANTS

A number of clinical or pathologic variants of MS have been identified. Marburg-type MS, or acute MS, is a variant with a fulminant, monophasic course. Schilder disease, or diffuse sclerosis, is a rapidly progressive variant associated with large cerebral demyelinated lesions. Baló disease is a pathologic variant in which concentric areas of demyelination occur in the cerebrum.[38]

Neuromyelitis optica, or Devic disease, is a rare but often severe syndrome that may be distinct from MS. It is characterized by the simultaneous or sequential involvement of the optic nerves and spinal cord with relative sparing of the brain, absence of oligoclonal bands, and longitudinally extensive lesions in the spinal cord on MRI. Demonstration of neuromyelitis optica IgG (NMO-IgG), a serum autoantibody that binds to a component of the cerebral vasculature, may aid in the diagnosis.[39] Treatment of neuromyelitis optica differs from that of typical MS: parenteral corticosteroids and, if necessary, rescue plasmapheresis can be used for acute attacks; systemic immunosuppression, usually with azathioprine and oral corticosteroids, may be recommended for relapse prevention; and rituximab may be beneficial.[40,41]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of MS depends on the clinical presentation. For a classic case of relapsing-remitting symptoms in a young adult with typical MRI findings, the differential diagnosis is limited. For an older patient presenting with a progressive myelopathy, the differential diagnosis is extensive.[42] There is no standard list of alternative diagnoses that should be considered in every patient suspected of having MS. Instead, the treating physician should carefully consider the clinical and laboratory features of the particular case to generate the relevant list of possible alternative diagnoses. Frequent diagnostic considerations include structural lesions, inherited demyelinating or degenerative diseases, vasculitides, vascular disease, chronic infections (e.g., syphilis, Lyme disease, and human T cell lymphotropic virus type I), vitamin B_{12} deficiency, and neurosarcoidosis.

TREATMENT

Treatment of MS can be discussed in terms of the management of acute relapses, the prevention of relapses as modification of the disease process, and the management of symptoms and fixed neurologic deficits.

Acute Relapse

Management of relapses varies with the severity of the presenting signs and symptoms. Mild attacks that do not significantly alter the patient's ability to function require no more than a supportive physician-patient relationship. High-dose corticosteroid therapy is indicated for exacerbations that adversely affect the patient's function. Intravenous methylprednisolone in daily doses of 0.5 to 1.0 g for 3 to 7 days reduces the duration of maximal neurologic signs and symptoms and usually rapidly reverses the fatigue that frequently accompanies acute attacks.[43,44] A short, tapering course of oral corticosteroids may be given afterward. Equivalent doses of oral corticosteroids may have a similar effect,[45] but treatment with lower doses (e.g., 1 mg/kg/day) is controversial. The early benefits may be similar, but the interval between attacks may be shorter with low-dose steroids.[46,47] The important roles of reduced physical activity during an exacerbation and early institution of rehabilitation therapy should not be ignored. Relative contraindications to corticosteroids include type 1 diabetes mellitus, uncontrolled hypertension, and prior steroid-induced depression or psychoses. Although corticosteroids have a short-term beneficial effect when used for acute exacerbations, their long-term effect on the course of MS is less clear.[48]

Prevention of Relapse

Three different medications that affect the long-term clinical course of MS are available: interferon beta-1b, interferon beta-1a, and glatiramer acetate. In patients with relapsing-remitting MS, these drugs reduce the frequency of attacks, reduce the rate of MS lesion accumulation on MRI, and reduce the accumulation of disability.

The beta interferons reduce major histocompatibility complex (MHC) class II antigen expression, alter the pattern of cytokine secretion, inhibit matrix metalloproteinase activity, and increase antigen-nonspecific suppressor mechanisms in model systems.[49] In clinical trials, they reduce the frequency of clinical attacks, decrease the number of contrast-enhanced lesions, and limit fixed-lesion accumulation on MRI. In early relapsing-remitting MS, they may delay the accumulation of disability. Recombinant human interferon beta-1b and interferon beta-1a vary in their routes of administration, side-effect profiles, and apparent magnitude of effects. These differences are only partially explained by the structural properties of the two molecularly engineered molecules and the study designs of their pivotal clinical trials. Both preparations induce antibodies that may limit clinical benefits.[23]

In an extended controlled study involving patients with re-

lapsing disease of mild to moderate severity, 0.25 mg (8 million IU) of interferon beta-1b, given subcutaneously every other day, reduced the annual exacerbation rate by 30%. This reduction was maintained for 5 years.[23] The frequency of contrast-enhanced lesions was markedly reduced; the total burden of disease, as measured by MRI, increased over time in the placebo group but stabilized for those on high-dose treatment. The benefits of treatment with interferon beta-1b were dose dependent, with better results seen at the higher dose. Antibodies that may limit the effect of the drug developed in up to 38% of treated patients.[50]

The majority of patients experience flulike symptoms of varying severity on initiation of therapy with interferon beta-1b. For most patients, these symptoms can be controlled with prior administration of a nonsteroidal anti-inflammatory drug.[51] The symptoms become less severe and may disappear over time. Local injection-site reactions are usually only of cosmetic concern, but frank skin necrosis can occur. About 20% of patients discontinue treatment because of local or systemic side effects or other issues. In some of those patients who tolerate treatment, therapeutic benefit may decrease as a result of the development of neutralizing antibody. Nevertheless, patients who avoid these pitfalls of treatment stand to benefit substantially; moreover, the benefits are independent of the disability status at initiation of therapy.[52]

Interferon beta-1a is currently available in two forms. One is given intramuscularly once weekly at a dose of 30 μg, and the other is given subcutaneously three times weekly at a dose of 44 μg for a total weekly dose of 132 μg. In patients with slight to mild disability who experience relapse, 30 μg given once a week reduced the relapse rate by 18% and reduced the proportion of patients with sustained progression of neurologic disability. When the same dose of interferon beta-1a was administered within several weeks of symptom onset in patients who had experienced a single attack and were at high risk for having a second, disease-defining attack, the time to the next attack was prolonged.[52] When interferon beta-1a was given subcutaneously at 44 μg three times a week to patients with mild to moderate disability, the relapse rate decreased by 33% and the accumulation of disability slowed.[53] In patients receiving interferon beta-1a, the number of contrast-enhanced lesions decreases and there is an improvement in the MRI burden of disease. In studies of both interferon beta-1a and interferon beta-1b, the beneficial effects were greater with higher doses.[54,55]

Glatiramer is a synthetic random polymer of four amino acids (hence its original name, copolymer-1). Its mechanism of action is not definitively established, but it promiscuously binds to MHC class II antigen and induces organ-specific T helper type 2 cell responses.[56] Glatiramer reduces the frequency of relapses in MS, may reduce accumulation of disability, and does not appear to induce host responses that limit its benefit over time. Glatiramer reduces the annual attack rate by 32%, with the greatest effect seen in those patients with the least neurologic impairment.[57] The progression of disability is also slowed, and benefits may be maintained over 6 or more years.[58] Over the first 9 months of treatment, the number of contrast-enhanced lesions is reduced by 35%, which correlates well with the effect on relapse rate.[59] Side effects are minimal, but a transient systemic reaction occurs in about 15% of patients after one or more injections of the drug. Essentially all patients treated with glatiramer develop antibodies that bind to the drug, but these do not appear to limit the drug's activity.[57]

Another drug for the prevention of relapses, with a mechanism of action different from that of glatiramer, was briefly marketed in the United States from November 2004 to February 2005. Natalizumab is a monoclonal antibody against the adhesion molecule α_4 integrin. The binding of the antibody to its target inhibits the adhesion of circulating lymphocytes to the blood vessel wall and thus prevents the subsequent migration of those lymphocytes into the CNS. When administered intravenously every 4 weeks for a total of six doses, natalizumab significantly reduced the number of new lesions seen on MRI, as well as the number of clinical relapses.[60] In a subsequent, larger study, natalizumab was given every 4 weeks for a year; this regimen resulted in a reduction of the relapse rate by 68% as compared with placebo. The Food and Drug Administration granted accelerated approval on the basis of these promising results. Soon afterward, however, two cases of progressive multifocal leukoencephalopathy, one of them fatal, occurred in patients treated with the combination of natalizumab and interferon. All use of natalizumab is currently suspended, and the future of this drug is uncertain.

In summary, prophylactic treatment with either a beta interferon or glatiramer is appropriate for patients with relapsing disease and mild to moderate disability. The choice of agent depends on the particular patient. Patients who are maintained on these therapies can expect an 18% to 50% reduction in attack frequency. With any of the available drugs, best responses appear to result when treatment is initiated relatively early in the disease course.

These agents have only modest effect when used as monotherapy; consequently, there is intense interest in using these agents in combination to achieve greater benefit. Numerous combinations have been proposed, including glatiramer plus interferon, interferon plus one of the many immunosuppressive agents, and glatiramer plus other agents. Some of these combinations are under active investigation, but to date, no adequate, completed clinical trial has demonstrated increased efficacy with combination therapy. For the present, monotherapy with either interferon or glatiramer is recommended for most patients with relapsing-remitting disease. Combinations of drugs, the use of other immunomodulatory drugs, and several antigen- or disease-specific interventions are currently under active study, and additional therapeutic alternatives may be available in the near future.

Clinically Isolated Syndromes

Neurologists frequently see patients who are having a first episode of neurologic symptoms and whose MRI scans show white-matter lesions. Many of the patients who experience these clinically isolated syndromes will go on to develop MS. Early treatment can delay a second episode in these patients.[61,62] The argument in favor of early treatment is that some of the future relapses, and possibly some of the future disability, can be prevented. Arguments against early treatment are the uncertainty of the diagnosis early in the course, the limited effect of the available treatments, and the possibility of benign disease. The number of patients that are needed to be treated to prevent a single relapse of the disease varies with the number of T_2 lesions found at presentation—a fact that helps guide the physician and patient in making a decision on early initiation of therapy.[63]

Progressive MS

Treatment of progressive MS is not as well established as it is for relapsing disease. As discussed [*see* Clinical Course, *above*],

disease that is progressive from onset is called primary progressive, whereas disease that is initially characterized by relapses and remissions and then enters a progressive phase is called secondary progressive. Results of interferon-beta treatment in secondary progressive MS have been mixed and disappointing. In one trial of interferon beta-1b, disease progressed in 50% of the patients who received placebo, whereas disease progressed in 39% of patients treated with interferon beta-1b.[64] However, subsequent studies of interferon beta-1a and beta-1b have not shown an effect on the progression of disability as measured by the Expanded Disability Status Scale (EDSS), the traditional measure of disability in MS.[65,66] Relapse rates and MRI measures of disease activity were decreased in all of these studies. The available data suggest that glatiramer acetate likewise has limited or no benefit in either secondary or primary progressive disease.[67] Together, these results suggest that the pathophysiologic processes causing progressive symptoms may be different from those causing acute exacerbations and CNS inflammation detected by MRI.

In addition to interferon and glatiramer, various aggressive immunosuppressive therapies have been tried. The cytotoxic drug mitoxantrone has been approved for the treatment of aggressive relapsing and secondary progressive MS. In a 2-year, placebo-controlled study of 194 patients, 12 mg/m^2 of mitoxantrone given every 3 months for 2 years reduced progression of disability, reduced relapse frequency by 67%, and decreased the accumulation of lesions and the number of enhancing lesions on MRI. In this study, the selection criteria were that the patients have active disease with recent deterioration and that they had not had previous therapy with interferon or glatiramer. Observed short-term side effects included nausea, hair loss, menstrual irregularities, and infections. The cumulative dose was limited because of the increasing risk of cardiotoxicity at higher doses.[68]

Mitoxantrone currently has a role for selected patients with very active disease, but its significant side effects limit its use. Several important questions about mitoxantrone remain to be answered. These include the duration of benefit, its effectiveness in patients with progressive disease without relapses, and its effectiveness in patients in whom interferon or glatiramer therapy has failed. Also of concern is the fact that numerous similar cytotoxic or immunosuppressive agents were previously fashionable for a time but are currently little used because of limited benefit and significant side effects. These include cyclophosphamide, cladribine, azathioprine, methotrexate, and cyclosporine.

Symptomatic Therapy

Several of the common symptoms of MS respond to pharmacologic treatment [*see Table 4*]. Prominent among the most frequent symptoms of MS are depression and fatigue.

Depression and fatigue Depression occurs in about 20% of MS patients, probably more frequently than anticipated for other chronic illnesses. Treatment of depression in MS patients does not differ from that in others. Fatigue is present in at least half of all MS patients; often, it is not proportional to the extent of neurologic compromise. It commonly occurs during relapses and can also be present between attacks. Fatigue in MS is differentiated from normal fatigue by its severity and by the fact that it is frequently unrelated to activity. About 50% of patients with MS obtain at least partial relief by treatment with amantadine, but dosing late in the day may induce insomnia and thus should be avoided. When amantadine fails to relieve fatigue, other agents that may be useful are modafanil,[69,70] methylphenidate, and selective serotonin reuptake inhibitors.

Spasticity Spasticity is another common symptom that is amenable to treatment. The increased extensor tone in the lower extremities can to some extent compensate for associated weakness, but excessive spasticity inhibits a fluid gait and may result in painful spasms or joint contracture. Centrally active γ-aminobutyric acid (GABA) agonists, such as baclofen, often reduce spasticity but preserve functional gait or lower-limb strength, which is needed for weight transfer. Effective doses of baclofen vary from as little as 5 mg to as much as 240 mg daily in divided doses. Treatment should be initiated at a low dose and titrated upward to the level that provides maximum benefit. Other drugs that may be helpful include diazepam, clonazepam, and the alpha agonist tizanidine. Although not specifically investigated as an antispasmolytic agent, gabapentin may be useful in reducing spasticity. Some patients benefit from dantrolene. Selected patients who have severe spasticity that is unresponsive to oral treatment may benefit from intrathecal baclofen or selective botulinum toxin injections.

Bladder dysfunction Bladder dysfunction is common in MS. The pathophysiology is complex; the symptoms of detrusor-sphincter dyssynergia, hyperactive detrusor function, and flaccid bladder may occur individually or in various combinations and often fluctuate over time. Formal urodynamic studies are essential to delineate these various patterns and to determine rational approaches to treatment. Most patients will present with urgency and frequency, which may be alleviated with smooth muscle relaxants and anticholinergic agents. Periodic determination of postvoid residual urine volumes is used to identify patients who will benefit from self-catheterization programs.

It is important to recognize that bladder infections are common in women with MS. Because of the frequent loss of perineal sensation, acute bladder infections may not cause dysuria but instead may become evident as a global deterioration of neurologic function, which may be mistaken for an acute relapse. The evaluation of patients in relapse should include a search for pyuria. Asymptomatic bacteriuria may demand concomitant treatment of acute relapses with a combination of methylprednisolone and an appropriate antibiotic. Significant urinary retention with overflow incontinence may be accompanied by reflex exaggeration of lower limb spasticity. Institution of a self-catheterization program for affected patients often reduces spasticity more effectively than pharmacotherapy.

Pain Pain is not uncommon in MS. Often, it is secondary to unusual mechanical stress resulting from asymmetrical weakness or spasticity. Appropriate orthotics, antispasmolytics, and self-performed exercise routines, supplemented by simple analgesics, are helpful. Paroxysmal pain syndromes, typified by trigeminal neuralgia, usually respond to low doses of carbamazepine or other antiepileptic drugs, particularly gabapentin. Distal dysesthetic sensations may also respond to these drugs. Low doses of tricyclic antidepressants may prove useful.

Ataxia and intention tremor These manifestations are particularly difficult to manage. Use of counterweights on limbs may aid some patients. Pharmacologic interventions are generally disappointing, but clonazepam or gabapentin at maximally

Table 4 Symptomatic Therapy for MS*

Indication	*Drug*	*Dosage*
Fatigue	Amantadine	100 mg b.i.d. or t.i.d.
	Methylphenidate	10 mg b.i.d. to 20 mg t.i.d.
	Modafinil	100 mg b.i.d.
Bladder		
Urgency	Oxybutynin	5 mg b.i.d. to q.i.d.
	Tolterodine	2 mg b.i.d.
	Imipramine	25 to 75 mg q.h.s.
	Hyoscyamine	0.125 mg b.i.d. to 0.25 mg q.i.d.
	Propantheline	7.5 mg t.i.d. to 15 mg q.i.d.
Dyssynergia	Phenoxybenzamine	10 mg b.i.d. to 20 mg t.i.d.
	Clonidine	0.1 mg b.i.d. to 0.2 mg t.i.d.
	Terazosin	1 to 5 mg q.d.
Retention	Intermittent catheterization	Four or more times daily
	Bethanechol	10 mg t.i.d. to 50 mg q.i.d.
Spasticity	Baclofen	5 mg t.i.d. to 20 mg q.i.d.
	Diazepam	2 mg t.i.d. to 10 mg q.i.d.
	Tizanidine	4 mg q.d. to 12 mg t.i.d.
	Clonazepam	0.5 mg t.i.d. to 5 mg q.i.d.
	Clonidine (adjunctive to baclofen)	0.1 mg b.i.d. to 0.2 mg t.i.d.
	Dantrolene	25 mg q.d. to 100 mg q.i.d.
Ataxia	Clonazepam	0.5 mg t.i.d. to 5 mg q.i.d.
	Gabapentin	100 to 600 mg t.i.d.
Pain		
Paroxysmal	Carbamazepine	100 to 300 mg t.i.d.
	Phenytoin	300 to 400 mg q.d.
	Misoprostol (trigeminal neuralgia)	100 to 200 μg q.i.d.
Dysesthetic	Amitriptyline	50 to 150 mg q.h.s.
	Phenytoin	300 to 400 mg q.d.
	Gabapentin	100 to 600 mg t.i.d.
	Valproic acid	250 to 1,000 mg t.i.d.

*Usual adult doses for medications commonly used to treat MS syndromes. See appropriate reference for complete prescribing information, including contraindications, warnings, side effects, and initiation and termination of treatment.

tolerated doses sometimes provides symptomatic relief for patients with disabling upper extremity ataxia.

PROGNOSIS

Although the course of MS varies from patient to patient, the effect of the disease in large cohorts of MS patients has been determined. The median time from onset of disease to disability severe enough for the patient to require aids for ambulation is 15 years. MS has minimal effect on life span.[20] For perhaps 10% to 15% of patients, MS has a relatively benign course, with patients experiencing minimal or no disability 20 years after onset of symptoms. For patients with relapsing-remitting disease, the mean relapse frequency is about once every 2 years. There are no known factors that are predictive of the clinical course in an individual patient, but female sex, younger age at onset, and optic neuritis or sensory symptoms as the presenting symptoms tend to be associated with a more favorable prognosis. A normal cerebral MRI in patients presenting with optic neuritis, partial transverse myelitis, and brain stem syndromes associated with MS predicts a mild course for the first decade or more of the disease.[71]

Optic Neuritis

Optic neuritis is an acute inflammatory optic neuropathy. The cardinal symptoms are unilateral vision loss and retrobulbar pain with eye movement. MRI of the orbits is indicated to confirm the presence of optic nerve inflammation; brain MRI results are useful in counseling patients regarding their risk of developing MS. Referral to an ophthalmologist to exclude uveitis, glaucoma, or other ophthalmologic causes of visual loss is indicated. Differential diagnosis includes anterior ischemic optic neuropathy, which is usually painless and typically occurs in patients older than 50 years; hereditary diseases, such as Leber hereditary optic neuropathy; and toxic or nutritional optic neuropathies.[72] Treatment with intravenous methylprednisolone at a dosage of 1 g/day for 3 days followed by oral prednisone for 11 days hastens recovery of vision but has little residual benefit at 1 year. One study showed that prednisone at 1 mg/kg/day for 14 days had no benefit and was associated with an excess of recurrences.[73] Even without treatment, almost all patients begin to recover vision within 4 weeks.

The relation of optic neuritis to MS is controversial. Some regard optic neuritis as a distinct entity, but others consider it part of the clinical continuum of MS. More than half of all patients with MS have optic neuritis at some time during the disease. Of patients who present with optic neuritis and who have no other neurologic deficit, almost 40% have one or more ovoid or periventricular lesions visible on brain MRI; clinically definitive MS eventually develops in 60%.[45,74] Patients with completely normal results on both MRI and comprehensive CSF evaluation seldom progress to MS.[75]

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is a monophasic syndrome that is usually preceded by a viral exanthem, an upper respiratory infection, or vaccination. The most commonly associated viruses are measles, paramyxovirus, varicella, rubella, and Epstein-Barr virus. Onset is often rapid and is characterized by meningeal signs, headache, seizures, and altered mental status. The associated neurologic deficits are variable and may include hemiplegia, paraplegia, sensory loss, vision loss, and transverse myelitis. ADEM can be fatal, but most patients begin to recover within 2 to 4 weeks.

Acute hemorrhagic encephalomyelitis is probably a fulminant variant of ADEM. The main pathologic features of ADEM are multiple areas of perivascular inflammation and demyelination, without evidence of active viral infection. ADEM may be caused by an autoimmune response against myelin antigens elicited by cross-reactive viral proteins. Usually, multiple white-matter lesions are seen on MRI, and the majority of the lesions can be enhanced with contrast.[76] Corticosteroid treatment is often used, although the efficacy of this approach has not been proved in clinical trials. Plasmapheresis may also be useful.[77] Prognosis varies with the inciting virus, but in one case series, 89% of patients had good recovery.[78]

Transverse Myelitis

Acute transverse myelitis is a syndrome of spinal cord dysfunction[79]; it has a rapid onset. Like ADEM, it may occur after infection or vaccination, or it may occur with no discernible precipitant. It may also be the initial presentation of MS. Symptoms include paraparesis, which is initially flaccid and then spastic; loss of sensation with a sensory level on the trunk; and bowel and bladder dysfunction. Back pain precedes the neurologic symptoms, and the sensory symptoms may begin distally and ascend. The thoracic cord is most often affected. The differential diagnosis includes other causes of acute myelopathy, such as compression of the cord by an extradural structural lesion, spinal cord neoplasms, ischemia, and systemic lupus erythematosus. MRI is extremely useful for excluding structural lesions and for confirming the presence of an intramedullary lesion at the level in the spinal cord commensurate with the symptoms. The lesions of acute transverse myelitis are typically hyperintense on T_2-weighted imaging; they involve the majority of the cross-sectional area of the cord over several segments and may be enhanced with contrast. The lesions may cause swelling of the spinal cord.[80,81] No treatment has proved beneficial, but corticosteroids are often used. Prognosis is variable: one third of patients have a good outcome, one third have a fair outcome, and one third do not recover.[82] Spinal shock, back pain, and catastrophic onset are associated with poor outcome.

Inherited Demyelinating Diseases

ADRENOLEUKODYSTROPHY

Adrenoleukodystrophy is an inherited disorder that is associated with progressive demyelination and dysfunction of the adrenal cortex.[83] The inheritance pattern may be either autosomal recessive or X-linked recessive. The X-linked form is caused by the mutation of a gene encoding an integral membrane protein found in the peroxisome. Defects in this gene lead to accumulation of very long chain fatty acids (VLCFAs). The phenotypes may vary considerably, even within the same family. In the childhood form, the patient presents with cognitive deficits, and rapid neurologic deterioration ensues, with death occurring in 2 to 5 years. The adult form, called adrenomyeloneuropathy, presents in patients at a mean age of 28 years as progressive spinal cord dysfunction with spastic paraparesis, sensory loss, and bowel and bladder symptoms. Cerebral involvement may be minimal. Only half of patients with adult-onset disease have brain abnormalities on MRI; these are most often found in the corticospinal tracts.[84] Most patients have diffuse atrophy of the spinal cord. Diagnosis is made on the basis of the combination of neurologic and adrenal involvement, family history, and elevated levels of serum VLCFAs. Dietary treatment with unsaturated fatty acids lowers the level of VLCFAs but does not significantly affect the progression of symptoms.[85] Bone marrow transplantation may be effective if performed before severe symptoms develop. Prognosis is poor for patients with the childhood form of disease. Patients with adult-onset disease usually require assistance with ambulation within 10 to 15 years; in a large percentage of patients, rapidly progressive cerebral lesions develop 5 to 10 years after the onset of spinal cord symptoms.[86]

METACHROMATIC LEUKODYSTROPHY

Metachromatic leukodystrophy is an autosomal recessive disorder that results in demyelination of axons in the central and peripheral nervous systems. It is caused by mutations in the gene for arylsulfatase A that lead to an accumulation of metachromatically staining sulfatides.[87] Onset usually occurs in infancy or childhood; adult onset is rare. The symptoms of adult-onset disease are progressive behavioral abnormalities, dementia, ataxia, and neuropathy.[88] MRI or CT of the brain demonstrates atrophy and diffuse white-matter abnormalities, particularly in the frontal lobes. Diagnosis is confirmed by measurement of arylsulfatase A activity in peripheral blood leukocytes, urine, or skin fibroblasts. True arylsulfatase deficiency must be distinguished from a common pseudodeficiency state that is caused by an allele with low enzymatic activity.[87] The symptoms of metachromatic leukodystrophy are relentlessly progressive, and earlier onset is associated with more rapid progression. The mean survival for adult-onset disease is about 12 years. No effective treatment is available, but allogeneic bone marrow transplantation and gene therapy are under investigation.

Metabolic Demyelinating Diseases

CENTRAL PONTINE MYELINOLYSIS

Central pontine myelinolysis (CPM) is a syndrome in which neurologic deficits occur after rapid correction of hyponatremia [*see 10:I Renal Function and Disorders of Water and Sodium Balance*].[89] CPM usually occurs in young to middle-aged adults and is often associated with alcohol abuse or malnutrition. Signs and symptoms usually begin 3 days after the start of sodium replacement and consist of changes in mental status, dysarthria and other signs of corticobulbar dysfunction, and spastic quadriplegia. Improvement usually begins about 2 weeks after the onset of symptoms, but the degree of recovery is variable. The most striking finding on pathologic examination is the presence of symmetrical demyelinated lesions in the central pons. Demyelinated lesions may also occur in a relatively symmetrical pattern in the basal ganglia, thalamus, internal capsule, subcortical white matter, and cerebellum. T_2-weighted MRI usually

demonstrates the presence of hyperintense lesions. These lesions usually do not enhance with contrast. CPM may also occur after liver transplantation. There is no specific treatment once symptoms have developed. Long duration and rapid correction of hyponatremia increase the risk of CPM; the recommended rate for correction of hyponatremia is no faster than 10 to 12 mEq in 24 hours.

VITAMIN B_{12} DEFICIENCY

Vitamin B_{12} deficiency results in demyelination of axons in the central and peripheral nervous systems. The dorsal and lateral white-matter tracts of the spinal cord are most affected—a characteristic that has given rise to the name subacute combined degeneration of the spinal cord. The most common presenting symptoms are paresthesias, sensory loss that begins in the feet and progresses proximally, and sensory ataxia.[90] Weakness almost always begins after sensory loss. Memory difficulties, irritability, and confusion occur in a minority of patients. On examination, patients usually have decreased vibration and position sense, which is worse in the feet than in the hands, and they may have spastic paraparesis. Pathologic examination reveals symmetrical loss of myelin in the posterior and lateral columns of the spinal cord and sometimes patchy demyelination in the cerebral white matter. MRI of the spinal cord often demonstrates white-matter lesions, which resolve with treatment. Diagnosis is made on the basis of the clinical findings and a low serum cobalamin level. Macrocytosis or anemia is present in most patients but cannot be used in place of the cobalamin level as a diagnostic measure.[91] For patients who have symptoms and a low-normal cobalamin level, demonstration of elevated levels of serum methylmalonic acid and total homocysteine can confirm the presence of a functionally significant cobalamin deficiency.

If cobalamin deficiency is present, the underlying etiology should be investigated. About 80% of patients with cobalamin deficiency have pernicious anemia. Administration of cobalamin prevents progression of symptoms and produces clinical improvement in most patients [*see 5:III Anemia: Production Defects*].[90] Nitrous oxide prevents the metabolism of cobalamin and can cause similar symptoms after prolonged exposure; after a single exposure, it can unmask a subclinical cobalamin deficiency.

Virus-Induced Demyelination

PROGRESSIVE MULTIFOCAL ENCEPHALOPATHY

Progressive multifocal encephalopathy is a lethal demyelinating disease caused by an opportunistic viral infection of oligodendrocytes in immunocompromised patients. The causative agent is JC virus, a ubiquitous papovavirus that infects the majority of the population before adulthood and establishes a latent infection in the kidney. In immunocompromised hosts, the virus can reactivate and productively infect oligodendrocytes. This previously rare condition is now more common because it occurs in 4% of patients with AIDS. It appears to complicate natalizumab treatment of both MS and Crohn disease. Patients usually present with relentlessly progressive focal neurologic deficits, such as hemiparesis or visual-field deficits, or with alterations in mental status. On brain MRI, one or more white-matter lesions are present; they are hyperintense on T_2-weighted images and hypointense on T_1-weighted images. There is no mass effect, and contrast enhancement is rare. Diagnosis can be confirmed by brain biopsy, with demonstration of virus by in situ hybridization or immunocytochemistry. Polymerase chain reaction amplification of JC virus sequences from the CSF can confirm diagnosis without the need for biopsy.[92] Currently, there is no effective therapy. Survival after diagnosis is about 3 to 5 months in AIDS patients [*see 11:XVII Central Nervous System Diseases Due to Slow Viruses and Prions*].

SUBACUTE SCLEROSING PANENCEPHALITIS

Subacute sclerosing panencephalitis (SSPE) is a rare late complication of measles virus infection. It occurs most often in patients whose initial infection with measles virus occurred before 2 years of age; the mean lag time between initial infection and SSPE is 7 years. The use of measles vaccine has greatly reduced the incidence of this complication in developed countries. The earliest symptom is usually progressive cognitive deterioration, which is followed by motor dysfunction and myoclonus associated with distinctive electroencephalographic abnormalities. Pathologic examination reveals active viral infection in the brain, with measles virus protein and RNA detectable in both oligodendrocytes and neurons, and a vigorous inflammatory response. The course is progressive, with occasional temporary remissions. There is no satisfactory treatment [*see 11:XVII Central Nervous System Diseases Due to Slow Viruses and Prions*].

X INHERITED ATAXIAS

S. H. Subramony, m.d.

The inherited ataxias are disorders that cause progressive imbalance as a result of pathology in the cerebellum and its various connecting pathways. Ever since Nicholas Friedreich's initial recognition, more than 100 years ago, that ataxia may result from genetic mechanisms, clinicians and investigators have been struck by the variability and complexity of the clinical, neuropathologic, and genetic aspects of these disorders. In addition to their difficulties with balance, persons with inherited ataxias often exhibit a variety of clinical signs that indicate dysfunction in the basal ganglia, the upper motor neuron, the oculomotor and other brain stem nuclei, the anterior horn cells, and the dorsal root ganglia. In some instances, vision loss and cognitive decline may occur as well.

Within the past decade, molecular genetic studies have identified specific gene mutations in many inherited ataxias and have localized the cause of others to specific chromosomal loci. This has led to the following advances:

1. Classification of these disorders on the basis of genotype.
2. Ability to identify the precise genotype in many patients.
3. Availability of predictive and prenatal diagnostic studies.
4. An understanding of some of the phenotypic variability related to mutations in the same gene.
5. Growing knowledge about the pathogenetic mechanisms of neuronal loss and clinical disease in the setting of specific gene mutations.
6. Early attempts at specific drug therapies in some of the diseases, based on this evolving knowledge.

Genotypic Classification

Within the past dozen years, the surprising genetic heterogeneity of the inherited ataxias has been amply documented. Some autosomal recessive and autosomal dominant ataxias have been defined at a molecular level [*see Tables 1 and 2*]. However, some early-onset ataxic syndromes remain poorly understood at a genetic level [*see Table 3*]. In addition, approximately a third of all autosomal dominant ataxias still have undiscovered gene loci. There are also ataxic disorders that have either mitochondrial or X-linked inheritance patterns.

Autosomal Recessive Ataxias

Friedreich ataxia

Friedreich ataxia (FA) is the most common type of recessively inherited ataxia; it has a prevalence of 2×10^{-5}.[1]

Genetics and Pathogenesis

The mutation in FA is an unstable expansion of a GAA trinucleotide repeat in the first intron of the gene *X-25*, located on chromosome 9q [*see Figure 1*]. Normal alleles have fewer than 40 GAA repeats; over 80% of these are short normal alleles, which carry six to 10 repeats.[1] Long normal alleles, which carry more than 12 repeats, may serve as a reservoir for expansion into pathogenic alleles; they appear to be confined to Indo-Caucasian populations. Enlarged alleles carry from 66 to over 1,000 repeats.[2-5] Most patients with FA are homozygous for the trinucleotide expansion; fewer than 5% of patients with typical FA, however, carry only one expanded allele coupled with a point mutation in the second allele.[6]

The presence of the expanded GAA sequence results in reduced transcriptional and translational efficiency of the gene, which leads to a deficiency of frataxin, a nuclearly encoded mitochondrial protein. This effect appears to be related to so-called sticky DNA, an unusual DNA configuration induced by the expansion.[7] In yeast, lack of the yeast frataxin homologue (YFH) causes a variety of disturbances, including reduced respiratory efficiency of mitochondria, loss of mitochondrial

Table 1 Autosomal Recessive Ataxias with Known Gene Loci

Disease	*Gene Locus*	*Gene*	*Mutation*
Friedreich ataxia	9q13-21.1	*X25*	GAA expansion
Ataxia-telangiectasia	11q22-23	*ATM*	Point mutations/deletions
Ataxia with isolated vitamin E deficiency	8q	*α-TTP*	Point mutations
Autosomal recessive ataxia of Charlevoix-Saguenay (ARSACS)	13q11	*SACS*	Point mutations
Ataxia with oculomotor apraxia	9p13	*Aprataxin*	Point mutations/deletions/insertions
Ataxia, neuropathy, high α-fetoprotein	9q33-34	Unknown	Unknown

SCA—spinocerebellar ataxia PKCγ—protein kinase Cγ

DNA, excess intramitochondrial iron, and increased susceptibility to oxidative stress.[8,9] A similar process may occur in human tissues. Iron accumulation has been noted in cardiac myocytes at autopsy and in the cerebellar dentate nuclei on magnetic resonance imaging.[10] Endomyocardial biopsies from patients with FA have shown a reduction in complexes I, II, and III, as well as levels of the enzyme aconitase. These enzymes share a common feature: the presence of iron-sulfur (Fe-S) clusters. Fe-S cluster proteins are especially susceptible to oxidative stress, which can be triggered by excess iron. It is also possible that the deficiency of Fe-S cluster enzymes may be related directly to frataxin deficiency.

Diagnosis

Clinical features The onset of symptoms in patients with FA is usually in the first or second decade of life but may be delayed to the third decade or later. The classic descriptions of the disease include progressive gait ataxia with onset before 25 years of age, loss of deep tendon reflexes, and proprioceptive loss in the limbs—all signs of major early pathology in the dorsal root ganglion cells and their peripheral sensory processes. Other signs include dysarthria, extensor plantar responses, and oculomotor abnormalities such as square-wave jerks. Muscle atrophy, weakness, and dysphagia occur late in the disease. Tremor, vision loss, and hearing loss may occur in a few patients. About 30% to 50% of patients develop symptomatic heart disease, including hypertrophic cardiomyopathy. Diabetes occurs in 10% of patients, and skeletal deformities, such as scoliosis, are frequent.

The FA GAA expansion has been shown to be associated with a more variable phenotype than the classic features (see above).[2-5] For example, the onset may be at a much older age (up to the early 50s). In addition, ataxia associated with preserved and, occasionally, brisk reflexes can occur. These phenotypes have been labeled late-onset Friedreich ataxia (LOFA) and Friedreich ataxia with retained reflexes (FARR), respectively. Age at onset is inversely correlated with the size of the GAA expansion, especially that of the smaller allele. Patients with heterozygous expansion coupled with a point mutation also often have atypical phenotypes with slower disease progression, especially when the point mutation occurs in the amino-terminal half of the protein.[6]

Laboratory tests One laboratory test that is of value is the FA mutation analysis. More than 95% of patients with typical FA will have a homozygous GAA expansion, but a heterozygous expansion is also diagnostic; in such cases, it can be presumed that the unexpanded allele has a point mutation. If the clinical picture is atypical, however, a heterozygous expansion may simply reflect an incidental carrier state. The FA mutation analysis is also indicated in almost all cases of recessive or sporadic ataxia of childhood or adult onset that cannot be readily categorized otherwise. Two other useful laboratory tests are nerve conduction tests, which show a predominantly sensory neuropathy, and brain imaging, which shows spinal cord atrophy with a relatively preserved cerebellum.

Differential Diagnosis

The phenotype of typical childhood-onset FA is usually not difficult to recognize. The major differential diagnoses include Charcot-Marie-Tooth disease and pure sensory neuropathies, as well as certain metabolic errors that can mimic FA disease, such as vitamin E deficiency.

Management

Laboratory studies have shown a beneficial effect of the coenzyme Q analogue idebenone on iron-induced oxidative damage. Idebenone has also been reported to have a therapeutic effect on the cardiomyopathy of FA.[11] More extended studies are in progress. A combination of coenzyme Q10 (400 mg daily) and vitamin E (2,100 units daily) has been shown to improve cardiac and skeletal muscle bioenergetics in FA patients, as assessed by magnetic resonance spectroscopy.[12]

Because the specific therapy for FA is still in an experimental stage, symptomatic management of the disease still requires attention. This includes appropriate rehabilitation

Table 3 Childhood or Young Adult–Onset Ataxias with Ill-Defined Genetic Abnormalities

Disease	*Clinical or Laboratory Feature*
Early-onset ataxia with retained deep tendon reflexes	Some have FA/ARSACS mutation; others unknown
Ataxia with hypogonadism (Holmes ataxia)	Primary or secondary hypogonadism
Ataxia with coenzyme Q10 deficiency	Low coenzyme Q10 levels in muscle
Ataxia with myoclonus	MtDNA mutations, sialidosis, ceroid lipofuscinosis

FA/ARSACS—Friedreich ataxia/autosomal recessive ataxia of Charlevoix-Saguenay

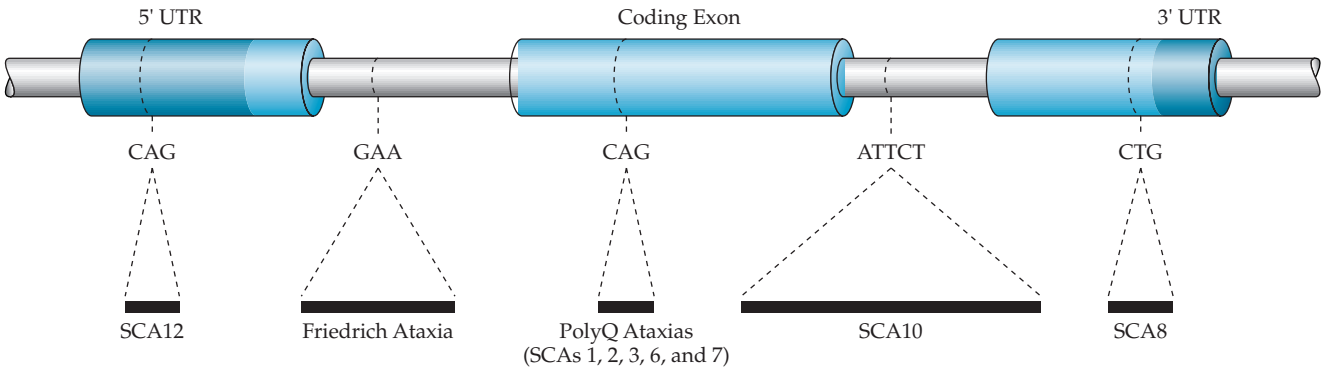

Figure 1 **Diagrammatic representation of the type of repeat expansions associated with ataxias. (SCA—spinocerebellar ataxia; UTR—untranslated region)**

measures; monitoring and treating the systemic features, such as cardiomyopathy and diabetes; surgical correction of skeletal deformity when appropriate; and other types of symptom management. In end-stage FA, appropriate palliative measures need to be taken.

FA families often need genetic counseling. The risk in siblings of patients is 25%. The carrier frequency in Indo-Caucasian populations has been estimated to be approximately one in 100.

ataxia with isolated vitamin e deficiency

Ataxia with isolated vitamin E deficiency (AVED) is a recessively inherited disorder that resembles FA, with childhood onset of ataxia, areflexia, and proprioceptive loss. Vitamin E levels are low, and vitamin E supplementation may arrest disease progression. Mutations in the α-tocopherol transfer protein gene (*TTP*) have been identified in AVED.[13] The phenotype can vary depending on the type of mutation and the degree of residual TTP activity; older age at onset and retention of tendon reflexes cannot exclude AVED. Thus, measurement of vitamin E levels is indicated in any case of sporadic or autosomal recessive ataxia with onset during childhood or the young-adult years.

ataxia-telangiectasia

Ataxia-telangiectasia (AT) typically manifests itself early in the first decade of life as increasing gait ataxia. Neurologic signs that evolve during the first decade include hypotonia, choreoathetosis, areflexia, and a characteristic oculomotor disorder that is associated with an impaired ability to generate saccades, which necessitates head thrusts to move the eyes. The typical telangiectasia appears in children at about 5 years of age and can be found over the conjunctiva, eyelids, and antecubital and popliteal fossae. These children have a high risk of malignancies, especially lymphomas. Measurement of altered radiation sensitivity and elevated α-fetoprotein levels in serum are useful to confirm the diagnosis.

The underlying gene defect in AT involves the AT mutated (*ATM*) gene, which is located on chromosome 11q. To date, AT has been linked to over 300 mutations in the *ATM* gene[14]; this knowledge has made prenatal molecular diagnosis of AT possible in some families The protein product of *ATM* appears to function as a protein kinase and is activated by ionizing radiation, with subsequent activation of cell cycle checkpoints. Defective checkpoint function may underlie some of the hematologic and immunologic phenotypes of AT. The molecular basis of Purkinje cell degeneration in AT is still poorly understood.

Because there are numerous mutations scattered over the *ATM* gene, DNA diagnosis of AT is more cumbersome than the clinical and biochemical diagnosis. Management of AT involves the care of its many systemic manifestations, such as neurologic deficits and increased susceptibility to infections and malignancies.

autosomal recessive ataxia of charlevoix-saguenay

This spastic ataxia with onset in early childhood, which was first described in a population in the Charlevoix-Saguenay province of Quebec, has recently been linked to mutations in the *Sacsin* gene, which is located on chromosome 13.[15] Ataxias in families in other parts of the world have been linked to the same locus, but the worldwide prevalence of this mutation in patients with non-FA childhood ataxia remains to be determined.

autosomal recessive ataxia with oculomotor apraxia

This childhood-onset ataxia is marked by oculomotor apraxia, areflexia, and cerebellar atrophy. The serum albumin level is low, and the serum cholesterol level may be elevated. Mutation in a gene encoding a widely expressed protein-sharing homology with the histidine-triad proteins (HIT) and with the DNA-binding zinc-finger proteins has been identified in this disease.[16,17] This gene may be involved in DNA single-strand break repair.

other disorders of dna break repair

Interestingly, additional abnormalities of DNA single- or double-strand break repair have been shown to cause autosomal recessive ataxias. These include ataxia-telangiectasia–like disorder (ATLD) related to mutations in the gene *mRE11* and spinocerebellar ataxia with axonal neuropathy (SCAN1) caused by a mutation in the gene encoding tyrosyl-DNA phosphodiesterase-1 (*Tdp1*).[18,19] Thus, the list of disorders of DNA break repair that have been noted to cause ataxia include AT, ataxia with oculomotor apraxia, ATLD, SCAN1, Cockayne syndrome, and xeroderma pigmentosum.

infantile-onset olivopontocerebellar atrophy

Infantile-onset olivopontocerebellar atrophy (IOSCA) has been described in a population isolate in Finland. Children with IOSCA present with ataxia, peripheral neuropathy,

areflexia, athetosis, and Babinski signs early in the first decade of life. Other clinical features include speech impairment, hearing loss, optic atrophy, seizures, and learning deficits. IOSCA has been mapped to chromosome 10q24.[20]

OTHER AUTOSOMAL RECESSIVE ATAXIAS

A significant proportion of childhood-onset or young-adult–onset ataxias remain unresolved at a molecular level. Koenig and coworkers have localized the gene for a syndrome comprising ataxia, neuropathy, cerebellar atrophy, and elevated creatine kinase levels to chromosome 9q33.3-34.3. They have also localized another disorder, involving ataxia, deafness, and optic atrophy, to chromosome 6p21-23.[21] Other investigators have described a childhood-onset ataxia with deficiency of coenzyme Q10 levels in muscle.[22]

The combination of youth-onset ataxia and myoclonus or myoclonic seizures can be seen under a variety of circumstances. The term Ramsay Hunt syndrome is loosely applied to this entity. One disorder that has this combination of features is Unverricht-Lundborg disease, which has been linked to mutations in the *cystatin B* gene.[23] Some patients with Ramsay Hunt syndrome may have defined diseases such as ceroid lipofuscinosis, sialidosis, and mitochondrial cytopathies.

The term early-onset ataxia with retained tendon reflexes was coined by the English neurologist Anita Harding in 1981 to describe children with progressive ataxia resembling FA, except for the retention of reflexes. Many of these patients are now known to harbor the FA mutation. In others, the genotype is still unknown. It is also known that a small minority of patients with the typical FA phenotype do not carry the FA mutation.[24]

Autosomal Dominant Ataxias

The autosomal dominant ataxias [*see Table 2*] are genetically heterogeneous but share many clinical features. Therefore, precise identification of the underlying genotype on the basis of clinical features alone can be difficult. A clinical diagnosis is often helped by examining several affected family members to assess the degree of phenotypic variability in the same family. Autosomal dominant ataxias with a progressive course are labeled SCA, for spinocerebellar ataxia, followed by a number that denotes the specific gene locus involved. The SCA nomenclature is administered by the Human Genome Organization [*see Sidebar* Selected Internet Resources for Information on Ataxias].

GENETICS AND PATHOGENESIS

Most of the autosomal dominant progressive ataxias elucidated to date are related to unstable expansions of repeated nucleotide sequences [*see Table 2 and Figure 1*]. A CAG expansion in the coding region of the gene occurs in SCA1, SCA2, SCA3, SCA6, SCA7, SCA17, and dentatorubral pallidoluysian atrophy (DRPLA).[25-28] These are all examples of polyglutamine disorders, because CAG codes for glutamine. A CAG expansion in the promoter region of the gene occurs in SCA12.[29] SCA8 has been related to a CTG expansion in an untranslated region of the gene[30] and SCA10 to a pentanucleotide repeat expansion.[31]

The CAG expansion disorders share certain features. The age at onset is typically inversely correlated with the number of CAG repeats in the expanded allele. In addition, the degree of expansion also correlates, to some extent, with rates of disease progression and some of the phenotypic features. Thus, larger expansions may result in more rapid loss of neuronal function and more widespread neuronal pathology. The normal alleles in these disorders are stable on intergenerational transmission. The expanded alleles are often unstable, and further expansion is more likely than contraction. Expansion of the repeat is more likely to occur with paternal inheritance than with maternal inheritance, and it often is of larger magnitude with paternal inheritance; this accounts for some of the anticipation (i.e., observed onset at a progressively earlier age in successive generations) in these disorders.

The genes with CAG expansions that are mutated in the autosomal dominant ataxias are widely expressed in neuronal and nonneuronal tissues. Such dominant ataxias are classified among the polyglutamine disorders because the CAG tract is translated into a polyglutamine stretch in the corresponding protein. There is increasing evidence that the polyglutamine disorders are related to the acquisition of an abnormal toxic property (gain of function) by the protein product of the

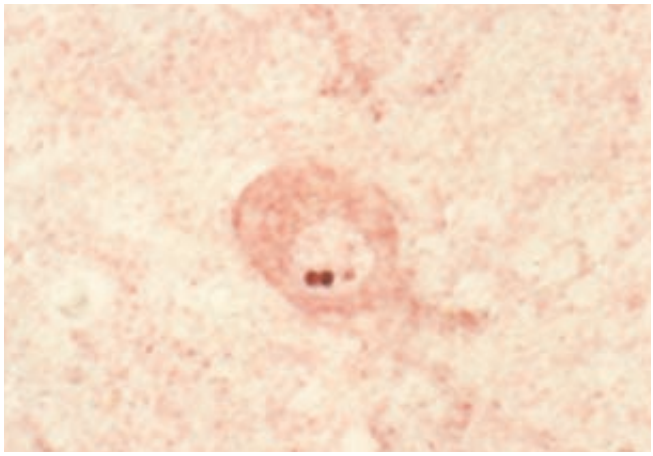

Figure 2 **Aggregates of ataxin 3 are visible within the nucleus of a pontine neuron from a patient with Machado-Joseph disease.**

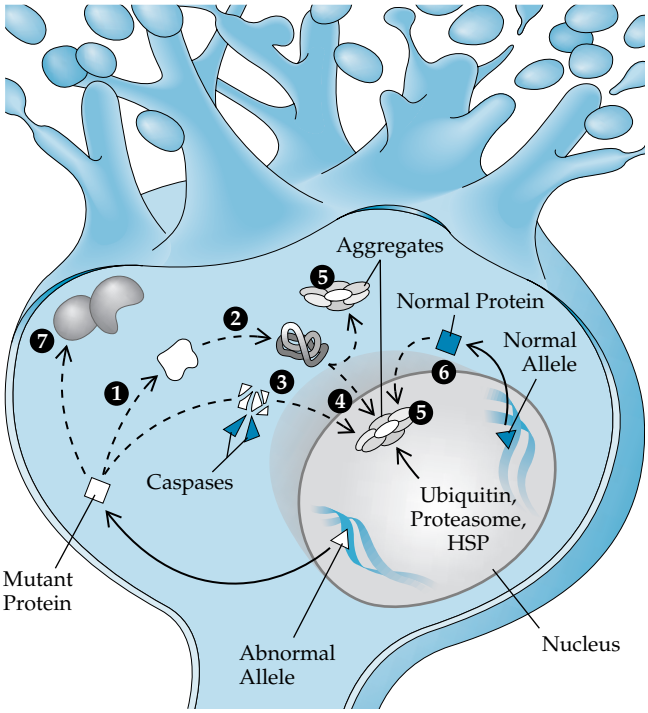

Figure 3 **Schematic picture of some of the proposed pathogenic mechanisms in the polyglutamine ataxias. The abnormal allele (Δ) is translated into a protein with abnormal molecular weight (□). The mutant protein with an excess number of glutamine molecules may have an altered conformation (1), allowing misfolding (2) and perhaps cleavage by caspases (3). The entire mutant protein or cleaved fragments may enter the nucleus and form aggregates (4) or may aggregate in the cytoplasm (5). These aggregates often recruit ubiquitin, proteasome, and components of the heat shock protein (HSP) chaperone system, suggesting misfolding and attempts at proteolysis. The product of the normal allele may also be recruited into these aggregates (6). The presence of mutant protein in the nucleus may alter expression of other genes essential for neuronal function. Abnormal interaction of mutant protein with other proteins (7) may account for some of the specificity of neuronal loss.**

mutated allele. Most of the gene products related to the CAG-expansion disorders are novel proteins of unknown function. Normally, many of these proteins are distributed diffusely in the cytoplasm and are variably present in the nucleus.

Both the messenger RNA (mRNA) and the protein corresponding to the normal and the expanded alleles can be detected in the tissues of the affected persons. In contrast to the diffuse localization of the normal protein, neurons in patients with the disease tend to show aggregates of the mutated protein, mostly within neuronal nuclei [*see Figure 2*] but also in the cytoplasm and in the neurites. The role of these nuclear inclusions (NIs) in the pathogenesis of the dominant ataxias is debated [*see Figure 3*]. However, many observations have been made, such as the following[25-27]:

1. NIs can be identified in many transgenic and transfection models of the ataxias.
2. NIs can be dissociated from the pathology; thus, genetic engineering can abolish the presence of NIs without reducing the pathology; this has been documented for SCA1.
3. In SCA1, preventing nuclear entry of mutated protein can prevent pathology.
4. Truncated constructs of the gene resulting in fragments of the protein containing the polyglutamine tract can often be more toxic than full-length protein.
5. Caspases may be involved in the generation of such truncated version of the proteins in vivo.
6. NIs usually recruit many other proteins; the presence of proteins belonging to the heat shock protein (HSP) chaperone system suggests that the mutated polyglutamine protein assumes a misfolded configuration. Also, the presence of proteins belonging to the ubiquitin-proteasome pathway in the NI indicates attempts at removing the aggregated protein. Manipulation of both the HSP and the ubiquitin paths can alter the intensity of NI and sometimes the pathogenic severity.
7. The aberrant interaction of the mutant protein in the nuclear context may alter many essential nuclear functions. Many of the mutant proteins can bind transcription factors such as the cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB)–binding protein (CBP). Others have RNA-binding activity. Such interaction may result in upregulation or downregulation of other important genes that can have pathogenetic implications.

The mechanism of disease in the nonpolyglutamine ataxias is still poorly understood. In the case of SCA8, the CTG expansion in the 3′ untranslated region of the gene may result in aberrant RNA activity that could be lethal to neurons.[32] In SCA6 and the episodic ataxia (EA) syndromes, which are related to mutations in channel proteins, abnormal electrical properties of the mutated channel may have a role.[33] Lastly, recent reports have identified point mutations in genes encoding protein kinase C-γ (in SCA14), as well as fibroblast growth factor 14, as causes of progressive spinocerebellar ataxias.[34,35]

DIAGNOSIS

Clinical Features

Patients with autosomal dominant ataxia present with progressive gait problems, dysarthria, and occasionally diplopia.[36-38] In addition to having cerebellar signs, these patients exhibit a variety of other neurologic deficits. As the disease progresses, eye-movement abnormalities such as gaze paresis, lid retraction, and blepharospasm, as well as bulbar signs such as facial and temporal atrophy, facial fasciculations, and mild tongue atrophy, may occur. Many of the disorders are associated with upper motor neuron signs such as brisk deep tendon reflexes, spasticity, and extensor plantar responses. Some of the genotypes are associated with basal ganglia signs such as an akinetic rigid syndrome, dystonia [*see Figure 4*], and choreoathetosis. Involvement of peripheral nerves can be found in the form of distal sensory loss and areflexia, as well as amyotrophy, fasciculations, and cramps. Tremor resembling essential tremor and torticollis can occur in some cases. Cognitive changes, seizures, and myoclonus reflect cortical pathology. Evidence of retinal disease occurs in certain genotypes. Patients typically lose ambulation 10 to 15 years after onset and, at this stage, develop increasing dysphagia; some may have urinary incontinence.

The EA syndromes cause intermittent episodes of ataxia; these are very short-lived (minutes) in EA-1 and longer (hours) in EA-2. Interictally, EA-1 can be associated with

Figure 4 **Dystonia in a patient with Machado-Joseph disease.**

skeletal muscle myokymia and EA-2 with nystagmus. The EA-2 phenotype can be variable and may be similar to SCA6 and may be associated with migraine (both SCA6 and familial hemiplegic migraine are allelic to EA-2).

The various autosomal dominant ataxias are marked by phenotypic differences [*see Table 4*]. It should be stressed, however, that phenotypic features alone are often insufficient to permit diagnosis of the genotype in individual patients. Within specific genotypes, the phenotype may vary significantly. In many instances, this variance is related to the duration of disease; however, the variation in the number of nucleotide repeats from generation to generation can influence the phenotype. Thus, in all CAG repeat disorders, there is an inverse relationship between the age at onset and the size of the expanded allele. Other modifier genes that can influence the phenotype are currently the focus of considerable interest.

Table 4 Phenotypic Features That May Indicate a Specific Genotype in Autosomal Dominant Ataxias

Phenotypic Feature	*Disorders*
Age at onset	Young adult: SCA1, SCA2, MJD
	Older adult: SCA6
	Childhood: frequent in SCA7/DRPLA
Degree of anticipation	More in SCA7, DRPLA
Benign course	SCA6
Upper motor neuron signs	SCAs 1, 7, and 8; MJD; rare in SCA2
Akinetic-rigid/Parkinson signs	MJD, SCA2, SCA17
Chorea	Prominent in DRPLA; late in SCA2, SCA1, MJD
Action tremor	SCA12, SCA16
Very slow saccades	Early in SCA2, SCA7; late in SCA1, MJD; never in SCA6
Downbeat nystagmus	SCA6, EA2
Generalized areflexia	SCA2, SCA4, older adult–onset MJD
Visual loss	SCA7
Seizures	SCA10, early-onset DRPLA, SCA7

DRPLA—dentatorubral pallidoluysian atrophy EA—episodic ataxia
MJD—Machado-Joseph disease SCA—spinocerebellar ataxia

Table 5 Normal and Expanded Range of Various Repetitive Nucleotide Sequences in Inherited Ataxias

Disease	*Repeat*	*Normal*	*Intermediate*	*Expanded*
SCA1	CAG	6–44		39–82[1]
SCA2	CAG	14–31	32–33	33–64
MJD	CAG	12–40		54–86
SCA6	CAG	4–18		19–30
SCA7	CAG	4–27	28–36	37–200
SCA8	CTG	16–91		107–127[2]
SCA10	ATTCT	10–22		1,000–4,500
SCA12	CAG	< 29		66–78
SCA17 (*TBP* gene)	CAG	25–44		50–63

Note: Pathogenic and nonpathogenic alleles of the same size can be distinguished by the presence of CAT interruptions in the latter. The test for CTG expansion in SCA8 has to be interpreted with caution; whether the CTG expansion is the specific cause for ataxia in SCA8 has been debated, because in many instances this expansion has been found in patients with unrelated disorders. Yet at least in one large family, the repeat expansion was significantly associated with ataxia.

MJD—Machado-Joseph disease SCA—spinocerebellar ataxia
TBP—TATA-binding protein

Laboratory Studies

Imaging studies typically show either isolated cerebellar atrophy (in SCA6 and other disorders with a so-called pure cerebellar presentation) or pontocerebellar atrophy (in SCA1, SCA2, SCA3, SCA7). Individual genotypes cannot be distinguished by imaging studies alone. T_2-weighted images may show increased signal density along the pontocerebellar fibers.

Nerve conduction studies often show evidence of an axonal neuropathy in some disorders (SCA 1 through 4). Brain stem evoked potentials are abnormal in the disorders associated with brain stem pathology. Abnormal results on electroretinography can antedate visual loss in patients with SCA7.

Molecular tests are now available for SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, SCA10, SCA12, SCA17, and DRPLA [*see Table 5*]. Gene tests are possible for the EA syndromes but involve sequencing or similar tests that are technically more difficult; these diseases are better diagnosed by clinical and biochemical parameters.

Differential Diagnosis of Inherited Ataxias

In patients presenting with progressive ataxia, a number of acquired disorders need to be excluded by appropriate imaging and laboratory studies. These disorders include vascular problems such as infarcts or malformations; tumors; demyelinating disease; paraneoplastic cerebellar degenerations; hypothyroidism; and cerebellotoxic disease, such as that related to alcohol, antiepileptic drugs, and cytosine arabinoside. Other possible immune etiologies for ataxic disorders have been proposed, including antibodies against glutamic acid decarboxylase and gliadin. Lastly, in a substantial number of patients, a definitive genetic or environmental cause cannot be established. Such patients are diagnosed as having late-onset sporadic or idiopathic ataxia.

In young adults or children, genetically determined metabolic errors may have ataxia as a dominant clinical fea-

ture. These disorders need to be excluded when appropriate. Examples of such diseases are Wilson disease, cerebrotendinous xanthomatosis, abetalipoproteinemia, some of the leukodystrophies and gangliosidoses, sialidosis, ceroid lipofuscinosis, carbohydrate-glycoprotein deficiency syndromes, and giant axonal neuropathy.

Management of Inherited Ataxias

Currently, no specific interventions are available for most of the inherited ataxias. The possible treatment strategies in FA have been discussed (see above). When specific biochemical defects are identified, these can possibly be corrected—for example, with vitamin E supplements in AVED, other vitamin therapy, or dietary manipulations. The episodic ataxias (EA-1 and EA-2) often respond to acetazolamide.

The progressive ataxias are treated by rehabilitative measures such as assistive equipment, home modification, dysphagia treatment, and physical therapy. Several symptoms may need to be treated, including depression, anxiety, and pain.

Genetic counseling is important. In the dominant ataxias, offspring of affected persons have a 50% risk of developing the disease. When the molecular defect in the family is known, predictive testing can be performed. The guidelines used for Huntington disease are usually adopted for this purpose.[39]

XI ALZHEIMER DISEASE AND OTHER MAJOR DEMENTING ILLNESSES

David S. Knopman, m.d.

Alzheimer Disease

definition

Alzheimer disease (AD) is histopathologically defined by neurofibrillary tangles and neuritic plaques in the cerebral cortex. AD is also commonly used as a clinical diagnosis for a dementia syndrome in which anterograde amnesia is a dominant symptom. The most common pathologic basis for the clinical syndrome AD is indeed the pathologically defined disease AD.

A person with the dementia of AD experiences a loss of cognitive function that interferes with social or occupational activities and generally results in a dependence on others for carrying out at least some necessary daily affairs. In the language of the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition:* "The cognitive deficits cause significant impairment in social and occupational functioning and represent a significant decline from a previous level of functioning."[1] The decline from a previously higher level of functioning distinguishes dementia from developmental delays or mental retardation. The sensorium (i.e., the person's level of arousal and alertness) is unaffected in dementia. This feature distinguishes dementia from delirium, in which cognition is impaired in the setting of an altered sensorium.

As defined, dementia is impairment of more than one area of cognitive function. In the dementia syndrome of AD, therefore, anterograde amnesia must be accompanied by impairment of at least one of the following: language, abstract reasoning, executive functioning, and visuospatial processing. The most widely used definition of AD is that based on criteria established by the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer Disease and Related Disorders Association (NINCDS-ADRDA) work group[2] [*see Table 1*].

The pivotal cognitive finding in AD is anterograde amnesia, which is an inability to learn new things. Persons with anterograde amnesia typically cannot keep track of the date, remember recent conversations, or remember where they set something down; and they often repeat themselves in conversation. Although these types of difficulties are commonly described as short-term memory loss, the key difficulty in anterograde amnesia of AD is in acquiring or learning new information. Failure to learn results in difficulties recalling related information a few minutes later. AD is not a generalized disorder of recall, however, because early in the disease—especially, but even into its moderate stages—persons with AD can retrieve and recall learned information from the remote past.

epidemiology

The prevalence of AD is approximately 8% of the United States population older than 65 years.[3] Approximately two to three million persons in the United States have AD; estimates vary somewhat because of different case definitions used.[3] If very mild AD cases are included, the number of affected persons exceeds four million.[4] The prevalence is strongly age related [*see Figure 1*]: AD is uncommon in persons younger than 65 years, but prevalence doubles every 5 years from then on. As many as 30% to 40% of persons older than 85 years have AD.

The incidence of AD mirrors the prevalence, being very low before 65 years of age and then steadily increasing into the 70s and 80s. By the age of 80, the annual incidence of AD approaches two per 100 persons. There is some controversy regarding the incidence of AD in the 10th and 11th decades of life; it probably continues to rise, but the methodology and numbers of cases at the extremes of life expectancy make for uncertainty.

There is also controversy as to whether women are more commonly affected than men. Most studies of prevalence and incidence show that women are slightly overrepresented. The difference is small, however, and could be an artifact of the overall lower life expectancy of men.[5] Emerging studies of dementia in African Americans[6] and Japanese Americans[7] suggest that there are no ethnic differences in the prevalence or incidence of AD.

protective and risk factors

Several factors appear to alter the risk of developing AD. The most prominent risk factors for AD are advancing age and a family history of dementia. Cardiovascular disease[8] and diabetes mellitus[9] both appear to be associated with an increased risk of AD. Elevated levels of homocysteine also are associated with a higher risk of AD.[10]

Table 1 Criteria for the Clinical Diagnosis of Alzheimer Disease*

A. Evidence from the history and mental-status examination that indicates a disorder characterized by major impairment of learning and of retaining new information, as well as at least one of the following:
   1. Impairment in handling complex tasks
   2. Impairment in reasoning ability
   3. Impaired spatial ability and orientation
   4. Impaired language

B. The disturbances listed under A above significantly interfere with work or usual social activities or relationships with other people.

C. The disturbances represent a significant decline from a previous level of functioning.

D. The disturbances are of insidious onset and are progressive, based on evidence from the history or serial mental-status examinations.

E. The disturbances are not occurring exclusively during the course of delirium.

F. The disturbances are not better accounted for by a major psychiatric diagnosis.

G. The disturbances are not better accounted for by a systemic disease or another brain disease.

*These criteria are based on the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer Disease and Related Disorders Association work group report[2] and the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*.[1]

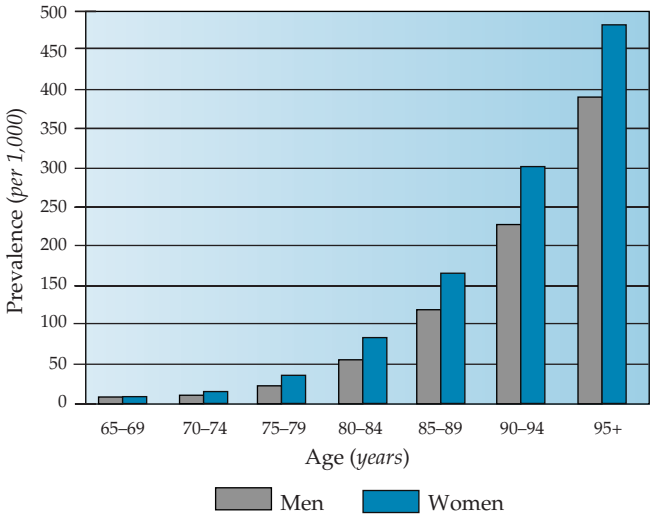

Figure 1 **Prevalence of Alzheimer disease per 1,000 population, by gender and age.**

Use of certain medications is associated with a lower risk of developing AD. These include estrogen, the statin-type cholesterol-lowering drugs, and nonsteroidal anti-inflammatory drugs (NSAIDs). For estrogen and the NSAIDs, medication use was assessed when persons were not demented, a methodological strategy that strengthened the belief that the observed reduction in risk was not an artifact of the appearance of early AD. Unfortunately, subsequent clinical trials of estrogen[11] and NSAIDs[12] in AD patients, as well as a very large prevention study using estrogen and progesterone,[13] have uniformly failed to show evidence of benefits for either class of drug. On the basis of the same types of observations,[14] clinical trials with statins in AD are under way. The disappointing study conclusion with estrogen and NSAIDs is that epidemiologic associations do not automatically translate into successful therapeutic interventions.

Level of educational attainment and intellectual performance in childhood also appear to be related to the risk of developing AD in later life. In a study of persons who took academic achievement tests at 11 years of age and then were evaluated in adulthood for dementia, there was a notable association between higher scores at age 11 and a lower likelihood of developing AD in later life.[15] Similarly, a study of elderly Catholic nuns who had written autobiographies when they entered the order, at approximately age 20, showed that the nuns with better vocabularies and syntactic abilities when young had a lower likelihood of developing AD in later life.[16] Many other studies have observed that educational attainment seems to be inversely related to the risk of AD, though questions have been raised as to whether the so-called education effect is actually of socioeconomic origin.[17]

GENETICS AND MOLECULAR BIOLOGY

The genetic basis of AD can be divided into four profiles: (1) the very rare autosomal dominant forms of AD; (2) the more common, later-onset form of AD, in which family history exerts a modestly strong risk; (3) sporadic AD, which comprises the majority of AD patients, including both early-onset and, especially, late-onset forms that appear to be nongenetic; and (4) persons with Down syndrome (trisomy 21).

The number of persons with autosomal dominant AD is infinitesimal compared with the large number of persons with late-onset sporadic AD. The autosomal dominant families have been pivotal, however, in providing insights into the mechanisms of the disease. In general, affected individuals in autosomal dominant AD families experience dementia in their 30s to 60s; the genetic disorder advances the age of onset of AD by roughly 2 to 3 decades relative to sporadic AD.

Three genes have been implicated in autosomal dominant AD. One is the amyloid precursor protein (*APP*) gene, on chromosome 21, which encodes the amyloid-β peptide [*see Figure 2*]. The amyloid-β peptide appears to be a key pathogenic molecule. Only a handful of families in the world harbor the mutations in this gene that cause AD. The other two genes involved in autosomal dominant AD are homologous; the much more common of the two is the presenilin-1 (*PS-1*) gene, located on chromosome 14. Approximately half of the few hundred autosomal dominant AD families have disease linked to mutations on chromosome 14.[18] The less common homologue, presenilin-2 (*PS-2*), is encoded by a gene on chromosome 1.[19] Families with the *PS-2* mutation are almost exclusively of one ethnic group—Germans whose ancestors emigrated to the western United States and Canada after a sojourn of a few hundred years in the Volga River area of Russia. The mutation is thought to have resulted from a founder effect, which propagated by virtue of the cultural isolation in a foreign land of this group of people.

In addition to the rare autosomal dominant families, a family history of AD, even of later onset, is a consistent risk factor for the disease.[20] One early study showed that the risk of AD in siblings of probands with autopsy-proven AD rose to nearly 50% by age 85 if two features were present: the presence of dementia in another first-degree relative and an age of onset under 70 years in the proband.[21] Subsequently, as families with late-onset AD were studied genetically, the apolipoprotein E (*APOE*) gene was found to account for a substantial fraction of the familial risk in late-onset AD.[22,23] The *APOE* gene has three allelic variations (ε*2*, ε*3*, and ε*4*) in humans, as a result of polymorphisms in two nucleotides. The *APOE* ε*4* allele is strongly associated with the development of AD at an earlier age than in non-ε*4* carriers.[24] However, the presence of an *APOE* ε*4* allele does not guarantee the development of AD in *APOE* ε*4* carriers, and its absence does not protect against AD in *APOE* non-ε*4* carriers.[25] There are no clinical differences between AD patients with and AD patients without the *APOE* ε*4* allele. No other gene has been linked definitively to risk of AD. Although there is intense interest in a region on chromosome 10, the exact gene has not been identified.

Progress in defining the molecular biology of AD has provided the framework for understanding the probable pathophysiologic pathways that lead to AD [*see Figure 2*]. In essence, the so-called amyloid hypothesis of AD asserts that the amyloid-β peptide is toxic either to neurons or to synaptic function in a dose-dependent fashion.[26,27] According to this theory, excess production or reduced clearance of the amyloid-β peptide will lead to AD, and the higher the amyloid-β peptide load, the earlier the onset of the dementia. Individuals with Down syndrome also exhibit AD pathology 3 to 4 decades earlier than that which is seen in patients with sporadic AD, presumably because of the extra chromosome 21 that contains the wild-type *APP* gene. The *APP* gene mutations lead to overproduction of the amyloid-β peptide because the mutations upset the balance of the three secretases involved in APP metabolism. The *PS-1* and *PS-2* genes appear to play an integral role in the action of one of those secretases, the γ-secretase. The mutations in *PS-1* and *PS-2* result in a

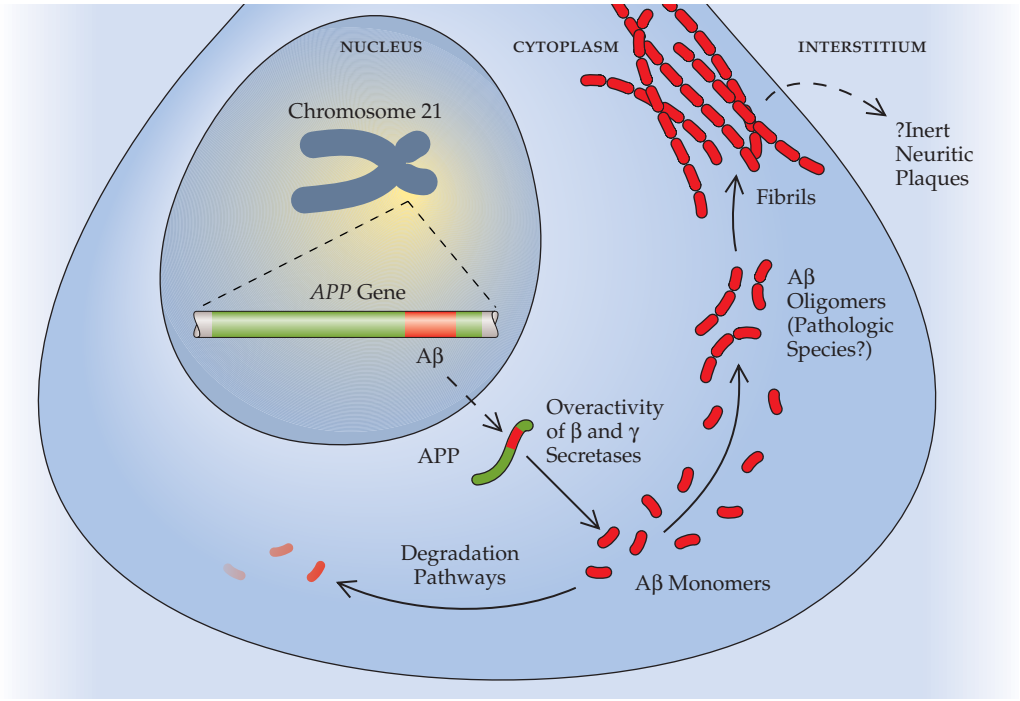

Figure 2 **Schematic overview of the amyloid-β peptide production pathway. The Alzheimer precursor protein (APP) is encoded by a gene on chromosome 21. Under certain circumstances, presumably involving relative overactivity of β and γ secretases compared with α secretase, the amyloid-β peptide is produced. It may assemble itself into dimers, trimers, or other oligomers, which are thought to be cytotoxic. Eventually, the oligomers polymerize into fibrils and, later, into plaques.[3]**

heightened activity of γ-secretase that also leads to excess production of the amyloid-β peptide. Individuals with the *APOE ε4* allele also have excess amyloid-β peptide in their brains, but the precise mechanism by which the *APOE* genotype modifies the molecular biology of AD is still a matter of debate.

PATHOPHYSIOLOGY

The brain of a patient who has died with the dementia syndrome of AD will usually show gross atrophy of the cerebral hemispheres, particularly in the posterior half of the brain. Microscopic examination of the brain is required to make a definitive diagnosis of AD, however.

There are two principal histologic findings in AD. The first is the neuritic plaque. Neuritic plaques are extracellular structures that contain a core made up of the amyloid-β peptide and surrounded by degenerated axonal and dendritic elements of many neurons [*see Figure 3*]. They can be imaged with routine hematoxylin and eosin staining, but they are best seen with silver stains. Neuritic plaques may be present in very small numbers in nondemented elderly persons, but in the typical patient with AD, neuritic plaques are numerous[28] and are located in many parts of the cerebral cortex.[29]

The genesis of neuritic plaques is better understood than it once was, but there are still gaps in the described pathway between an excess of the amyloid-β peptide and the appearance of neuritic plaques. It is currently believed that the amyloid-β peptide polymerizes and that the oligomer consisting of a few copies of the amyloid-β peptide is neurotoxic. Presumably, the amyloid-β peptide oligomers continue to aggregate and eventually form the amyloid core of the neuritic plaques. Many experts believe that the oligomeric form of the amyloid-β peptide is the key pathogen in AD[30] and that the neuritic plaques merely represent the end stage of the pathologic process.

The other principal histologic feature in AD is the intracellular neurofibrillary tangle [*see Figure 4*]. Neurofibrillary tangles are found inside neurons and consist of a protein known as tau that has been pathologically modified so that it has polymerized into an insoluble form that assembles itself into filaments. Neurofibrillary tangles may be seen in nondemented elderly persons in the entorhinal cortex and even in the hippocampus, but when neurofibrillary tangles are found in larg-

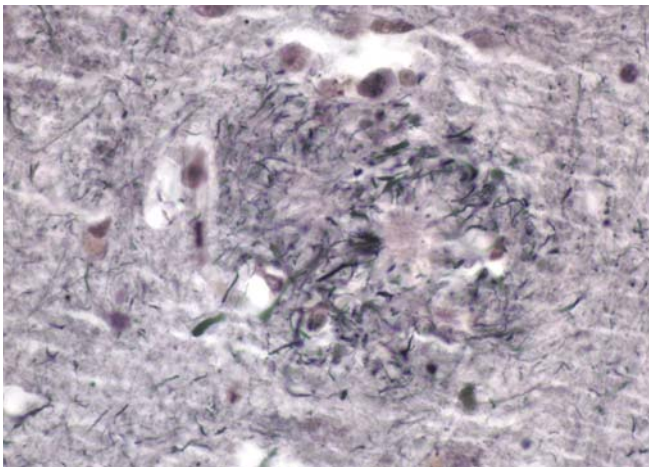

Figure 3 **Photomicrograph of a neuritic plaque in the cortex of a patient with Alzheimer disease.**

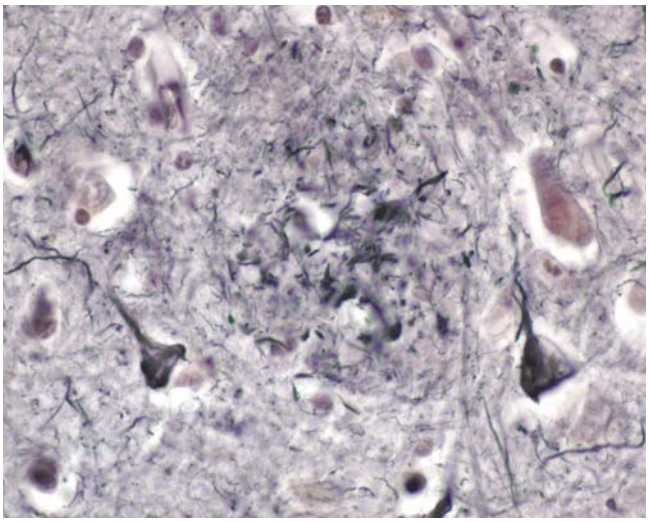

Figure 4 **Photomicrograph of several neurons containing neurofibrillary tangles from the cortex of a patient with Alzheimer disease.**

er numbers in the neocortex of the temporal or parietal lobes, the person will almost invariably have had AD dementia.[29,31]

The tau protein is the most important molecule in neurofibrillary tangles. It is ordinarily involved in stabilizing the cytoskeletal elements in neurons (i.e., the microtubules). In AD, tau becomes excessively phosphorylated and aggregated.[32] Curiously, despite the discovery of mutations in the *tau* gene that cause other forms of dementia, no *tau* gene mutations have been associated with AD. It seems most likely that formation of neurofibrillary tangles represents a technically normal but ultimately disastrous response to injury caused by the amyloid-β peptide. The amyloid-β peptide induces excessive phosphorylation of tau protein, which destabilizes microtubules and leads to aggregation of hyperphosphylated tau into fibril.[33]

DIAGNOSIS

Clinical Manifestations

The dementing illness in AD is almost always very gradual and insidious in its onset. Typically, once the condition is diagnosed, changes in memory and daily functioning will have been evident for at least a year, if not 2 or 3 years. Once the dementia is diagnosed, the clinical course usually plays out over 3 to 7 years before severe dementia becomes present.[34] The median duration from the onset of symptoms to death is approximately 7 years.[35,36] It is longer in younger patients and somewhat shorter in patients who are in their 80s and 90s.

The earliest clinical manifestations of AD typically involve problems related to the anterograde amnesia (i.e., the short-term memory difficulties). Persons with AD often experience short-term memory loss as the only difficulty for several years. This condition is referred to as mild cognitive impairment (MCI). MCI is recognized as a risk state for the subsequent development of AD.[37] Patients who eventually develop AD always pass through a stage of MCI, if only briefly, but not all patients with MCI inevitably go on to develop dementia.

One of the most frustrating and challenging aspects of the evolution of the clinical syndrome of AD is the gradually intensifying loss of self-awareness and insight.[38] This is referred to as anosognosia, a loss of awareness of one's deficits. AD is almost unique among medical conditions in that patients themselves are usually not instrumental in bringing their problem to medical attention. Affected persons will sometimes articulate concerns about their memory, but family members are the ones who force the issue in the majority of instances.

The anterograde amnesia of AD typically manifests itself in the daily affairs of the patient as a difficulty in recalling recent events and conversations, a tendency to repeat oneself in conversation, and a difficulty in keeping track of the date. At first, these behaviors may be intermittent or may appear only during times of stress or when the person is taken out of his or her usual routines. Gradually, as the condition progresses, the instances of forgetfulness become more frequent and lead to mistakes in daily affairs. These errors may include forgetting appointments, difficulties in shopping, and problems in following multistep instructions (e.g., recipes) or in following directions while traveling.

During the early evolutionary phases of the dementia, other cognitive deficits begin to emerge and intrude into daily affairs. These deficits may include a loss of facility with common words or a difficulty with remembering names of family and acquaintances. Other developments include a reduced ability to solve common household or daily problems; reduced ability to manage financial affairs; and greater difficulty in planning a meal, a family gathering, or a trip. Difficulties with planning, mental agility, problem solving, and abstract reasoning are sometimes referred to as executive dysfunction. Geographic disorientation is also a feature of emerging dementia from AD, and it manifests itself as getting lost in what was once familiar territory. A typical story is that the patient sets out by automobile to visit a friend but becomes confused about the way to get there. Patients will sometimes drive around for hours trying to reorient themselves; in other instances, they will simply give up and try to return home.

As the dementia continues to emerge, changes in behavior and mood often occur, but not always. A loss of interest in previously enjoyed pastimes and a loss of interest in family affairs are manifestations of the apathy and loss of initiative that are common in early AD. Less commonly, the person experiences substantial alterations in mood, such as tearfulness, melancholia, or anxiety. Interestingly, depression is less common than might be predicted, perhaps because of the concomitant loss of insight that accompanies early AD dementia.[39]

The progression of AD from mild to severe has been characterized by a number of different staging systems. Most systems define mild AD as that stage in which patients can care for their basic needs and still carry out some activities, such as simple hobbies and participation in social activities. Severe dementia is usually defined as the point at which the loss of ability to manage basic activities of daily living (e.g., bathing, dressing, toileting, or eating) becomes evident. The progression of the symptoms of AD varies tremendously from one person to the next.

Another way of characterizing the symptoms and the progression of AD is by assessments of mental functioning. Such assessments can be done either by a primary care physician in the routine office setting or by a neuropsychologist in a special laboratory. The two methods are concordant and rely on the same principles of assessment of cognitive abilities. The neuropsychological approach is more time consuming, but as a consequence, it provides a more detailed view of the patient's cognitive functioning.

Mental-Status Examination

The mental-status examination is a cornerstone of the diagnosis of AD. The Mini-Mental State examination (MMSE) is widely

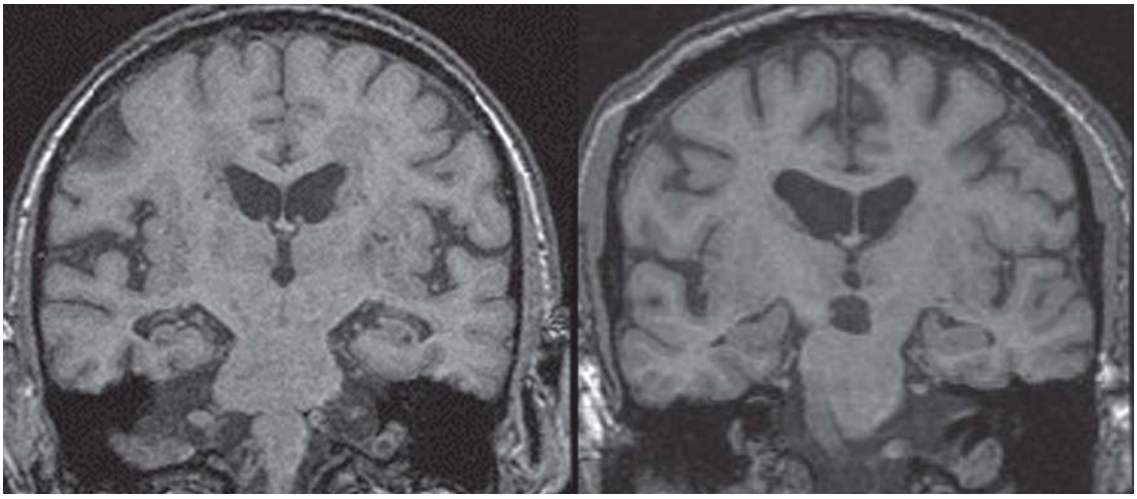

Figure 5 **Coronal MRI scan demonstrating hippocampal atrophy in a patient with clinically diagnosed Alzheimer disease (left), compared with a scan of a normal person of comparable age (right).**

used and has norms for age and education.[40] It consists of questions assessing orientation and includes evaluations of language, visuomotor function, mental agility, and delayed recall. Although the MMSE lacks sensitivity for detecting mild cognitive dysfunction, it is a very effective tool for clinicians. At the Mayo Clinic, we have been using the short test of mental status instead, because it was constructed to be more sensitive to early dementia.[41] The two examinations are highly correlated. With either test, clinicians can gain an objective view of the patient's cognitive function. Typically, patients with early AD make one or two errors on orientation to time or place and fail to recall any items specifically presented to be remembered a few minutes later, but they make no errors on reading, writing, naming simple items, or following multistep commands. As the dementia of AD progresses, performance on the mental-status examination steadily declines. On the MMSE, AD patients lose an average of three points a year. However, the range of performance from one year to the next in a particular patient can vary considerably, from no loss of points to a loss of six or seven points.

Clinical Assessment

The diagnosis of AD remains a clinical one that is based on the history, mental-status examination, remainder of the neurologic examination, and general physical examination.[42] There is no laboratory marker for AD that is sufficiently accurate to replace or supersede the judgment of an experienced physician. The physician weighs the evidence from the history of cognitive decline and judges that history in the light of the mental-status examination. To make a diagnosis of AD dementia, the history of cognitive decline and the findings on the mental-status examination should be concordant. When the history strongly suggests a cognitive disorder but the mental-status examination result is normal, it is still possible that one could be dealing with a very early case of AD, especially in a highly educated person. When the result of the mental-status examination is quite abnormal but family members say that the patient has not had difficulties with daily functioning, AD must also be considered, although delirium or a rapidly progressive disorder may be more likely. Family members sometimes understate the degree of impairment of a loved one because of lack of observation, denial, or lack of sophistication.

Laboratory Testing

Laboratory testing has a role in the assessment of dementia patients even when AD seems most likely on clinical grounds.[42] Blood tests such as a complete blood count and measurements of electrolytes, calcium, urea nitrogen, thyrotropin, and vitamin B_{12} are needed to rule out previously overlooked metabolic or hematologic derangements. Screening for neurosyphilis can be considered in regions where primary or secondary syphilis is seen with any frequency. Although none of these tests are particularly sensitive or specific for a commonly encountered dementing illness, they are simple and inexpensive tests and help exclude common general medical conditions. Examination of the cerebrospinal fluid, a urinalysis for detection of toxins, and electroencephalograms are not needed except when specific indications exist.

Imaging Studies

Brain imaging is necessary for the initial diagnostic evaluation of demented patients. A brain CT scan may be adequate, but an MRI scan without contrast enhancement will yield more clinically useful information. The fundamental purpose of a brain-imaging study is to rule out space-occupying lesions such as tumors and subdural hematomas. MRI is becoming increasingly useful for assessing the burden of cerebral infarcts, as well. Elderly persons are at increased risk for small infarcts in deep brain structures that may occur covertly.[43]

MRI can also detect hippocampal atrophy when imaging is performed in a plane perpendicular to the axis of the temporal lobe[44] [*see Figure 5*]. Hippocampal atrophy is commonly seen in AD, but this finding is suggestive rather than diagnostic of AD because it is also seen both in normal elderly patients and in those with other dementing illnesses.

Positron emission tomography (PET) that uses fluorodeoxyglucose as a tracer may show reduced metabolic activity in the temporoparietal regions in AD,[45] but it is not clear whether this technique augments the clinical diagnosis. A PET tracer known as Pittsburgh compound B (PIB) has been shown to label brain amyloid in patients with AD. Studies are under way to determine whether PET imaging using PIB is of value in the diagnosis of AD.[46]

Evaluation of proteins in the CSF for the specific diagnosis of AD has been encouraging but has not yet reached the stage of definite clinical utility. Tests for three proteins—amyloid-β peptide,[47] tau,[47] and neural thread[48]—have shown modest sensitivity and specificity for differentiating AD from other conditions. However, in almost all instances, these tests have added little to the information derived from the clinical evaluation.

Genotyping of dementia patients for diagnostic purposes is not recommended at this time. Its additive value to the history and examination is quite modest.

DIFFERENTIAL DIAGNOSIS

When considering the diagnosis of dementia from AD, the clinician should first determine whether the patient's clinical profile fits that of dementia—that is, daily functioning has declined from a previously higher level and is now impaired. If the patient was cognitively intact at some earlier point, this eliminates developmental disorders such as mental retardation. The presence of broadly normal levels of arousal and attention excludes delirium. For dementia from AD, onset and progression should be gradual. The general time frame of onset of symptoms is at least 6 months; more often, it is a year or longer. More rapid onset of dementia (i.e., over weeks or months) raises the possibility of Creutzfeldt-Jakob disease [*see 11:XVII Central Nervous System Diseases Due to Slow Viruses and Prions*].

Seizures and headaches are not part of the initial presentation of AD dementia. A patient who presents with dementia, seizures, and headaches should receive a workup for a space-occupying lesion of the brain, such as a brain tumor, subdural hematoma, or CNS infection, all of which typically progress over days to weeks.

When clinical strokes precede dementia, particularly when a stroke occurred within 3 months before the onset of dementia, vascular dementia should be seriously considered. The possibility of vascular dementia also arises when imaging studies disclose bilateral gray-matter infarcts, even if the infarcts were not associated with overt clinical stroke. In patients lacking either of these features, vascular dementia is unlikely.

The presence of parkinsonism or other prominent disorders of motor function points to a diagnosis other than AD. Dementia with Lewy bodies should be considered in a person with Parkinson disease who develops dementia or in someone who initially has dementia and then begins to display signs of parkinsonism, such as a stooped posture and impaired gait and balance. Additional features that suggest dementia with Lewy bodies rather than AD are day-to-day fluctuations in alertness and a peculiar sleep disorder [*see* Dementia with Lewy Bodies, *below*].

The cognitive deficits necessary for making a diagnosis of AD include impairment of short-term memory and of at least one other cognitive domain. However, when disturbances of speaking or language predominate over short-term memory deficits, the diagnosis of progressive aphasia or a disorder known as semantic dementia should be considered. The diagnosis of frontotemporal dementia is suggested when changes in behavior, conduct, or personality overshadow memory difficulties.

In persons older than 60 years, AD constitutes 60% to 80% of all dementias.[49-51] Thus, with patients in this age range, it is reasonable to suspect AD unless some feature in the history or examination strongly points to another specific diagnosis. In contrast, the differential diagnosis of dementia in patients younger than 60 years is quite different. In younger patients, disorders involving altered metabolic pathways are more likely; these include mitochondrial diseases, Wilson disease, and metachromatic leukodystrophy. Diseases such as multiple sclerosis should be considered. In addition, the overlap between psychiatric diseases and dementia may be a prominent diagnostic challenge in younger persons, as may the overlap of substance abuse and progressive cognitive impairment.

TREATMENT

Therapy for AD can be primary or secondary. Primary therapies are intended to stabilize the core symptoms. Secondary therapies are intended to address such problems as depression, anxiety, sleep disorders, and agitation.

Primary Therapies

The cholinesterase inhibitors donepezil,[52] galantamine,[53] and rivastigmine[54] have been approved by the Food and Drug Administration for the treatment of AD. Clinical trials with each of these agents have shown that compared with no treatment, long-term use results in modest stabilization of cognitive and functional status for approximately 6 to 12 months. A particularly illuminating study was one in which patients with mild to moderate AD were randomly assigned to receive either donepezil or placebo for up to 1 year. The end point of therapy was the loss of a predefined degree of daily functioning. Whereas 51% of placebo-treated patients had lost a critical amount of daily functional ability after 12 months of treatment, only 38% of donepezil-treated patients did so.[55]

A 3-year study of donepezil in mild cognitive impairment showed that donepezil delayed progression to AD for about 1 year[56]; the magnitude of the drug's effect in mild cognitive impairment is comparable to that reported in studies on AD.

Side effects of the cholinesterase inhibitors are primarily gastrointestinal and consist of nausea; loss of appetite; diarrhea; and, less commonly, vomiting. These side effects are strongly dose related and often occur when the drugs are initiated or the dose is raised.

Patients with mild to moderate AD are the appropriate candidates for cholinesterase-inhibitor therapy. These patients need a designated caregiver to supervise the use of the medication. Treatment with the cholinesterase inhibitors should be maintained until the patient reaches a stage of severe dementia, in which further decline is expected.

Vitamin E is often recommended for patients with AD because a 2-year study of AD patients with moderate dementia showed that vitamin E (α-tocopherol, 2,000 IU a day) delayed the progression to severe dementia by about 200 days.[57] A study of the use of vitamin E in patients with mild cognitive impairment failed to show any benefits.[56] These results call into question the rationale for vitamin E treatment in patients with mild AD.

Memantine is now also approved by the FDA for the treatment of AD. This agent, a glutamate modulator that is a noncompetitive receptor antagonist of *N*-methyl-D-aspartate, has been the subject of several clinical trials that have reported positive results in moderate to severe dementia.[58,59] It is hypothesized that glutamatergic overstimulation is a part of the pathogenic cycle in AD. In the clinical trials, memantine delayed symptom progression. There is no evidence that memantine affects the biologic course of AD, however. Studies of patients with mild to moderate AD have been completed, but no results are yet available. The results of a study that paired memantine with donepezil suggest that patients with moderate to severe AD should receive both agents.[59]

The field of therapeutics in AD is rapidly evolving, but as yet, no agents in phase II trials about to enter the pivotal phase III trials have shown strong efficacy results. The use of secretase inhibitors involved in the production of the amyloid-β peptide are in early stages of development. A trial using the amyloid-β peptide as a vaccine was halted after serious toxicity emerged, but the general approach of an immunologic attack on the amyloid-β peptide is still receiving serious consideration.

Secondary Therapies

Treatment of depression or anxiety in patients with AD should be pursued as aggressively as in patients without AD, with adherence to the best practices of geriatric pharmacology. Depression frequently coexists with AD and contributes to morbidity and loss of function.[60] The newer agents, such as citalopram, paroxetine, sertraline, and mirtazapine, are generally well tolerated in dementia patients. Dosing can begin at a lower level than might be used in a young adult, and dose increases should be spaced further apart.

Treatment of anxiety presents somewhat more of a challenge in AD patients, because the agents commonly used in younger patients, the benzodiazepines, have distinctly unwanted side effects in AD patients. Drugs such as lorazepam and alprazolam can increase confusion in AD patients. The longer-acting agent clonazepam may be a better choice. Buspirone is another alternative for the treatment of anxiety in AD patients.

Treatment of agitation—which may manifest itself as physical aggressiveness, disruptive verbal agitation, or frightening or anxiety-provoking hallucinations—generally requires antipsychotics. Quetiapine has the significant advantage of being much less likely to induce extrapyramidal effects than both newer and older agents. One of the challenges in using any antipsychotic in elderly patients with AD is that a low dose must be used at initiation of treatment. Several dose increments may be needed to reach the effective therapeutic dose. Given the sometimes catastrophic nature of physical aggressiveness or severe hallucinations in AD patients, caregivers can easily and justifiably become frustrated if control of the symptoms is delayed. Unfortunately, an overly aggressive approach to antipsychotic use can lead to oversedation and serious side effects.

Caregiver Support

Support for the caregivers of AD patients must be an integral part of management. The emotional and physical health of caregivers is critical to long-term patient outcomes. Support may take the form of providing one-on-one education and encouraging participation in support groups, involvement in the Alzheimer's Association (http://www.alz.org), and the use of day care and respite care. For primary care physicians, knowing where to find specialized dementia expertise and how to contact the Alzheimer's Association may be as important as making a correct diagnosis and initiating therapy.

GENETIC COUNSELING

Genetic counseling for individuals with a family history of late-onset AD is usually complex and often must be carried out with incomplete information about the family history. Diagnoses of AD in parents may have been made retrospectively or without autopsy confirmation, and the family history often contains many gaps. Nonetheless, studies in the literature can be useful for gaining some insights into the risks of AD in siblings or children of an AD patient.[20,21,61] Two studies suggest that as age of onset in the proband rises, the genetically mediated risk of AD decreases.[21]

Non–Alzheimer Disease Dementias

VASCULAR DEMENTIA

Vascular dementia (VaD) is the name now used to define dementing illness that results from cerebral infarcts, supplanting older, less precise terms. The definition of VaD unfortunately lacks consensus; several sets of diagnostic criteria are currently in use. The National Institute of Neurological Disorders and Stroke–Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) criteria for probable VaD[62] are most widely used and have been adopted for clinical trials. The primary NINDS-AIREN criteria are that (1) the onset or worsening of dementia occurred within 3 months after a clinical stroke; (2) imaging studies show evidence of bilateral infarcts in cortical regions, basal ganglia, thalamus, or white matter; and (3) neurologic examination shows focal neurologic deficits. Although all three criteria are required for VaD, the third criterion is probably redundant if the first two are present; the temporal relationship between a stroke and dementia and the presence of infarcts on imaging are the key clinical features for VaD. Clinical-pathologic correlation studies have shown that this definition is quite specific, meaning that patients who meet these criteria are highly likely to have VaD pathologically. However, the NINDS-AIREN criteria are very insensitive, failing to diagnose VaD in the majority of patients who prove to have VaD at autopsy.[50] Many VaD patients have one key feature but not the other. At the price of sacrificing some specificity to increase sensitivity, the Mayo Clinic criteria for VaD[49] stipulate that either stroke and dementia must be temporally related or bilateral infarcts must be present on imaging.

Prevalence and incidence of VaD are approximately 10% to 20% of those of AD.[63,64] Like AD, VaD becomes more common with advancing age. Risk factors for VaD are identical to those for cerebrovascular disease and include hypertension, diabetes, and cardiovascular disease.

There is no genetic predilection for the typical forms of VaD, but there are very rare hereditary forms of dementia from vasculopathy, such as the CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) syndrome.[65]

The dementia of VaD often becomes apparent in the recovery period after a stroke. Because the motor and sensory deficits of stroke are often overwhelming, the cognitive impairment is often overshadowed at first. VaD may also begin insidiously, because there is a substantial percentage of VaD cases that appear to result from the accumulation of a series of so-called silent or covert infarcts.[43] Patients in this group do not meet the diagnostic criteria of dementia temporally linked to stroke, but they do have brain infarcts, which are best visualized with MRI.

Neuroimaging is essential for the proper diagnosis of VaD. MRI is preferable to CT scan because of its superior ability to detect lacunar infarcts. Typically, a patient with VaD has extensive infarcts [*see Figure 6*]. For VaD, the volume of infarction may not be as critical as its location. Bilaterality of ischemic injury is also relevant, although strategically placed unilateral infarcts in such locations as the caudate nucleus, thalamus, hippocampal formation, or parietal lobe can produce cognitive symptoms that close-

Figure 6 **MRI scan of a patient with vascular dementia showing multiple infarcts (arrows): one parieto-occipital cortical infarct and two white-matter infarcts.**

ly approximate those seen in dementia. White-matter hyperintensities, by themselves, are not sufficient evidence for infarcts.[66]

The cognitive deficits in VaD do not follow a particular pattern. Hence, there is no VaD profile of cognitive dysfunction. VaD patients tend to have more deficits in executive function because infarcts in the caudate nuclei, thalami, or white matter of the frontoparietal lobes tend to disrupt circuits that are involved in executive functions, but some VaD patients have prominent anterograde amnesia just like that of AD, without a prominent executive component.

Therapy for VaD should be primarily directed at prevention through smoking cessation and treatment of hypertension, diabetes mellitus, and known risks for cerebral embolization. Several studies have shown modest reductions in the incidence of dementia (presumably, dementia with a vascular component) by treatment of hypertension.[67,68] In patients with VaD, cholinesterase inhibitors[69,70] and memantine[71] have been effective in delaying progression of symptoms.

The natural history of VaD is variable. Some patients experience prolonged plateaus if they cease having strokes, whereas other patients decline inexorably. VaD patients whose disorder meets NINDS-AIREN criteria have considerably lower survival rates than AD patients.[35]

DEMENTIA WITH LEWY BODIES

Definition of the dementing illness associated with Parkinson disease has undergone several amplifications over the past decade. Dementia is recognized as a relatively common concomitant syndrome in Parkinson disease, and the coappearance of motor system dysfunction from Parkinson disease and dementia from AD is also recognized more commonly. In addition, dramatic alterations in daytime alertness and arousal, as well as the rapid eye movement sleep behavior disorder (RBD; see below), are coming to be recognized as associated with the dementia of Lewy body parkinsonism.

The term dementia with Lewy bodies (DLB)[72] is in vogue as a label for patients who have spontaneous (i.e., not drug-induced) parkinsonism, dementia, and often symptoms of disordered arousal. Although the consensus criteria for DLB lack precision, the importance of the disorder is not in doubt. After AD, DLB is one of the major dementing illnesses of later life,[50] occurring with approximately the same frequency as VaD. The demographics of DLB closely resemble those of AD.

The pathology of DLB includes both the typical Lewy body pathology in the brain stem seen in Parkinson disease and the appearance of cortical Lewy bodies. There is a spectrum of cortical pathology in DLB that ranges from modest numbers of cortical Lewy bodies and prominent AD pathology to profuse cortical Lewy bodies with minimal AD pathology.

The cognitive disorder of DLB can closely resemble AD, but in many patients, there are some notable differences.[73] These differences in DLB include a slightly less prominent deficit in learning and memory and more prominent difficulties with visuospatial functions, performance on timed tasks, and executive functions. The neuropsychological profile is not diagnostic, however.

The parkinsonism in DLB can range from a relatively isolated gait instability with frequent falling to a typical pattern of Parkinson disease with rest tremor, rigidity, bradykinesia, and postural instability.

Patients with DLB often experience marked fluctuations in their alertness and level of arousal from one day to the next. They often sleep excessively. RBD can often precede the dementia and the movement disorder by years and is highly specific for DLB.[74] In RBD, patients engage in dream enactment, thrashing about in bed or talking in their sleep. Another feature of DLB that may be related to the disorder of arousal is frequent daytime hallucinations that can be very vivid and detailed. It is postulated that the prominent hallucinations in DLB represent a sleep activity inappropriately intruding into wakefulness.

The diagnosis of DLB is a clinical one, based on the history and neurologic examination. The differential diagnosis of a dementia with parkinsonism in an elderly person also includes less common movement disorders such as corticobasal degeneration, progressive supranuclear palsy, and multisystem atrophy.

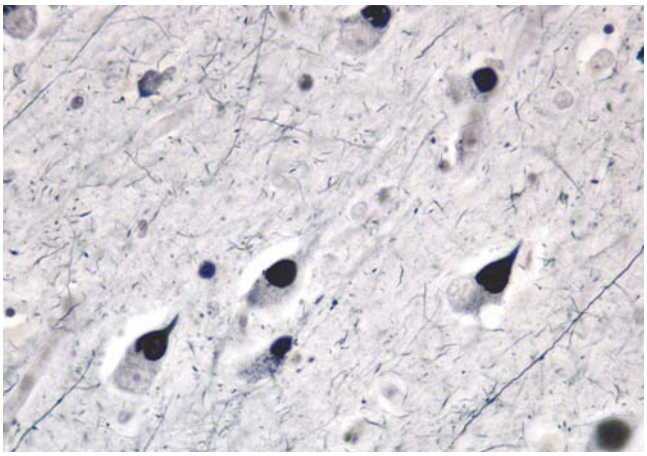

Figure 7 **Photomicrograph of Pick bodies, a feature of a frontotemporal lobar degeneration involving abnormalities of the tau protein.**

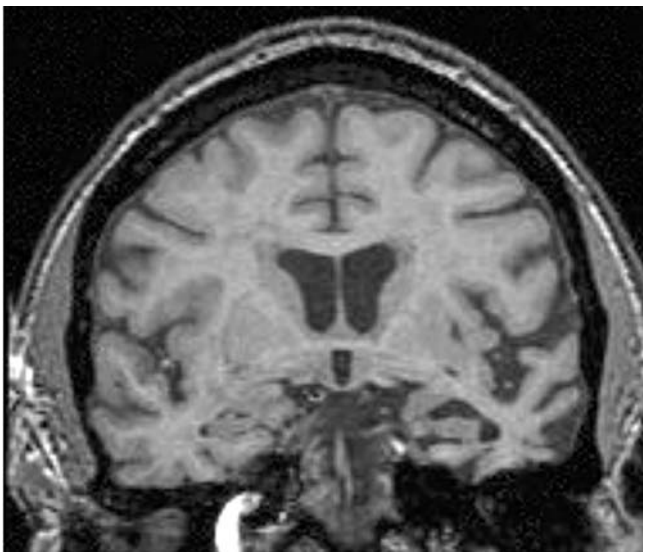
a



b

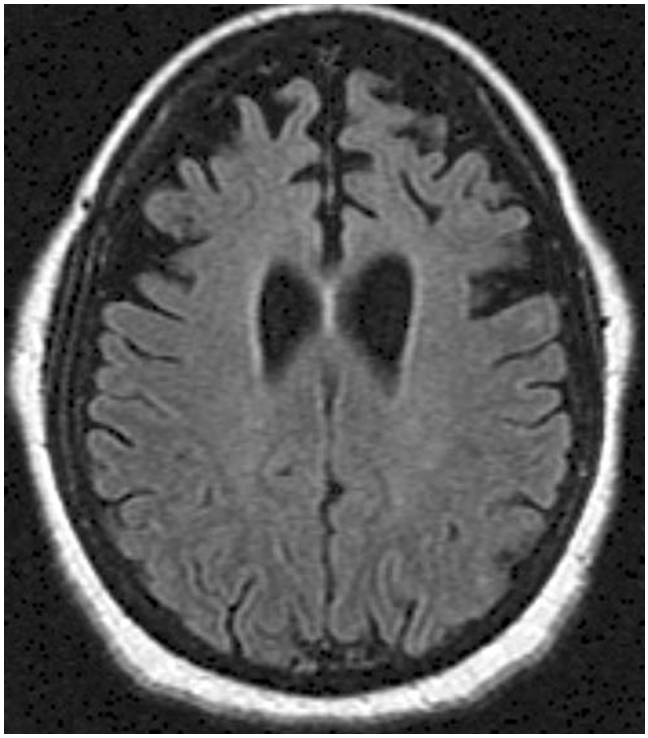


Figure 8 **MRI scan of focal temporal (*a*) or frontal atrophy (*b*) in patients with frontotemporal lobar degenerations.**

In younger patients, Wilson disease or Huntington disease should be considered.

The treatment of DLB can be complex because it involves the interplay of three symptom domains (dementia, movement disorder, and behavioral disturbances) and because medications for one domain may impact another domain. Cholinesterase inhibitors are of some benefit in DLB and do not appear to worsen the parkinsonism or behavior.[75] Levodopa may be essential to manage the gait and balance problems, but it may increase hallucinations or confusion. Antipsychotic agents such as quetiapine or clozapine will not exacerbate the parkinsonism or the confusion.

FRONTOTEMPORAL LOBAR DEGENERATIONS

The frontotemporal lobar degenerations (FTLDs) constitute a much less common subgroup of the dementias.[76] The term FTLD is currently preferred over the older eponymous name Pick disease because of the idiosyncratic and restricted meaning that Pick disease has acquired.

Recognition of the three different types of FTLD—frontotemporal dementia (FTD), progressive aphasia, and semantic dementia—is important because the principal management issues and the prognoses are quite different from those of AD, with which they are unfortunately often confused.

The most common of the three FTLDs is frontotemporal dementia. FTD presents as a disorder of behavioral control and loss of social skills, as well as a disorder of executive cognitive function.[77] Short-term memory may show impairment, but it is either quite modest or definitely less intrusive than the disorder of behavior and social conduct. Progressive aphasia may often not be a dementia, per se, but represents a difficulty with expressive language and increasing impairment in word-finding (anomia). The expressive speech of most patients with progressive aphasia becomes increasingly nonfluent, meaning that the number of words per utterance diminishes, the melody of speech vanishes, speech becomes more labored, and anomia becomes severe. Initially, comprehension and other cognitive functions are often preserved. Some patients with progressive aphasia go on to become demented, whereas others remain nondemented despite worsening expressive speech. The least common of the FTLDs is semantic dementia, a condition in which fluent speech is preserved but loss of word meaning is profound.

Some of the FTLDs have a genetic basis. Mutations in the *tau* gene, on chromosome 17, cause FTLD.[78] The mutations decrease the ability of the tau protein to bind to microtubules, which leads in turn to aggregation of tau molecules into an insoluble fibrillar form. Abnormal accumulations of tau protein are observed in the Pick bodies and the swollen neurons that are seen in some of the FTLDs. In the United States, *tau* mutations in patients with sporadic FTLD are exceedingly rare.[79]

The pathology of the FTLDs is also distinct from that of AD. The brunt of the pathology is localized to frontal and anterior temporal regions. Microscopically, there are several variants of FTLD. In one variant, cellular inclusions known as Pick bodies are seen [*see Figure 7*]; these were the basis for the diagnosis of Pick disease in the past. Pick bodies are positive for the tau protein. In another variant, an amorphous intracellular accumulation of tau protein–positive material can be seen in neurons. In these two pathologic variants of FTLD, the molecular composition of the tau proteins is different from that seen in AD. In the most commonly encountered pathology in the FTLDs, there is a loss of cortical neurons, an intense astrocytic reaction, and often ubiquitin-positive but tau-negative inclusions. The link between the tau-positive and tau-negative FTLDs has not yet been clarified.

The FTLDs can be diagnosed at the time of their initial presentation on the basis of the distinctive clinical profile, neuropsychometric testing, and neuroimaging. Neuropsychological profiles of patients with an FTLD are usually distinguishable from those of AD patients.[80] Many, although not all, patients with an FTLD have focal frontal or anterior temporal lobe atrophy, either symmetrically or asymmetrically [*see Figure 8*]. In addition, functional neuroimaging techniques such as PET and single-photon emission computed tomography are useful in demonstrating reduced metabolism or perfusion in frontal or anterior temporal

regions. There is currently no treatment for the FTLDs, other than the use of agents to control depression, anxiety, or agitation.

The author has received research grants from Elan Pharmaceuticals, Inc., and consulting honoraria from GE Healthcare, Myriad Pharmaceuticals, Inc., and Neurochem, Inc..

Cholinesterase inhibitors have not been approved by the FDA for use in the treatment of non-Alzheimer dementias.

XII EPILEPSY

James W. Wheless, m.d.

Definition

Seizures are caused by transient, paroxysmal, and synchronous discharges of groups of neurons in the brain. Although considered abnormal, seizures can occur in both normal and abnormal brain tissue. Seizures are one of the most common neurologic disorders and may occur at any age. More than 10% of the population will have a seizure or a few seizures during a lifetime. The clinical manifestations of seizures depend on the location and number of the neurons involved in the seizure discharge, the spread of the discharge to other parts of the brain, and the duration of the discharge. Seizures may be caused by a transient abnormality of brain function resulting from such clinical events as hypoglycemia, hyponatremia, and drug toxicity. In these circumstances, a person usually has only a single seizure or a few seizures at most; treatment of the underlying abnormality corrects the seizure disorder.

Epilepsy is defined as recurrent seizures. Epilepsy occurs in 1% to 2% of the population. The incidence of epilepsy is high in infancy but decreases during childhood; it is lowest in adolescence and adulthood but increases greatly in the elderly.[1]

Epilepsy may result from hereditary or acquired factors. Hereditary epilepsies typically have a complex pattern of inheritance, with simultaneous involvement of multiple genes, and the identity of genes that govern susceptibility remains largely unknown.[2] An increasing number of hereditary epileptic syndromes have been traced to mutations in genes that encode for ion channels—membrane-spanning proteins that form selective pores for sodium, potassium, chloride, or calcium ions and that provide the basis for regulating excitability in the central nervous system. Diseases resulting from mutated ion channels are termed channelopathies.[3]

Acquired epilepsy is often the result of a chronic, static neurologic abnormality. Causes include head trauma, CNS infection, structural brain malformations, vascular malformations, strokes, and cerebral neoplasm.

Classification

The International League Against Epilepsy has classified epileptic seizures on the basis of clinical and electroencephalographic criteria [*see Table 1*]. Proposed in 1981, this classification is widely accepted by neurologists but is still not well known among nonneurologists. The classification divides seizures into three major categories: partial, generalized, and unclassified.[4]

Partial seizures

Partial seizures are described as either simple or complex, depending on whether consciousness remains intact or is impaired during the seizure.[5] Simple partial seizures can arise from any neocortical region. The manifestations fall into four categories: motor, sensory, autonomic, or psychic. Motor symptoms include focal myoclonus of a limb or region of the hand or face. Sensory symptoms include seeing colored spots or lines, as occurs with discharge in the primary visual cortex. A common autonomic symptom in mesial temporal lobe epilepsy is a rising epigastric sensation. Psychic symptoms may involve memory (e.g., déjà vu), affect, or other complex phenomena.[5]

In complex partial seizures, the focal discharge involves brain regions subserving awareness or spreads widely enough to reach those regions, whereby the patient loses conscious contact. Although the patient's level of consciousness is a key component of the definition of complex partial seizures, this information may be difficult to obtain. During altered conscious contact, patients are unable to respond to commands, interact with their surroundings, or recall events that occurred during the seizure. A report of behavior observed by a witness such as a family member can be important for differentiating a simple seizure from a complex one. For example, a patient may lose the ability to speak during a simple seizure originating in the dominant temporal, frontal, or parietal cortex. However, if the patient followed commands during a seizure or recalled specific verbal information, the physician can conclude that the patient retained cognition during the seizure.[6]

Complex partial seizures usually begin with arrest of motion and a blank stare. Automatisms (e.g., simple hand movements), oroalimentary behavior (e.g., tasting movements or swallowing), or verbal utterances may occur either initially or during the seizure. If the patient is engaged in a complex motor task at the beginning of a seizure, that activity may continue, but the accuracy of the behavior will deteriorate. Key historical points are the duration of the seizure, because most complex partial spells

Table 1 International Classification of Epileptic Seizures*

- *Partial (Focal, Local) Seizures*
  - Simple partial seizures (consciousness not impaired)
    - Motor signs
    - Somatosensory or special sensory symptoms
    - Autonomic symptoms or signs
    - Psychic symptoms
  - Complex partial seizures (consciousness impaired)
    - Simple partial onset followed by impaired consciousness
    - Consciousness impaired at onset
  - Partial seizures evolving to generalized seizures (tonic, clonic, or tonic-clonic)
    - Simple partial seizures evolving to generalized seizures
    - Complex partial seizures evolving to generalized seizures
    - Simple partial seizures evolving to complex partial seizures evolving to generalized seizures
- *Generalized Seizures (Convulsive or Nonconvulsive)*
  - Absence seizures
    - Typical (brief stare, eye flickering, no emotion)
    - Atypical (associated with movement)
  - Myoclonic seizures
  - Clonic seizures
  - Tonic seizures
  - Tonic-clonic seizures
  - Atonic seizures
- *Unclassified Epileptic Seizures*

*From the Commission on Classification and Terminology of the International League Against Epilepsy.[4]

last only a minute or two, and the stereotyped nature of behaviors. A seizure is stereotyped when the behaviors are the same or similar for each seizure. At the termination of the seizure, the patient may be momentarily confused, fatigued, or disoriented. This alteration is of critical diagnostic importance and must be sought with leading questions by the physician. Postictal effects differentiate a complex partial seizure of temporal lobe origin from an absence seizure; in the latter, the patient does not have any postictal symptoms.[7]

Complex partial seizures may be heralded by sensory, autonomic, or psychic symptoms that precede impairment of consciousness. These symptoms are referred to as an aura.

Simple and complex partial seizures may secondarily generalize and produce a tonic-clonic seizure or a convulsion. Spread of discharge from a localized focus to encompass the entire brain is common, but clinically, most partial seizures do not progress to a secondarily generalized tonic-clonic seizure.

Because the focal manifestation of a secondarily generalized convulsion may not be identified by observers or recalled by the patient, it is best to assume that a newly diagnosed generalized tonic-clonic seizure originated from a focus until such a process can be excluded.[8] Focal processes to consider in an adult with new-onset partial or tonic-clonic seizures include brain tumor, cerebral infarction, or infection.

GENERALIZED SEIZURES

Generalized seizures cause a spectrum of behavior from the nonconvulsive pattern of simple absence seizure through myoclonus to the fully developed generalized tonic-clonic seizure.[4] Absence seizures, which are manifestations of an epilepsy syndrome that begins in childhood, are brief, usually lasting 10 seconds or less. The seizures are not preceded by an aura or followed by postictal effects. During an absence seizure, the patient has arrest of behavior and a blank stare. Occasionally, mild clonic manifestations occur, such as subtle eyelid blinking and changes in postural tone. A specific electroencephalographic pattern of generalized spike-and-wave discharges at 3/sec occurs during absence seizures. This EEG abnormality can be activated by deliberate hyperventilation. EEGs taken between seizures (interictal) may show unrecognized absence seizures or short bursts (usually less than 3 seconds) of the generalized discharge. Patients with these abnormalities have normal intellectual and neurologic function.

Atypical absence seizures differ from simple absence seizures in that onset occurs at an earlier age in childhood, the interictal EEG background is abnormal, and the EEG discharges are slower than 3/sec. Patients with these seizures may also have atonic and myoclonic seizures. Patients with atypical absence seizures may be mentally retarded.

Myoclonus consists of brief jerks or contractions of a specific muscle or group of muscles. Hypnagogic myoclonus is both common and normal. Focal myoclonus may be caused by destructive lesions of the brain stem or spinal cord. Metabolic disease, hypoxia, toxic processes, and infectious disease may cause focal or diffuse myoclonus. Myoclonus associated with epilepsy is commonly symmetrical. Myoclonus is a component of several epilepsy syndromes and occurs before or as a part of both absence and generalized tonic-clonic seizures. One important syndrome to identify is juvenile myoclonic epilepsy (see below). Myoclonic seizures may be caused by disorders other than primary brain dysfunction; these include metabolic diseases or genetic brain disorders such as Lafora disease.

Atonic seizures involve a sudden loss of postural tone and may cause falls, with trauma to the head or body. This treatment-refractory seizure type is often associated with the Lennox-Gastaut syndrome.

Convulsions are the most common type of generalized

Table 2 International Classification of Epilepsies, Epilepsy Syndromes, and Related Seizure Disorders*

Localization-related (focal, local, partial) epilepsies†	Idiopathic Benign childhood epilepsy with centrotemporal spikes Childhood epilepsy with occipital paroxysms Primary reading epilepsy Symptomatic Temporal lobe epilepsy Frontal lobe epilepsy Parietal lobe epilepsy Occipital lobe epilepsy Chronic progressive epilepsia partialis continua Cryptogenic (presumed to be symptomatic but cause is unknown) Temporal lobe epilepsy Frontal lobe epilepsy Parietal lobe epilepsy Occipital lobe epilepsy Chronic progressive epilepsia partialis continua
Generalized epilepsies	Idiopathic Benign neonatal convulsions (familial and nonfamilial) Benign myoclonic epilepsy in infancy Childhood absence epilepsy Juvenile myoclonic epilepsy Epilepsy with generalized tonic-clonic seizures on awakening Symptomatic Nonspecific etiology Early myoclonic encephalopathy Early infantile epileptic encephalopathy with suppression burst Other symptomatic generalized epilepsies Cryptogenic West syndrome (infantile spasms) Lennox-Gastaut syndrome Epilepsy with myoclonic-astatic seizures Epilepsy with myoclonic absences Specific syndromes (disease states in which seizures are a presenting or predominant feature)
Undetermined epilepsies	Generalized and focal features Neonatal seizures Severe myoclonic epilepsy of childhood Epilepsy with continuous spike waves during slow-wave sleep Acquired epileptic aphasia (Landau-Kleffner syndrome) Other undetermined epilepsies without unequivocal generalized or focal features
Special syndromes	Situation-related seizures Febrile convulsions Isolated seizures or status epilepticus Seizures caused by an acute or toxic event, such as alcohol or drug overdose, eclampsia, or hyperglycemia

*From the Commission on Classification and Terminology of the International League Against Epilepsy.[4]

†Syndrome defined by seizure type and other clinical features, including anatomic localization and etiology.

seizures. They are characterized by loss of consciousness associated with apnea and violent contractions of the musculature of the trunk and extremities. Frequently, patients suffer mouth trauma and have bladder incontinence. Salivation often increases, and both pulse rate and blood pressure rise during the seizure. Most generalized convulsions begin with a tonic phase, in which there is sustained contraction of all muscles with extended legs and either flexed or extended arms. This phase lasts for several seconds and is followed by a clonic phase, in which there are rhythmic contractions of the limbs that begin with high-frequency, low-amplitude movements and then gradually decrease in frequency for several seconds to a few minutes. Some patients may have only tonic seizures or only clonic seizures. A sequence of alternating tonic and clonic movements may be observed in patients with primary generalized seizures. After the violent muscle contractions subside, the patient enters a postictal phase, in which breathing resumes and unresponsiveness is followed by gradual recovery of consciousness. The patient may remain confused for several minutes or longer and may subsequently complain of muscle pain and headache. This sequence of behavior is stereotyped, occurring regardless of cause. If a localized structural lesion in the brain cannot be found, the convulsion is an idiopathic or a primary generalized seizure. If the convulsion is preceded by a partial seizure, it is said to be a secondarily generalized seizure. About 75% to 85% of convulsions in adults are preceded by partial seizures.

Epilepsy Syndromes

In 1989, the International League Against Epilepsy recognized that many patients with seizures have brain abnormalities that affect their quality of life independent of the epilepsy alone. This classification[4] recognizes that an epilepsy syndrome encompasses not only the behavior during a seizure but also the EEG changes, the patient's mental and motor development, and the family history [*see Table 2*]. Because the repertoire of seizure manifestations is limited, similar seizure types may be found as components of several syndromes with widely divergent prognoses. Defining a specific epilepsy syndrome often requires repeated assessment, evaluation of development, and review of responses to treatment. Syndromes are considered to be either benign or progressive. These terms are usually applied to ultimate outcome of intellectual function and survival. Although some syndromic seizures are benign in their impact on intellectual function, lifelong treatment with antiepileptic drugs (AEDs) may be required. Five pertinent epilepsy syndromes are described in this subsection: febrile seizures, benign childhood epilepsy with centrotemporal spikes, childhood absence epilepsy, juvenile myoclonic epilepsy, and chronic progressive epilepsia partialis continua.

FEBRILE SEIZURES

Febrile seizures affect 2% to 5% of children. These seizures typically occur before 6 years of age. Although one third of children who have a febrile seizure will have recurrent febrile seizures, only a small minority develop afebrile seizures. A syndrome called febrile seizures plus is now recognized; patients with this syndrome have febrile seizures that continue beyond 6 years of age or have associated afebrile tonic-clonic seizures. Febrile seizures plus is self-limited, with seizures typically ceasing by mid-adolescence. The syndrome appears to be genetic, with an autosomal dominant inheritance pattern. In turn, febrile seizures plus appears to be one manifestation of a broader syndrome termed generalized epilepsy with febrile seizures plus, whose spectrum of clinical manifestations also includes febrile seizures. Genetic linkage studies have mapped the syndrome to multiple loci.[9,10] Patients with this syndrome may have febrile seizures in childhood, followed by a quiescent interval of many years and then the onset of seizures of a different type.

BENIGN CHILDHOOD EPILEPSY WITH CENTROTEMPORAL SPIKES

This common syndrome is characterized by hemifacial motor seizures that are brief, partial, usually nocturnal, and occasionally generalized. Patients also have somatosensory symptoms such as facial twitching and tongue numbness. These children develop normally and have no focal changes evident on brain imaging. The EEG shows sleep activation of high-voltage centrotemporal spikes, with a blunt configuration and a characteristic slow wave. Complete remission by the mid-teenage years is usual in more than 90% of cases.[11]

CHILDHOOD ABSENCE EPILEPSY

The prevalence of childhood absence epilepsy is estimated to be 2% to 8%. The associated EEG abnormality of spike-and-wave discharges at 3/sec occurs in the milieu of a normal background EEG pattern [*see Figure 1*].[12] Remissions of 80% are reported in patients with uncomplicated absence seizures. However, tonic-clonic seizures develop in some cases, and only 30% of those patients have complete resolution without antiepileptic medication. Patients who are at least 15 years old at onset of absence epilepsy also do not have a good prognosis for complete resolution without antiepileptic medication.[13] Remission is most likely with short duration of illness, which highlights the need for early identification of patients and rapid institution of treatment. Factors associated with a good prognosis are normal intelligence quotient (IQ) and no history of generalized tonic-clonic seizures. Unfortunately, tonic-clonic seizures complicate the course of absence epilepsy in about 50% of patients.[11] Risk factors for development of tonic-clonic seizures include later age at onset of absence epilepsy, difficulty in controlling absence seizures with medication, and abnormal background activity on the EEG.[12,14] Before the development of broad-spectrum drugs, some patients were given an additional drug to prevent tonic-clonic seizures. This dual-drug approach has been supplanted by the use of valproate, a broad-spectrum medication with combined efficacy against both absence and generalized tonic-clonic seizures. Discussion of treatment with patients and parents must include informing them of the risk of developing tonic-clonic seizures.[15]

JUVENILE MYOCLONIC EPILEPSY

Although the onset of juvenile myoclonic epilepsy occurs in childhood, the disorder typically persists throughout adulthood. Juvenile myoclonic epilepsy is genetically transmitted; patients typically have a family history of seizures. The genetic defect is an abnormality on the short arm of chromosome 6.

Patients with juvenile myoclonic epilepsy have characteristic myoclonic jerks, generalized tonic-clonic seizures, and photosensitivity that is revealed by EEG. Precipitants of seizures include sleep deprivation, stress, and alcohol use. The myoclonic jerks are quite prominent in the morning and may involve the large muscles of the legs. The correct diagnosis is important because these seizures are usually well controlled with valproate.

Figure 1 **Electroencephalogram obtained from electrodes affixed to the patient's scalp and reformatted with analog-to-digital conversion. The normal background patterns are interrupted by generalized polyspike and then spike and slow-wave discharges at 3/sec. This EEG is typical for that recorded from patients with childhood absence epilepsy. The dark vertical lines denote 1 second; the sensitivity is 7 μV/mm.**

The prognosis for normal intellectual function is usually good; however, the outlook for drug-free remission is poor.[13]

CHRONIC PROGRESSIVE EPILEPSIA PARTIALIS CONTINUA

Patients with partial seizures or a focal brain abnormality may experience continuous focal seizures. The EEG shows continuous focal spikes and slow waves. Prognosis is related to the underlying pathogenic lesion and is usually not associated with progression in clinical pattern. The childhood form (Rasmussen encephalitis)[16] begins with focal seizures involving motor systems and then progresses to motor deficits and mental deterioration.[11] This rare form of encephalitis also occurs in adults.

Diagnostic Evaluation

Whereas the patient's history forms the basis for characterization of seizures, several laboratory studies are required to establish the diagnosis, management regimen, and prognosis in epilepsy. Most patients with epilepsy have more than one type of seizure. Integrating the clinical and laboratory data can allow the clinician to identify the epilepsy syndrome involved; this provides a powerful tool for patient care.[5]

ELECTROENCEPHALOGRAPHY

An EEG is a graphic or electronic display of amplified physiologic brain activity recorded from electrodes attached to a patient's scalp in a standardized array. Focal or generalized seizure patterns interrupting background patterns confirm the diagnosis of epilepsy. Because sleep increases epileptiform activity, the diagnostic yield of an EEG is improved when the patient is sleep deprived, so that natural sleep will occur during the study. Patients with partial seizures arising in mesial temporal lobe structures often have a normal EEG on the initial study. Repeated EEGs are needed to obtain a confirmatory study. Diagnostic patterns include focal spikes, sharp waves, or spike-wave complexes [*see Figure 2*]. Generalized abnormalities range from momentary suppression of background rhythms to clusters of multiple rapid spikes to the classic pattern of spike-and-wave discharges at 3/sec characteristic of absence epilepsy.

Video-Electroencephalographic Monitoring

In most patients with epilepsy, routine EEG provides sufficient diagnostic information. In selected patients with recurrent unprovoked seizures that are refractory to therapy, the combination of video and EEG can help confirm the diagnosis of a seizure disorder and classify seizure type. In some cases, video-EEG monitoring discloses physiologic or psychological disorders that have been confused with epilepsy. Video-EEG monitoring can be performed on an outpatient basis or in an epilepsy monitoring unit.[17]

BRAIN IMAGING

Because epilepsy is a symptom, particularly in adults, treatable illnesses must be excluded in the initial diagnostic evalua-

Figure 2 **Electroencephalogram obtained from electrodes affixed to the patient's scalp and reformatted with analog-to-digital conversion. An isolated focal epileptiform discharge present in the lower four traces occurs 7 seconds after the beginning of this EEG epoch. This interictal EEG pattern is typical for a patient with complex partial seizures of temporal lobe origin. The darker vertical lines denote 1 second; the sensitivity is 7 μV/mm.**

tion. A CT scan of the brain will reveal whether the patient has lesions needing urgent treatment, but magnetic resonance imaging is the preferred method for studying brain structure in a patient with epilepsy; indeed, structural MRI is a routine part of the epilepsy workup. Patients with intractable complex partial seizures arising from temporal lobe structures have mesial temporal atrophy or sclerosis as their most common focal lesion; detecting such lesions is of prognostic value.[18] MRI changes in these patients typically consist of increased signal intensity and loss of detailed hippocampal structure with atrophy [*see Figure 3*]. Quantitative MRI aids in identification of hippocampal atrophy.[19]

MRI is both sensitive and specific in patients with partial seizures, allowing noninvasive diagnosis through detection of many types of lesions.[20] These lesions include such neoplastic changes as low-grade glioma and ganglioglioma and specific lesions such as dysembryoplastic neuroepithelial tumors. Vascular changes include arteriovenous malformation, cavernous hemangioma, venous angioma, and telangiectasias. Developmental abnormalities include such neuronal migration disorders as lissencephaly, pachygyria, band or laminar heterotopia, and subependymal heterotopias. More restricted lesions include focal cortical dysplasia, polymicrogyria, focal subependymal heterotopia, and schizencephaly.[20]

Imaging techniques that show cerebral function play a growing role in the evaluation of epilepsy. Such techniques include functional MRI, magnetoencephalography (MEG), magnetic resonance spectroscopy (MRS), single photon emission computed tomography (SPECT), and positron emission tomography (PET).[21]

The use of functional MRI to evaluate epilepsy is a relatively recent development. Functional MRI can detect transient focal or regional changes in cerebral blood flow associated with seizure activity. The technique shows promise in the preoperative assessment of candidates for surgical excision of epileptogenic foci.[21,22]

MEG is a noninvasive method of imaging brain function. MEG identifies the location of activated sets of neurons, on the basis of the associated magnetic flux on the head surface, and projects the location onto an MRI for visualization of the activated region. Currently, MEG is the only imaging modality approved by the Food and Drug Administration that can provide noninvasive imaging of the motor cortex, the sensory cortex, and language function. MEG has an emerging role in the preoperative evaluation of patients with refractory epilepsy.[23]

MRS measures concentrations of a variety of substances within the brain, offering a way to obtain metabolic information in patients with epilepsy. It can be used to detect increased inorganic phosphate concentration, altered pH, and decreased levels of phosphomonoesters. Alterations in levels of *N*-acetylaspartate, choline, and creatine/phosphocreatine and increased lactic acid concentration postictally may aid identification of the location of onset of focal seizures.[24]

SPECT reveals decreased blood flow in the region of seizure

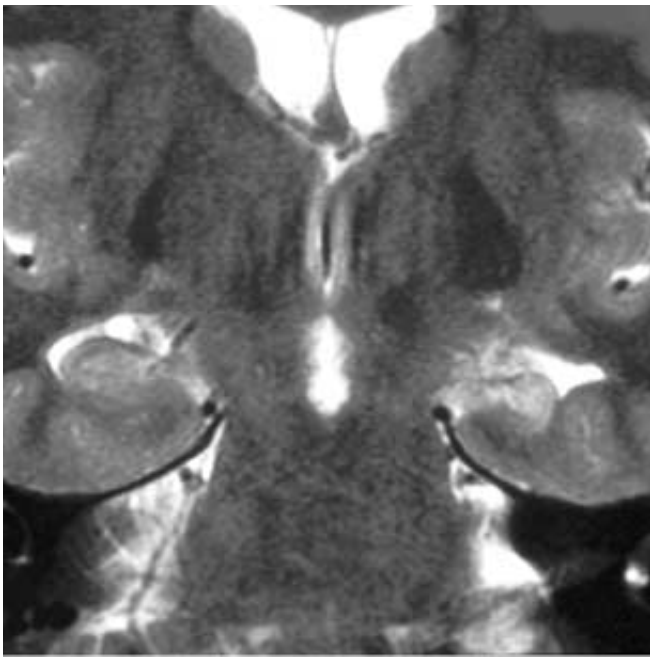

Figure 3 **Mesial temporal sclerosis, a cause of seizures that may be amenable to surgical correction, is visible only on MRI with a specific epilepsy sequence. This coronal view, obtained perpendicular to the hippocampus, demonstrates left mesial temporal sclerosis (the left hippocampus is on the right side of the figure). Note the smaller size and increased signal (brighter appearance) of the left hippocampus and the compensatory increased size of the adjacent temporal horn of the lateral ventricle. The patient, an adult, presented with new-onset complex partial seizures and a history of two prolonged febrile seizures in childhood. A CT scan of the brain was normal.**

origin in some patients.[25] Use of SPECT alone between seizures is currently of little value, but ictal SPECT may be helpful with patients (especially those with temporal lobe epilepsy) in whom other imaging techniques give normal results. In the future, the most important role for SPECT may be its use in combination with MRI for presurgical evaluation. So-called ictal difference images, which are created through coregistation of interictal and ictal SPECT images, can in turn be coregistered with MRI results to provide an accurate picture of cerebral function.[21]

In the past, PET with 18-fluorodeoxyglucose to image the cerebral metabolic rate was useful for detecting a seizure focus that might be amenable to surgery. With advances in MRI technology, however, the value of PET is now limited to selected patients with normal MRI results.[21] In patients with complex partial seizures of temporal lobe origin, PET may reveal interictal hypometabolism, depending on the duration of epilepsy.[26]

Differential Diagnosis

Although sudden alterations in neurologic function are characteristic of seizures, sudden alterations also occur when intracranial structures are deprived of glucose or oxygen. Failure to maintain adequate cerebral perfusion will cause loss of consciousness, as in syncope of any cause. Motor activity during simple syncope is uncommon. However, prolonged interruption of cerebral perfusion may cause convulsive movements or even tonic-clonic seizures.

Sensory or motor dysfunction can be caused by transient ischemia, which may result from embolic cerebrovascular disease, extracranial carotid or basilar artery disease, and migraine. Seizures may occur with embolic strokes. Metabolic disease, particularly disease related to glucose metabolism that requires regulation of blood glucose concentration with insulin therapy, may be associated with episodes of hypoglycemia. Both focal and generalized seizures can be manifestations of hypoglycemia or of hyperosmolar states.

All patients with initial presentation of a seizure must undergo a complete blood count and blood chemistry studies. The CBC results may suggest infection, a platelet abnormality, or anemia. The blood chemistry studies must include measurement of glucose, urea nitrogen, electrolyte, and liver enzyme levels.

Lumbar puncture with a cerebrospinal fluid study should be performed if the patient is febrile or has altered cognitive function, such as behavioral changes, that could be ascribed to an encephalopathic process. To prevent complications from lumbar puncture, the clinician must first exclude the presence of an intracranial mass or increased intracranial pressure.

NONEPILEPTIC SEIZURES

Approximately 20% of patients admitted to epilepsy monitoring units for diagnostic evaluation have episodic behavioral alterations that are not caused by physiologic dysfunction of the brain.[27] In the past, these alterations were described as pseudoseizures. Although that term is still used for communication among physicians, it is not appropriate for communication with patients.[28] Currently, the preferred term is nonepileptic seizures (or nonepileptic events). Use of these terms tends to help patients understand their problem and facilitates referral for behavioral therapy. Patients react angrily to the term pseudo and are less likely to believe the physician is interested in their problem.

An important clue to the diagnosis of nonepileptic seizures is that they are periodic events that tend not to be stereotyped. Both patients and observers report varied behaviors with each event. Another clue is prolonged duration. Nonepileptic seizures may last 30 minutes to several hours. Epileptic seizures, both partial and generalized, seldom continue for more than several minutes. Patients with both nonepileptic seizures and epilepsy pose a challenging clinical problem; this combination is occasionally found in patients undergoing assessment in epilepsy monitoring units. Treatment of nonepileptic seizures requires behavioral intervention. If both disorders are found, treatment of epilepsy needs to be continued in parallel with behavioral therapy.

Treatment of Seizures and Epilepsy

Historically, drug therapy with AEDs has been the mainstay of treatment for seizures. Nonpharmacologic options have gained greater prominence in recent years, however. Use of vagus nerve stimulation devices is growing rapidly. Some patients may be candidates for surgical treatment. In children, the ketogenic diet has reemerged.

DRUG THERAPY

Antiseizure medications, usually referred to as antiepileptic drugs, have been available for more than a century. However, the modern era of AED therapy began in the early 20th century with the introduction of phenobarbital. More than two dozen agents available in the United States are classified as AEDs.

Most were introduced before 1980, but a number of new drugs were licensed for epilepsy treatment in the 1990s.

AED treatment should be directed at both controlling seizures and, when possible, correcting the underlying disease or disorder. AEDs may be used only briefly, if at all, in patients with a single seizure or a few seizures resulting from a transient disorder, such as drug intoxication, withdrawal from alcohol or sedative-hypnotic drugs, hyponatremia, or hypoglycemia. Patients who have recurrent seizures secondary to a treatable neurologic disease, such as brain tumor or intracranial infection, should be treated with AEDs; the underlying problem should also be treated. In many patients, such as those with completed cerebral infarction or brain contusion secondary to head injury, recurrent seizures result from the prior insult or from an undefined process. In these patients, AEDs are the only possible therapy. Patients with chronic recurrent seizures, regardless of etiology, should be treated with AEDs.

Whether to start AED treatment after a single unprovoked first seizure is a controversial issue. Many authorities argue that because many patients will not have a second seizure during several years of follow-up, there may be no justification for beginning AED treatment and subjecting patients to possible side effects.[29] In support of this idea is a retrospective study reporting that only 60% of patients who had a single convulsion had a second one within 5 years.[30] Also, the risk of seizure recurrence diminishes progressively the longer a patient remains seizure free. Because many patients have recurrent seizures, however, not all physicians accept that justification is lacking for AED treatment after single first seizures. I recommend not treating patients after a single seizure if results of the neurologic examination, EEG, and imaging study of the brain are normal. In addition, the patient must be willing to accept the risks associated with another seizure. Treatment with an AED should be initiated for most patients after a first seizure when evaluation reveals any structural or functional brain abnormality such as epileptiform discharges on the EEG.

Treatment with AEDs should follow certain basic principles. Therapy should be started with a single suitable agent. Seizure control should be achieved, if possible, by increasing the dosage of this agent rather than by adding a second one. If seizure control cannot be achieved with the first medication, a second, alternative agent should be considered. Monotherapy—usually with the first or second agent chosen—can control seizures in about 60% of patients with newly diagnosed epilepsy. In the remainder of cases, control is often difficult from the outset.[31]

The use of two or more AEDs in combination should be avoided whenever possible, but rational drug combinations may be useful when monotherapy fails. Drug selection should be guided by the patient's seizure type and epilepsy syndrome classification, in concert with the mechanisms of action and side effects of the individual agents.[31] Changes in dosage should be guided by the patient's clinical response rather than by drug levels, with inadequate seizure control indicating the need for raising the dosage and toxicity indicating the need to lower the dosage.

Monitoring of drug levels is usually not necessary for patients who tolerate their medication well and have adequate seizure control. Under some circumstances, however, monitoring drug levels may be useful to determine prescription compliance or explain changes in seizure control or drug toxicity.

Mechanisms of Action of AEDs

AEDs appear to control seizures by decreasing neuronal excitability or enhancing inhibition of neurotransmission. This is achieved by altering intrinsic membrane currents, such as sodium, potassium, and calcium conductance through ion channels, or by affecting the activity of various neurotransmitters, such as γ-aminobutyric acid (GABA), glutamate, or other neurotransmitters that may take part in seizure activity. Although several AEDs have common mechanisms, each seems to have distinct actions. Each AED has been reported to have several molecular and cellular actions, but probably only some of these individual actions are responsible for the anticonvulsant and antiepileptic effects.

The intrinsic membrane currents affected by AEDs are primarily those involving the voltage-gated sodium channel and the calcium channel. The drugs that act at sodium channels in therapeutic concentrations—phenytoin, carbamazepine, primidone, valproate, and lamotrigine—inhibit high-frequency neuronal discharge.[32] Because they block the sodium channel gradually and in proportion to the rate of firing (i.e., they are both use dependent and voltage dependent), they have little effect on normal neuronal activity. However, during high-frequency firing, which typically occurs at seizure onset, they delay reactivation of the sodium channel and produce an increasing inhibitory effect on the action potential until firing is completely blocked.

Some AEDs act at both the sodium and the calcium channel, such as phenytoin, carbamazepine, valproate, lamotrigine, and zonisamide.[32] Other AEDs that act at calcium channels include ethosuximide and phenobarbital. Ethosuximide selectively blocks the T-type calcium current, which is not greatly affected by most of the other AEDs (except zonisamide). This current is thought to act as a pacemaker in thalamic neurons and may be important in absence seizures. Valproate and lamotrigine are also effective against absence seizures; however, it remains to be determined whether their efficacy results from action on the T-type calcium current or from some yet undefined mechanism. The blockade of other calcium currents, such as the L and N types, may be a less specific effect that affects neuronal excitability and propagation of seizure activity.[33]

Drugs that alter synaptic function act primarily by enhancing GABA-mediated neuronal inhibition, the brain's main inhibitory mechanism; these drugs include phenobarbital and benzodiazepines. Each of these drugs acts through a different mechanism to augment GABA influences in the CNS.[34] Benzodiazepines increase the frequency of GABA-mediated $GABA_A$ receptor channel openings, and barbiturates increase the duration of channel openings. A different strategy to increase extracellular GABA uses inhibition of transporters. Tiagabine delays the reuptake of GABA from the synaptic cleft, effectively enhancing the GABA effect after synaptic release. Vigabatrin, which is not available in the United States, increases GABA concentration by irreversibly binding to GABA transaminase, the enzyme that metabolizes GABA.[35]

The mechanisms of anticonvulsant and antiepileptic action of the major drugs used as therapy for seizure disorders are not completely understood. Some AEDs may affect ionic conductances other than those discussed, and some may directly or indirectly affect neurotransmitter processes other than the GABA system; these actions may be important for their clinical effects. For example, felbamate and topiramate may block glutamate receptors to interfere with excitation.[35] Additional research is needed to completely define the molecular and cellular mechanisms and the sites of action of AEDs.

Table 3 Antiepileptic Drugs

Agent (Trade Name)	*Formulations*	*Dosage*	*Principal Sites of Action*	*Targeted Seizure Type*
Carbamazepine (Tegretol, Tegretol-XR, Carbatrol)	Tablets: 200 mg Chewable tablets: 100 mg Suspension: 100 mg/5 ml Extended-release tablets: 100, 200, and 400 mg Extended-release capsules: 200 and 300 mg	10–40 mg/kg/day in three or four divided doses (regular tablets or suspension) or two divided doses (extended-release forms)	Sodium channels	Focal and secondary GTC
Clonazepam (Klonopin)	Tablets: 0.5, 1, and 2 mg	0.01–0.30 mg/kg/day in two or three divided doses or h.s.	GABA receptors	All generalized focal and secondary GTC
Diazepam for rectal administration (Diastat)	Rectal syringe: pediatric: 2.5, 5, and 10 mg; adult, 10, 15, and 20 mg	2–5 yr: 0.5 mg/kg 6–11 yr: 0.3 mg/kg > 12 yr: 0.2 mg/kg	GABA receptors	Acute repetitive seizures
Ethosuximide (Zarontin)	Capsules: 250 mg Suspension: 250 mg/5 ml	15–40 mg/kg/day in two or three divided doses	T-type calcium channels	Absence
Felbamate (Felbatol)	Tablets: 400 and 600 mg Suspension: 600 mg/5 ml	15–45 mg/kg/day (or 1,200–3,600 mg/day) in two or three divided doses	NMDA receptors Sodium channels GABA receptors	Focal and secondary GTC Lennox-Gastaut syndrome
Fosphenytoin (Cerebyx)	Injection: 50 mg/ml (phenytoin-equivalent)	10–20 mg/kg I.V. loading dose	Sodium channels	Status epilepticus
Gabapentin (Neurontin)	Tablets: 600 and 800 mg Capsules: 100, 300, and 400 mg Suspension: 250 mg/5 ml	10–60 mg/kg/day	Increases GABA release	Focal and secondary GTC
Lamotrigine (Lamictal)	Tablets: 25, 100, 150, and 200 mg Chewable tablets: 2, 5, and 25 mg	200–500 mg/day in two divided doses Slow titration required, especially if taken with valproic acid or valproate.	Sodium channels (modulating EAA release) Calcium channels	Focal and secondary GTC Absence Tonic/atonic GTC Myoclonic
Levetiracetam (Keppra)	Tablets: 250, 500, and 750 mg	1,000–3,000 mg/day in two divided doses	Potassium channels Calcium channels	Focal and secondary GTC
Lorazepam (Ativan)	Injection: 2 or 4 mg/ml	0.05–0.1 mg/kg I.V. (total dose)	GABA receptors	Status epilepticus
Oxcarbazepine (Trileptal)	Tablets: 150, 300, and 600 mg Suspension: 300 mg/5 ml	900–2,400 mg/day in two divided doses	Sodium channels	Focal and secondary GTC

AED Selection

The principal AEDs used to treat patients with epilepsy in the United States are carbamazepine, ethosuximide, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, phenobarbital, phenytoin, primidone, topiramate, tiagabine, valproate, and zonisamide [*see Table 3*]. Some benzodiazepines, including clonazepam, diazepam, and lorazepam, are also used to treat seizures. With the exception of clonazepam, the benzodiazepines are used for short-term treatment of acute seizures or status epilepticus and are usually administered parenterally. Clonazepam can be used to treat epilepsy but is not recommended, because most patients develop tolerance to its antiepileptic effect. Felbamate should be reserved for use in selected patients with uncontrolled seizures. Because of the high incidence of serious adverse effects associated with felbamate, treatment with this drug should be managed by experienced clinicians in established epilepsy centers.[36] Several additional drugs, including methsuximide and acetazolamide, are used occasionally; none of these drugs will be considered in this subsection.

Partial seizures Most epileptologists agree that the drugs of choice for partial seizures are carbamazepine and phenytoin, which are highly effective and have acceptable adverse effects.[37] Valproate also has been demonstrated to be effective in the treatment of partial seizures.[38,39] Both phenobarbital and primidone are probably as effective as carbamazepine or phenytoin, but the two barbiturates are associated with a much higher incidence of adverse effects, particularly sedation and impaired cognition.[37] Gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, and zonisamide are effective against partial seizures; each is usually used in combination with one of the older agents. However, of the newer AEDs, oxcarbazepine is approved as monotherapy, lamotrigine is approved as monotherapy after initial adjunctive use, and topiramate has a monotherapy application pending. Partial seizures that secondarily generalize respond to these same AEDs.

Generalized convulsive seizures Valproate, lamotrigine, and topiramate are the AEDs of choice for patients with primary generalized convulsions, because some of these patients may also have other generalized seizures that can be controlled with one of these agents. Carbamazepine and phenytoin were used historically to treat generalized convulsive seizures. The barbiturates are not favored in the treatment of generalized convulsive seizures, primarily because of their sedative effects. Zonisamide and levetiracetam may benefit some patients with generalized convulsive seizures.

Table 3 Antiepileptic Drugs (*continued*)

Agent (Trade Name)	*Formulations*	*Dosage*	*Principal Sites of Action*	*Targeted Seizure Type*
Phenobarbital (Solfoton, Luminal)	Tablets: 8, 15, 16, 30, 32, 60, 65, and 100 mg Injection: 30, 60, 65, and 130 mg/ml Solution: 20 mg/5 ml	2–5 mg/kg/day q.d. or in two divided doses	Chloride channels	Focal Primary and secondary GTC
Phenytoin (Dilantin, Phenytek)	Chewable tablets: 50 mg Extended-release capsules: 30, 100, and 300 mg Suspension: 125 mg/5 ml Injection: 50 mg/ml	Maintenance: 3–7 mg/kg/day in three divided doses; single dose or two divided doses for extended-release forms	Sodium channels Calcium channels NMDA receptors	Focal Primary and secondary GTC
Primidone (Mysoline)	Tablets: 50 and 250 mg Suspension: 250 mg/5 ml	500–1,500 mg/day in two or three divided doses	Chloride channels GABA uptake	Focal Primary and secondary GTC
Tiagabine (Gabitril)	Tablets: 2, 4, 12, 16, and 20 mg	32–56 mg/day in two to four divided doses	Sodium channels Potassium channels Glutamate receptors Carbonic anhydrase inhibition	Partial Focal and secondary GTC Tonic/atonic GTC Myoclonic
Topiramate (Topamax) Valproic acid/valproate sodium (Depakene/Depacon)	Tablets: 25, 100, and 200 mg Capsules: 15 and 25 mg Capsules: 125, 250, and 500 mg Extended-release capsules: 250 and 500 mg Syrup: 250 mg/ml Injection: 100 mg/ml	500–3,000 mg/day in two to four divided doses	Sodium channels Calcium channels	Focal and secondary GTC Absence Tonic/atonic GTC Myoclonic
Vigabatrin (Sabril)†	Tablets: 500 mg	2–4 g/day	GABA transaminase	Focal and secondary GTC Infantile spasms Lennox-Gastaut syndrome
Zonisamide (Zonegran)	Capsules: 100 mg	200–600 mg/day in two divided doses	Sodium channels Calcium channels Carbonic anhydrase inhibition	Focal Primary and secondary GTC Poor or none

*Rarely, lamotrigine may exacerbate myoclonic seizures
†Not available in the United States
EAA—excitatory amino acids GABA—γ-aminobutyric acid GTC—generalized tonic-clonic NMDA—*N*-methyl-D-aspartate

Generalized nonconvulsive seizures Generalized nonconvulsive seizures, particularly absence seizures, can be treated with ethosuximide, lamotrigine, or valproate. For patients who have only absence seizures, ethosuximide is satisfactory. However, for patients who have absence seizures in conjunction with other types of seizures, such as generalized convulsions or myoclonic seizures, valproate is the drug of choice; lamotrigine may also be effective. Some patients may respond to therapy with topiramate or zonisamide.

AED Pharmacokinetics

All AEDs are given orally once daily or more frequently [*see Table 3*]. Absorption of most AEDs usually occurs slowly over a period of hours and may be incomplete, especially in the case of gabapentin. Protein binding varies considerably among the drugs, ranging from 0% for gabapentin to 90% or more for phenytoin. Except for gabapentin, levetiracetam, and vigabatrin, all AEDs are metabolized in the liver before renal excretion. Additionally, zonisamide and topiramate have significant renal excretion.

AED clearance and half-life vary from hours to days. The half-lives of carbamazepine, valproate, primidone, and gabapentin are relatively short, ranging from 4 to 8 hours, which necessitates administering these agents at least three times daily (although extended-release formulations of valproate and carbamazepine allow twice-daily dosing). Phenytoin, lamotrigine, phenobarbital, and zonisamide have half-lives of a day or longer and may be administered once or twice daily. Phenytoin, carbamazepine, and the barbiturates cause enzyme induction, and long-term treatment with these drugs can affect their own rates of metabolism. Perhaps as important, these agents may affect metabolism of other medications the patient is taking. All AEDs that are metabolized in the liver can compete with other drugs that also undergo hepatic metabolism and so can delay clearance of those drugs. Because of their ability to induce or block drug metabolism, all of the AEDs except gabapentin, levetiracetam, and vigabatrin may be associated with pharmacokinetic drug interactions in which drug levels and effects can be markedly altered by the concomitant administration of two or more drugs. This kind of interaction should be anticipated in all patients. It can be detected from clinical symptoms and levels of AED in the blood, especially free drug levels, and can be corrected by adjustment of dosages. Pharmacodynamic drug interaction may also occur. In this situation, the combination of two or more drugs with similar or antagonistic mechanisms causes their clinical effects to be enhanced or diminished, and these changes may necessitate adjustment of dosages. Pharmacodynamic drug interactions can be anticipated when drug mechanisms of action are known.

Adverse Effects of AEDs

All AEDs can produce adverse effects, which are numerous

Table 4 Idiosyncratic Reactions to Antiepileptic Drugs[83,84]

Agent	*Agranulocytosis*	*Allergic Dermatitis/ Rash*	*Aplastic Anemia*	*Hepatic Failure*	*Pancreatitis*	*Serum Sickness Reaction*	*Stevens-Johnson Syndrome*	*Teratogenic Effects (FDA Pregnancy Category*)*

and vary considerably from patient to patient. Most of the adverse effects caused by AEDs can be tolerated. However, rare idiosyncratic effects may be life threatening [*see Table 4*]. Good medical practice demands that physicians obtain screening studies before starting a patient on AED treatment. However, prospective studies of the effect of routine blood and urine assessment in patients receiving long-term AEDs showed no value in asymptomatic patients.[40] On the other hand, clinical monitoring—by reviewing and reporting symptoms or by physical examination—is cost-effective and practical. Routine laboratory monitoring, as currently practiced, is not effective in anticipating life-threatening effects associated with the major AEDs, including carbamazepine, phenytoin, phenobarbital, lamotrigine, and valproate. Continuing communication with the patient and family is the best strategy for monitoring for adverse events. They must be aware of potential complications and the symptoms that might herald an adverse event. An approach that combines clinical expertise with educating patients and caregivers about the risks and benefits of treatment and enlisting their active participation is becoming the standard of care.

Some of the undesirable side effects of AEDs, such as neurotoxicity, are clearly dose related. Other adverse effects, such as some forms of hepatotoxicity or aplastic anemia, seem to be idiosyncratic. Still others have other mechanisms. An efficient way to understand the adverse effects of AEDs is to define them according to the affected organ system.

Effects on the central nervous system All AEDs can cause depression of cortical function, with symptoms of sedation and lethargy. Dose-dependent neurologic toxic changes are the most common adverse effects of AEDs and limit the amount of drug that may be used. CNS symptoms are used to titrate to an acceptable dose; this is independent of AED blood levels, because the therapeutic range is statistically derived and may not apply to an individual patient. For example, carbamazepine causes diplopia or sedation; either one serves as an indication that the patient has reached the maximum tolerated dose. If AED blood levels reach the upper limit of the therapeutic range but seizures continue to be uncontrolled and the patient remains free of side effects, the dose is increased until neurotoxicity develops. This defines the maximum tolerable dose for that patient.

Although dose-related effects of phenytoin on the cerebellum are classic indicators of toxicity, the typical findings are often blunted or inapparent because of individual patient responses.[40] The expected progression of symptoms from nystagmus to ataxia and confusion or feelings of intoxication does not always occur. Residual ataxia after prolonged phenytoin intoxication can probably occur, especially in vulnerable patients.[41]

Persistent or fluctuating ataxia appears to be related to long duration of epilepsy, use of multiple drugs, and persistently high serum drug levels. Changes in intellectual function and alterations in personality or even psychiatric effects have been re-

ported with several AEDs. Altered IQ in children treated with phenytoin and primidone appears to be related to higher blood levels of the drugs. Assessment of cognitive function in patients treated in random fashion failed to reveal any differences among the major AEDs, although phenobarbital appears to have a greater effect than other medications.[42] Drugs administered to children may have unpredictable or paradoxical effects; for example, barbiturates are well known to cause hyperactivity in children. Depression and psychosis may be caused by AEDs. Most effects on behavior appear to be dose related. Psychosis after seizure control has been reported, as have other behavioral problems; in some cases, this appears to be related to normalization of the EEG and is termed forced normalization.[43]

Phenytoin may cause dose-related abnormal movements; carbamazepine seldom causes involuntary movements. Valproate may cause tremor.[43]

Mild sensory neuropathy has been reported in 8% to 15% of patients treated with older AEDs[44] and seems to require long-term exposure. Prolonged exposure to high plasma levels causes loss of large myelinated fibers and clustered nonrandom distribution of segmental demyelination that suggests a pattern of axonal neuropathy and secondary demyelination. Use of multiple drugs also is associated with chronic neuropathy. Altered peripheral nerve function is thought to be an effect of AEDs on folate metabolism, with resultant mild alteration of peripheral nerve function. Usually, the clinical effect is not severe, but loss of deep tendon responses or vibratory sensibility at the ankles may occur.

Aside from these dose-dependent effects, AEDs may induce a reversible encephalopathy and even progressive mental deterioration or delirium. On rare occasions, the initial exposure of a patient to valproate causes coma; the mechanism of this effect may be related to mitochondrial metabolism.[45]

Gastrointestinal and hepatic effects Valproate produces hepatic failure in approximately one in 10,000 patients. The highest rate of hepatic failure is observed in children younger than 2 years who are treated with multiple drugs. Older patients on monotherapy have a much lower rate: one in 45,000.[46] The mechanism of valproate-induced hepatotoxicity is unknown but may involve toxic metabolites of the drug. Hepatic damage associated with phenytoin, carbamazepine, or phenobarbital therapy is infrequent. The mechanism that causes the hepatic failure is thought to be an idiosyncratic hypersensitivity reaction.

Pancreatitis has been observed during valproate therapy, and fatalities have occurred in both children and adults.[47] Reexposure of affected patients has caused recurrent pancreatitis, but the mechanism of this adverse effect has not been established.[47]

Hematologic effects Adverse hematologic reactions associated with idiosyncratic responses to AEDs range from a mild decrease in the number of blood cells to aplastic anemia. Fortunately, serious problems are infrequent. Phenytoin may alter lymphocyte function, given that 21% to 25% of patients on long-term therapy have decreased circulating levels of IgA along with depressed lymphocyte phytohemagglutinin transformation.[48] Phenytoin hypersensitivity may cause generalized lymphadenopathy and in rare instances may be associated with lymphoma.[49] Carbamazepine treatment commonly causes hematologic changes. Dose-related leukopenia is reported to occur in 12% of treated patients.[40] In my experience, this estimate is low. The mechanisms leading to this effect on granulocytes is unknown, but the effect appears to be dose related and does not herald more serious reactions. There appears to be little need for concern until the total white blood cell count is less than 2,500/mm^3 or the total granulocyte count is less than 750/mm^3.

Aplastic anemia occurs infrequently with AEDs, and no single drug, with the exception of felbamate, seems to be more likely than another to produce this serious complication. Aplastic anemia associated with carbamazepine treatment seems to be related to dosing patterns and advanced patient age.[40] Of 65 patients who died of aplastic anemia associated with carbamazepine, only four were children.[40] Valproate causes a dose-related decrease in the level of circulating platelets that is only occasionally symptomatic.[50] Occurrence of purpura or petechial hemorrhage requires discontinuance of the drug. The mechanism is a change in platelet adhesiveness, with acceleration in the second stage of platelet consumption causing accelerated loss of circulating platelets. An IgM platelet autoantibody is occasionally detected.[51] Mild macrocytosis and decreased red blood cell folate levels occur with antiepileptic drug therapy, particularly phenytoin. Megaloblastic anemia is an occasional effect of antiepileptic drug treatment that appears to be related to alterations in metabolism of folate. Folate supplementation is required in some cases.

Dermatologic reactions Skin reactions to AEDs are not uncommon, but life-threatening dermatologic responses are rare.[52] Drug-induced eruptions range from mild erythema, with or without pruritus, to serious exfoliative reactions or development of bullae. Dose-related exanthema is the most common skin reaction. This form of rash may respond to dose reduction. The rash may be pruritic, maculopapular, or morbilliform, and about 50% of patients may have prodromal symptoms that include malaise and fever. Drug eruptions that begin as pruritic effects with morbilliform or scarlatiniform rashes may progress to severe exfoliative dermatitis. In such cases, the offending drug must be discontinued promptly and another AED substituted. The mechanism of skin reaction may be determined by pharmacogenetic factors related to the ability to metabolize arene compounds formed during drug metabolism.[52] The exfoliative dermatitides produced by AEDs include erythema multiforme, Stevens-Johnson syndrome, and Lyell syndrome.[52] Exfoliative dermatitis commonly occurs within 1 to 4 weeks after initiation of treatment and may be fatal. The drug responsible for the reaction must be discontinued and treatment with systemic steroids instituted. Erythema multiforme as a drug reaction is rapid in onset, with erythematous lesions that range from a macular pattern with varied shapes to the development of vesicles or bullae. If mucosal lesions are present, the reaction has evolved to the Stevens-Johnson syndrome. In either case, dermatologic consultation is imperative. Acne is a common minor skin problem associated with phenytoin use. Hypertrichosis is associated with both phenytoin and carbamazepine. Alopecia occurs during the first few weeks of treatment with valproate. Administration of multivitamins containing zinc appears to prevent this change in hair-shaft strength.

Connective tissue disorders AEDs may cause lupus erythematosus, scleroderma, Sjögren syndrome, and eosinophilic fasciitis. Lupus occurs in both a discoid and a systemic pattern. Criteria for diagnosis include malar erythema with discoid skin

changes, photosensitivity, oral ulceration, nonerosive arthritis, serositis, and nephropathy. Hematologic and immunologic changes are revealed by positive lupus erythematosus cell preparations, anti-DNA (double stranded) antibodies, and antinuclear antibodies.[53] Drugs may precipitate lupus, exacerbate existing lupus, or be associated with an isolated drug-related form. Drug-related lupus usually abates after discontinuance of the inciting drug. Further, the pattern of organ involvement usually spares skin, kidneys, and the CNS. The immunologic pattern usually does not involve the induction of antibodies to double-stranded DNA. Long-term phenytoin use has caused a syndrome of ecchymoses, gingival bleeding, and lupus anticoagulant antibodies associated with prothrombin deficiency. Carbamazepine and ethosuximide have also been associated with the development of drug-induced lupus.

Metabolic and endocrine effects Hyponatremia is a dose-related effect of carbamazepine that seems to occur only in adults. Oxcarbazepine is also associated with dose-related hyponatremia, primarily in adults; this occurs more commonly than with carbamazepine.[54] Central effects on antidiuretic hormone and peripheral or renal effects have been considered as mechanisms, but the exact pathogenesis remains unknown. With either drug, the hyponatremia seldom causes a clinical problem. Effects of phenytoin on pituitary-adrenal function are related to the peripheral effects of induction of cytochrome P-450 hepatic enzymes, with resultant accentuation of metabolism of endogenous hormone. Accelerated metabolism of exogenously administered steroid hormone, such as birth control pills, may cause contraceptive failure. Hypothalamic function may be affected by phenytoin. Changes include altered release of antidiuretic hormone, block of thyroid-stimulating hormone effect by thyrotropin-releasing hormone, and, in women, augmentation of secretion of follicle-stimulating hormone and luteinizing hormone.[55,56] Phenytoin can alter the results of thyroid function studies: it lowers total triiodothyronine (T_3) and thyroxine (T_4), so patients may have a decreased free T_4 level, with a normal thyroid-stimulating hormone (TSH) level; however, phenytoin also increases free T_4 and T_3 by induction of displacement from thyroxine-binding globulin, which may normalize free T_4 levels. Most patients remain clinically euthyroid.[55]

Weight gain may occur with valproate or gabapentin; weight loss may occur with topiramate or zonisamide. The exact mechanisms are unknown. Other AEDs are considered weight neutral.

Discontinuing AED Therapy

Most patients treated with AEDs require treatment for several years. When a patient has remained seizure free after several years of AED therapy and the underlying epilepsy syndrome is not one that is known to require continuous treatment (e.g., juvenile myoclonic epilepsy), the question arises as to whether to discontinue treatment. A meta-analysis[57] concluded that the likelihood of successful AED withdrawal was highest in patients meeting the following criteria: (1) they have been seizure free from 2 to 5 years on AED treatment, (2) they have a single type of partial seizure (simple partial, complex partial, or secondary generalized tonic-clonic seizure) or single type of primary generalized tonic-clonic seizure, (3) their neurologic examination results and IQ are normal, and (4) their EEG has normalized with treatment.

VAGUS NERVE STIMULATION

Electrical stimulation of the vagus nerve has both acute and chronic antiepileptic effects. The acute effects result from polysynaptic transmission and activation of key inhibitory pathways; the chronic effects may be the result of persistent changes in neurotransmitters or changes in cortical and subcortical synaptic activity.

Vagus nerve stimulation (VNS) is now the second most common treatment for epilepsy in the United States, after AEDs. VNS devices were approved by the Food and Drug Administration in 1997, and over 16,000 of these devices have now been implanted in patients worldwide.[58]

Implantation of a VNS device usually takes less than 1 hour and can be done as an outpatient procedure. The generator, which measures 6.9 by 52 mm and is made of titanium, is placed subcutaneously in the left upper chest. The lead wires are placed on the left cervical vagus nerve and tunneled to the generator. VNS devices have programmable settings; the intensity and duration of the pulses (e.g., 1.5 mA for 30 sec) are tailored to the individual patient. Once programmed, the device operates on its own. In addition, patients can activate the device themselves, through the use of a handheld magnet, which triggers a switch that initiates a separate program in the device. This ability to abort seizures gives patients an active role in the treatment of their epilepsy and is an important psychosocial benefit of VNS therapy.

Criteria for VNS placement include partial onset seizures that persist despite adequate trials of two or three AEDs (preferably, AEDs with differing mechanisms of action). Nonepileptic events must be excluded. The patient should not be a good candidate for focal resective surgery (see below); in patients who are good candidates, this surgery is preferred to VNS because it is more likely to render the patient seizure free. In the United States, the use of VNS is limited to patients older than 12 years; in the European Union, there is no age limit with VNS therapy, although the size of the device may limit its use in children younger than 3 or 4 years.[59]

SURGICAL TREATMENT

Surgical treatment is an option for patients who have failed to respond to conventional AED treatment or who have had intolerable adverse drug effects, whose seizures have a focal origin, and whose seizures originate in tissue that can be removed without causing disability.[60] Epilepsy may be associated with a structural lesion in the region of seizure onset. The presence of a seizure focus in the hemisphere dominant for language and the occurrence of complex partial seizures arising in extratemporal tissue necessitate special assessment. Detection of bilateral epileptiform discharges, development of secondarily generalized seizures, and occasional onset of a seizure from contralateral tissue tend to add to the complexity of preoperative assessment.[61]

Current standards for surgery require locating the seizure focus by several means. Although ictal and interictal scalp EEG and intraoperative electrocorticography have been used, these methods may fail to provide adequate lateralizing or localizing information. Therefore, most epilepsy centers require combined video and scalp EEG recording of at least three of a patient's typical seizures. Additional localizing information is obtained from MRI, neuropsychology, and isotope studies of blood flow or metabolism. Location of memory function and speech lateralization are also important. Insertion of intracranial electrodes is required should the scalp EEG fail to provide adequate lateral-

izing or localizing information. However, because of the small but significant morbidity associated with invasive electrode studies, functional imaging [*see* Brain Imaging, *above*] is being explored as an alternative.[21]

The most commonly performed surgical procedure for epilepsy is temporal lobectomy. After this procedure, approximately 70% of patients remain seizure free, and an additional 20% show marked improvement. Histopathologic assessment shows that in at least 60% of patients, sclerotic changes occur in the resected hippocampus. Long-term follow-up studies have shown a fixed rate of recurrent seizures after temporal lobectomy, so these patients are no longer taken off AEDs postoperatively.[62] The goal of this procedure is not to eliminate AED use; it is to eliminate seizures. Patients may be able to reduce the number of AEDs or lower the dose, but even those who remain on the same AED regimen generally enjoy significant improvement in their quality of life.

Complications associated with resective surgery remain low and generally acceptable. A superior quadrantic visual field defect may occur in patients undergoing classic temporal lobectomy. Permanent hemiparesis is reported in up to 2.4% of patients; mortality varies from 0% to 1.7%.[60]

More advanced procedures (i.e., resection of extratemporal foci, sectioning of the corpus callosum, and functional hemispherectomy) are performed in special epilepsy centers. Corpus callosotomy is a palliative procedure for patients who sustain injuries secondary to falls during seizures.[63] It has largely been supplanted by VSN device implantation, however.

THE KETOGENIC DIET

A diet high in fat and low in carbohydrates can prevent seizures by maintaining the patient in ketosis. The use of ketogenic diets for epilepsy was pioneered in the 1920s. Such diets remained a standard aspect of epilepsy treatment until the last decades of the 20th century, when their popularity was eclipsed by that of AEDs. However, the ketogenic diet has reemerged, and clinical studies have confirmed its efficacy in almost all seizure types.[59]

The classic ketogenic diet has a 4-to-1 ratio of calories derived from fats to calories derived from proteins and carbohydrates. The diet is individualized, to the extent possible, according to the patient's food preferences and eating habits. Initiation of the diet is done with the patient in hospital. Strict adherence to the diet is necessary.

Ketogenic diets are used principally in children. Although the exact antiepileptic mechanism of ketogenic diets remains unknown, it is known that during the diet, the brain utilizes ketone bodies for fuel. With maturity, the brain's ability to extract ketones from the blood decreases as much as fivefold, and this may make the ketogenic diet slightly less effective in adults. Most often, however, adults do not use the diet because they find it impractical.

Treatment of Status Epilepticus

Status epilepticus is a danger to the patient and a treatment challenge to the physician. The cardinal feature of this serious epileptic state is continuous seizures or two or more seizures occurring in sequence without recovery of consciousness between them. Status epilepticus has varied forms of clinical presentation, including repeated generalized convulsive seizures, with coma between seizures; nonconvulsive seizures, causing a change in cognitive function; and sequential focal seizures, including focal motor seizures or focal sensory complaints.

Generalized convulsive status epilepticus is the most common and most challenging form of status epilepticus. The patient has convulsive movements and is unconscious. The motor manifestations of convulsive status epilepticus may be symmetrical, with tonic and then clonic activity. If the generalized seizures arise from a focus, lateralized movements occur at the onset or during seizures.

In practical terms, any patients who are in seizure when they reach the emergency department or who are observed having a seizure for 10 minutes must be treated on the assumption that they are in status epilepticus. Treatment is divided into acute management and drug therapy [*see Figure 4*].

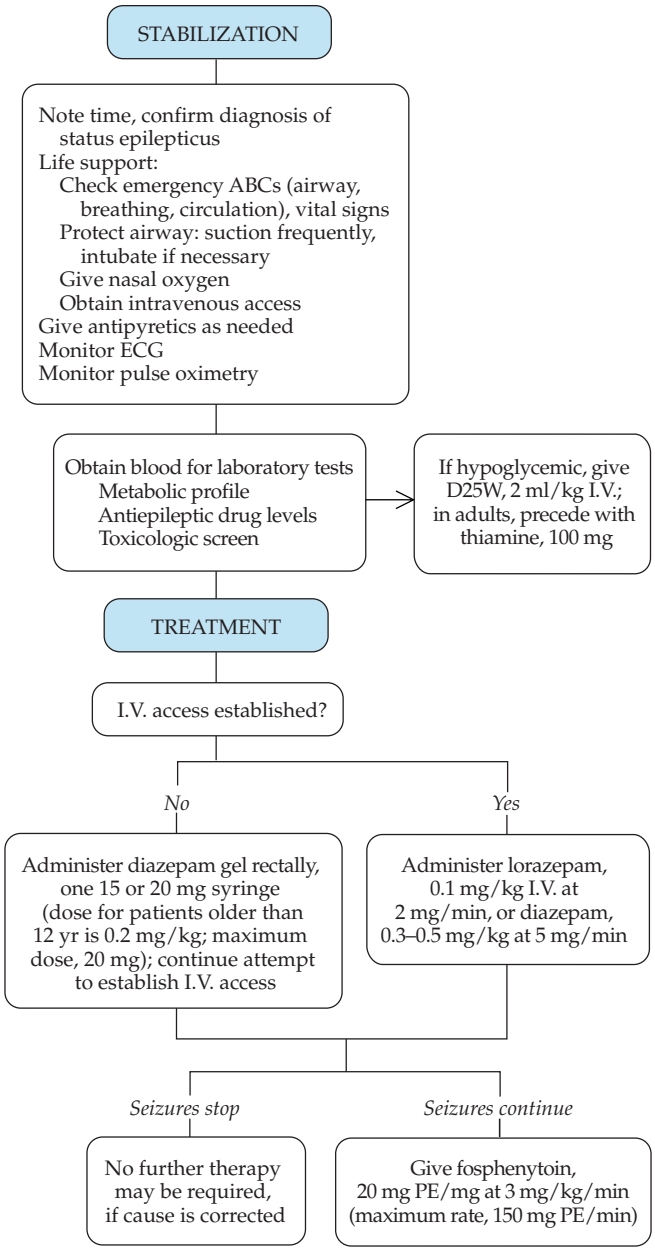

Figure 4 **Treatment of convulsive status epilepticus. (D25W—25% dextrose in water; ECG—electrocardiogram; PE—phenytoin equivalents)**

ACUTE MANAGEMENT

Treatment begins with life support, including clearing the airway and supporting ventilation, maintaining blood pressure, and establishing intravenous access. The airway must be protected and appropriate oxygenation ensured. Although intubation may be necessary, the decision to use it must be made in parallel with selection and administration of an anticonvulsant drug. Physiologic monitoring must include assessment by electrocardiography and measurements of blood pressure, levels of blood gases, levels of biochemical markers, and body temperature.

Hypoglycemia must be excluded or if present, corrected. Blood glucose levels must be measured promptly. If this is not possible, the patient should be treated empirically with intravenous glucose. Adults should first receive thiamine, 100 mg intravenously, to avoid precipitating Wernicke disease in thiamine-deficient alcoholic patients. The dose of glucose for adults is a bolus of 50 ml of 50% glucose; for children, the dose is 2 ml/kg of 25% glucose solution.

DRUG THERAPY

Clinical and electrical seizures must be terminated rapidly because total duration of convulsive status epilepticus correlates with response to treatment and with outcome.[64] Physicians treating patients with convulsive status epilepticus must be familiar with the drugs available, including methods of administration, dosages, and acute side effects. Best outcomes are associated with having a treatment plan, using effective drugs administered by the appropriate route and in adequate doses, and anticipating apnea. A protocol should be followed, and drugs should be administered intravenously (except for diazepam gel per rectum [see below]). Currently, intramuscular administration has no role in treatment. The clinical situation determines which drug should be administered. If a patient is having a seizure at the time of assessment, a benzodiazepine is needed. If the patient has a history of serial seizures but convulsive seizures have abated, administration of a long-acting AED is the best choice.[65] In the only randomized, controlled trial comparing initial intravenous treatments for status epilepticus (which was conducted at Veterans Affairs hospitals), lorazepam was found to be more effective than phenytoin and easier to use, although no more effective than phenobarbital alone or diazepam followed by phenytoin.[66]

Benzodiazepines

The benzodiazepines are effective and highly potent. Diazepam and lorazepam are commonly used. A rectal gel formulation of diazepam is currently available, packaged in predosed syringes. Because it can be administered to a patient with no intravenous access, it is suited for use in the home, in the field, and in the emergency department while intravenous access is being obtained. Diazepam is highly lipid soluble and penetrates the brain rapidly. However, redistribution into nonneural fatty tissue causes rapid decline in both brain and blood concentrations of the drug. If diazepam is used to terminate seizures, a long-acting AED such as fosphenytoin must be administered. Lorazepam has a longer duration of action than diazepam but is associated with a prolonged time to full recovery.[65] Both of these drugs cause depression of breathing and even apnea, so ventilation must be supported, and intubation may be necessary.

Fosphenytoin

Convulsive status epilepticus can be terminated by intravenous loading of fosphenytoin, a water-soluble prodrug form of phenytoin. Fosphenytoin is administered in phenytoin equivalents of up to 150 mg/min, or 3 mg/kg/min in children weighing less than 50 kg. It is rapidly converted by phosphatases into phenytoin, leading to blood levels equivalent to those achieved with phenytoin itself, but without the difficulties of administration and risk of tissue injury.

During fosphenytoin treatment, the elderly and patients with cardiac disease or with difficulty maintaining blood pressure require careful monitoring of cardiac rhythm and rate along with blood pressure. Those with hypotension require a slower rate of infusion. Electrocardiographic monitoring may show widening of the QT interval or even induction of arrhythmia. These changes signal the need to slow the rate of infusion even further.

Phenobarbital

Phenobarbital is highly effective and is known to many physicians. The adult dose is 10 to 20 mg/kg. Sedation may result, and apnea is a risk, particularly if the patient has taken benzodiazepines. Blood pressure monitoring is critical; hypotension responds to slowing the rate of administration.

TREATMENT OF REFRACTORY STATUS EPILEPTICUS

If a patient fails to regain consciousness or continues to have seizures after first-line therapy, neurologic consultation is required. Such a patient requires urgent EEG recording,[67] and anesthesia must be considered. An effective anesthetic drug is pentobarbital, although some authors suggest use of propofol or midazolam.[65,68] Midazolam (0.2 mg/kg administered by slow I.V. bolus injection followed by 0.75 to 10 μg/kg/min) and propofol (1 to 2 mg/kg with 2 to 10 mg/kg/hr) appear to be replacing pentobarbital as the drugs of choice.[65] The patient must be intubated and appropriate intensive care monitoring established. Patients are maintained in anesthetic coma for variable periods. Continued management requires gradual tapering of the maintenance dose at 4 hours, again at 8 hours, and on a regular schedule thereafter, with observation to determine whether seizures have abated and the EEG remains free of seizure discharges. Vasopressors may be needed during pentobarbital coma. Subtle convulsive status epilepticus occasionally develops. EEG assessment is required, particularly when motor changes are not obvious.[67]

AFTERCARE

After initial diagnostic studies are performed and the seizures controlled, the cause of status epilepticus must be sought. Medical and neurologic evaluations are important. When the patient is known to have epilepsy and the chart is available for review, further evaluation may be unnecessary. Brain-imaging studies are appropriate after seizures are under control. A history of head trauma, focal seizures, or signs of systemic illness should guide evaluation. If the patient is febrile, a lumbar puncture with examination of the CSF is needed, but only after mass lesions and ventricular obstruction are excluded by CT or MRI. An EEG is indicated in all patients with new-onset status epilepticus or those with treated status epilepticus who are not recovering their previous neurologic baseline. The clinical situation must determine decisions.

Prognosis of Epilepsy with Treatment

The likelihood of control or remission of epilepsy varies ac-

cording to the particular epilepsy syndrome, as well as factors specific to the individual case. Control, when applied to epilepsy, means lack of seizures with use of medication. Remission means lack of seizures without medication.

Prognosis with medical control of generalized and partial seizures has improved with better methods for assessment, introduction of new drugs, and more rational use of older agents.[69] The simultaneous use of EEG and video monitoring has improved diagnostic accuracy. Of patients with new-onset seizures, 60% to 65% achieve good control with a single drug.[70] Some studies show a 5-year absence of seizures in at least 70% of patients who were followed for 20 years. Of these patients, 50% were in remission—that is, they were not taking any medication.[29]

Control is difficult to achieve in patients with epilepsy of longer duration, with partial seizures, with more seizures before the start of treatment, with seizures that are of known cause, and with epileptiform patterns on EEG.[69] Poor seizure control also is associated with various types of seizures with abnormalities on EEG, delay in the start of treatment for more than 1 year, and frequent seizures; poor control may result in impaired social adjustment.[69]

The prognosis for control is less favorable with complex partial seizures than with generalized seizures. Of patients with complex partial seizures, the outcome tends to be better in those who have normal mentation, short duration of illness, and low seizure frequency.[29,69] However, if complex partial seizures are complicated by generalized tonic-clonic seizures, complete control is difficult to achieve. Patients at high risk for development of intractable complex partial seizures are those with clusters of seizures, more than one seizure a day, aura at the onset of seizures, and psychiatric disease.[69] In drug trials using high-dose carbamazepine, phenytoin, and barbiturates to the point of clinical toxicity in patients with intractable seizures, high-dose therapy resulted in complete control in 22% of patients; 38% had either an increase or no change in seizure frequency, and approximately 30% were not affected by any drug.[71]

Epilepsy may affect life span. Review of coroners' cases reveals common factors in sudden death in epileptic patients. Most deaths occurred when patients were in bed, with 6% to 30% occurring during sleep. At autopsy, few patients had therapeutic blood levels of prescribed AEDs; 50% had no detectable levels. Seizures are not always immediately associated with death[72]; cardiac arrhythmia has been implicated.[72,73] The prevalence of sudden death is between one in 2,000 and one in 900 patients with epilepsy, with higher rates occurring in patients with refractory epilepsy and nocturnal convulsive seizures.

Special Issues

BRAIN TUMORS

Brain tumors heighten susceptibility to seizures; by the time of diagnosis, 20% to 40% of patients with brain tumors have experienced a seizure. Treatment with anticonvulsant medications is clearly indicated for brain tumor patients who have had a seizure. Prophylactic AEDs should not be used routinely in patients with newly diagnosed brain tumors, however, because these agents are not effective in preventing first seizures in this population, and AED side effects are more frequent and more severe.[74]

PSYCHOSOCIAL DISABILITY

Chronic medical conditions causing the need for continuous medical treatment affect self-image and self-esteem. Epilepsy has the added adversity of inducing a fear of loss of control and presents situational pressures such as difficulties in gaining employment, inability to obtain insurance, and driving restrictions. All of these problems exacerbate social isolation. Local resources, such as a chapter of the Epilepsy Foundation of America [*see Sidebar* Internet Resources on Epilepsy], provide an opportunity for patients to receive help with these important problems. Each patient must be instructed about driving in accordance with state law, and this warning must be recorded on the patient's chart.

ORAL CONTRACEPTIVES

Enzyme-inducing AEDs accelerate metabolism of oral contraceptives; these include carbamazepine, oxcarbazepine, phenobarbital, phenytoin, and topiramate (in doses over 200 mg daily).[75] Birth control pills may fail; the dose of hormone needs to be adjusted, and the patient must be informed of this important drug interaction. This discussion must be recorded on the patient's chart.

PREGNANCY

Women are instructed by gynecologists to avoid medication during pregnancy, yet women with epilepsy may require long-term AED treatment to control seizures. Physicians must review issues regarding teratogenesis with all women capable of childbearing, and this discussion must be recorded on the patient's chart.[76] Maternal epilepsy is associated with risk of fetal malformations, and treatment with AEDs increases the risk from between 2% and 3% to between 4% and 6%.[77] All of the commonly used AEDs cause major malformations, including ventricular septal defects and cleft lip and palate. Valproate and carbamazepine treatment are associated with spina bifida; the

	Valproate	125–250 b.i.d.	250–500	1–2	750–1,500 divided t.i.d.
	Zonisamide	100 q.o.d.–q.d.	100	2	200–600 divided b.i.d.

Avoid using in the elderly: felbamate may cause acute, sometimes fatal, fulminant hepatic failure or aplastic anemia.

†Lamotrigine may cause a dose-dependent rash. Dosing depends on whether patient is concurrently taking an inducer or inhibitor of hepatic cytochrome P-450 enzymes.

incidence is 1% to 2%, which is 10 to 20 times greater than that in the general population.[78,79] Minor morphologic malformations, however, are common. Midface abnormalities, digital hypoplasia, and nail-bed hypoplasia have been observed in 5% to 30% of infants of mothers treated with AEDs. Women requiring valproate and carbamazepine especially need preconception counseling.

Mechanisms of teratogenesis are unknown, but recommendations have been developed on the basis of population studies. Epileptic mothers should be treated with the lowest effective dose of a drug, and the frequency of doses should be designed to avoid high peak serum levels during each day. Use of a single drug is best, if possible. All women with epilepsy who are planning a pregnancy must be given supplemental folate before conception and daily throughout pregnancy. Vitamin K_1 must be given to mothers during the last 4 weeks of gestation to reduce the occurrence of coagulopathy in the infant. If the mother is inclined to consider therapeutic abortion should the fetus have a neural tube defect, careful assessment with ultrasonography and amniocentesis will be needed.[76,77]

ELDERLY PATIENTS

The incidence of epilepsy among the elderly is increasing as longevity increases. Given the steady growth in this population segment, the elderly are likely to become the most common source of new-onset seizures.[80] Whereas generalized epilepsies peak in the first 5 years of life, focal epilepsies predominate in patients 65 years of age and older.

Acute seizures in the elderly can result from conditions such as drug intoxication or withdrawal (including prescription drugs and ethanol) and electrolyte disorders. Causes of focal epilepsy include strokes (especially hemorrhagic stroke), cerebral neoplasm, degenerative brain disease, and closed head trauma. Only a minority of patients who experience early seizures after strokes (within the first 2 weeks, typically within 24 to 48 hours) will develop epilepsy, but the majority of those with late seizures (beyond 2 weeks afterward) develop epilepsy. Epilepsy is sixfold to eightfold more common in patients with dementia and may occur within 3 to 4 years after the onset of dementia.

Clinical features of specific epilepsy syndromes are the same in the elderly, but postictal symptoms tend to be more marked and much more prolonged; whereas postictal features typically resolve within 30 minutes in younger persons, in the elderly they may last as long as 4 to 8 days. Diagnostic testing in the elderly is complicated by the fact that in between seizures, epileptiform abnormalities on EEG become less common with advancing age. The differential diagnosis should include syncope (which may be preceded by auralike symptoms and accompanied by tonic or myoclonic jerks) and transient ischemic attacks.

The choice of drugs is similar to that for younger patients, but changes in body function associated with aging complicate treatment.[81] Decline in renal and hepatic function reduces drug protein binding and clearance. Altered body mass and structure change tissue-penetration kinetics. Consequently, introduction of AED therapy in elderly patients follows the so-called low and slow rule: treatment should start with lower doses and titrate slowly [*see Table 5*]. Because plasma levels of AEDs correlate less

well with efficacy and toxicity in the elderly, physicians should instead use clinical end points to guide dosing (e.g., seizure frequency to determine efficacy, and vigilance to detect symptoms of drug side effects). If blood levels of protein-bound AEDs are measured, measurement of unbound drug levels provides more useful information than total plasma levels, because serum protein levels decline with advancing age.[82] Finally, many elderly patients are receiving pharmacologic treatment for other concomitant illnesses, and the resulting polypharmacy can lead to adverse drug interactions.

XIII DISORDERS OF SLEEP

SUDHANSU CHOKROVERTY, M.D.

Sleep and wakefulness are two basic biologic processes that have independent functions and controls. Sleep has been defined on the basis of behavioral criteria (e.g., lack of mobility or slight mobility, closed eyes, a markedly reduced response to external stimulation, a characteristic sleeping posture, and a reversibly unconscious state) and physiologic criteria (e.g., readings obtained by electroencephalography [EEG], electro-oculography [EOG], and electromyography [EMG]).[1-3]

The exact biologic functions of sleep are not known, although it is known that sleep is essential and that sleep deprivation leads to impaired attention and decreased performance, in addition to sleepiness. Sleep is believed to have restorative, conservative, adaptive, thermoregulatory, and consolidative functions. Sleep is also required for maintenance of synaptic and neuronal network integrity.[1] The theory that memory reinforcement and consolidation take place during sleep has been strengthened by scientific data.[4,5] Although the exact physiologic functions of dreaming are unknown, they may include activation of the neural networks of the brain, restructuring and reinterpretation of data stored in memory, and removal of unnecessary and useless information from the brain.

Primary care physicians should have a high index of suspicion for the presence of sleep disorders. Most sleep disorders, once recognized, can be managed with limited consultation. The initial step is to treat any condition that may be secondarily responsible for hypersomnia or insomnia. However, the treatment of primary sleep disorders is best handled by a sleep specialist.

Physiology of Sleep

SLEEP ARCHITECTURE AND STAGES

Sleep is divided into two independent states: non–rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. NREM sleep is further divided into four stages [*see* Non–Rapid Eye Movement Sleep, *below*], primarily on the basis of electroencephalographic criteria [*see Figure 1a*]; together, stage III and stage IV NREM sleep constitute slow wave sleep. NREM and REM sleep alternate, with each cycle lasting about 90 to 100 minutes. Four to six such cycles are noted during a normal sleep period. The first third of a normal sleep period is dominated by slow wave sleep (see below), and the last third is dominated by REM sleep.

Non–Rapid Eye Movement Sleep

In stage I NREM sleep, the alpha wave (8 to 13 Hz) rhythms characteristic of wakefulness diminish to less than 50% in an epoch (i.e., a 30-second segment of a polysomnographic tracing with a speed of 10 mm/sec), and a mixture of slower rhythms called theta waves (4 to 7 Hz) appears; EMG activity decreases slightly, and slow, rolling eye movements may be apparent [*see Figure 1b*]. Toward the end of stage I NREM sleep, vertex sharp waves appear. In normal persons, stage II NREM sleep begins

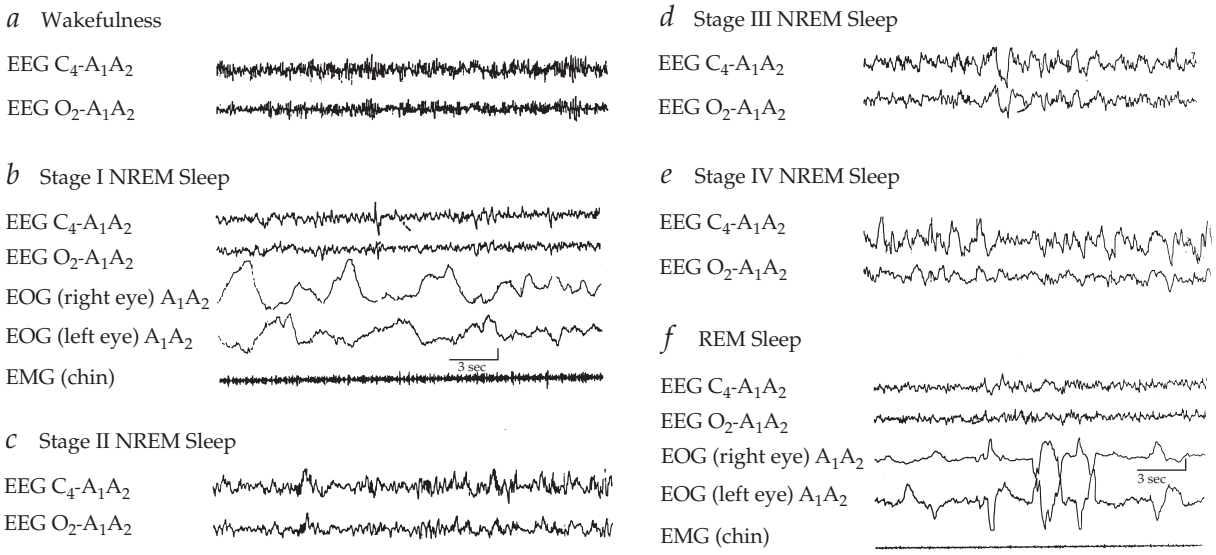

Figure 1 **Human sleep and wakefulness stages are characterized by readings obtained by electroencephalography (EEG), electro-oculography (EOG), and electromyography (EMG). (*a*) An EEG tracing shows the alpha wave (9 to 10 Hz) activity representative of wakefulness in adults. (*b*) Stage I non–rapid eye movement (NREM) sleep is characterized by low-amplitude theta wave (4 to 7 Hz) activity mixed with a small amount (< 50%) of alpha wave activity and vertex sharp waves in the EEG tracing; slow, rolling movements in right and left eye EOG recordings; and tonic chin EMG activity. (*c*) EEG tracings of stage II NREM show sleep spindles. (*d*) EEG tracings reveal that in stage III NREM sleep, 20% to 50% of an epoch is occupied by waves of 2 Hz or less with an amplitude of greater than 75 mV. (*e*) In stage IV NREM sleep, these waves make up more than 50% of an epoch. Together, stages III and IV constitute slow wave sleep. (*f*) REM sleep is characterized on EEG tracings by low-amplitude mixed-frequency theta wave and beta wave (> 13 Hz) activity, including a small amount of alpha waves without sleep spindles or K complexes. Rapid eye movements are seen in the EOG readouts. The chin EMG shows marked reduction or absence of tonic activity.**

after about 10 to 12 minutes of stage I NREM sleep. The characteristic EEG features of stage II NREM sleep are sleep spindles (12 to 18 Hz, most often 14 Hz) and K complexes intermixed with vertex sharp waves [*see Figure 1c*]. The background rhythms of stage II NREM sleep consist of theta waves and delta waves (< 4 Hz). Less than 20% of the epoch is occupied by delta waves. Stage II NREM sleep lasts for about 30 to 60 minutes. During stage III NREM sleep, the delta waves occupy 20% to 50% of the epoch [*see Figure 1d*], and during stage IV NREM sleep, the delta waves occupy more than 50% of the epoch [*see Figure 1e*].

Rapid Eye Movement Sleep

Sixty to 90 minutes after the onset of sleep, the first REM sleep episode is noted. The EEG tracings during REM sleep are characterized by fast rhythms and theta wave activities, some of which may have a sawtooth appearance [*see Figure 1f*]. The hallmark of REM sleep is the presence of rapid eye movements in all directions and the marked diminution or absence of muscle activities in the chin EMG. Tonic REM sleep is characterized by a desynchronized EEG and muscle atonia, and phasic REM sleep is characterized by REMs as well as phasic swings in blood pressure and heart rate, irregular respiration, and phasic tongue movements. A few periods of apnea or hypopnea may arise during REM sleep.

SLEEP PATTERNS ACROSS THE LIFESPAN

Sleep requirements change dramatically from infancy to old age. Newborns have a polyphasic sleep pattern, with a total of 16 hours of sleep a day. By the time a child is 3 to 5 years of age, the sleep requirement falls to about 10 hours a day. In preschool children, sleep assumes a biphasic pattern. Adults exhibit a monophasic sleep pattern, with an average duration of 7.5 to 8.0 hours a night, but the pattern reverts to biphasic in elderly persons.

In newborn infants, the amount of sleep time spent in the REM state is about 50%, but by 6 years of age, REM sleep has decreased to the normal adult pattern of 25%. By 3 months of age, the NREM-REM cyclic pattern of adult sleep is established and sleep spindles appear. K complexes are first seen in infants at about 6 months of age. Attenuation of the amplitude of delta waves and repeated awakenings—including early morning awakenings—are important features of sleep in elderly persons.

FUNCTIONAL NEUROANATOMY

The neuroanatomic substrates for REM sleep and NREM sleep are located in separate parts of the central nervous system.[2,6] REM sleep is generated by neurons in the pontomesencephalic region.[6,7] The cells that activate REM sleep are cholinergic neurons located in the pedunculopontine tegmental nucleus and the laterodorsal tegmental nucleus in the pontomesencephalic region; these cells fire maximally during REM sleep. The cells that deactivate REM sleep are aminergic neurons located in the locus coeruleus and raphe nuclei; these cells are inactive during REM sleep. A reciprocal interaction in the brain stem between REM-activating and REM-deactivating neurons is responsible for REM generation and maintenance.

The active hypnogenic neurons for NREM sleep are located primarily in the preoptic area of the hypothalamus, the basal forebrain area, and the solitary nucleus region of the medulla. The reticular nucleus of the thalamus is thought to be responsible for sleep spindle generation.

Sleep most likely results from both passive and active mechanisms.[6] Muscle hypotonia during REM sleep is thought to depend on the inhibitory postsynaptic potentials generated by dorsal pontine descending axons.[8,9] The roles of neurotransmitters and neuropeptides are not clearly delineated; they are believed to modulate various sleep stages and cycles. It has been shown that

Table 1 Behavioral and Physiologic Characteristics of States of Awareness

	Characteristics	*Awake*	*NREM Sleep*	*REM Sleep*
Behavioral	Posture	Erect, sitting, or recumbent	Recumbent	Recumbent
	Mobility	Normal	Mildly reduced to absent; postural shifts	Moderately reduced to absent; myoclonic jerks
	Response to stimulation	Normal	Mildly to markedly reduced	Moderately reduced to absent
	Alertness level	Alert	Reversibly unconscious	Reversibly unconscious
	Eye position and movements	Open	Closed	Closed
		WEMs	SEMs	REMs
Physiologic	EEG	Alpha waves Desynchronized	Synchronized	Theta or sawtooth waves Desynchronized
	EMG (muscle tone)	Normal	Mildly reduced	Moderately to severely reduced or absent
	EOG	WEMs	SEMs	REMs
	Heart rate	Normal sinus rhythm	Bradycardia	Bradytachyarrhythmia
	Blood pressure	Normal	Decreases	Variable
	Cardiac output	Normal	Decreases	Decreases further
	Respiratory rate	Normal	Decreases	Variable Apneas may occur
	Alveolar ventilation	Normal	Decreases	Decreases further
	Upper airway muscle tone	Normal	Mildly reduced	Moderately to markedly reduced or absent
	Upper airway resistance	Normal	Moderately increased	Markedly increased
	Cerebral blood flow	Normal	Decreased or normal	Markedly increased
	Parasympathetic activity	Normal	Moderately increased	Markedly increased
	Sympathetic activity	Normal	Mildly reduced	Moderately to markedly reduced or variable
	Penile or clitoral tumescence	Normal	Normal	Markedly increased
	Thermoregulation	Normal	Mildly reduced	Absent

NREM—non–rapid eye movement REM—rapid eye movement SEM—slow eye movement WEM—waking eye movement

adenosine may fulfill the major criteria for neural sleep factor, which mediates the somnogenic effects of prolonged wakefulness.[10]

The recently described hypocretin (orexin) peptidergic system, which is located in the lateral hypothalamic region and perifornical area and has widespread ascending and descending projections, is thought to play a role in the control of sleep and wakefulness.[11-13] Sleepiness may be induced by reduction of activity of the hypocretin projections to the locus coeruleus; midline raphe; and the mesopontine, posterior hypothalamic, and tuberomammillary regions.

PHYSIOLOGIC CHANGES DURING SLEEP

A variety of behavioral and physiologic changes occur during normal wakefulness, NREM sleep, and REM sleep [*see Table 1*]. These changes are most commonly noted in the somatic and autonomic nervous systems (ANS); in the respiratory, cardiovascular, and gastrointestinal systems; in endocrine, renal, and sexual function; and in thermoregulation.[2,14] The fundamental changes in the ANS consist of an increase in the parasympathetic tone and a decrease in sympathetic activity during NREM sleep, with further increase of parasympathetic tone and decrease in sympathetic activity during REM sleep. During the REM sleep phase, however, sympathetic activity increases intermittently. Sympathetic nerve activity in muscle and the vascular beds of the skin, as measured by microneurographic technique, is reduced during NREM sleep but is increased during REM sleep.[15]

During both NREM and REM sleep, the respiratory neurons in the pontomedullary region show a decreased firing rate. Muscle tone in the upper airway decreases in NREM sleep and disappears in REM sleep, resulting in an increase in upper airway resistance. Two separate systems—the metabolic (or automatic) and voluntary (or behavioral) systems—control respiration during sleep and wakefulness. Both the metabolic and the voluntary system operate during wakefulness, whereas only the metabolic system operates during NREM sleep. The wakefulness stimuli that act through the ascending reticular activating system also act as tonic stimuli to ventilation. Hypercapnic and hypoxic ventilatory responses are moderately reduced in NREM sleep but are more markedly decreased during REM sleep. Tidal volume and alveolar ventilation decrease during sleep; arterial oxygen tension is mildly decreased and arterial carbon dioxide tension is increased during both NREM and REM sleep. Thus, respiration is vulnerable during normal sleep, and a few periods of apnea may occur, especially at the onset of sleep and during REM sleep. Heart rate, blood pressure, cardiac output, and peripheral vascular resistance decrease during NREM sleep and decrease still further during REM sleep. Cerebral blood flow and cerebral metabolic rates for glucose and oxygen decrease during NREM sleep but increase to above waking values during REM sleep.

Profound changes in endocrine secretions are registered during sleep. Growth hormone secretion exhibits a pulsatile increase during NREM sleep in the first third of the normal sleep period. Prolactin secretion also rises 30 to 90 minutes after the onset of sleep. Sleep inhibits cortisol secretion. Secretion of thyroid-stimulating hormone reaches a peak in the evening and then decreases throughout the night. Testosterone levels in men increase during sleep, rising from trough levels at 8 P.M. to peak levels at 8 A.M., but no clear relation has been demonstrated between levels of gonadotropic hormones and the sleep-wake cycle in children or adults. Melatonin, which is released by the pineal gland, attains its highest secretion level between 3 A.M. and 5 A.M., then decreases to low levels during the day.

Body temperature begins to fall at the onset of sleep and reaches its lowest point during the third sleep cycle. Thermoregulation is maintained during NREM sleep but is nonexistent in REM sleep. Penile erection and clitoral tumescence occur during REM sleep.

CIRCADIAN RHYTHMS

Circadian means a period of about 24 hours; however, the human circadian rhythm cycle is about 25 hours. The existence of circadian rhythms has been known since 1731, when the French astronomer J. J. D. de Mairan noted a circadian rhythm in a plant.[16] The suprachiasmatic nucleus of the hypothalamus is thought to be the site of this biologic clock. The body temperature rhythm closely follows the circadian rhythm of sleep and wakefulness but is independent of it. Dysfunction of circadian rhythms results in some important human sleep disorders.[17]

General Approach to Disorders of Sleep

Sleep complaints are very common in the general population. According to the report of the National Center on Sleep Disorders Research, more than 40 million persons in the United States suffer from chronic disorders of sleep and wakefulness.[18]

CLASSIFICATION

The second edition of the International Classification of Sleep Disorders (ICSD-2) lists eight categories of sleep disorders.[17] In addition, two appendices in the ICSD-2 list sleep disorders associated with other conditions, as well as psychiatric and behavioral disorders frequently encountered in the differential diagnosis of sleep disorders [*see Table 2*].[17]

DIAGNOSIS

Clinical Manifestations

The four major sleep-related complaints for which patients seek medical attention are excessive daytime somnolence (EDS), insomnia, abnormal movements or behavior during sleep, and an inability to sleep at the desired time. Insomnia patients may complain of some or all of the following: difficulty initiating or maintaining sleep, repeated awakenings or early morning awakenings, nonrestorative sleep, daytime fatigue, lack of concentration, irritability, anxiety, depression, and muscle aches and pains. Insomnia may be idiopathic (i.e., no cause is found) or comorbid with other conditions [*see Table 3*]. Patients with hypersomnia may complain of EDS, a lack of relief of symptoms after additional nighttime sleep, inability to concentrate, and impaired cognition and motor skills. The most common cause of EDS is behaviorally induced insufficient sleep syndrome (sleep deprivation) [*see Table 2*]. Some patients with restless legs syndrome (RLS), periodic limb movements in sleep (PLMS), or circadian rhythm sleep disorders may also experience hypersomnolence in the daytime.

The first step in assessing a patient with a sleep disturbance is obtaining a history, which should include a family history and directed inquiries on sleeping habits, drug and alcohol consumption, and previous or current psychiatric, medical, and neurologic illnesses. Diagnostic tests must be confirmatory and subservient to the clinical history and physical examination. Electrophysiologic investigation of patients with suspected sleep disorders is resource intensive and is best planned in consultation with a sleep specialist.

Table 2 International Classification of Sleep Disorders, Second Edition[17]

Insomnia
- Acute insomnia
- Psychophysiologic insomnia
- Paradoxical insomnia (sleep-state misperception)
- Idiopathic insomnia
- Insomnia due to mental disorder
- Inadequate sleep hygiene
- Behavioral insomnia of childhood
- Insomnia due to drug or substance
- Insomnia due to medical condition
- Insomnia not due to substance or known physiologic condition, unspecified (nonorganic)
- Physiologic insomnia, unspecified (organic)

Sleep-Related Breathing Disorders
- Central sleep apnea syndromes
  - Primary central sleep apnea
  - Central sleep apnea due to Cheyne-Stokes breathing pattern
  - Central sleep apnea due to high-altitude periodic breathing
  - Central sleep apnea due to medical condition not Cheyne-Stokes
  - Central sleep apnea due to drug or substance
  - Primary sleep apnea of infancy (formerly primary sleep apnea of newborn)
- Obstructive sleep apnea syndromes
  - Obstructive sleep apnea, adult
  - Obstructive sleep apnea, pediatric
- Sleep-related hypoventilation/hypoxemic syndromes
  - Sleep-related nonobstructive alveolar hypoventilation, idiopathic
  - Congenital central alveolar hypoventilation syndrome
- Sleep-related hypoventilation/hypoxemia due to medical condition
  - Sleep-related hypoventilation/hypoxemia due to pulmonary parenchymal or vascular pathology
  - Sleep-related hypoventilation/hypoxemia due to lower airway obstruction
  - Sleep-related hypoventilation/hypoxemia due to neuromuscular and chest wall disorders
- Other sleep-related breathing disorder
  - Sleep apnea/sleep-related breathing disorder, unspecified

Hypersomnias of Central Origin Not Due to a Circadian Rhythm Sleep Disorder, Sleep-Related Breathing Disorder, or Other Cause of Disturbed Nocturnal Sleep
- Narcolepsy with cataplexy
- Narcolepsy without cataplexy
- Narcolepsy due to medical condition
- Narcolepsy, unspecified
- Recurrent hypersomnia
  - Kleine-Levin syndrome
  - Menstrual-related hypersomnia
- Idiopathic hypersomnia with long sleep time
- Idiopathic hypersomnia without long sleep time
- Behaviorally induced insufficient sleep syndrome
- Hypersomnia due to medical condition
- Hypersomnia due to drug or substance
- Hypersomnia not due to substance or known physiologic condition (nonorganic hypersomnia, not otherwise specified [NOS])
- Physiologic (organic) hypersomnia, unspecified (organic hypersomnia, NOS)

Circadian Rhythm Sleep Disorders
- Circadian rhythm sleep disorder, delayed-sleep-phase type (delayed-sleep-phase disorder)
- Circadian rhythm sleep disorder, advanced-sleep-phase type (advanced-sleep-phase disorder)
- Circadian rhythm sleep disorder, irregular sleep-wake type (irregular sleep-wake rhythm)
- Circadian rhythm sleep disorder, free-running type (nonentrained type)
- Circadian rhythm sleep disorder, jet-lag type (jet-lag disorder)
- Circadian rhythm sleep disorder, shift work type (shift-work disorder)
- Circadian rhythm sleep disorder due to medical condition
- Other circadian rhythm sleep disorder (circadian rhythm disorder, NOS)
- Other circadian rhythm sleep disorder due to drug or substance

(*continued*)

Laboratory Studies

The two most important laboratory tests for sleep disorders are the all-night polysomnography (PSG) study and the Multiple Sleep Latency Test (MSLT). All-night PSG studies simultaneously record several physiologic variables (i.e., EEG, EMG, EOG, electrocardiography, airflow at the nose and mouth, respiratory effort, and oxygen saturation) and are important in confirming a diagnosis of EDS or obstructive sleep apnea syndrome (OSAS), as well as documenting the severity of sleep apnea, hypoxemia, and sleep fragmentation. Overnight PSG determines the optimal pressure for continuous positive airway pressure (CPAP)—a treatment for OSAS—and is also helpful for supporting the diagnosis of narcolepsy and the parasomnias. Overnight PSG with simultaneous video recording can confirm REM sleep behavior disorder (RBD) and is particularly useful for the documentation of unusual movements and behavior during nighttime sleep in patients with parasomnias and nocturnal seizures.

The MSLT is essential in documenting pathologic sleepiness (e.g., sleep-onset latency of less than 5 minutes)[19] and in diagnosing narcolepsy. The presence of two sleep-onset REMs on four or five nap studies and sleep-onset latency of less than 8 minutes strongly suggest a diagnosis of narcolepsy.

Another important laboratory test for assessing sleep disorders is actigraphy.[20] This technique utilizes an actigraph (also known as an actometer) worn on the wrist or ankle to record acceleration or deceleration of body movements, which indirectly indicates sleep-wakefulness. Actigraphy for days or weeks is a useful laboratory test in patients with insomnia and circadian rhythm sleep disorders, as well as in some patients with prolonged daytime sleepiness.

Magnetic resonance imaging studies and other neuroimaging techniques should be performed to exclude structural neurologic lesions. Appropriate laboratory tests should always be performed to exclude any suspected medical disorders that may be the cause of the patient's insomnia or hypersomnia.

Specific Disorders of Sleep

OBSTRUCTIVE SLEEP APNEA SYNDROME

Apnea, or cessation of breathing during sleep, consists of three types: central, obstructive, and mixed.[2] In central apnea, both the airflow at the upper airway (e.g., pharynx and nose) and the effort by the diaphragm and other respiratory mus-

Table 2 (*continued*)

- *Parasomnias*
  - Disorders of arousal (from non–rapid eye movement [REM] sleep)
    - Confusional arousals
    - Sleepwalking
    - Sleep terrors
  - Parasomnias usually associated with REM sleep
    - REM sleep behavior disorder (including parasomnia overlap disorder and status dissociates)
    - Recurrent isolated sleep paralysis
    - Nightmare disorder
  - Other parasomnias
    - Sleep-related dissociative disorders
    - Sleep enuresis
    - Sleep-related groaning (catathrenia)
    - Exploding head syndrome
    - Sleep-related hallucinations
    - Sleep-related eating disorders
    - Parasomnia, unspecified
    - Parasomnia due to drug or substance
    - Parasomnia due to medical condition
- *Sleep-Related Movement Disorders*
  - Restless legs syndrome
  - Periodic limb movement disorder
  - Sleep-related leg cramps
  - Sleep-related bruxism
  - Sleep-related rhythmic movement disorder
  - Sleep-related movement disorder, unspecified
  - Sleep-related movement disorder due to drug or substance
  - Sleep-related movement disorder due to medical condition
- *Isolated Symptoms, Apparently Normal Variants, and Unresolved Issues*
  - Long sleeper
  - Short sleeper
  - Snoring
  - Sleep talking
  - Sleep starts (hypnic jerks)
  - Benign sleep myoclonus of infancy
  - Hypnagogic foot tremor and alternating leg muscle activation during sleep
  - Propriospinal myoclonus at sleep onset
  - Excessive fragmentary myoclonus
- *Other Sleep Disorders*
  - Other physiologic (organic) sleep disorder
  - Other sleep disorder not due to substance or known physiologic condition
  - Environmental sleep disorder
- *Sleep Disorders Associated with Conditions Classifiable Elsewhere*
  - Fatal familial insomnia
  - Fibromyalgia
  - Sleep-related epilepsy
  - Sleep-related headaches
  - Sleep-related gastroesophageal reflux disease
  - Sleep-related coronary artery ischemia
  - Sleep-related abnormal swallowing, choking, and laryngospasm
- *Other Psychiatric and Behavioral Disorders Frequently Encountered in the Differential Diagnosis of Sleep Disorders*
  - Mood disorders
  - Anxiety disorders
  - Somatoform disorders
  - Schizophrenia and other psychotic disorders
  - Disorders usually first diagnosed in infancy, childhood, or adolescence
  - Personality disorders

cles cease. By contrast, during obstructive apnea, the airflow stops while the effort continues [*see Figure 2*]. In mixed apnea, an initial period of central apnea is followed by a period of obstructive apnea. The most common type of apnea is OSAS.[21] Sleep hypopnea, defined as a decrease of breathing to half the volume measured during the preceding or following respiratory cycle accompanied by an arousal or oxygen desaturation of 3% to 4% or more, has the same significance as apnea.[2,21] To qualify as pathologic sleep apnea or hypopnea, the decreased breathing must last for at least 10 seconds and the apnea-hypopnea index or respiratory disturbance index (i.e., the number of episodes of apnea-hypopnea per hour of sleep) must be at least five.[2,21]

OSAS is common in middle-aged and elderly men. An important study indicated a prevalence of 4% in men and 2% in women between 30 and 60 years of age.[22] In women, the incidence of OSAS is greater after menopause. The pathogenesis of OSAS includes local anatomic factors (e.g., narrowing of the upper airway and excessive relaxation of the upper airway muscles during sleep, with increased upper airway resistance) and neurologic factors that may cause dysfunction of the respiratory neurons in the brain stem [*see 14:VI Ventilatory Control during Wakefulness and Sleep*].

Diagnosis

Nocturnal sleep symptoms of OSAS are loud snoring (often with a long history), choking, cessation of breathing, sitting up

Table 3 Conditions Comorbid with Insomnia

- Psychiatric disorders
  - Mood disorders (e.g., major depressive and bipolar disorders)
  - Anxiety disorders (e.g., panic and posttraumatic stress disorder)
- Stress
- Other psychophysiologic factors
- Medical disorders
  - Bronchial asthma
  - Coronary artery disease
  - Peptic ulcer disease
  - Rheumatic disorders
- Neurologic disorders
  - Stroke
  - Neurodegenerative diseases
  - Brain tumors
  - Headache syndromes
  - Neuromuscular disorders (e.g., painful peripheral neuropathies)
- Traumatic brain injury
- Fatal familial insomnia (a rare prion disease)
- Pain anywhere in the body
- Sleep-wake schedule disruptions
- Other disorders of circadian sleep rhythms
- Drug or alcohol abuse

and fighting for breath, abnormal motor activities and thrashing about in bed, gastroesophageal reflux, nocturia and nocturnal enuresis (seen mostly in children), and, occasionally, hyperhidrosis.

The major daytime symptom of OSAS is EDS; patients fall asleep during the day at inappropriate times and in inappropriate places and may be involved in driving accidents. They cannot function adequately during the day and may complain of morning headaches and forgetfulness; men may report impotence. The prolonged duration and the nonrefreshing nature of daytime sleep in EDS differentiate it from narcoleptic sleep attacks. Physical examination reveals obesity in about 70% of patients; in many cases, local anatomic abnormalities of the upper airway are found. Repeated hypoxemia associated with cessation of breathing during sleep can lead to hypertension, cardiac arrhythmias, heart failure, and stroke.[23]

Treatment

The general treatment of OSAS consists of avoiding sedatives, hypnotics, and alcohol and, in obese patients, reduction of body weight. Mild cases of OSAS may improve with these measures. Pharmacologic treatment remains unsatisfactory.[2,21]

Application of CPAP is effective in over 70% of moderate to severe cases of OSAS and is the best treatment available.[24] CPAP opens up the upper airway passages and acts as a pneumatic splint, thereby eliminating obstructive apneas, hypoxemias, snoring, and sleep fragmentation. The optimal pressure of CPAP must first be determined during overnight PSG. The patient can then purchase a home unit to use during nightly sleep. Manufacturers have devised auto-CPAP machines, which automatically titrate pressure according to detected problems. The role of these devices remains to be determined.

In the few severe cases of OSAS in which CPAP therapy fails, uvulopalatopharyngoplasty or other surgical approaches may be needed, although their roles remain uncertain. Laser or radiofrequency uvulopalatopharyngoplasty has been tried. Severe respiratory compromise or severe apnea associated with dangerous cardiac arrhythmias creates a life-threatening situation that may require emergency tracheostomy. In patients with neuromuscular disorders, intermittent positive pressure ventilation through a nasal mask may be needed to treat sleep hypoventilation or apnea. In some mild to moderate cases of OSAS, dental appliances may be tried.

NARCOLEPSY

The most important clinical manifestations of narcolepsy are sleep attacks and cataplexy, although the ICSD-2 includes one category as narcolepsy without cataplexy.[17,25] Narcoleptic sleep attacks usually begin in patients between 15 and 25 years of age but may occur earlier or later. Narcolepsy is a lifelong disorder, but it becomes less severe with old age. From 1% to 2% of the first-degree relatives of narcoleptic patients manifest the illness, compared with 0.02% to 0.18% in the general population.[26] The cause of narcolepsy is unknown and is thought to result from an interplay of genetic and environmental factors. There is a strong association between narcolepsy and the presence of the HLA DQB1*0602 subtype.[26]

The most exciting recent development in our understanding of narcolepsy is the documentation of an abnormality in the hypocretin (orexin) neurons in the lateral hypothalamus.[27-32] Human narcolepsy-cataplexy can be considered a hypocretin (orexin) deficiency syndrome. Four lines of evidence can be cited in support of hypocretin abnormality in narcolepsy: (1) induction of narcolepsy-like symptoms after mutation of the hypocretin receptor 2 gene in dogs and after preprohypocretin knockout in mice, (2) decreased hypocretin 1 levels in the cerebrospinal fluid of narcolepsy-cataplexy patients, (3) postmortem documentation of decreased numbers of hypocretin neurons in narcoleptic brains, and (4) preprohypocretin gene mutation in a child with severe narcolepsy associated with generalized absence of hypocretin peptides in the brain.

Diagnosis

The classic narcoleptic sleep attack consists of an irresistible desire to sleep in an inappropriate place and under inappropriate circumstances. Attacks generally last from a few minutes to 30 minutes, and the patient feels refreshed on awakening. The initial manifestations of narcolepsy are generally sleep attacks; after months or years, 60% to 70% of patients experience cataplexy, during which they transiently lose muscle tone (e.g., sagging of the head, drooping of the eyelids, and buckling of the knees). Cataplexy is often triggered by a sudden emotional outburst. The patient may momentarily collapse and fall to the ground or may simply slump forward for a few seconds before regaining awareness.

Additional manifestations of narcolepsy include hypnagogic or hypnopompic hallucinations (fearful or vivid dreams at sleep onset or end), sleep paralysis (feeling of loss of power or focal weakness on one side of the body or in one limb during the transition period between sleep and wakefulness), disturbance of nocturnal sleep, and automatic behaviors (during which the patient might keep doing one thing repeatedly or drive to a place without recollection of the events). In some patients, narcoleptic sleep attacks may be associated with sleep apnea, REM behavior disorder, or PLMS.

Treatment

The administration of a stimulant (e.g., modafinil, methylphenidate, dextroamphetamine, or methamphetamine) is the treatment of choice for narcoleptic sleep attacks.[25] In newly diagnosed patients, the drug most commonly used initially is modafinil, a novel wakefulness-promoting agent, or methylphenidate. Dextroamphetamine and methamphetamine are used in patients who do not respond satisfactorily to these stimulant drugs.

Tricyclic antidepressants (e.g., protriptyline, imipramine, and clomipramine) and selective serotonin reuptake inhibitors (SSRIs, such as fluoxetine) are used to treat cataplexy or other auxiliary symptoms of narcolepsy. Sodium oxybate, which is more commonly known as γ-hydroxybutyric acid (GHB) [*see 8:I Management of Poisoning and Drug Overdose*], has been approved by the Food and Drug Administration for the treatment of cataplexy. It is an endogenous hypnotic that acts by consolidating REM and slow wave sleep. The medication is administered in two divided doses at night. The first dose is taken at bedtime; the patient must awaken 2.5 to 4 hours later to take the second dose. Taking short daytime naps and joining narcolepsy support groups can be useful approaches as well.

IDIOPATHIC HYPERSOMNIA

The International Classification of Sleep Disorders defines idiopathic hypersomnia as a disorder of excessive sleepiness of presumed CNS cause that is associated with major sleep episodes.[17] The disorder is further categorized as with or without long sleep time (over 10 hours or from 6 to 10 hours, respectively). The disease develops insidiously, generally between the ages

of 15 and 30 years. It closely resembles narcolepsy. Affected patients generally sleep for hours, and the sleep is not refreshing. The patient does not give a history of cataplexy or snoring.

Idiopathic hypersomnia is a disabling and lifelong disorder. The MSLT shows a mean sleep latency of less than 8 minutes without sleep-onset REMs. The treatment of idiopathic hypersomnia is similar to the stimulant treatment of narcolepsy; however, the therapeutic response is unsatisfactory.

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS IN SLEEP

Restless Legs Syndrome

RLS is a lifelong sensorimotor neurologic disorder that may begin at any age.[33] RLS is most severe in middle-aged or elderly persons, in whom it has a chronic, progressive course. The prevalence of RLS has been estimated to be about 10% for all adult populations, particularly those of European descent. However, in some surveys from Asia, the prevalence is extremely low, suggesting a possible ethnic and racial difference in RLS prevalence.

Clinical features Minimal criteria for the clinical diagnosis of RLS include the following four sensorimotor features[33,34]: (1) the patient has an urge or compulsion to move the legs, usually accompanied by uncomfortable or unpleasant sensations, primarily in the legs (generally below the knees) but sometimes in the arms; (2) the urge to move or uncomfortable sensations begin or worsen during rest and repose or inactivity; (3) the urge to move or uncomfortable sensations are partially or totally relieved by movement, at least in the beginning of the illness, and at least as long as the activity continues; (4) the uncomfortable sensations or the urge to move is worse in the evening or early part of the night than during the day.

Supportive diagnostic criteria include responsiveness to dopaminergic drugs, at least early in the disease; presence of periodic limb movements; and positive family history.[34] Up to about 50% of patients have a family history of a similar condition, suggesting a dominant mode of inheritance. At least 80% of RLS patients have PLMS (see below). In addition, many RLS patients also have periodic limb movements in wakefulness (PLMW). Associated features of RLS include a progressive clinical course, nor-

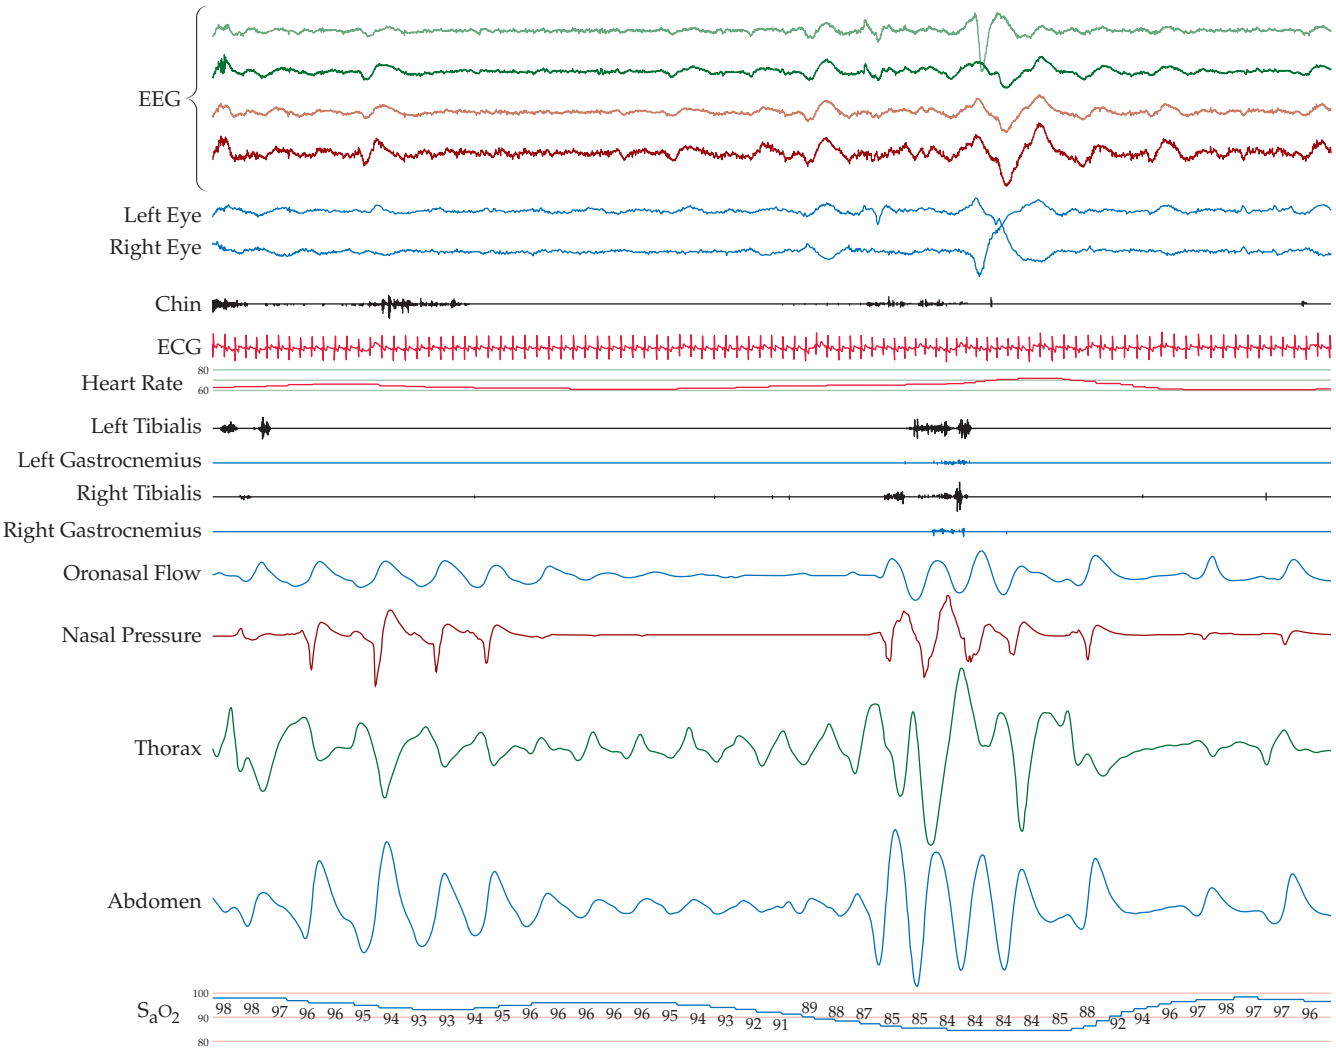

Figure 2 **Polysomnographic (PSG) recording of a patient with sleep apnea syndrome includes EEG tracings (top four channels), EOG readouts of the left and the right eyes, EMG of mentalis muscle (chin), electrocardiogram, EMG of the left tibialis and right tibialis and gastrocnemius muscles, and recordings of oronasal airflow, nasal pressure, respiratory effort (thoracic and abdominal readings), and oxygen saturation (S_aO_2). The PSG study shows episodes of obstructive sleep apnea during stage II NREM sleep, followed by arousals.**

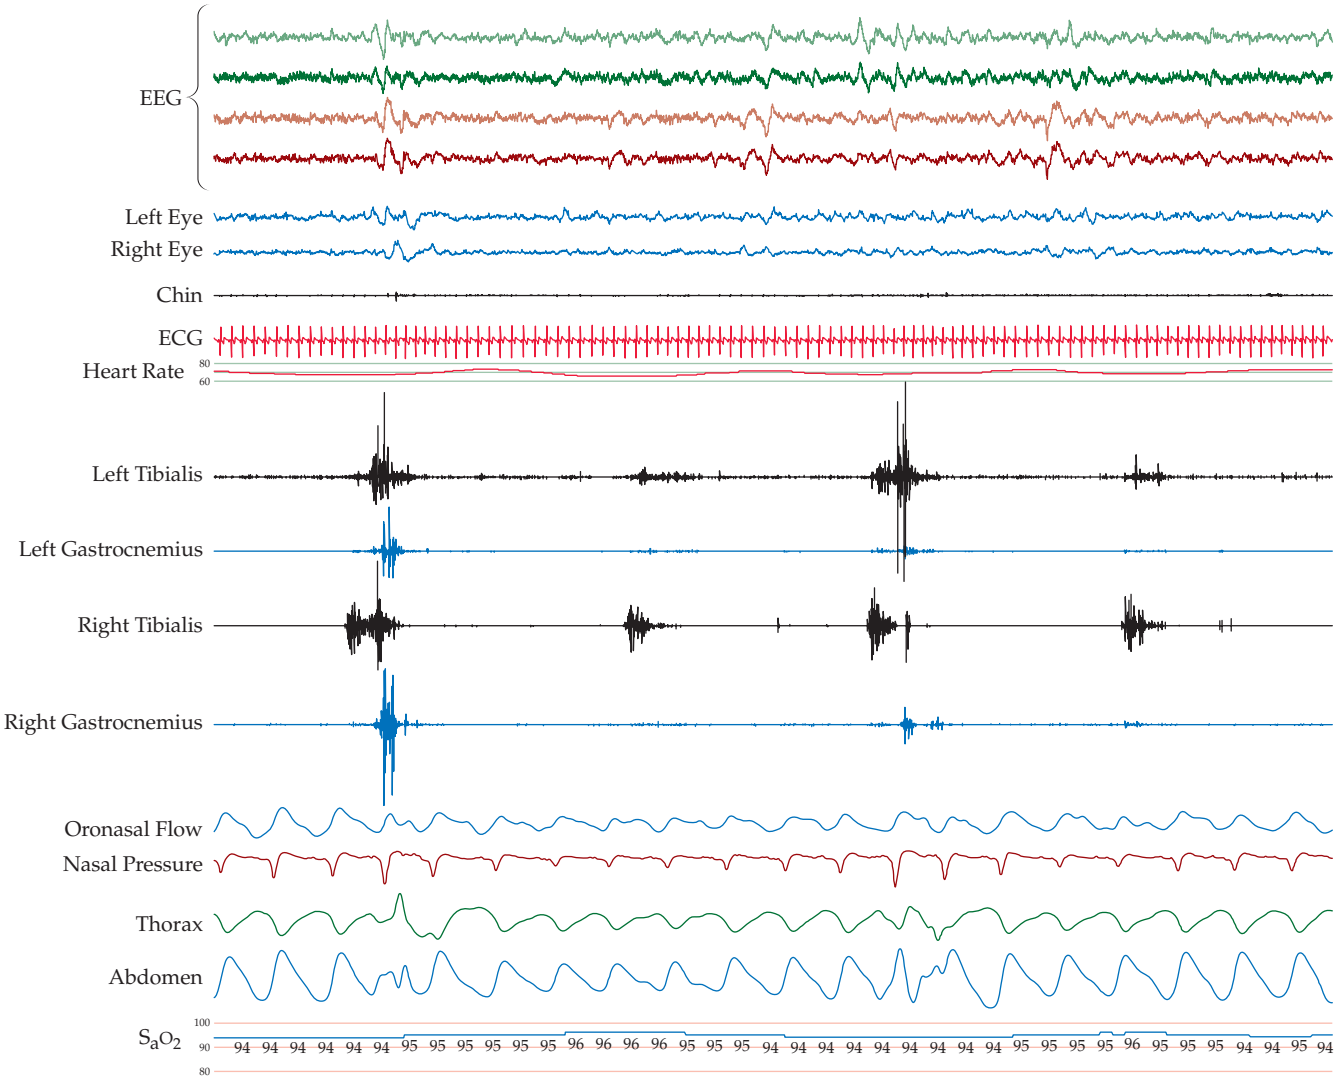

Figure 3 **Polysomnographic recording of a patient with restless legs syndrome includes EEG tracings (top four channels), EOG readouts of the left and the right eyes, EMG of the mentalis muscle (chin), electrocardiogram, EMG of the left and the right tibialis and gastrocnemius muscles, and recordings of oronasal airflow, nasal pressure, respiratory effort (thoracic and abdominal readings), and oxygen saturation (S_aO_2). The tibialis and gastrocnemius EMG recordings reveal periodic limb movements in sleep.**

mal neurologic examination in the idiopathic or primary type of RLS, and sleep disturbance.[34]

It is important to exclude potential underlying causes of RLS (e.g., iron deficiency anemia, uremia, and polyneuropathy). The condition may have a profound impact on sleep, and occasionally, patients have sleep apnea or daytime hypersomnolence.

Periodic Limb Movements in Sleep

PLMS is common in the general population, with increasing prevalence in persons of advanced age; patients may remain completely asymptomatic.[35,36] PLMS is a polysomnographic finding and is characterized by repetitive, often stereotyped limb movements during NREM sleep. The characteristic movements are usually extension of the great toe, dorsiflexion of the ankle, and flexion of the knee. Similar movements are sometimes seen in the arms. At least four consecutive movements occur on a pseudoperiodic basis, with an average interval of 20 to 40 seconds (range, 5 to 90 seconds) and a duration of 0.5 to 5.0 seconds [*see Figure 3*]. PLMS appears most commonly in RLS and may also occur in a large number of other medical, neurologic, and sleep disorders and with medication (e.g., tricyclic antidepressants, SSRIs, and levodopa). PLMS may occur with or without awakenings. Whether PLMS occurs as a primary condition unassociated with RLS causing repeated awakenings and sleep fragmentation remains controversial. In the current International Classification of Sleep Disorders, periodic limb movement disorder (PLMD) is listed as a separate entity.[17] A growing body of evidence suggests that PLMS may not have any clinical significance and is simply a polysomnographic observation noted in a variety of sleep disorders but present in the majority of patients with RLS.[35,36]

Treatment

Four groups of drugs are available to treat RLS and PLMS[33]: dopaminergic drugs (e.g., carbidopa-levodopa and dopamine agonists such as pergolide, pramipexole, ropinirole, and cabergoline); benzodiazepines (e.g., clonazepam); opioids (e.g., codeine,

propoxyphene, oxycodone, and hydrocodone); and anticonvulsants (e.g., gabapentin). The best drug for initial therapy in most cases is a dopamine agonist. The only drug currently approved by the Food and Drug Administration for use in RLS is ropinirole, but several clinical trials have proved that other agents can be used for this disorder.

CIRCADIAN RHYTHM SLEEP DISORDERS

In circadian rhythm sleep disorders, patients have difficulty sleeping as a result of desynchronization between their internal circadian rhythms and external time.[37] The insomnia of these disorders is often associated with other somatic complaints. The most common circadian rhythm sleep disorders are jet lag (associated with high-speed air travel across time zones) and shift-work sleep disorder (seen in patients who work nonstandard shifts). In delayed-sleep-phase syndrome, the patient has difficulty sleeping early in the evening, goes to sleep late (e.g., 2 A.M.), and wakes up late in the morning. Patients with advanced-sleep-phase syndrome go to sleep early in the evening and wake up early in the morning; this disorder is often seen in patients with depression and in normal elderly persons.

Appropriately timed bright-light therapy and chronotherapy may be effective in these disorders.[37] Jet lag and shift-work sleep disorder may also be treated with zolpidem. Melatonin has been found to be useful in some persons with jet lag and shift-work sleep disorders, as well as in patients with non–24-hour circadian rhythm disorders. There is no generally accepted standard dose for melatonin; in general, 0.5 to 3 mg has been used for jet lag, and 5 to 10 mg for non–24-hour syndrome. Melatonin has also been used in combination with bright-light therapy in patients with delayed-sleep-phase syndrome.

INSOMNIAS

Insomnia may occur at any age. The patient may complain of difficulty initiating or maintaining sleep or of awakening early in the morning and being unable to go back to sleep, as well as nonrestorative sleep or poor quality of sleep.[38] Insomnia may be associated with a variety of medical, psychiatric, and neurologic illnesses or may be drug- or alcohol-induced [*see Table 3*]. Insomnia is most commonly caused by psychiatric or psychophysiologic disorders, with depression and anxiety among the most important. Early morning awakening is a characteristic finding in depression. In some cases, no cause of the insomnia is found; this disorder is termed idiopathic, or primary, insomnia and is a lifelong condition.

For transient insomnia or insomnia of short duration, treatment with sedative-hypnotics (e.g., zolpidem, zaleplon, or eszopiclone) or short- or intermediate-acting benzodiazepines (e.g., temazepam) for a few nights to a few weeks is appropriate [*see Table 4*]. Hypnotic medications should not be used for chronic insomnia. The best treatment for patients with chronic insomnia consists of a combination of sleep hygiene measures (e.g., setting fixed times for retiring and awakening; avoidance of caffeinated beverages, tobacco, and alcohol before retiring; and regular exercise, preferably undertaken 4 to 6 hours before bedtime), stimulus-control therapy, sleep restriction, relaxation training, and other psychological treatments.[38] One study showed a trend toward better outcomes with a combination of cognitive-behavioral therapy (i.e., stimulus control, sleep restriction, sleep hygiene, and cognitive therapy) and pharmacotherapy.[39] Sedative-antidepressants should be used for insomnia associated with depression.

Table 4 Short-Term Drug Therapy for Insomnia

Category	*Agent*	*Dose (mg)**
Sedative-hypnotics	Zaleplon	5–10
	Zolpidem	5–10
	Zolpidem extended release	6.25–12.5
	Eszopiclone	1–3
	Ramelteon	8
Short-acting or intermediate-acting benzodiazepines	Temazepam	7.5–30
	Triazolam	0.125–0.250
	Flurazepam	15–30
	Estazolam	1–2

*All agents are given at bedtime for a few nights to a few weeks.

PARASOMNIAS

Partial Arousal Disorders

Partial arousal disorders include confusional arousals, sleepwalking, and sleep terrors.[40] Confusional arousals, which occur during slow wave sleep, mostly in children younger than 5 years, are characterized clinically by confusion and mild automatic and inappropriate behavior. Most confusional arousals are benign.

Sleepwalking, or somnambulism, is most common in children between 5 and 12 years of age. Sleepwalking begins with abrupt motor activity arising out of slow wave sleep during the first third of the sleep period. Episodes generally last less than 10 minutes. There is a high incidence of positive family history in sleepwalking. Injuries and violent actions have been reported during sleepwalking episodes. Sleep deprivation, fatigue, concurrent illness, and sedatives may act as precipitating factors.

Sleep terrors, or pavor nocturnus, also occur during slow wave sleep. Peak onset is between 5 and 7 years of age. As with sleepwalking, a high incidence of familial cases is seen in sleep terrors. Episodes of sleep terrors are characterized by intense autonomic and motor symptoms, including a loud, piercing scream. Many patients also have sleepwalking episodes. Precipitating factors are similar to those described with sleepwalking.

No special treatment is needed for most of the parasomnias. If attacks of sleepwalking or sleep terrors are frequent, treatment with an antidepressant or benzodiazepine may be tried for a short period.

Nocturnal Frontal Lobe Epilepsy

Nocturnal frontal lobe epilepsy (NFLE) was formerly known as nocturnal paroxysmal dystonia. NFLE may occur at any time from infancy to the fifth decade of life[41]; the disorder is seldom familial. The attacks occur suddenly during NREM sleep. The most common type is a spell of short duration (lasting from 15 seconds to less than 2 minutes). In rare cases, the spell is of longer duration (lasting from 2 minutes to more than 1 hour). The attacks are characterized by ballismic, choreoathetoid, or dystonic movements, which may occur in clusters. The EEG is generally normal. Carbamazepine is the treatment of choice for NFLE. Several families with autosomal dominant NFLE have been described.[42]

REM Sleep Behavior Disorder

REM sleep behavior disorder is an important REM sleep parasomnia commonly seen in elderly persons.[43] A characteristic clinical feature of RBD is intermittent loss of REM-related muscle hypotonia or atonia and the appearance of a variety of abnormal

motor activities during sleep. The patient presents with violent, dream-enacting behavior during REM sleep, often causing self-injury or injury to the patient's bed partner. Initially, it was thought that RBD was mostly idiopathic, but as more patients were described, it was realized that most cases are secondary and associated with neurodegenerative diseases. RBD occurs with increasing frequency in patients with Parkinson disease (PD), multiple system atrophy (MSA), diffuse Lewy body disease (DLBD), olivopontocerebellar atrophy (OPCA), progressive supranuclear palsy (PSP), and corticobasal ganglionic degeneration (CBD).[44] RBD has also been described in many cases of narcolepsy, which may be considered a degenerative disease of hypocretin-containing neurons in the hypothalamus. In many of these neurodegenerative diseases (e.g., PD, MSA, and DLBD), α-synuclein inclusions have been noted; some authors even propose that RBD may be an α-synucleinopathy disorder.[44] The findings of reduced striatal presynaptic dopamine transporter on positron emission tomographic scans and of a reduction of postsynaptic D_2 dopamine receptors on single-photon emission computed tomography scans suggest the linking of RBD to dopamine cell dysfunction.[45] RBD may precede many of these neurodegenerative diseases or coexist with these disorders. RBD may also be associated with structural lesions of the brain stem and is sometimes associated with alcoholism or the ingestion of drugs (e.g., sedative-hypnotics, tricyclic antidepressants, SSRIs, and anticholinergics). On polysomnographic studies, the prominent finding is REM sleep without muscle atonia. In experiments on cats, similar behavior has been produced by a bilateral perilocus coeruleus lesion. Most cases of RBD respond to a low dose of a benzodiazepine (e.g., clonazepam).

The author has been a member of the speakers' bureau for Sanofi-Aventis and has served as a consultant for Boehringer Ingelheim Corp.

XIV PAIN

Alan Carver, m.d.

Definitions and Overview

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1] Although pain most often has a proximate physical cause, the current definition avoids tying pain directly to a stimulus, because pain of probable psychological origin may be reported in the absence of actual tissue damage or any other likely pathophysiologic cause.

Pain is not simply the unidirectional transmission of data along hardwired tracts from peripheral tissue to the central nervous system.[2] Indeed, pain is experienced within a complex biologic, emotional, psychological, and social context that may defy physical examination findings, diagnostic procedures, and laboratory tests.

Pain may be considered to consist of four broad components: nociception, perception, suffering, and behaviors.[3] Nociception is the detection of tissue damage by specialized receptors (nociceptors) on A-delta fibers and C fibers. This is a dynamic process in which the action of nociceptors is influenced by the local chemical environment and by neural changes set into motion by local tissue damage.[4] Perception of pain, although often triggered by local injury, may also result from lesions in the peripheral nervous system or the CNS; pain may thus be perceived in the absence of nociception. The intensity of pain may have little or no relation to the extent of objective pathology. Suffering may be defined as the state of severe distress associated with events that threaten the intactness of the person.[5] Suffering can include physical pain but is not limited to it. Pain behaviors are observable, quantifiable behaviors arising from pain and suffering; such behaviors include restricting activity, verbally complaining of pain, or seeking health care.

There are several different types of pain, with differing mechanisms, temporal courses, and management options. Transient pain results from the activation of nociceptors in the absence of tissue damage; it is not a clinically significant cause of health care utilization. Acute pain is marked by an extensive nociceptive and behavioral cascade triggered by local tissue damage. It is a normal physiologic response to adverse chemical, mechanical, or thermal stimuli. Although acute pain is not defined by time course, it will generally subside within weeks. Chronic pain most often occurs when an initial injury exceeds the body's capacity for healing or involves the nervous system itself. Pain is defined as chronic rather than acute not on the basis of its duration, per se, but on the basis of the body's inability to restore physiologic function to homeostatic levels. The intensity of chronic pain may bear little relation to initial tissue damage or subsequent quantifiable pathology; indeed, a number of chronic pain syndromes lack any identifiable tissue damage or trigger injury.[6]

The complexity of pain physiology may lead to suboptimal pain assessment and management, as occurs when patient complaints are not believed because of a lack of objective data or when clinicians lack an understanding of pain physiology. Surveys of physicians and medical students have repeatedly confirmed the need for improved education and training in pain recognition and treatment.[7] Provider surveys reveal that many practitioners do not feel comfortable with pain management. One large study found that 86% of physicians believed that most of their patients with pain were undertreated, whereas only 51% felt pain control in their practices was "good" or "very good."[8] A model of care that is oriented toward diseases rather than symptoms may incorrectly minimize the therapeutic importance of symptom management. In addition, attitudes of both physicians and patients toward opioids and the fear of patient addiction contribute to the inadequate treatment of pain associated with cancer and a variety of other chronic conditions.[9]

Epidemiology

Acute pain is the most common symptom for which patients seek medical evaluation.[10] New pain complaints result in 40 million visits to the doctor annually, and 45% of persons in the United States will visit a doctor for pain at some point in their lives.[11] The prevalence of various chronic pain syndromes in the United States is estimated to range from 2% to 40%.[12] Approximately 75 million persons in the United States live with "serious pain," and nearly 50 million are partially or totally disabled by pain.[13] In addition, recurrent acute pain is a prominent feature of a number of diseases, such as sickle cell anemia, AIDS, and malignancy. The prevalence of pain in cancer patients is estimated to range from 14% to 100%, with pain more frequent in advanced disease and certain types of malignancy.[14] Estimates of the prevalence of pain in AIDS patients vary from 30% to 90%; in one study, ambulatory AIDS patients experienced two to three concurrent pains.[15] The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) found that approximately 50% of adults who die in hospitals experience moderate to severe pain in the period immediately before death.[16]

The financial costs of pain, especially untreated pain, to society are significant—approximately $100 billion annually in the United States.[17] The American Productivity Audit estimates that losses in productivity because of common painful conditions in active workers costs the economy $61.2 billion annually, with the majority of this cost related to reduced performance while at work rather than absence from the job.[18] One study found that 13% of the total workforce experienced a loss in productive time during a 2-week period because of a common pain condition. The cost of chronic back pain alone has been estimated to be $28 billion per year.[19] In addition, pain results in 50 million lost work days a year in the United States. Both acute and chronic pain are significant drivers of increased utilization of health care resources. Persons with chronic pain are five times as likely as those without chronic pain to use health care services.

Neurobiology of Pain

Peripheral Pain

Nociception

Nociception is the reception of signals in the CNS evoked by the activation of specialized sensory receptors (nociceptors) that provide information about tissue damage [*see Figure 1*]. Nociceptors are the free peripheral endings of primary sensory neurons;

the cell bodies of nociceptors are located in the dorsal root and trigeminal ganglia. Nociceptors are the least differentiated of cutaneous sensory receptors; unlike other somatic sensory receptors, they lack the structures for filtering peripheral stimuli.

Different classes of nociceptive afferent fibers react to different types of stimuli. A-delta fibers function as thermal and high-threshold mechanical receptors. Activation of these fibers generally results in short sensations of sharp, pricking pain. A-delta fibers are of small diameter and are thinly myelinated; they conduct impulses at the relatively fast rate of 5 to 30 m/sec. They terminate in laminae I and V of the dorsal horn. C fibers function as polymodal receptors and are activated by various high-intensity mechanical or chemical stimuli, as well as by hot (> 45° C) or cold stimuli. Activation of C fibers results in more prolonged sensations of dull pain. C fibers are small in diameter; they are unmyelinated and conduct impulses at the slow rate of 0.5 to 2 m/sec. C fibers have smaller receptive fields than the A-delta nociceptors. They terminate in lamina II. Polymodal C fibers compose a large majority of peripheral nociceptors. The cell bodies of both A-delta fibers and C fibers reside in the dorsal root ganglion. Some nociceptors, which are termed silent or sleeping, have such a high activation threshold that under normal circumstances they do not react to most stimuli; they are recruited under conditions of inflammation and tissue damage (see below). All classes of nociceptive fibers are widely distributed throughout cutaneous and deeper tissue.

Nociceptors do not fire spontaneously at rest. Their electrical action potential is triggered by transduction, which occurs when a noxious stimulus of sufficient strength depolarizes the nociceptor membrane. The specific receptive properties of nociceptors are determined by their expression of transducing ion-channel receptors. These ion channels are nonselective potassium or sodium channels gated by temperature, chemical stimuli, or mechanical shearing forces rather than by voltage. Activation of the channels by an appropriate stimulus leads to an inward current that depolarizes the receptor membrane. If this depolarizing current is sufficient to activate voltage-gated sodium channels, further depolarization of the membrane will occur, and a burst of action potentials will be initiated. The duration and frequency of this burst are determined by the duration and intensity of the noxious stimulus. Many, but not all, of these transducing receptors have been identified.

The typical noxious stimulus affects some combination of the different types of nociceptors in a given area of tissue damage. A-delta fibers provide sensory input for immediate, sharp pain, whereas C fibers are responsible for delayed, dull pain. The summation of input from both types of nociceptors provides the sensory basis for the perception of pain.

Peripheral Sensitization

The nociceptive process occurs in the context of a number of changes in the chemical environment brought about by local tissue damage and the release of a variety of inflammatory mediators. Some of these mediators act to enhance the sensation of pain in response to subsequent stimuli in the affected area by decreasing nociceptor stimulus thresholds and increasing and prolonging receptor firing and intensity in response to a suprathreshold stimulus, a process called peripheral sensitization.[20-22] Prostaglandin E_2, released from arachidonic acid–damaged cells, binds to G protein–coupled prostaglandin E receptors to sensitize nociceptors. Interleukin-1b and tumor necrosis factor–α, released by immune system cells involved in the inflammatory response, induce the release of cyclooxygenase-2 (COX-2) several hours after the start of inflammation. COX-2 converts arachidonic acid to prostaglandin H, which is subsequently converted into prostanoid species, including prostaglandin E_2. Bradykinin, a peptide derived from plasma kininogen, sensitizes primary afferent neurons via its constitutive B_2 receptor. Nerve growth factor sensitizes nociceptor terminals by binding to the G protein–coupled tyrosine kinase A receptor. Leukotrienes derived from arachidonic acid–damaged cells also alter the sensitivity of nociceptor terminals. Certain peptides released by primary afferent neurons themselves support the process of peripheral sensitization. Substance P, released from activated nociceptors, acts on local mast cells to increase histamine release.

Peripheral sensitization is thought to be one of the processes underlying the phenomenon of primary hyperalgesia, whereby injury to peripheral tissues results in an enhanced sensation of pain in response to subsequent suprathreshold stimuli in the damaged area. Experimental evidence supports the ability of heat stimuli to yield primary hyperalgesia; data concerning mechanical stimuli are not as clear. The evolutionary purpose of hyperalgesia is to discourage further contact with damaged tissue, thereby expediting the healing process. Peripheral sensitization and the consequent hyperalgesia normally resolve as tissue heals. However, chronic pain (see below) may occur if the body is unable to restore homeostasis because the initial injury has exceeded the body's capacity for recovery or the injury involves the nervous system itself. Secondary hyperalgesia—the expansion of hyperalgesia beyond the region of initial tissue damage in the absence of ongoing or recurrent injury—is caused by additional nervous system changes secondary to the initial insult [*see* Central Sensitization, *below*].

DORSAL HORN PHYSIOLOGY

Nociceptive fibers bifurcate upon entering the spinal cord laterally in the dorsal root, with branches of each axon ascending and descending for several segments in the tract of Lissauer. A-delta and C fibers terminate mainly in lamina I (marginal zone) and lamina II (substantia gelatinosa) of the dorsal horn [*see Figure 2*]. In addition, some A-delta fibers terminate in lamina V.

The primary afferent fibers communicate directly or indirectly with two major classes of neurons in the dorsal horn: projection neurons and local circuit interneurons. Projection neurons are contacted directly by A-delta fibers and relay sensory data to the brain stem, hypothalamus, and thalamus. They stretch the length of the spinal cord, with cell bodies in laminae I and V of the dorsal horn. Nociceptive-specific (NS) projection neurons relay data solely from A-delta and C fibers, whereas wide-dynamic-range (WDR) projection neurons relay both noxious data from nociceptors and a variety of innocuous stimuli from low-threshold mechanoreceptors. Both NS and WDR neurons are important in the relaying of nociceptive information; NS data signal the presence of possible tissue damage, whereas WDR data concern stimulus quality and, possibly, location. Local circuit interneurons modify the output of projection neurons. Excitatory interneurons relay sensory input from C fibers to projection neurons; inhibitory interneurons regulate and suppress the flow of nociceptive data to higher centers.

The relaying of nociceptive data in the dorsal horn involves several different neurotransmitters. Both A-delta and C fibers release glutamate, an excitatory amino acid that is the major fast excitatory neurotransmitter for all nociceptive modalities. Glutamate acts at two major classes of glutamate receptors on sec-

ondary afferent neurons: ionotropic and metabotrophic. Ionotropic glutamate receptors, which include the receptors for *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate (AMPA), and kainite, mediate fast synaptic transmission, the rapid depolarization of the secondary afferent neuron membrane. This depolarization will generate an action potential if the threshold is met. Metabotrophic glutamate receptors are coupled to a variety of intracellular second messenger systems via G proteins. These receptors are expressed presynaptically and postsynaptically in the dorsal horn and throughout the neuraxis, and they play a role in the modulation of pain. The presynaptic receptors on the central terminals of nociceptors may alter neurotransmitter release; they are a major target of analgesic therapies.

In addition to glutamate, nociceptive afferents (primarily C fibers) release a large variety of neuropeptides, including substance P, calcitonin gene–related peptide, cholecystokinin, somatostatin, galanin, gastrin-releasing peptide, and substance K. The neuropeptides act on G protein–coupled receptors and are responsible for evoking slow excitatory postsynaptic potentials in the secondary afferent neurons of the dorsal horn.

Initial modulation of the transmission of pain data from the

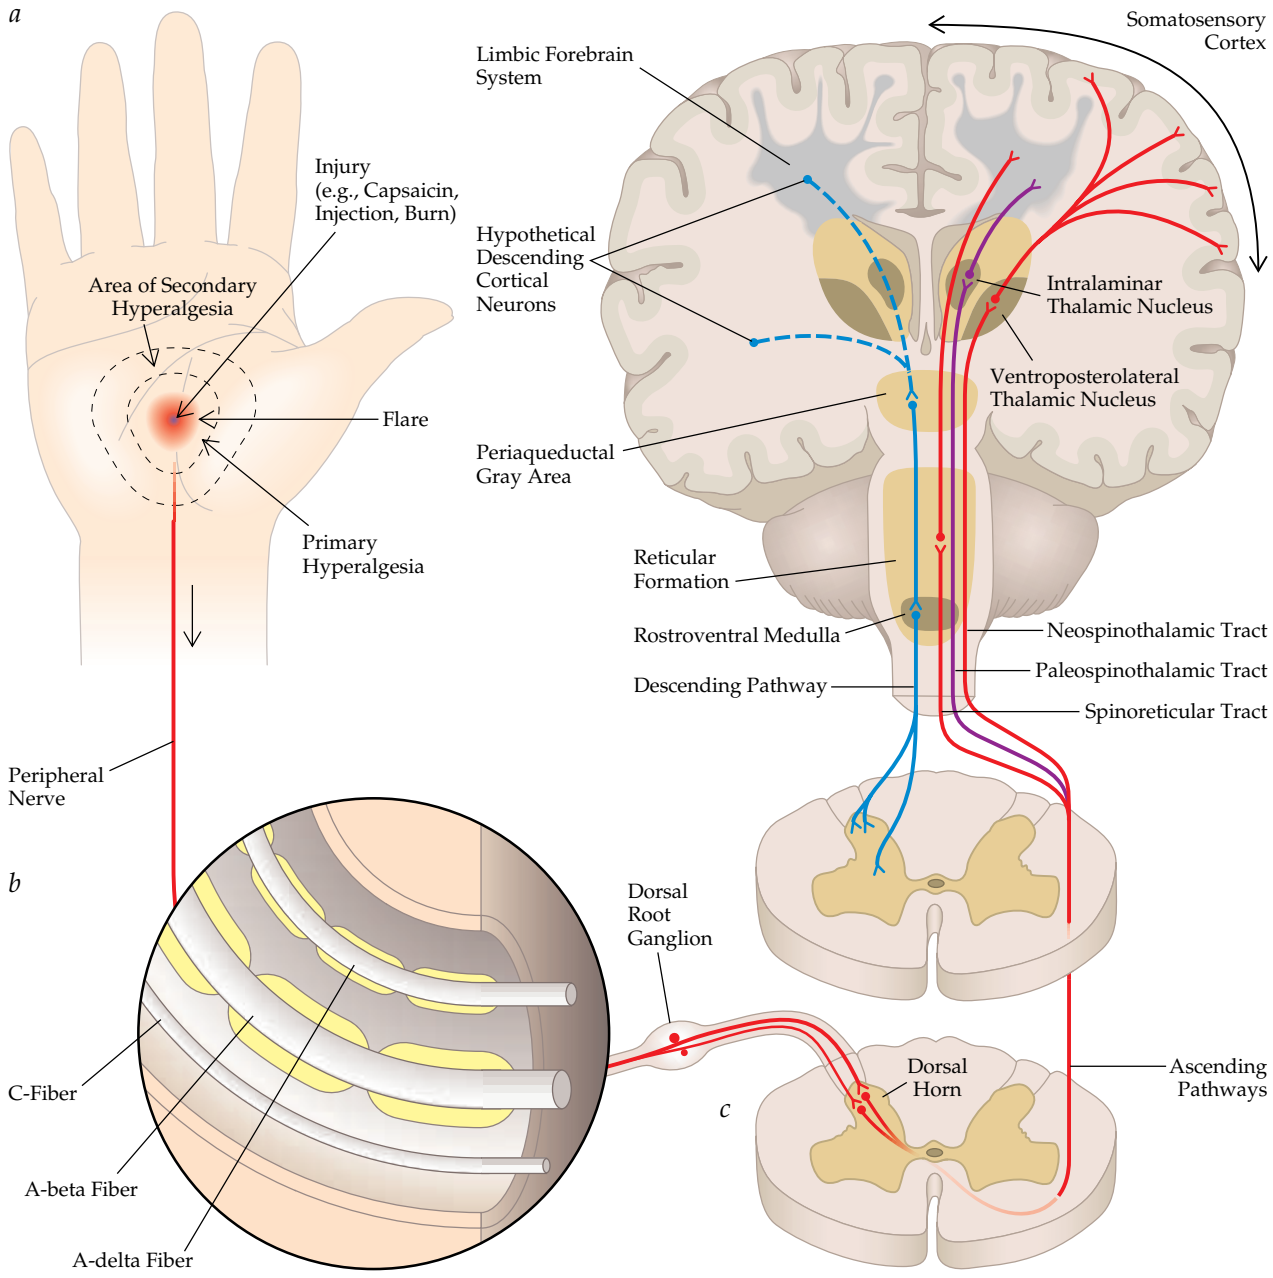

Figure 1 **(*a*) Stimulation of C fibers by intradermal injection of capsaicin or thermal injury produces spontaneous pain and pain evoked by light touch at the site of injury (primary hyperalgesia). In addition, an area of secondary hyperalgesia (increased pain after a noxious stimulus) outside of the area of primary injury is produced by the activation of *N*-methyl-D-aspartate (NMDA) receptors in the central nervous system, which occurs as a consequence of the afferent nociceptive impulse traffic. (*b*) When activated by mechanical, thermal, and chemical stimuli, nociceptors conduct afferent impulses toward the spinal cord. (*c*) When areas in the thalamus and cerebral cortex are activated, secondary projections in the spinothalamic tract, dorsal column tract, and other nociceptive pathways lead to the conscious perception of pain.**

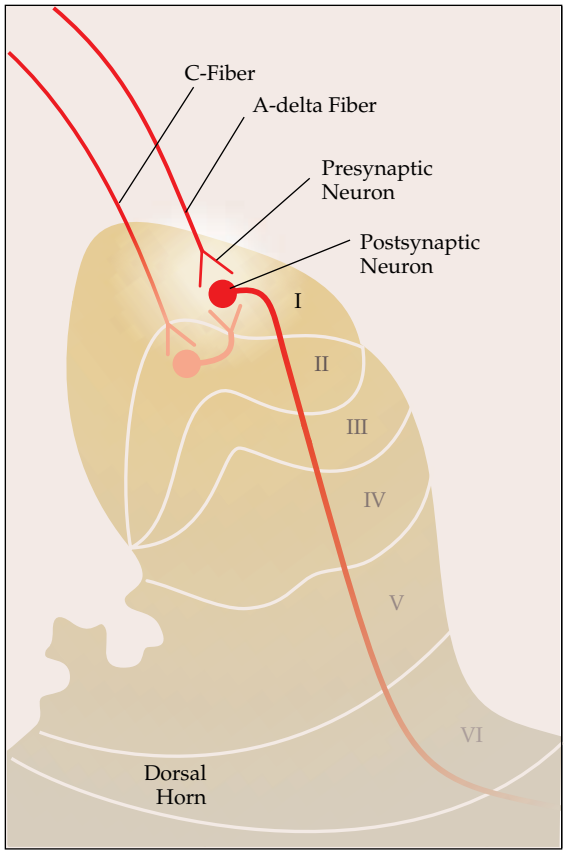

Figure 2 **Upon entering the spinal cord laterally in the dorsal root, A-delta fibers and C fibers terminate mainly in lamina I (marginal zone) and lamina II (substantia gelatinosa) of the dorsal horn. In addition, some A-delta fibers terminate in lamina V. Secondary afferent neurons of the dorsal horn are involved in determination of which action potentials trigger a reflex response to avoid further injury from noxious stimuli, as well as which action potentials are transmitted to the brain. A major role of the dorsal horn is to suppress pain. Most sensory information relayed to the secondary afferent neurons of the dorsal horn does not evoke an action potential.**

periphery to higher centers occurs in the dorsal horn. Secondary afferent neurons of the dorsal horn are involved in the determination of which action potentials trigger reflex action to avoid further injury from noxious stimuli, as well as which action potentials are transmitted to the brain. Inhibitory interneurons release the neurotransmitter γ-aminobutyric acid (GABA), which acts at receptors on secondary afferent neurons to produce inhibitory postsynaptic action potentials, modulating the transmission of excitatory action potentials received from primary afferents. A major role of the dorsal horn is to suppress pain. Most sensory information relayed to the secondary afferent neurons of the dorsal horn does not evoke an action potential.

GATE CONTROL THEORY

The gate control theory of pain, originally described by Melzack and Wall in 1965, posits that input from large-diameter primary afferent fibers in the peripheral nervous system activate inhibitory interneurons in the substantia gelatinosa (lamina II of the dorsal horn).[23] Activation of these inhibitory interneurons, in turn, reduces the effectiveness of nociceptive input from small-diameter primary afferent fibers in activating projection neurons of the spinothalamic, spinoreticular, or spinomesencephalic tracts. Thus, large-diameter input "controls the gate" by which small-diameter input transmits data on noxious stimuli to higher pain centers. This concept is the theoretical basis for the inhibition of pain by rubbing or vibration, as well as therapeutic modalities such as transcutaneous electrical nerve stimulation (TENS).[24]

CENTRAL SENSITIZATION

Central sensitization is a pathologic state in which dorsal horn excitability is increased and gatekeeping function is lost.[25-27] This facilitated responsiveness to sensory input leads to primary hyperalgesia (as is seen in peripheral sensitization). It also leads to secondary hyperalgesia, in which an exaggerated response to noxious stimuli is observed beyond the region of actual tissue damage. Allodynia, in which pain is generated by a low-intensity stimulus that would not be noxious to normal tissue, is also seen.

The pathogenesis of central sensitization may be thought of as occurring in two phases. The first stage is triggered by intense nociceptive input to the secondary afferent neurons of the dorsal horn and may thus be considered activity dependent. This excessive input may arise from persistent acute injury, surgical insult, peripheral sensitization of nociceptors during inflammation, ectopic discharge from nerve injury, a variety of chronic pain syndromes, or certain other conditions. The activity-dependent stage of central sensitization occurs rapidly; hyperresponsiveness of spinal neurons may be seen within seconds of massive sensory input triggered by an appropriate initial insult.

NMDA receptors on secondary afferent neurons of the dorsal horn are of critical importance in the pathology of central sensitization. Under normal conditions, glutamate does not have activity at the NMDA receptor during nociception. This is because the receptor has a voltage-dependent magnesium ion block on its calcium channel; glutamate is rapidly cleared from the synaptic cleft, and the neuron is not depolarized long enough to allow the magnesium ion block to be dislodged. However, excessive frequency of nociceptive input—primarily, temporally summated slow excitatory postsynaptic potentials from C fibers—lead to a persistent net increase in the amount of glutamate in the synaptic cleft and depolarization of secondary afferent neurons of sufficient duration to dislodge the magnesium ion block. The resultant activation of NMDA receptors by glutamate leads to a number of signaling cascades initiated by increased intracellular calcium influx, including G protein–coupled neurokinin receptors and receptor tyrosine kinases, as well as phosphokinases.[28] Activation of protein kinases leads to phosphorylation of the NMDA receptor ion channels, decreasing the magnesium block at resting membrane potentials and prolonging channel opening time. As a result, sensitized secondary afferent neurons respond more easily to continued signals from C fibers; in addition, spontaneous or ectopic signal discharge may occur in the context of loss of gatekeeping function.

Central sensitization is mediated by both postsynaptic (see above) and presynaptic NMDA receptors in the dorsal horn. Many small-diameter primary afferent fibers synapsing in the dorsal horn express NMDA receptors. Glutamate released from the presynaptic terminal may use these receptors to enhance its own release in a feed-forward mechanism in response to subsequent stimuli. Presynaptic NMDA receptors can facilitate the transmission of nociceptive messages secondary to the release of substance P, calcitonin gene–related peptide, and glutamate from primary afferent terminals.

The second stage of central sensitization is sustained beyond the initial insult by transcriptional changes in the cell and may be

considered transcription dependent. Two basic types of transcriptional change occur. One type is restricted to parts of the nervous system receiving sensory input from injured tissue; this process is activity driven. The other type of transcriptional change is widespread and produces a variety of functional effects. Induction of COX-2 in the central nervous system after peripheral inflammation is an example of this process; widespread production of COX-2 leads to a diffuse increase in prostaglandin E_2, with consequent diffusely increased neuronal excitability.

ASCENDING PATHWAYS

Nociceptive input to the dorsal horn is relayed to higher centers via one of a number of ascending pathways.

Spinothalamic Tract

The spinothalamic tract is the most prominent ascending pathway for nociceptive neural transmission. Axons from WDR and NS neurons in laminae I and V decussate diagonally in the anterior white commissure before ascending in the contralateral anterolateral white matter, becoming the ascending projections of the neospinothalamic and paleospinothalamic tracts. As their names imply, the neospinothalamic tract is a phylogenetically younger system than the paleospinothalamic pathway. The neospinothalamic tract relays information concerning sharp pain that may be graded in intensity and localized to a specific region of the body. Axons of this tract terminate monosynaptically in the ventroposterolateral (VPL) nucleus of the thalamus. As such, information traveling this pathway is not modulated before arriving at the thalamus.

The majority of spinothalamic tract axons belong to the paleospinothalamic pathway. This pathway produces diffuse, aching pain that is difficult to localize but lets the body know that it must take action to avoid further injury. The paleospinothalamic tract sends multiple projections to the brain stem reticular formation in the medulla and pons and the medial thalamus before terminating in the VPL nucleus. A series of nuclei in the medulla and pons act to modify ascending nociceptive data in the paleospinothalamic tract. For instance, the locus ceruleus nucleus of the pons produces glutamate and serotonin precursors in response to fear or shock; these act to reduce the transmission of pain beyond the pons in acutely fear-producing situations (a mechanism of obvious survival value). The brain stem reticular formation also has extensive connections with a number of structures in the midbrain, including the periaqueductal gray matter, deep layers of the superior colliculus, the red nucleus, anterior and posterior pretectal nuclei, the nucleus of Darkschewitsch, and the interstitial nucleus of Cajal. These structures may act in conjunction with the reticular formation to further modulate data in the paleospinothalamic pathway.

Spinoreticular Tract

The spinoreticular tract is composed of axons of nociceptive neurons in laminae VII and VIII that ascend in the ipsilateral anterolateral quadrant of the spinal cord, joining the spinothalamic tract in the medial lemniscus in the brain stem before terminating at many sites throughout the medullary, pontine, and mesencephalic reticular formation. In addition, some axons send branches that terminate in both the reticular formation and the thalamus. Of note, some spinoreticular fibers do not cross the midline before terminating. Neurons of the reticular formation project, directly or indirectly, to many areas of the brain, including the thalamus, hypothalamus, limbic system, and neocortex. Nociceptive data relayed to the reticular formation by the spinoreticular tract contribute to the affective, motivational, and aversive response components of pain. This tract predates the more direct spinothalamic pathway in vertebrate evolution.

Spinomesencephalic Tract

This tract consists of nociceptive neurons originating in lamina I and laminae IV through VI that project to the mesencephalic reticular formation, the lateral portion of the periaqueductal gray region, the nucleus cuneiformis, the superior colliculus, and other sites in the midbrain. The periaqueductal region, in turn, has reciprocal connections with the limbic system via the hypothalamus.

The spinomesencephalic tract is involved in the production of fear and related affective and aversive behaviors associated with pain. The tract's connections may also initiate orienting responses to noxious stimuli. Spinomesencephalic communication with the periaqueductal gray matter activates the system of descending pain modulation that subsequently produces endogenous analgesia.

Spinocervicothalamic Tract

Although most neurons in laminae III and IV of the dorsal horn respond solely to tactile stimuli, a minority respond to noxious stimuli as well. Spinocervicothalamic neurons project through the ipsilateral dorsolateral spinal cord to the lateral cervical nucleus in segments C1 and C2. Axons from this nucleus then decussate, ascending in the medial lemniscus in the brain stem to midbrain nuclei and to the ventroposterior lateral and posterior medial nuclei of the thalamus.

Postsynaptic Dorsal Column Fibers

Some nociceptive neurons in laminae III and IV project their axons in the dorsal column of the spinal cord to the cuneate and gracile nuclei in the medulla. Internal arcuate fibers then connect these nuclei with the contralateral VPL nucleus of the thalamus. Transmission of nociceptive data through the dorsal column in this fashion may be responsible for the persistence of painful symptoms after selective ablation of the spinothalamic tract (i.e., cordotomy). Stimulation of these fibers is a target for pain relief.

Visceral Nociceptive Tracts in Dorsal Columns

The dorsal columns of the spinal cord are primarily associated with discriminatory touch and proprioception; classically, they were not thought to be involved in pain transmission. However, a number of studies indicate that the dorsal columns have a role in the processing of visceral pain. In addition to relaying viscerosensory information, this pathway may also facilitate spinal neuronal sensitization of visceral origin; creation of dorsal column lesions reduced such sensitization in a model of chronic visceral pain. In a number of recent clinical studies, the creation of lesions in the dorsal columns resulted in good relief of visceral pain in cancer patients.

Spinohypothalamic Tract

The spinohypothalamic tract consists of a large number of neurons widely distributed throughout the spinal cord that communicate with the hypothalamus without synapse in the reticular formation. In addition, widespread collateral branching from spinohypothalamic tract neurons to a variety of targets in the medulla, pons, midbrain, and thalamus has been described. This pathway is involved in autonomic, neuroendocrine, and affective/emotional responses to noxious and other somatosensory

stimuli of cutaneous or visceral origin. Some studies suggest that the majority of spinohypothalamic tract neurons respond exclusively or preferentially to noxious stimuli.

Thalamocortical Pathways

Thalamus The ascending pathways project directly or indirectly to a number of nuclei in both the lateral and medial thalamus. In the lateral thalamus, the VPL nucleus is a main site of information relay from ascending pathways to the cortex. VPL neurons are primarily involved in sensory-discriminative aspects of pain perception, such as localization; however, the VPL may also be involved in visceral and referred pain. Neurons of the VPL nucleus, with receptive fields that are restricted in size, respond maximally to noxious mechanical stimuli; they also respond to noxious heat and C-fiber volleys. In addition, they respond weakly to nonnoxious mechanical stimuli. Most VPL neurons respond to both cutaneous and visceral stimuli; cutaneous input is somatotopic, but visceral input is not similarly arranged. Almost all VPL neurons project to the primary somatosensory cortex.

In the medial thalamus, the spinothalamic tract projects to the central lateral nucleus and other intralaminar nuclei, as well as to the ventromedial preoptic nucleus (VMpo), whereas the spinomesencephalic and spinoreticular tracts project heavily to the intralaminar nuclei and other medial thalamic nuclei via the reticular formation. The medial thalamic nuclei appear to play their most significant role in processing the affective and motivational components of pain. Primate studies suggest that neurons of the intralaminar nuclei have large, bilateral receptive fields (presumably limiting their role in sensory discrimination, or at least in localization). VMpo neurons, which have small, somatotopically organized receptive fields, project to the insula, a fact that suggests they have a role in affective and motivational responses to pain, as well as memory processing.

Cortex There is still a great deal of uncertainty concerning cortical processing of pain. There is no single discrete cortical pain center. Indeed, imaging studies support activation of a number of cortical areas in response to painful stimuli, including the anterior cingular, insular, parietal, frontal, premotor, and primary and secondary somatosensory cortices.[29] Patterns of cortical activation seen in experimentally induced pain may not match those seen in chronic pain, however.[30] Positron emission tomography studies have associated experimentally induced pain with increased regional cerebral blood flow to the bilateral anterior insular and posterior parietal cortices, bilateral inferior lateral prefrontal cortices, and cerebellar vermis and decreased blood flow to the contralateral posterior thalamus.[29]

The preponderance of imaging studies that associate activity in the anterior cingulate cortex (ACC) with both pain and behavioral drive and volition support a primary role for this region in the cortical processing of the motivational and affective components of pain. The critical role of the ACC in processing nociceptive data has raised interest in this cortex as a target of neuroablative therapy for intractable pain.[31] The anterior cingulate cortex, a major destination of outflow from the medial thalamus, is selectively activated by painful thermal stimuli and appears to be important in the processing of affective components of the pain experience.

Lesion studies suggest that large areas of damage to the somatosensory cortex do not yield impaired response to noxious stimuli. Cortical stimulation in general is only infrequently associated with the production of pain; large lesions of the somatosensory cortex may produce minimal or no pain, whereas small lesions elsewhere in the cortex may be associated with spontaneous pain or increased pain perception.[32]

DESCENDING PATHWAYS

The perception of pain at higher levels of the CNS triggers activation of descending pain suppression pathways involving numerous cortical and subcortical structures, as well as a variety of neurotransmitters.[33,34] The existence of such descending pathways was first suggested by the finding that brain stem stimulation inhibited nociceptive neurons in the dorsal horn of the spinal cord, but such suppression was negated by lesions of the dorsolateral funiculus. Neurons in the midbrain periaqueductal gray matter (PAG) and periventricular gray matter make excitatory connections to the nucleus raphe magnus (NRM) and the adjacent nucleus reticularis paragigantocellularis in the rostroventral medulla, as well as the locus ceruleus, among other nuclei. Neurons from these regions, especially the NRM and adjacent reticular formation, then make inhibitory connections in laminae I, II, and V of the dorsal horn. Thus, stimulation of PAG and subsequent stimulation of rostroventral medullary neurons lead to inhibition of dorsal horn neurons that transmit nociceptive data. Neurotransmitters involved in this pathway include endogenous opiates, serotonin, and norepinephrine. Noradrenergic projections from the dorsolateral pons to the dorsal horn of the spinal cord, relayed through the raphe magnus and pallidus, PAG, and ventrolateral reticular formation, constitute another significant antinociceptive pathway. Studies of stimulation-invoked analgesia also support roles for neurons of the reticular formation and anterior pretectal nucleus in descending antinociception. Stimulation of the VPL or ventroposteromedial thalamic nuclei leads to reduction in severity of several painful syndromes. Inhibition of spinothalamic tract neurons secondary to thalamic stimulation may result from antidromic activation of axons of spinothalamic tract neurons sending collaterals to brain stem nuclei such as the PAG. As described, sensory and descending neurons and interneurons converge in the dorsal horn of the spinal cord. These local circuits play a significant role in modulating descending pathway activity.

Endogenous opiates include enkephalins, dynorphins, and β-endorphins. Enkephalins and dynorphins are found in the PAG and rostroventral medulla, as well as in the dorsal horn of the spinal cord (especially laminae I and II). β-Endorphins are found in hypothalamic neurons that project to the PAG and noradrenergic nuclei in the brain stem.

Three major classes of opiate receptors are found in the descending pain suppression pathways and are widely distributed throughout the CNS. Enkephalins are active at the mu and delta receptors, whereas dynorphin is active at the kappa receptor. The primary classes of opiate receptors may be further subdivided into distinct subtypes. The different receptor classes may modulate the activity of different types of nociceptive inputs.

Opiate alkaloids such as morphine are potent agonists of the mu receptor, found in high concentration in the PAG and the superficial dorsal horn of the spinal cord. Opiates act at supraspinal levels (i.e., the raphe nuclei and PAG) to suppress GABA-releasing interneurons that normally inhibit descending pathway activity. This disinhibitory mechanism thus serves to activate the descending pain suppression pathways. Opiates also exhibit analgesic activity at the level of the primary afferent synapse in the dorsal horn of the spinal cord. The superficial dorsal horn has a large number of enkephalin- and dynorphin-con-

taining interneurons. Mu opiate receptors are located on the terminals of nociceptive afferents and the dendrites of postsynaptic dorsal horn neurons.

Opiate alkaloids and endogenous opioid peptides act presynaptically to suppress neurotransmitter release from sensory neurons. They also act postsynaptically to suppress the activity of the nociceptive dorsal horn neurons. That opioid receptors are ubiquitous throughout the CNS suggests that modulation of nociceptive data may occur at multiple sites, in addition to the aforementioned descending pathways and dorsal horn.

Neurobiology of Specific Pain Types

CANCER PAIN

Approximately 70% to 90% of patients with advanced cancer have chronic pain; pain is directly related to the presence of primary or metastatic cancer in up to three quarters of these patients.[35] Although cancer pain may involve any tissue, certain pain syndromes are commonly seen in the setting of malignant disease. Common mechanisms for cancer-related pain include direct effects of tumor growth, visceral involvement, bony metastases, soft tissue invasion, and nerve infiltration or compression. Exposition of the full range of cancer-related pain is beyond the scope of this chapter; some of the more common or significant syndromes are discussed.

Bone Pain

Tumor involvement of bone is the most frequent cause of cancer pain. Multiple myeloma and metastatic disease of the breast, lung, thyroid, and prostate are the cancers that most commonly involve bone. Different tumor types may produce primarily lytic or blastic metastases, but the majority result in mixed lesions. Osteoclast-mediated destruction of bone appears to be an important mechanism of pain in malignant disease. Tumors may also cause bone pain via ischemia, pressure, or secretion of chemical mediators. Pathologic fracture secondary to significant infiltration of bone may lead to an acute increase in pain severity, as well as neural impingement or compression. Metastasis to the vertebral column (see below) may lead to a wide variety of pain symptoms. Although the clinical experience of pain will vary with the mechanisms of the pain, most cancer-related bone pain is described as focal and constant, increasing in severity over time with progression of disease.

Plexopathy

A number of plexopathies are seen in cancer patients. Brachial plexopathy secondary either to metastasis or to tumor spread from lymphoma or from lung, breast, or thyroid cancer is a common cause of rapidly progressive arm or shoulder pain in cancer patients. Horner syndrome may also be seen in this setting. Brachial plexopathy may also result from radiotherapy (see below). Cervical plexopathy results from malignant invasion of the cervical plexus by head and neck tumors and produces pain in the ear or neck. Lumbosacral plexopathy may produce some combination of local, referred, or radicular pain in the low back, abdomen, perineum, or leg.

Back Pain

The prevalence of back pain in cancer is not known, but one large series found that it was the most common neurologic symptom in patients with a history of systemic cancer.[36] Back pain in this setting is typically from bone or epidural metastases; up to one third of cancer patients may develop metastases to the spine, with the thoracic vertebral column being the most frequent site of bony metastases. Acutely worsening back pain or increasing neurologic symptoms may indicate involvement of the spinal cord or one or more nerve roots. Any patient with a history of cancer who complains of back pain must be evaluated emergently to rule out epidural spinal cord compression [*see 12:XII Oncologic Emergencies*]. Less commonly, back pain may be caused by retroperitoneal tumors.

Headache

Estimates of the prevalence of headache in patients with brain tumors vary widely, from 8% to 71%.[37] Infratentorial and intraventricular tumors, multiple metastases, and leptomeningeal carcinomatosis are most commonly associated with cancer-related headache. Headache in the setting of brain tumor is generally from traction on and displacement of intracranial pain-sensitive structures, such as cranial and cervical nerves, blood vessels, and dura. Pain may also arise from inflammation or direct infiltration of those structures. It may also occur as the result of disturbance or obstruction of the flow of cerebrospinal fluid; sagittal sinus occlusion; stroke; or other causes. Cancer-related headache pain is variable in presentation but is most often described as being of mild or moderate intensity, lasting for hours, possibly developing over weeks or months, and possibly associated with nausea, vomiting, mental status changes, or focal neurologic findings. Forsyth and colleagues reported that patients with a history of headache who develop brain tumors are more likely to complain of headache as their primary presenting tumor symptom than patients without a history of headache.[38] These data underscore the critical importance of a comprehensive neurologic assessment in all patients presenting with headache.

Abdominal Pain

Primary or metastatic intra-abdominal malignancy may cause poorly localized visceral pain, sometimes with associated nausea, vomiting, or systemic symptoms. Causes of pain include direct invasion of tissue, peritoneal inflammation, and vascular or lymphatic obstruction. Pain secondary to abdominal cancers may be referred elsewhere, as when diaphragmatic irritation results in shoulder pain. Alternatively, pain from spinal malignancy may be referred to the abdomen.

Iatrogenic Pain

Many of the diagnostic and therapeutic modalities utilized in the care of cancer patients can result in pain.[35] Radiotherapy is associated with such painful conditions as osteonecrosis, acute and chronic enteritis, mucositis, and brachial plexopathy. Chemotherapeutic agents may produce painful neuropathies, as well as a variety of distressing side effects. Steroid therapy may lead to avascular necrosis, as well as to ultimately painful consequences of immunosuppression. Preparation for bone marrow or stem cell transplantation leads to mucositis in 70% of patients. Pain after cancer surgeries may be severe. In addition, chronic pain syndromes have been identified after mastectomy, thoracotomy, amputation, and radical neck dissection. Surgery for abdominal malignancies may lead to adhesions and subsequent painful bowel obstruction. Common hospital procedures may also be a significant source of pain and distress.

HIV INFECTION AND AIDS PAIN

HIV infection and AIDS can lead to pain through numerous distinct pathophysiologic mechanisms. Pain in this setting may be attributable to the direct neurotoxic effects of HIV on central or peripheral nerves, opportunistic infection or malignancy secondary to immunosuppression, or medication side effects. In one survey, 67% of AIDS patients reported pain in the previous 4 weeks[39]; many pain syndromes in ambulatory AIDS patients are directly related to infection or other consequences of immunosuppression. Most underlying causes of pain in AIDS are treatable.

HIV-associated peripheral neuropathy is the most frequent neurologic complication of AIDS, affecting almost one third of patients with the disease.[40] Distal symmetrical polyneuropathy (DSP), the most common form, is characterized by paresthesias, dysesthesias, or numbness occurring in a stocking-and-glove distribution. Distal pain, often described as sharp, stabbing, or burning, may become excruciating. DSP is seen primarily in advanced disease or secondary to antiretroviral treatment. Clinically, DSP caused by HIV infection is indistinguishable from DSP caused by antiretroviral agents, except for the latter's response to reduction or withdrawal of antiretroviral agents. Acute inflammatory demyelinating polyneuropathy (AIDP), characterized by muscle weakness, tingling, and ascending paralysis, may be the initial manifestation of HIV infection. Chronic inflammatory demyelinating polyneuropathy, a chronic form of AIDP marked by reduced reflexes and patchy weakness or numbness, may develop at seroconversion or a later stage of disease. Progressive polyneuropathy is characterized by rapidly progressive flaccid paraparesis, subacute low back and radicular pain and paresthesias, areflexia, and sphincter dysfunction. Most often, it is secondary to cytomegalovirus infection; it is observed most frequently in advanced HIV disease. Mononeuropathy multiplex occurring in early HIV disease is marked by self-limited sensory and motor deficits in the distribution of individual peripheral nerves; in advanced disease, multiple nerves in multiple extremities or cranial nerves may be involved. In mononeuropathy multiplex secondary to vasculitis, pain will precede sensory and motor deficits. Diffuse infiltrative lymphocytosis syndrome (DILS) is a subacute, often painful, distal sensorimotor neuropathy associated with parotid enlargement and sicca syndrome; there is sometimes systemic involvement (i.e., lymphadenopathy, splenomegaly, or interstitial pneumonia). DILS may occur during symptomatic HIV infection.

Pain Management

BARRIERS TO EFFECTIVE PAIN MANAGEMENT

Undertreatment of pain remains a significant clinical problem. SUPPORT found that 50% of adults dying in the hospital experienced moderate to severe pain in the period immediately before death.[16] In one large multicenter study, 86% of physicians felt that the majority of their patients with pain were undertreated.[8] The preponderance of studies suggest that most cancer patients do not receive adequate pain relief.

A number of barriers to effective pain management relate to health care delivery systems. Most health care organizations have not implemented procedures to ensure accountability for adequate assessment and treatment of pain. Many organizations fail to make pain relief a visible priority through such measures as adoption of standardized protocols or provision of sufficient time for training. Fragmentation of patient care across multiple clinical settings increases the likelihood of poor care. Use of gatekeepers and an emphasis on cost control by managed care organizations provide further systemic disincentives for the treatment of pain. Restrictive laws governing the use of controlled substances may have a significant effect on analgesic prescribing patterns. Clinician pain management practices are likely influenced by concerns about licensing, state disciplinary actions, and legal penalties arising from opioid prescribing patterns.

Table 1 Principles of Pain Assessment

1. Believe the patient's complaint of pain
2. Take a careful pain history
   - Onset
   - Temporality
   - Location
   - Quality (sensory versus affective)
   - Intensity
   - Aggravating/relieving factors
   - Associated symptoms
3. List and prioritize each pain complaint
4. Evaluate the response to current and previous treatment approaches
5. Evaluate the patient's psychological state
6. Assess patient function
7. Ask about a history of alcohol or drug dependence
8. Consider relevant past medical history
9. Perform a comprehensive medical and neurologic examination
10. Order and review appropriate diagnostic procedures
11. Make relevant referrals for multidisciplinary assessment
12. Assess patient expectations and goals

Several barriers center on physician attitudes or practices. A paucity of time devoted to the subject in the curricula of most United States medical schools and residencies has led to deficiencies in the pain management skills of many clinicians. In one study of physician attitudes regarding cancer pain, inadequate assessment skills were identified most frequently as a significant impediment to effective pain relief.[8] In another study, 70% to 80% of neurologists did not feel adequately trained to diagnose or treat patients with pain.[41] Some physicians are reluctant to prescribe opioids in any setting other than end-stage terminal illness. Clinician discomfort with opioid use is multifactorial; sources of unease include inadequate knowledge of opioid management, fear of patient addiction, and fear of professional censure or legal penalties for excessive use of these analgesics. Some clinicians do not view pain relief as central to the treatment of disease, or they may have low expectations regarding adequate pain relief. Physicians may not accept patient self-reports of pain as reliable.

Other barriers relate to patients' attitudes. Patients may be reluctant to report pain for any of a number of reasons. They may fear appearing "difficult" or "problematic," or they may have low expectations of obtaining relief. Alternatively, they may deny pain because of fear of its potential implications for their underlying illness. Patients may be reluctant to take prescribed opioids because of concerns about addiction or drug side effects. Patients with chronic pain may cease seeking medical treatment out of frustration with previous unsuccessful attempts at pain relief. In a survey of parents of children who had died of cancer, the parents reported overall satisfaction in the care their children received despite noting that pain was inadequately controlled.[42]

Financial and cultural barriers may also prevent effective pain management in some populations.

PRINCIPLES OF PAIN ASSESSMENT

Accurate pain assessment is the necessary precursor to effective pain management. At least one large multicenter study named inadequate pain assessment skills as the most frequent barrier to the provision of effective pain care.[8] Adherence to the following principles of pain assessment will greatly improve the treatment of pain [*see Table 1*].[43]

- Believe the patient's complaint of pain. Accepting that a patient's complaint is real and therefore deserving of further investigation is the logical prerequisite to further effective pain assessment. The patient's self-report is the single most accurate indicator of the existence and severity of pain. Fear of drug-seeking may predispose some physicians to disbelieve the pain complaints of some patients. However, lack of trust is associated with poor pain management and corresponding poor outcomes.
- Take a careful pain history. As with the medical workup of any complaint, a thorough history of the present illness is necessary. Specific areas to evaluate include the following.

Pain onset When did the pain begin? Was the onset spontaneous or gradual? Was there a possible precipitating event (e.g., trauma or surgery)? If so, the physician should obtain relevant details of the precipitating event (e.g., the nature and extent of trauma, any treatment at time of trauma). Did the patient ever experience similar pain?

Temporality What is the duration of the pain? Is it chronic, episodic, or intermittent? Is it acute or subacute? Is breakthrough pain experienced? Is it incidental?

Location Where is the pain? Is it in one or multiple locations? Does it radiate? Does the location of pain vary?

Quality What does the pain feel like? What word or words are used to describe the pain (e.g., sharp, dull, burning)? Adjectives chosen often fall into two broad categories: sensory, in which pain is described in essentially physical terms; and affective, in which the pain experience may have a significant emotional component. Particular words chosen may also provide important clues to the etiology of pain (e.g., neuropathic versus musculoskeletal).

Intensity Pain may be measured by use of a variety of scientifically validated assessment tools.[44] The Numeric Pain Intensity Scale, in which the patient rates his or her pain on a scale from zero to ten (0 = no pain, 10 = worst pain imaginable), allows for quantification of pain severity, evolution over time, and response to treatment. Use of the Visual Analog Scale or the Simple Descriptive Pain Intensity Scale may be better for some patient populations. In the Visual Analog Scale, a mark on a horizontal line denotes pain intensity; in the Simple Descriptive Pain Intensity Scale, the patient picks an appropriate verbal pain descriptor. The Faces Pain Scale for Adults and Children and the Wong-Baker Faces Rating Scale consist of multiple faces with various expressions; the patient may select the facial expression most consistent with his or her current level of pain. This methodology has been validated for use in the pediatric population. Several more extensive tools for assessing pain and its impact on the activities of daily living, such as the Initial Pain Assessment Tool, Brief Pain Inventory, McGill Pain Questionnaire, Memorial Pain Assessment Card, Neuropathic Pain Scale, and Memorial Symptom Assessment Scale [*see CE:X Symptom Management in Palliative Medicine*], permit valid serial assessment of pain and its functional import. For general clinical practice, however, simple assessment tools are sufficient.

Aggravating or relieving factors What exacerbates the pain? What relieves it?

Associated symptoms Is the patient experiencing any other symptoms, such as nausea, vomiting, diarrhea, or anorexia? Such symptoms may relate to the pain itself or to an underlying disease process.

- List and prioritize each pain complaint. Prioritization of multiple pain complaints should be based primarily on the patient's subjective ranking of significance.
- Evaluate the response to current and previous treatment approaches. What is being done for pain relief at present? What pharmacologic or other therapeutic approaches have been attempted in the past? Were adequate trials of medications given? Were these approaches successful? Has the patient experienced adverse events associated with pain management modalities?
- Evaluate the patient's psychological state. Consideration of psychological and psychosocial factors should start at the time of initial pain assessment and continue throughout treatment. Are there any recent sources of stress (e.g., marital or vocational problems)? Has the pain affected the patient's mood? Is the patient suffering from any psychiatric illness? Is this illness treated or untreated? Certain psychiatric conditions, such as depression, anxiety, and posttraumatic stress disorder, frequently coexist with chronic pain and may have significant somatic components. Clinical depression may have a profound influence on the patient's perception of pain and on the patient's ability to comply with subsequent treatment. Thus, simultaneous treatment of psychiatric pathology may be an integral part of the pain management plan. Depression and anxiety may lead to somatic complaints, and untreated pain may exacerbate depression and anxiety. Instruments such as the Medical Outcomes Study 36-Item Short Form (SF-36) and the Sickness Impact Profile may be used to assess the broader impact of pain on quality of life, including social, psychological, and spiritual well-being; these instruments are available through the Medical Outcomes Trust (http://www.outcomes-trust.org/instruments.htm). The patient's mental status should also be assessed. Cognitively impaired patients can sometimes give reliable reports of pain, but other assessment tools may be needed. Obtaining a history from family members, friends, or both is critical in caring for such patients.
- Assess patient function. How has the pain affected work, family, or social responsibilities or relationships? Have activities of daily living been impaired? What (if any) important activities is the patient unable to perform? Is the patient eating and sleeping as he or she did before the pain? In the case of chronic pain, what support structures does the patient have? The Wisconsin Brief Pain Questionnaire, or Brief Pain Inventory (http://www.stat.washington.edu/TALARIA/attachb1.html), is one of the instruments that may be used to evaluate the effect of pain on various domains of function.
- Evaluate for a history of alcohol or drug dependence. Previous or current substance abuse or dependence may impact

the patient's compliance with analgesic regimens, psychological state, function, and other domains. Ensuring the safety of the patient in the community when considering prescribing potent analgesic medication is of paramount importance [*see 13:VI Drug Abuse and Dependence*].

- Consider relevant past medical history. Many acute and chronic conditions may present as or eventually lead to pain; these include diabetes, coronary artery disease, malignancy, and the various chronic pain syndromes. A comprehensive medical history may provide important cues for treatment.
- Perform a comprehensive medical and neurologic examination. Performance of a physical examination will, at the very least, reassure the patient that his or her complaint is being taken seriously. The examination may also reveal the pathologic basis of pain. Often, the revealed disease process is unsuspected; in one study, pain consultants discovered a previously undiagnosed cause of pain in 64% of patients seen.[45] The examiner should look for any pain behaviors (e.g., abnormal gait or posture, guarding) and interpret their presence or absence in terms of the patient's overall presentation and social interaction. Observation for signs of systemic illness should accompany a detailed evaluation of reported pain sites. Every patient with a complaint of pain should, at minimum, undergo a neurologic examination. Chronic pain is often a sequela of neurologic pathology, and such patients are best cared for within a neurologic framework.
- Order and review appropriate diagnostic procedures. Although the diagnosis of painful conditions is usually made on the basis of the history and physical examination, and pain per se is not identifiable by any diagnostic modality, imaging and other studies such as laboratory tests, electromyelography, nerve conduction studies, or diagnostic nerve blocks may be valuable in the assessment of disease processes that can give rise to pain. Certain disease-specific laboratory measurements (e.g., tumor markers in some malignancies) are sensitive indicators of disease progression and may correlate with painful symptoms. Findings on imaging studies do not correlate, or correlate weakly, with patient pain experiences.
- Make relevant referrals for multidisciplinary assessment. Many painful conditions may be managed adequately by a patient's primary care physician. However, referral to a pain specialist or a team approach may be best for certain cases of chronic, cancer-related, or otherwise complex pain that is debilitating or refractory to treatment. Important members of the pain management team may include neurologists, psychiatrists, anesthesiologists, physiatrists, physical or occupational therapists, clergy, social workers, and counselors. Pain clinics may bring all relevant team members "under one roof." Many pain specialists believe that referrals frequently are made past the so-called golden hour when their intervention may be of maximal effectiveness, especially in cases of neuropathic and cancer pain. Referral to a pain specialist ideally should occur before significant disability or loss of function occurs; pain behaviors or the emergence of maladaptive coping strategies may serve as cues for referral.
- Assess patient expectations and goals. What does the patient expect or hope for in terms of treatment outcomes? Patient goals should be assessed in a number of domains, including pain intensity, daily function, and quality of life. Having patients set goals will keep the physician from taking a narrow focus on physical factors such as pain intensity, to the exclusion of the larger aspects of pain's impact on the patient's life.

Principles of Pain Management

Eleven principles should guide the management of pain [*see Table 2*].

- Take a detailed history of the patient's pain (see above). An accurate assessment of the patient's pain is essential for the direction of future therapy.
- Design a patient-specific diagnostic and therapeutic approach. Although there are numerous guidelines for treatment of pain in different conditions, pain is a complex subjective experience requiring an individualized approach. Management of pain should take into account such factors as the underlying cause (or causes) of pain, medical comorbidities, psychological state, response to prior therapies, functional status, compliance with or tolerance of different therapeutic regimens, and objectives of therapy.
- Ensure the availability of expertise to provide therapeutic alternatives. Pain may be managed in a variety of clinical settings. In a multidisciplinary pain treatment center, expertise on a variety of alternative therapies may be readily available. When primary management of pain occurs in other settings, access to external resources must be assured.
- Choose the simplest approach before attempting more complicated and invasive techniques. As initial therapy of a given painful condition, medical management may be superior to invasive techniques on the basis of risk/benefit assessment, cost, and other factors. For drug treatment, selection of agents can follow the stepwise approach advocated by the World Health Organization (WHO).[46]
- Maintain ongoing communication between physician and patient in defining therapeutic options and potential risk-to-benefit ratios of each approach. Patients may respond better to therapeutic regimens that they helped to select and in which they therefore feel invested.
- Titrate doses to maximize efficacy and minimize side effects. Inadequate dosing of analgesics may be the most frequent cause of undertreatment of pain. To provide optimal pain management, physicians require training in proper dosing of pain medications, guidelines for dose titration, and significant side effects of pharmacologic agents (see below). Optimal titration will vary between patients. Physicians who adhere to accepted management guidelines need not fear legal or professional repercussions from their treatment of patients in pain.
- Anticipate and treat side effects. Poor management of side effects is associated with suboptimal treatment compliance, leading to continued pain and such secondary pain-related problems as mood disturbance, inactivity, and impaired function.
- Utilize adjuvant medications for analgesia and for specific pain syndromes. Specific painful conditions may best be treated with multiple analgesics. Adjuvant medications should be employed when clinical evidence supports their use.
- Distinguish physical dependence from psychological dependence. Surveillance for and prevention of psychological dependence (i.e., addiction) is a legitimate concern when opiates are used for pain management. Nevertheless, excessive fear of addiction is a significant barrier to optimal pain management. Patient (and physician) fears and misconceptions should be dealt with in frank discussion. Patients must be counseled that in the absence of a history of substance abuse, the likelihood of developing addiction while taking opioid medications for pain has proved exceedingly rare (occurring in less than 1% of patients in many studies).[47] Physical dependence, a common phe-

nomenon, must be defined and differentiated from addiction. Especially with new patients, it is important for physicians to be familiar with the diagnostic criteria for substance abuse disorders; these disorders present a different set of management problems [*see 13:VI Drug Abuse and Addiction*].

- Provide continuity of care throughout evaluation and treatment. Fragmentation of care is a significant contributor to the suboptimal medical treatment often received by patients with chronic or complex pain. Failure to establish a durable physician-patient relationship may lead to the incorrect perception of so-called doctor-shopping and drug-seeking behavior by a patient who lacks a coordinated pain management strategy. Involvement of numerous providers in the pain management process may predispose to such fragmentation.
- Continually reassess the degree of pain relief and the impact of treatment on mood, function, and overall quality of life. Ongoing assessment of the degree to which treatment goals are being met allows for appropriate adjustment of the therapeutic regimen. Reassessment is especially critical after changes in pharmacologic agent or dosing, as well as after nonpharmacologic interventions. Much of the clinical import of pain relates to its impact on mood, function, and quality of life; assessment of the effect of therapy on these secondary variables is of special significance. Assessment of ongoing patient pain complaints may also be a valuable part of monitoring underlying disease processes.

The frequency of pain reassessment should be keyed to the nature of the pain. Reevaluation of acute pain is usually done after therapeutic interventions over a short time frame. Reassessment of chronic pain is more likely to occur at predetermined intervals over an extended period. Frequency will also vary with clinical setting. For example, inpatients and long-term care residents may undergo pain assessment as the so-called fifth vital sign on nursing rounds, whereas outpatients may have follow-up as appropriate. The specific tools with which pain is reassessed will vary with patients as necessary.

Management of Pain in Specific Conditions

CANCER

Most pain in patients with advanced cancer is caused by the cancer itself (e.g., tumor growth leading to tissue invasion, painful metastases, or involvement of the nervous system or visceral structures).[35] Therefore, treatment of the underlying malignancy with chemotherapy, radiotherapy, or surgery is a vital component of the management of cancer pain. However, symptomatic relief is often necessary as well, which is commonly achieved with drug therapy.

The WHO's three-step analgesic ladder can be used to guide the selection of pain medication [*see Figure 3*].[48] In validation studies, the WHO ladder was found to be effective in 69% to 100% of adults with cancer.[48-50] In step one, nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen are used for patients with mild pain. If the pain persists or increases (i.e., becomes moderate pain), treatment progresses to step two, in which nonopioids are combined with opioids such as codeine and hydrocodone or are given in the form of combination analgesics such as oxycodone with acetaminophen. For severe pain, treatment progresses to step three, which involves opioids with higher potency (e.g., morphine, methadone, hydromorphone, or fentanyl), with or without nonopioids. Adjuvant drugs may be utilized at any level of the ladder. Common adjuvants include corticosteroids (the most widely used agents for this purpose); antidepressants, anticonvulsants, and other agents for neuropathic pain; bisphosphonates and radionuclides for bone pain; and antibiotics for pain from ulcerating tumors. Nonpharmacologic adjuvant treatments such as external-beam radiation, neurosurgical ablative procedures, psychiatric therapy, and anesthetic interventions may also be employed. Management of cancer pain may be complicated significantly by the simultaneous need to manage multiple other symptoms of advancing malignancy, including fatigue, depression, dyspnea, anorexia, cachexia, chronic nausea, and anxiety.

Table 2 Principles of Pain Management

1. Take a detailed history of the patient's pain
2. Individualize the therapeutic approach
3. Ensure the availability of expertise to provide therapeutic alternatives
4. Choose the simplest approach before more complicated and invasive techniques
5. Maintain ongoing communication between physician and patient in defining therapeutic options and potential risk-to-benefit ratios of each approach
6. Titrate doses to maximize efficacy and minimize side effects
7. Anticipate and treat side effects
8. Utilize adjuvant medications for analgesia and in specific pain syndromes
9. Distinguish physical dependence from psychological dependence
10. Provide continuity of care throughout evaluation and treatment
11. Continually reassess the degree of pain relief and the impact of treatment on mood, function, and overall quality of life

HIV/AIDS

The increasing life expectancy of patients with HIV infection has led to the characterization of HIV/AIDS-related pain as a type of chronic pain. Management of pain in this setting is complicated greatly by the diversity of pathologic mechanisms un-

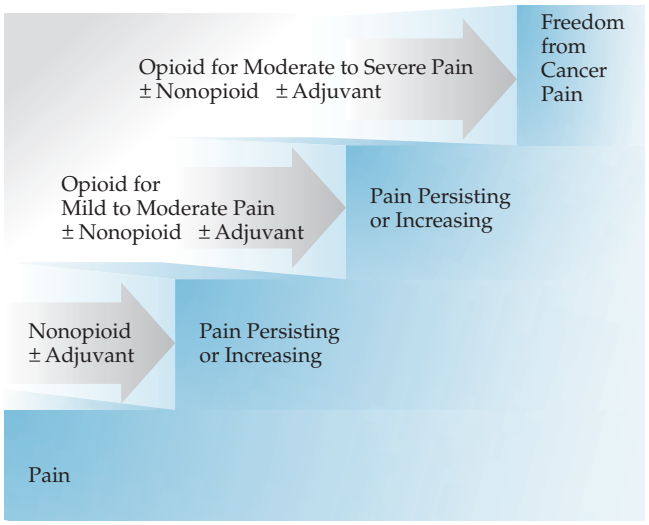

Figure 3 **The World Heath Organization's three-step analgesic ladder can be used to guide the selection of pain medication.**

derlying the variety of pains and pain syndromes seen in these patients. The Agency for Healthcare Policy and Research (AHCPR) recommends that the WHO approach to cancer pain management (see above) be used for the treatment of painful conditions in HIV/AIDS patients.

It has been suggested that as many as 85% of patients with HIV/AIDS-related pain do not receive adequate pain treatment. Women, substance abusers, and patients of low socioeconomic status are particularly vulnerable.[51]

Pharmacologic Management of Pain

The WHO, the American Pain Society, and the AHCPR have published specific guidelines on analgesic use.[45,47,52] Although the WHO analgesic ladder (see above) provides a useful construct for drug selection, pharmacotherapy ultimately must be tailored to the individual patient, taking into account the patient's medical comorbidities, response to prescribed drugs, side effects experienced, and a wide range of psychosocial and quality-of-life variables.

OPIOID ANALGESICS

Indications

Opioids play a significant role in the treatment of a number of conditions, including acute pain, trauma-related pain, postoperative pain, cancer pain, and some types of chronic noncancer pain, including osteoarthritis, low back pain, and neuropathic pain. Because responsiveness to opioids varies between patients, failure of response to an adequate trial of one opioid should be followed by an adequate trial of another opioid. Within a given potency range, there is little evidence to recommend one opioid over another as the initial prescribed agent. Selection of initial analgesic agent often is based on a combination of drug characteristics (e.g., half-life and duration of effect, speed of onset, route of administration) and patient characteristics (e.g., prior response to different opioids) [*see Tables 3 and 4*].

Table 3 Opioid Analgesics Used for Mild to Moderate Pain

Drug	*Dosage (Oral)**	*Analgesic Equivalence (mg)†*	*Duration*
Codeine	15–60 mg q. 4 hr	200	3–4 hr
Hydrocodone	5–15 mg q. 4–6 hr	200‡	3–5 hr
Meperidine	50–150 mg q. 3–4 hr	300	2–3 hr
Propoxyphene	65 mg q. 4 hr	200	3–6 hr

*These agents are typically combined with acetaminophen or aspirin, which limits dose escalation.
†Compared with 30 mg of oral morphine.
‡Equivalence unsubstantiated but thought to approximate codeine.

Neuropathic pain The role of opioids in neuropathic pain has been established since the late 1990s, when a series of well-designed randomized controlled clinical trials clearly demonstrated efficacy in neuropathic pain states such as diabetic neuropathy. Current data suggest that neuropathic pain may be managed more effectively when morphine is combined with gabapentin than when either agent is used alone [*see* Antiepileptic Drugs, *below*]. Although monotherapy is often tried initially in managing neuropathic pain (most commonly with gabapentin), many patients are best served by a so-called cocktail approach that targets multiple mechanisms.

Mechanism

Opioids achieve their analgesic effects chiefly by interacting with opioid receptors in the CNS. This binding inhibits the transmission of nociceptive impulses from periphery to spinal cord, activates descending pain suppression pathways, and modulates activity in the limbic system. Pain relief from opioids may also derive in smaller part from activity at receptors in the peripheral nervous system. Individual opioids display different affinities for, and interactions with, each of the three types of opioid receptors (mu, kappa, and delta; see above). Many of the most commonly used opioids are mu agonists. Differences in binding patterns underlie many of the differences in side effect

Table 4 Opioid Analgesics Commonly Used for Moderate to Severe Pain

Drug	*Dose*	*Half-life (hr)*	*Comment*
Morphine	10 mg I.V., 30 mg p.o.	2–4	Standard of comparison for opioid analgesics; start with a lower dose in patients with respiratory insufficiency, increased intracranial pressure, liver failure, or renal failure
Hydromorphone	1.5 mg I.V. , 7.5 mg p.o.	2–3	Slightly shorter acting
Methadone	10 mg I.V., 20 mg p.o.	15–20	Good oral potency; long plasma half-life, so repetitive dosing may result in accumulation and excessive sedation
Fentanyl	100 μg = 4 mg I.V. morphine	1–2	Short half-life; transdermal and transmucosal preparations available
Meperidine	75 mg I.V., 300 mg p.o.	2–3	Not recommended for patients with chronic cancer pain or impaired renal function or those receiving monoamine oxidase inhibitors
Levorphanol tartrate	2 mg I.V., 4 mg p.o.	12–16	—
Oxycodone	30 mg p.o.	3–4	Typically used in combination with nonopioid analgesics that limit dose escalation
Oxymorphone	1 mg I.V., 6 mg p.r.	2–3	Not available orally

profile among individual agents. Although opioid receptors are found primarily in the CNS and the gastrointestinal tract, they are widely distributed throughout the body; the potential analgesic significance of receptor networks outside the CNS is not fully understood at present.

Administration and Formulation

Opioids may be administered via a wide range of routes—oral, sublingual, rectal, intravenous, transdermal, intrathecal, epidermal, and subcutaneous. The preferred mode of administration will vary with the specific opioid, the severity of pain, and the patient's medical condition. Not all opioids are available in all dosing forms. The oral route is usually used for systemic administration. For mild to moderate pain, there is no consistent evidence that any route of systemic administration is superior to oral administration; other systemic routes may be preferred for more severe pain. Oral or transdermal administration generally is preferred for treatment of chronic conditions. Medical factors may prevent oral administration. For example, patients with end-stage dementia often lose the ability to swallow medications, and 80% of cancer patients are unable to take oral opioids for some time before death, because of intractable nausea, oral mucositis, dysphagia or aspiration concerns, bowel obstruction, or other conditions. Oral administration may be impractical for very high dose opioid therapy because the patient would have to swallow an unreasonable number of tablets.

Intravenous opioid administration has a number of other advantages. Intravenous administration provides rapid onset of effect and allows rapid titration to optimal analgesia. Avoidance of first-pass hepatic degradation yields higher bioavailability and thus an opportunity to reduce total dosage. Continuous intravenous administration may provide the patient with a consistent level of analgesia. However, the greater potency of intravenous opioids increases the risk of systemic side effects, particularly if rapid dose escalation occurs or if the patient is opioid naïve.

Subcutaneous injection may be used when small fluid volumes are sufficient to deliver the prescribed opioid dose. This route enables rapid titration and onset of analgesia; however, a shortened duration of effect necessitates frequent redosing to maintain constant pain relief. The risk of side effects is greater with subcutaneous than with oral administration. Rectal administration offers ease of use but the variation in absorption and first-pass metabolism from patient to patient can make efficacy unpredictable. Furthermore, rectal dosing cannot be used in the setting of diarrhea, transmucosal lesions, neutropenia, or severe thrombocytopenia. Transdermal administration may be useful when the oral route is unavailable; however, this dosing method is limited by the amount of available skin surface and is not effective for control of fluctuating pain levels. Intramuscular administration should, in general, be avoided because of erratic absorption and pain associated with the procedure.

Patient-controlled analgesia (PCA) devices allow patients to adjust opioid delivery according to their level of pain. PCA may be used for initiation of parenteral opioid therapy, rapid opioid titration, or treatment of incident pain. The devices are programmed for dose size, lockout interval, and cumulative dose allowable over a given period; continuous infusion may be programmed to supplement PCA doses, enabling sleep and covering baseline pain. Safety features prevent the delivery of more medicine when the patient is excessively sedated. Compared with conventionally administered opioids, PCA provides equivalent or superior analgesia with less total opioid consumption, fewer side effects, and no greater likelihood of dependence. PCA may be used in the home, allowing severely ill patients to receive adequate pain relief outside of the hospital.

Intraspinal opioid administration is useful for patients requiring such large amounts of opioids that systemic side effects prevent the maintenance of adequate drug levels. Delivery of opioids to the epidural or intrathecal space exploits the large concentration of opioid receptors in the dorsal horn of the spinal cord, achieving analgesia at significantly smaller doses of opioid than would be required with systemic administration. Compared with the intravenous route, intrathecal and epidural morphine are 100 times and 10 times more potent, respectively. The smaller opioid doses required for intraspinal administration result in effective analgesia at a greatly reduced side-effect burden. Implantable intrathecal drug delivery systems consist of an implanted programmable pump that delivers small doses of morphine directly to the spinal fluid. Although intraspinal opioid therapy has obvious benefits, it is not a first-line treatment. It is indicated only for patients who have experienced some degree of pain relief in multiple trials of different systemically administered opioids but who have suffered intolerable side-effect burdens that effectively prohibited the continued use of these regimens.

Desired duration of drug action varies with clinical circumstances. Long-acting and sustained release formulations are useful for patients in continuous pain; these drugs reduce severity of end-of-dose pain and may let patients sleep through the night. Sustained-release formulations are frequently used to treat patients with cancer pain. Most opioids may be given on an around-the-clock or an as-needed basis, but around-the-clock administration may improve patient outcomes and adherence. Long-acting formulations also may improve patient adherence. Short-acting formulations are used to manage intermittent pain and breakthrough pain.

Dosing

Titration to optimal dosage generally involves gradual adjustment of a small initial dose, on the basis of both the pain relief achieved and the severity of side effects encountered. A patient may be given an immediate-release oral formulation of an agent with a short half-life for a limited time (e.g., 24 to 48 hours), during which medication consumption, efficacy of pain relief, and side effects encountered are recorded in a patient diary. Alternatively, patients in severe pain may need rapid titration of a potent opioid via continuous intravenous infusion. Once pain control has been achieved and the optimal dose determined, the opioid may (if desired) be prescribed in long-acting or sustained-release form.

The opioid dose required to control pain in a given patient is influenced significantly by the type and severity of pain, any preexisting opioid tolerance, psychological distress, age, and genetic factors. Changes in dose may be required if pain severity increases. In general, dose changes should be made in increments of one third to one half the prior dose and should be modified according to the patient's use of breakthrough medications. This formula also applies to the reduction or cessation of opioid dose in patients whose source of pain is eliminated. Gradual reduction of the daily dose (i.e., reductions in increments of less than 25%) is necessary to prevent symptomatic withdrawal.

Patients receiving long-acting opioid therapy may experience episodes of acute pain that cannot be adequately controlled by the baseline analgesia provided by long-acting opioids. Short-acting, immediate-release opioids are used to cover this break-

through pain and are a critical component of long-term opioid therapy. There is no standard methodology for the dosing of breakthrough medications. Single rescue doses are commonly set at either 10% to 20% of the total daily dose or 25% to 30% of the single standing dose. As is the case with standing doses, breakthrough doses should be adjusted as appropriate for the individual patient. When possible, the same agent should be used for standing and breakthrough medications; this approach eases titration and eventual conversion (see below).

Weak opioids often are compounded with a nonopioid analgesic (commonly, acetaminophen). This combination may result in an opioid dose-sparing effect; however, it does not consistently reduce side effects. In addition, the potential for overdose of the nonopioid component limits escalation of the opioid dose. This may necessitate a switch to another opioid or combination if pain increases in severity.

Opioid Conversion

Although there is no theoretical upper limit to the dose of most opioids, practical ceilings for a given agent may be imposed by side effects, administration concerns (e.g., excessive injectate volume or skin surface area required for patches), or lack of apparent response to the drug. Such impediments to dose escalation may require switching of agent, route of administration, or both. When changing from one agent to another is necessary, clinicians often make use of published equianalgesic conversion charts. However, these standardized tables were constructed on the basis of limited data; therefore, they should serve as only a starting point for opioid conversion dosing.

Consideration of opioid conversion because of increasing pain should begin with a comprehensive assessment of the nature of the pain necessitating the switch. Pain caused by a worsening underlying medical condition may require a change in the treatment of that condition in addition to, or in place of, a change in analgesic. Pain attributable to inflammatory or neuropathic etiologies may be better treated with adjuvant analgesics than with a modification of opioid therapy. Pain purely attributable to opioid side effects may simply require treatment of the adverse effects (see below). Opioid conversion for refractory pain or intolerable side effect burden is justified if the pain is opioid-responsive, the current analgesic has been titrated to maximal effect, and side effects are already optimally managed.

Little evidence supports a particular selection order of opioid analgesics. The choice of a new agent may be made on the basis of such factors as the patient's prior experience with opioids of a given class or receptor profile. Once the new agent has been selected, equianalgesic conversion tables should be consulted to arrive at a starting point for dosing [*see Tables 3 and 4*]. If the patient had been receiving multiple opioids, conversion should be based on the total dose of all prior agents, expressed as morphine equivalents. The calculated dose should then be individualized according to the nature and severity of the patient's pain. If opioid conversion was necessitated by intolerable side effects in the setting of adequate pain control, the calculated dose should be reduced by approximately 25% to 50%; this will allow for the lack of cross-tolerance among agents. Alternatively, if conversion was prompted by inadequate analgesia and significantly impaired quality of life, the new agent may be started at or near an equianalgesic dose. Additional short-acting opioids should be made available to the patient during titration of the new drug in order to achieve stable analgesia. Breakthrough medication is especially important during opioid conversion. Continuous reassessment of the patient's pain and total daily dosage (extended release plus immediate release) should occur for the first 2 weeks after opioid conversion, with titration of the extended-release and breakthrough doses as appropriate. Both inadequate pain control and excessive narcosis are threats in the immediate conversion period.

Patients whose pain cannot be controlled with opioids should be considered for invasive pain control modalities. In general, however, such modalities should not be explored until adequate trials of several opioids have been completed.

Opioid Side Effects

Sedation Most patients experience sedation with initiation of therapy or an increase in dosage, but this sedation commonly resolves within 3 to 7 days; chronic sedation occurs in a small minority of patients. Sedation is a special concern in the elderly and in patients taking other sedating medications. Sedation may also reflect the relief of pain itself, as patients recoup rest previously lost to discomfort. Nonessential medications with sedating effects should be eliminated in patients experiencing opioid-related sedation. Stimulants such as caffeine or methylphenidate should be considered for use in cancer patients with significant persistent sedation, although the use of psychoactive medication in the elderly should always be approached with caution.[53] Stimulants are not recommended for patients experiencing sedation caused by opioid management of chronic pain.

Nausea Opioids may cause nausea and vomiting by both central and peripheral mechanisms. Centrally, opioids directly stimulate the chemoreceptor trigger zone in the medulla. Peripherally, opioids slow gastric motility. Additionally, many patients receiving opioid therapy will also have medical comorbidities or will be receiving treatments (e.g., chemotherapy) that contribute to nausea and vomiting. Use of a variety of antiemetics during the first 1 or 2 days of opioid administration may successfully control nausea and vomiting. Ondansetron, prochlorperazine, or hydroxyzine may alleviate centrally-induced nausea, whereas metoclopramide may reduce nausea from slowed gastric motility. Scopolamine may alleviate motion-exacerbated nausea in ambulatory patients.[54] Anticholinergic side effects of common antiemetics may be clinically significant, particularly in the elderly. As is the case with sedation, nausea and vomiting frequently resolve shortly after onset of treatment.

Constipation Constipation is a common and clinically significant side effect of all opioids. It is caused by decreased peristalsis and intestinal secretions and increased electrolyte and water resorption in the large intestine. Additional risk factors for constipation include advanced age, impaired mobility, concurrent medications with constipating side effects, and gastrointestinal comorbidities. Unlike sedation and nausea, constipation does not improve with time. This side effect is underdiagnosed and may lead to anorexia, vomiting, abdominal pain, obstruction, impaction, and perforation.

Dietary changes to prevent constipation should be implemented with opioid administration. All patients on around-the-clock opioids should undergo regular assessment for constipation and be given a stool softener and a stimulant laxative. Additional agents may be used if constipation is severe or persists; prolonged absence of bowel movements should result in assessment for fecal impaction, with treatment if necessary. Peripheral opioid antagonists are currently being tested and may prove useful.

Respiratory depression Respiratory depression, caused by direct inhibition of brain stem respiratory centers when the dose is escalated too rapidly, is a rare side effect of opioid therapy. Respiratory depression is primarily of concern in opioid-naïve patients receiving large opioid doses; it also may be seen in the setting of head injury or concurrent pulmonary disease. Sedation level and respiratory status should be monitored regularly during the first 24 hours of therapy in opioid-naïve patients. If respiratory depression occurs, the opioid may be stopped until the depression resolves, after which therapy may be continued at 75% of the previous dose. Spirometry and supplemental oxygen may be useful in these patients. Severe respiratory depression may be treated with intravenous naloxone.[54] Fear of respiratory depression should never preclude the effective delivery of pain relief.

Confusion Opioid-induced neurotoxicity is a relatively recently identified syndrome that occurs primarily in patients receiving high-dose or prolonged opioid therapy and in those with decreased renal function.[55] Patients with previous cognitive impairment are at additional risk. Delirium, agitation, myoclonus, and hyperalgesia are features of this condition. Confusion is a side effect of particular concern in the elderly or in patients with concurrent CNS disease. Nonessential medications with CNS effects should not be prescribed for elderly patients requiring opioid therapy. Neuroleptics may be useful against confusion, mental clouding, or persistent delirium.

Other side effects Pruritus secondary to histamine release is an additional opioid side effect; it is generally managed with diphenhydramine or hydroxyzine. Myoclonus may be treated with clonazepam. Urinary retention, vertigo, sweating, and hypotension are less frequently reported side effects of opioid therapy.

Tolerance, Physical Dependence, and Psychological Dependence

Tolerance Tolerance occurs when exposure to a drug changes the dose-response relationship, such that a higher dose of agent is required to maintain a given effect. There is no clinical limit to tolerance, and wide ranges of opioid requirements have been reported. Patients in the last 4 to 6 weeks of life require an average of 400 to 600 mg of morphine equivalents per 24 hours, and up to 10% of patients require more than 5,000 mg.[56] As noted, opioids do not have a ceiling effect per se and may be titrated to very large doses as required for optimal pain relief. Progression of side effects with increasing dosage may be managed with opioid rotation, adjuvant analgesic drugs, and epidural local anesthetics. Tolerance rarely develops in patients with stable disease; increasing requirements in the setting of previously controlled chronic pain should prompt a comprehensive medical evaluation.

Physical dependence Physical dependence describes a state of adaptation, often including tolerance, in which a drug class–specific withdrawal syndrome could be produced by abrupt cessation of drug administration, rapid reduction in dose, decreasing blood level of drug, or administration of an antagonist or mixed agonist-antagonist. Physical dependence is virtually universal with prolonged opioid therapy; to avoid withdrawal syndrome, all patients receiving opioids for 1 week or longer should have the drug tapered off rather than abruptly discontinued.

Psychological dependence Psychological dependence, or addiction, is a primary, chronic, neurobiologic disease whose development and manifestations are influenced by genetic, psychosocial, and environmental factors. Addiction is characterized by impaired control over drug use, compulsive use, continued use despite harm, and craving. The psychologically dependent person has a consuming involvement with drug use, which typically results in a range of social, vocational, economic, and legal difficulties.

Fear of addiction on the part of both physicians and patients is a significant cause of underutilization of opioids in the treatment of pain, yet this fear is largely unfounded. Numerous studies have shown that the prevalence of psychological dependence in patients receiving opioids for the relief of pain is extremely low—0.03%, in one study.[47]

More common in this population is pseudoaddiction, a condition in which patients with poorly managed pain mimic many of the signs of psychological dependence. Pseudoaddiction is characterized by drug seeking, or an increased focus on obtaining medications, and possibly illicit drug use or deception. The defining distinction between addiction and pseudoaddiction is that pseudoaddiction behaviors resolve with effective pain management. As such, pseudoaddiction is best managed with effective pain relief and is likely to be exacerbated by the curtailing of opioid therapy.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND ACETAMINOPHEN

Indications

NSAIDs, acetaminophen, or both may be employed against a variety of types of acute and chronic pain. They are especially useful for certain types of somatic pain, including muscle and joint, bone, dental, postoperative, and inflammatory pain. These drugs may provide sufficient relief for mild or moderate pain. In the setting of severe pain, they may be added to an opioid regimen for their opioid-sparing effect. Combination opioid-nonopioid therapy may allow for enhanced pain relief with reduced side effect burden.

Mechanism

NSAIDs act primarily through inhibition of cyclooxygenase, thereby decreasing prostaglandin synthesis. Nonselective NSAIDs inhibit both COX-1 (a normal constituent of blood vessels, stomach, and kidney) and COX-2 (an enzyme induced in the setting of peripheral inflammation); COX-2 inhibitors selectively inhibit the COX-2 enzyme. All NSAIDs have analgesic, anti-inflammatory, and antipyretic effects. Acetaminophen works via a central mechanism; its actions are primarily analgesic and antipyretic.

Administration Route and Formulation

Most NSAIDs and acetaminophen are taken orally, although other routes of administration exist. Numerous formulations are available without prescription. In addition, combinations of NSAIDs or acetaminophen with opioids or members of other drug classes are commonly used.

Dosing

Dosing amount and frequency vary across preparations [*see Table 5*]. NSAIDs and acetaminophen exhibit a dosage ceiling, beyond which additional side effects accrue without additional therapeutic benefit.

Side Effects

Exact side effect profiles vary with individual drugs, but non-

Table 5 Nonopioid Analgesics Commonly Used for Mild to Moderate Pain

Drug Name	*Starting Oral Dose (mg)*	*Comments**
Aspirin	650	Often used in combination with opioid analgesics; reduces platelet function; avoid in pregnant patients and those with clotting disorders; avoid concomitant use with steroids
Choline magnesium trisalicylate	1,500	Does not affect platelet function
Acetaminophen	650	Does not affect inflammation or platelet function; use with caution in patients with hepatic dysfunction
Ibuprofen	200–400	Higher analgesic potential than aspirin
Diflunisal	500–1,000	Longer duration of action than ibuprofen
Naproxen	250–300	Longer duration of action than ibuprofen
Ketorolac tromethamine	10	Do not use for more than 5 days; I.M. formulation can be given in dose of 30 mg
Tramadol	50–200	Weak mu agonist and serotoninergic and catecholamine reuptake inhibitor
Celecoxib	100–200	Cyclooxygenase-2 inhibitor; contraindicated in sulfa-allergic patients

*Except for acetaminophen, tramadol, and celecoxib, all these drugs are nonselective nonsteroidal anti-inflammatory agents and share the side effects of this class of agents [*see text*].

selective NSAIDs as a class exhibit certain characteristic side effects, including gastrointestinal disturbances, bleeding, hypersensitivity, and CNS effects. In addition, nonselective NSAIDs have nephrotoxic potential, especially in patients with renal dysfunction who require prostaglandins for maintaining renal vasodilatation. NSAID side effects are often dose dependent; use of these drugs at low doses for short periods may minimize their impact. Additionally, preventive strategies may be employed, such as coadministration of gastrointestinal tract–protective drugs (e.g., lansoprazole, esomeprazole, or misoprostol). Although the reputation of selective COX-2 inhibitors was tarnished by the discovery of life-threatening side effects with rofecoxib and valdecoxib and the subsequent withdrawal of these agents from the market, celecoxib remains a very helpful agent for some patients, particularly those with low or no risk of coronary artery or cerebrovascular disease. Nonopioids have a ceiling effect for analgesia; increasing dosage above a certain level will increase side effect burden without yielding enhanced analgesia. Neither tolerance nor physical dependence is seen with NSAID use.

Acetaminophen provides pain relief comparable to most NSAIDs without the gastrointestinal disturbances and bleeding seen with NSAIDs. Acetaminophen must be used with caution, if at all, in patients with liver disease. In patients with normal livers, however, hepatic toxicity is rare with dosages beneath the ceiling of 3 to 4 g/day.

CORTICOSTEROIDS

Indications

Corticosteroids are the most widely used general adjuvant analgesics.[57] In the setting of cancer, they are especially useful for relief of acute pain associated with spinal cord compression, increased intracranial pressure, superior vena cava syndrome, metastatic bone pain, neuropathic pain secondary to infiltration or compression by tumor, and hepatic capsule distension. High-dose corticosteroids are often used for inpatients with advanced disease who are in acute pain crisis.[58] Corticosteroids are commonly used for pain related to musculoskeletal conditions.

Mechanism

Steroids act through an anti-inflammatory mechanism. They also produce glucocorticoid and mineralocorticoid effects.

Administration Route and Dosing

Corticosteroids are commonly given in oral or injectable form. Dosing varies with agent and indication.

Side Effects

Steroids are generally well tolerated for short-term treatment; however, toxicities often arise with prolonged high-dose therapy. Common toxicities include adrenocortical insufficiency, hypertension, immune suppression, the masking of signs of infection, glaucoma, electrolyte imbalances, gastrointestinal ulceration and bleeding, osteoporosis and pathologic fracture, and psychiatric disturbance or psychosis. Care must also be taken to prevent withdrawal syndrome upon discontinuance.

ANTIEPILEPTIC DRUGS

Indications

Antiepileptic drugs (AEDs) such as gabapentin, carbamazepine, and topiramate may be useful as adjuvant drugs in the treatment of a variety of forms of neuropathic pain, including peripheral diabetic neuropathy, postherpetic neuralgia, reflex sympathetic dystrophy, trigeminal and glossopharyngeal neuralgia, HIV neuropathy, and spinal cord injury–related dysesthesias. These agents are also useful for postlaminectomy, phantom limb, and cancer pain.

Considerable clinical data suggest that gabapentin should be a first-line treatment for neuropathic pain, because of its greater clinical efficacy and a more favorable side effect profile than seen with older AEDs and other agents such as tricyclic antidepressants (TCAs).[59,60] Gabapentin does not interact with other drugs. Carbamazepine should be considered as only a second- or third-line agent for most neuropathic pain conditions. However, carbamazepine remains the first-line treatment for trigeminal neuralgia [*see 11:II Diseases of the Peripheral Nervous System*]. Topira-

mate is increasingly used off-label as an adjuvant analgesic agent for neuropathic pain.

Mechanism

The exact mechanism of the analgesic effect of AEDs is unknown. These agents reduce membrane excitability, thereby possibly suppressing discharges from pathologically altered neurons, likely primarily by the inhibition of sodium channel transmission.

Administration Route and Dosing

AEDs are administered orally. Current guidelines recommend starting gabapentin at a dosage of 100 mg every 8 hours; however, optimal control of neuropathic pain often requires titration to 3,600 mg a day in divided doses. Topiramate must be titrated slowly (i.e., no faster than 25 mg a week) to decrease the incidence of side effects. Although daily doses of up to 400 mg are used for epilepsy, 100 to 200 mg is a more typical dose for pain. Dosing of other AEDs varies with agent and indication.

Side Effects

Gabapentin is generally well tolerated; some patients experience mild sedation and gastrointestinal effects. However, elderly patients often have poor tolerance of gabapentin because of cognitive effects, particularly at higher dose levels. Topiramate can cause cognitive slowing and paresthesias, especially with overly rapid titration.

The most common side effects seen with other AEDs include sedation, nausea and vomiting, and dizziness. Carbamazepine may cause thrombocytopenia or liver damage. Phenytoin may induce dose-related CNS effects, as well as hepatotoxicity, hypersensitivity reactions, and lymphadenopathy at high serum concentrations.

ANTIDEPRESSANTS

Tricyclic Antidepressants

Indications Amitriptyline, nortriptyline, imipramine, and other TCAs are frequently used as adjuvant analgesics in the treatment of a variety of types of neuropathic pain (e.g., painful diabetic neuropathy, postherpetic neuralgia, chronic facial pain, central pain) and chronic pain (e.g., cancer pain, chronic low back pain, osteoarthritis). TCAs have efficacy equivalent to AEDs in the treatment of certain types of neuropathic pain.[61] Efficacy is comparable among most TCAs.

Mechanism The analgesic effect of antidepressants may derive from the inhibition of norepinephrine and serotonin reuptake in the CNS, thereby increasing the activity of endogenous pain suppression pathways.

Administration route and dosing TCAs are taken in oral form. Although the effect of these agents may be seen at low doses, achieving optimum analgesic efficacy may require higher dose titration. Amitriptyline, desipramine, doxepin, and nortriptyline are typically started at a dose of 10 to 25 mg and may be titrated to a maximum daily dose of 150 mg, if tolerated.

Side effects Common side effects of TCAs as a class include anticholinergic effects such as sedation, hypotension, constipation, and urinary retention; the elderly are most susceptible to these effects. Amitriptyline has the strongest anticholinergic profile and for that reason is given at bedtime; nortriptyline, which has a less prominent anticholinergic profile, is generally a better choice for older patients. At doses above those typically prescribed for pain, lethal cardiac arrhythmias may occur; thus, these medications are contraindicated in patients with conduction abnormalities.

Selective Serotonin Reuptake Inhibitors

Overall, selective serotonin reuptake inhibitors (SSRIs) have been disappointing as primary analgesic agents compared with TCAs and AEDs, despite their favorable side effect profiles. Both paroxetine and venlafaxine (which blocks reuptake of norepinephrine as well as serotonin) have been shown in randomized controlled trials to be useful in managing neuropathic pain, but both agents are generally considered to be second-line choices; they are used when refractoriness or poor tolerability has been demonstrated with other agents such as TCAs, AEDs, and opioids.

TOPICAL ANALGESIC AGENTS

There has been a growing interest in the role of topical therapy in the management of neuropathic pain. The enthusiasm has been partly driven by the discovery of the role of peripheral nociceptor modulation in dampening pain transmission and partly by the perpetual difficulty in certain populations with tolerability of systemic medications.

Transdermal Lidocaine

Approved by the Food and Drug Administration for the treatment of postherpetic neuralgia in 1999, the 5% lidocaine patch is now a first-line agent in managing postherpetic neuralgia. Patients are instructed to wear the patch for 12 consecutive hours over the area of pain and to then discard it; they are further instructed to wait to apply a new patch until another 12 hours have passed. One to three patches can be used at any one time, depending on the surface area of the pain site. There have been reports that transdermal lidocaine is effective in other painful conditions, such as low back pain, but few published data support the use of this patch in conditions other than postherpetic neuralgia.

EMLA

EMLA cream (lidocaine 2.5% and prilocaine 2.5%) has been shown to be very effective in children undergoing painful procedures, such as needle insertions and blood draws. Its role in managing neuropathic pain has yet to be demonstrated.

NEW APPROACHES

Patients with pain have benefited enormously in the past 10 to 15 years from the attention paid to the mechanism of pain, which has moved the field of pain research from empiricism to scientific validity. Several drugs have sprung from such scientific discoveries; some are now in development and some have been approved for use.

Ziconotide

Approved by the FDA in 2004, ziconotide is a synthetic version of a South Pacific marine snail toxin that blocks calcium transmission. It is 1,000 times more potent than morphine and thus may only be delivered intrathecally by an implantable pump.

Duloxetine

Duloxetine, a norepinephrine and serotonin reuptake inhibitor, was approved by the FDA in 2004. Its main indication is for burning peripheral neuropathy, although there is hope that it may be helpful as an antidepressant as well, in view of its mechanism of action.

Capsaicin

Capsaicin contains the ingredient in chili peppers that causes a burning sensation. Although a weak formulation of capsaicin has been available over the counter for many years, trials are now under way of a far more potent version, which may decrease pain more successfully by dampening pain transmission at the skin receptor level.

Pregabalin

The success of gabapentin as a first-line agent for neuropathic pain has resulted in the development of the related compound pregabalin, which is expected to be introduced in the United States in the second half of 2005. Although the mechanism of action of pregabalin is similar to that of gabapentin, there is hope that this newer agent may be useful as an alternative when patients do not respond adequately to other agents.

XV PARKINSON DISEASE AND OTHER MOVEMENT DISORDERS

Jorge L. Juncos, m.d.
Mahlon R. DeLong, m.d.

Most movement disorders result from diseases that affect the basal ganglia. Clinically, movement disorders can be divided into hypokinetic and hyperkinetic disorders: hypokinetic disorders are characterized by slow, impaired voluntary movements typified by parkinsonism; hyperkinetic disorders are characterized by involuntary movements, including chorea, ballismus, dystonia, tremor, tic, and myoclonus. Because of shared neural mechanisms, movement disorders with different etiologies may have similar motor manifestations. This clinical overlap, together with the lack of biologic markers for many of these disorders, can make etiologic diagnosis a challenging exercise. Nevertheless, major advances in the understanding of the genetics, molecular biology, and pathophysiology of these disorders have led to the availability of genetic testing for a selected few and to the development of effective pharmacologic and surgical treatments for others. Furthermore, the symptomatic therapies used today are often effective irrespective of etiology.

Movement disorders usually coexist with psychiatric, cognitive, and sleep disturbances that can contribute significantly to disability and that may even dominate the clinical picture. For example, depression can impair the response to otherwise adequate treatment of motor symptoms. In many instances, treatment of these comorbid conditions is an important aspect of management.

Pathophysiology

Movement disorders may arise from dysfunction in the basal ganglia, the thalamocortical motor circuits, or brain stem connections [*see Figure 1*].[1] Alterations of basal ganglia output at the level of the internal segment of the globus pallidus (GPi) and the subthalamic nucleus (STN) can lead both to impairment of voluntary movements and to involuntary movements.[2]

A pathophysiologic model of parkinsonism has been developed on the basis of animal studies [*see Figure 2*]. The biochemical hallmark of this syndrome is dopamine deficiency in the putamen and the caudate nucleus, which promotes excessive excitatory drive from the STN to the GPi and, in turn, abnormal output from the GPi.[2] Although initially, attention was focused on the increased inhibitory output from the GPi, it now appears that changes in the pattern of GPi output play a major role as well. That impairment of movement results from the excessive and abnormal GPi output is supported by studies demonstrating that treatment directed toward the GPi or STN (either surgery or deep brain stimulation) greatly improves the motor signs of Parkinson disease (PD).[3] Moreover, in patients with PD, the restoration of cortical activation during a movement task has been demonstrated by comparing positron emission tomography (PET) scans taken before and after treatment with pallidotomy (a procedure that surgically destroys the motor segment of the GPi) or with electrical stimulation of the STN.[4]

In contrast to hypokinetic disorders, hyperkinetic disorders appear to result from abnormally low and altered GPi output [*see Figure 2*].[5,6] Reduced STN output leads to a reduction in the thalamic inhibition by GPi. In hemiballismus, this stems from damage to the STN or its connections. In Huntington disease, it is the result of selective loss of striatal neurons that project to the external portion of the GPi or the substantia nigra.[7] Just as the same pathophysiologic changes in GPi and STN output are responsible for the disturbances of eye movements that occur in PD and Huntington disease, it is tempting to speculate that changes in the other basal ganglia–thalamocortical circuits contribute to behavioral, cognitive, and limbic signs and symptoms that parallel many of the motor symptoms and signs of these disorders.[8]

Hypokinetic Disorders

Parkinsonism is a clinical syndrome with multiple etiologies that is characterized by varying degrees of bradykinesia, tremor, rigidity, and postural instability.[9] The common denominator of all forms of parkinsonism is the reduction of striatal dopaminergic transmission in the nigrostriatal pathways. Parkinsonism may be subdivided into PD, which accounts for approximately 75% of cases, and atypical forms of parkinsonism, which account for the rest [*see Table 1*]. It is important to distinguish PD from these other forms of parkinsonism because prognosis and treatment differ significantly in each. Early etiologic diagnosis will become increasingly important in the coming years, with the emergence of therapies that may be specific to subtypes of PD.

PARKINSON DISEASE

Epidemiology, Etiology, and Genetics

PD is a progressive neurodegenerative disorder that afflicts more than one million persons in the United States, including 1% of the population older than 55 years.[10] A genetic contribution to familial forms of PD has now been firmly established; thus, these forms should be considered primary rather than idiopathic PD. Accordingly, PD is now considered a syndrome with many genetic and nongenetic causes. Genetic forms are associated with at least eight identified autosomal dominant and autosomal recessive mutations.[11] PD resulting from these mutations often has an earlier onset (occurring in patients younger than 50 years) and a severely progressive course compared with the typical sporadic form of PD, which has a mean age of onset of 60 years. In some of these disorders, signs of parkinsonism develop before age 20; these are termed juvenile parkinsonism. The genetic basis of most cases of early-onset disease is further supported by epidemiologic studies in monozygotic and dizygotic twins.[12]

One line of PD research has addressed the possible causative role of environmental factors (e.g., head injury, rural living, exposure to pesticides). Current thinking, which is influenced by evidence from animal models of PD, is that any role of environmental factors is almost exclusively limited to persons with a genetic predisposition.[13,14]

Autosomal dominant cases of PD are linked to two independent mutations in the α-synuclein gene.[11,15] The first α-synuclein mutation, *PARK1,* was found in a large Italian kindred and in three unrelated families of Greek origin.[15] This gene is located on chromosome 4q21 and codes for α-synuclein, the precursor protein of the non–β-amyloid component of Alzheimer disease found

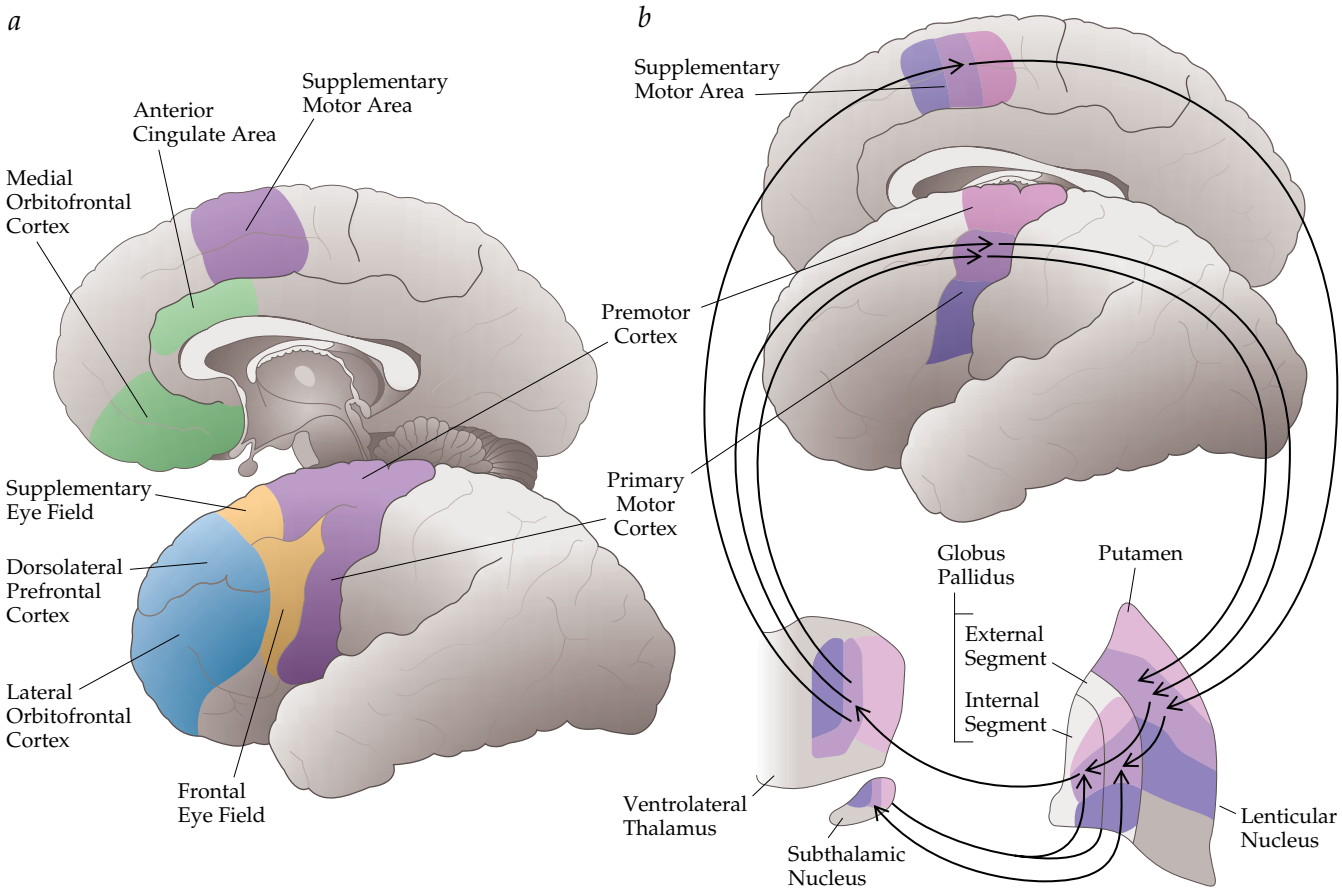

Figure 1 **Functional anatomy of the basal ganglia. (*a*) The basal ganglia are appropriately viewed as components of larger cortical-subcortical reentrant pathways that also include portions of the thalamus. These form a family of functionally segregated circuits that subserve and ultimately target the skeletomotor, oculomotor, associative (cognitive), and limbic cortices of the frontal lobes. (*b*) The basal ganglia comprise the corpus striatum (caudate nucleus and putamen), the globus pallidus, the subthalamic nucleus, and the two parts (pars compacta and pars reticularis) of the substantia nigra. These components are found deep in the cerebral hemispheres and nearby parts of the diencephalon and midbrain. The figure illustrates a simplified schema of the motor circuit. The segregated organization of the cortical-subcortical circuits permits simultaneous and independent parallel processing of diverse motor and nonmotor inputs (e.g., representation of face, arm, and leg). For each circuit, output (i.e., cortical impulses) from a specific cortical area passes through a unique portion of the striatum (e.g., putamen), the external and internal segments of the globus pallidus, the substantia nigra pars reticularis (not shown in this figure), the subthalamic nucleus, and the ventrolateral thalamus and returns to the specific frontal cortical area—in this case, the area related to motor function (i.e., premotor cortex, primary motor cortex, and supplementary motor cortex). The motor circuit originates from the precentral and postcentral sensorimotor fields, engages specific portions of the basal ganglia and motor thalamus, and ends back in the precentral motor fields of the frontal lobe. For example, voluntary movements are normally initiated in cortical areas that provide input to the basal ganglia and thalamus, which in turn modify these same cortical areas via the return projection through the motor circuit.**

in neuritic plaques. The protein is found in presynaptic terminals, and its distribution in the brain is identical to that of Lewy bodies. Its normal function is still unclear. For PD from the *PARK1* mutation, disease onset occurs before age 50; the disease generally has a rapid course and is often accompanied by dementia.

A second form of autosomal dominant, Lewy body–positive PD has been linked to the *PARK3* mutation on chromosome 2p13. *PARK3* may also play a role in sporadic PD, given that PD develops in only 40% of persons with this mutation and that the age of onset and response to levodopa therapy in these cases are indistinguishable from those in sporadic cases.[16]

There are at least six other rare autosomal dominant mutations that can cause parkinsonian syndromes similar to idiopathic PD. Clinically, these conditions resemble autosomal recessive juvenile parkinsonism (AR-JP), but they are often also associated with ataxia and amyotrophy.[16,17]

One form of AR-JP is linked to the *parkin* gene, which has been mapped to a large region of chromosome 6 (*PARK2*) and is found in Japanese and some European families.[18-20] In these patients, an initially robust response to levodopa is soon complicated by severe motor fluctuations. Pathologically, these patients do not have Lewy bodies but instead express Lewy fibrils and neurites that are immunohistochemically positive for α-synuclein. Two autosomal recessive forms, involving the *PARK2* and *PARK7* mutations, have atypical features and very early (juvenile) onset.

In the vast majority of patients with sporadic PD, no strong genetic determinant appears to play a role. It is believed, however, that these patients may share an as yet undefined genetic vulnerability that results in clinical illness only when the individual is exposed to as yet uncertain internal or external environmental factors.[12] Genetic vulnerability may be attributed to deficits in

mitochondrial oxidative phosphorylation genes (*OXPHOS* complex I), cytochrome P-450, and other polymorphisms, as well as to deficits in oxidative radical scavenging enzyme activity (e.g., glutathione transferases).

Certain epidemiologic factors have been linked to a reduced incidence of PD. These include coffee drinking, cigarette smoking, use of nonsteroidal anti-inflammatory drugs (NSAIDs), and estrogen replacement in postmenopausal women.[21-23]

Pathophysiology and Pathogenesis

The classic pathologic hallmarks of PD are degeneration of the dopaminergic cells of the substantia nigra pars compacta (SNc) and the presence of Lewy bodies in pigmented brain stem neurons, including the locus coeruleus, the pontine raphe nuclei, and the dorsal motor nucleus of the vagus nerve. The earliest pathologic changes may occur in the mesenteric plexus of the intestine and in the anterior olfactory nuclei.[24] The process spreads rostrally to the dorsal motor nucleus of the vagus and glossopharyngeal

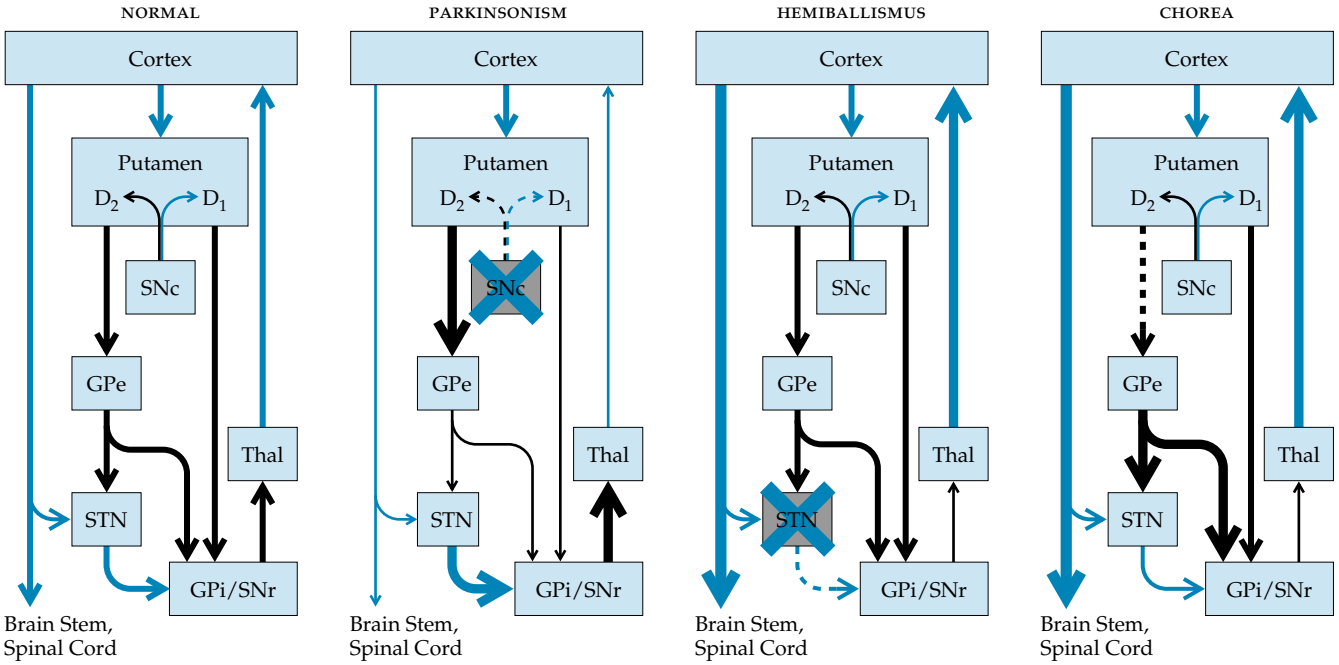

Figure 2 **This figure gives a more detailed illustration of striatal outflow and its functional significance in movement disorders. The corpus striatum serves as the input or receptive stage of the basal ganglia portion of the circuit, whereas the internal segment of the globus pallidus (GPi) and the substantia nigra reticularis (SNr) serve as output stages. The output nuclei of the basal ganglia are linked to the corpus striatum by a direct pathway between the corpus striatum and the GPi and the SNr and an indirect projection to the GPi via the external segment of the globus pallidus (GPe) and the subthalamic nucleus (STN). Other than the excitatory (glutamatergic) STN-GPi pathway (blue arrows), all projections of the direct and indirect pathways are inhibitory, or GABAergic (black arrows). (Note that the pathways from the cortex to the putamen, from the thalamus to the cortex, and from the cortex to the brain stem are also excitatory.) Considering the polarity of these connections and the fact that GPi/SNr output is tonic and inhibitory on thalamic neurons, it follows that activation of the direct pathway by cortical input (or dopamine stimulation) will reduce the activity of the output nuclei GPi and SNr and, thereby, disinhibit (by removal of inhibitory input) thalamocortical projection neurons, which will in turn facilitate movement. In contrast, activation of the indirect pathway, which has a net excitatory effect on GPi/SNr activity, will act to inhibit thalamocortical neurons or inhibit movements that may conflict with the intended movement. Too much activity of this pathway leads to movement inhibition in general and thus to parkinsonism. Dopamine is released by the terminals of the substantia nigra pars compacta (SNc) projections to the corpus striatum (putamen) and acts to modulate the activity in these circuits. Dopamine differentially influences the balance between the two pathways by inhibiting transmission in the indirect pathway via D_2 dopamine receptors on striatal neurons projecting to GPe and by facilitating transmission in the direct pathway via D_1 dopamine receptors on striatal neurons projecting to GPi. Thus, release of dopamine in the corpus striatum reduces basal ganglia output to the thalamus (Thal), whereas loss of dopamine increases output.**

Disturbances of the proper balance between the two circuits result in a variety of clinical syndromes. For example, in Parkinson disease, which is a hypokinetic disorder, dopamine deficiency increases the activity of the indirect pathway and thus the excitatory drive from STN to GPi/SNr. This condition stimulates inhibitory output from GPi and results in the increased inhibition of thalamocortical neurons, which renders cortical projection areas less responsive to inputs normally involved in the initiation and execution of movement. This process is illustrated by the reduced thickness of the excitatory arrows from the thalamus to the cortex and from the cortex to the brain stem and spinal cord. Changes in the pattern of GPi discharge are also a major factor in Parkinson disease.

In the hyperkinetic disorder hemiballismus, a lesion in the STN knocks out the excitatory drive from the STN to the GPi, which leads to loss of inhibition, or stimulation of the thalamocortical neurons, rendering cortical projection areas highly responsive to inputs involved in the initiation and execution of movement (illustrated by the thick excitatory arrows from the thalamus to the cortex and from the cortex to the brain stem and spinal cord). In the case of chorea, early selective loss of striatal neurons projecting to GPe via the indirect pathway (e.g., Huntington disease or proposed neuroleptic-induced toxicity in tardive dyskinesia) leads to the disinhibition of the GPe and thus excessive inhibition of striatal outflow (GPi/SNr). The result is a loss of inhibition of the excitatory thalamocortical pathway that consequently leads to the multiple, poorly synchronized movements of chorea.

Table 1 Differential Diagnosis of Parkinsonism

Primary	Idiopathic (sporadic) Parkinson disease Most common form; clinical expression may be influenced by so-called vulnerability genes Genetically mediated (primary) Parkinson disease Identified mutations (rare) PARK1 (α-synuclein; two mutations) PARK2 (*Parkin* gene mutation) with multiple polymorphisms PARK3
	Other neurodegenerative disorders α-Synuclein disorders Multiple-system atrophies (glial and neuronal inclusions) Striatonigral degeneration Olivopontocerebellar atrophy Shy-Drager syndrome Motor neuron disease with parkinsonian features Lewy body dementia (cortical and brain stem neuronal inclusions) Tauopathies (disorders with primary tau pathology) Progressive supranuclear palsy Corticobasal degeneration Frontotemporal dementia Amyloidopathies (disorders with primary amyloid pathology and secondary tau pathology and dementia) Alzheimer disease with parkinsonism (sporadic, amyloid precursor protein–related, presenilin 1– and presenilin 2– related)
	Genetically mediated disorders with occasional parkinsonian features Wilson disease Hallervorden-Spatz disease Chédiack-Higashi syndrome Spinocerebellar ataxia type 3 X-linked dystonia parkinsonism (DYT3) Huntington disease (Westphal variant) Prion disease
Secondary	Miscellaneous acquired conditions Vascular parkinsonism Normal-pressure hydrocephalus Catatonia Cerebral palsy Repeated head trauma (dementia pugilistica) Infectious and postinfectious diseases Postencephalitic Parkinson disease Neurosyphilis
	Toxins Carbon disulfide Carbon monoxide Cyanide Manganese Methanol MPTP (1-methyl-4-phenyl-1,2,4,6-tetrahydropyridine) *n*-Hexane?
	Drugs Neuroleptics (typical antipsychotics) Selected atypical antipsychotics [*see text*] Antiemetics (e.g., prochlorperazine, metoclopramide) Dopamine-depleting agents (e.g., reserpine, tetrabenazine) α-Methyldopa Lithium carbonate Valproic acid Fluoxetine
	Metabolic Conditions Hypoparathyroidism or pseudohypoparathyroidism with basal ganglia calcifications

nerves, with progressive ascending involvement of anatomically connected brain stem nuclei, the basal forebrain nuclei, and the SNc. Adding to the appeal of this hypothesis is the concept that the intestine and its plexus may serve as the portal of entry for environmental factors that may influence the expression of PD.

Ultimately, cell depletion occurs gradually in the SNc and other areas; parkinsonian signs begin to develop after 50% to 80% of midbrain dopamine neurons are lost and compensatory mechanisms fail [*see Figure 3*]. Involvement of the other pathologically involved nuclei may play a major role in the development of associated nonmotor aspects of PD (e.g., autonomic dysfunction, sleep disorders, depression).

Considerable attention has focused on the role of oxidative stress in PD and the damage that may be caused by free radicals produced by the metabolism of dopamine.[25,26] Mitochondrial dysfunction is another possible factor that may contribute to vulnerability to oxidative stresses. There is now solid evidence of mitochondrial dysfunction in the brain and platelets of patients with PD.[27,28] Defects in energy metabolism may interact with the protein products of mutations, leading to protein aggregation, low-grade inflammation, microglial activation, and further escalation of oxidative stress.[29] Other factors, such as accumulation of protein aggregates as a result of proteosomal dysfunction, may play a role as well in some cases of PD.[30,31]

For example, it has been postulated that the mutated α-synuclein protein of *PARK1* has an abnormal tertiary structure that makes it prone to self-aggregation and thus formation of the amyloidlike cores of Lewy bodies.[15] Mice that hyperexpress this gene develop granular intracytoplasmic inclusions similar to Lewy bodies.[15] In vitro, low concentrations of aggregated fibrillogenic fragments of α-synuclein are toxic to dopamine neurons,[32] and mutations that alter the expression of the α-synuclein protein make dopamine neurons highly vulnerable to oxidative stress.[33,34]

Clinical Features

The cardinal clinical features of PD are bradykinesia, muscular rigidity, and a rest tremor of 4 to 6 cycles per second (hertz [Hz]). The presence of two of the three cardinal signs and a robust clinical response to levodopa, the amino acid precursor of dopamine, are sufficient to make a probable diagnosis of PD.[9] Onset of symptoms on one side of the body and the presence of rest tremor further support a diagnosis of PD. Masklike facies [*see Figure 4*], decreased blinking, stooped posture, decreased arm swing when walking, and micrographia are often present early in the disease.

Diagnosis of PD in its early stages may be difficult unless the characteristic rest tremor is present. In the absence of tremor, the most common complaints are nonspecific; patients note weakness, fatigue, and muscle aches.

Parkinsonian tremor typically begins as a so-called pill-rolling motion of the fingers of one hand. The tremor usually spreads proximally in the arm and sometimes to the leg before crossing to the other side of the body over the next 1 to 2 years. The face, tongue, and jaw may be involved, but typically, the patient does not have voice tremor (lingual titubation). In contrast to essential and cerebellar tremors, parkinsonian tremor is usually present at rest and attenuates or disappears during movement. It may reappear after the movement is completed, even when a posture is sustained. However, postural or essential tremor may sometimes precede and coexist with parkinsonian rest tremor.

Bradykinesia (slowness of movement) and akinesia (paucity of movement) are among the most disabling features of PD be-

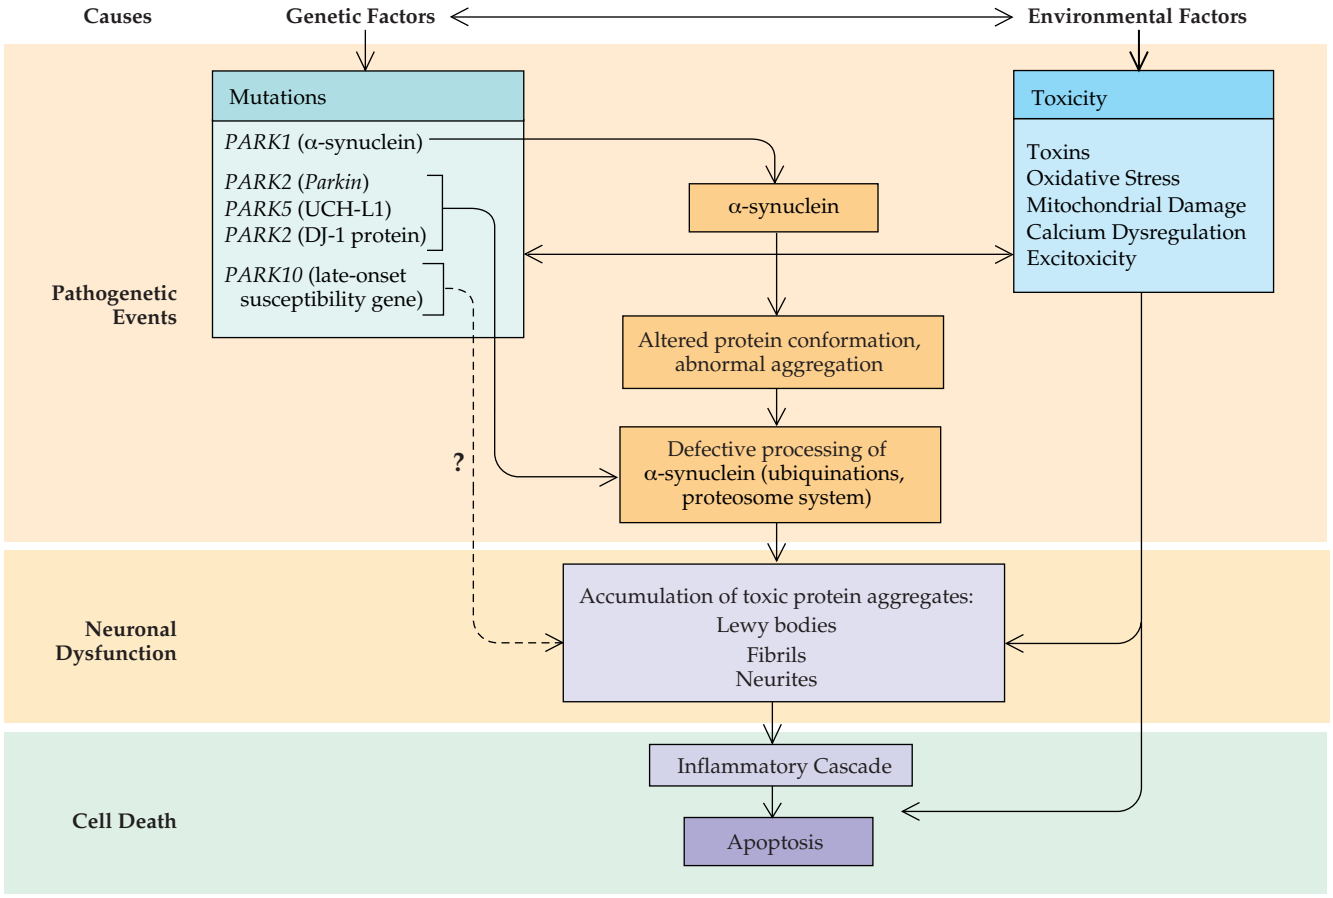

Figure 3 **Proposed cascade of pathogenic events leading to the death of neurons in Parkinson disease. Note the possible interaction between genetic and environmental factors.**

cause they interfere with all aspects of daily living, especially ambulation. Fine motor control is also affected, as manifested by impaired finger dexterity and micrographia. Hypophonia and monotonic speech are manifestations of bradykinesia affecting the cranial musculature.

Rigidity in PD represents a uniform increase in resistance to passive movement throughout the full range of motion of all muscle groups acting around a joint. Brief, regular interruptions of resistance during passive movement, corresponding to subclinical tremor, may give rise to a cogwheeling sensation. Combinations of rigidity and dystonia typically result in neck flexion, stooping, and a tendency to hold the arms in a flexed, adducted position.

Parkinsonian gait is usually associated with shuffling, short steps and a tendency to turn en bloc. In advanced stages of disease, gait initiation and turning become increasingly difficult. Advanced PD may be marked by festinating gait, which is characterized by stiff flexion at the knees and hips, an absence of arm swinging, and short steps (often on tiptoe) that accelerate in an apparent effort to catch up with the body's center of gravity. Postural instability is one of the most disabling and refractory features of parkinsonism and a major contributor to falls. Although decreased postural reflexes may be noted early in PD, significant postural instability is rarely a problem until the disease progresses to more advanced stages. Indeed, significant postural instability early in the course of the illness suggests a diagnosis other than PD.

Freezing, a feature of more advanced PD, occurs most commonly at the initiation of locomotion (start hesitation), when attempting to change direction, or upon entering a crowded or

Figure 4 **Face of a patient with Parkinson disease. Note the lack of expressivity and poor definition of the nasolabial fold. Scaling seborrhea is also common.**

narrow space (e.g., a doorway). Freezing is most commonly a manifestation of inadequate dosing or wearing off of medication but may occasionally occur in well-medicated patients (so-called on freezing). The presence of an ataxic or otherwise atypical gait, however, suggests an alternative diagnosis, such as normal-pressure hydrocephalus, multiple system atrophy with cerebellar involvement, or spinal stenosis.

Nonmotor disturbances In addition to motor symptoms, many patients with PD experience disturbances of cognition, mood, sensation, sleep, and autonomic function. Changes in cognition, behavior, and mood may result in part from involvement of nuclei in the brain stem and elsewhere, as well as disruption of the nonmotor circuits of the basal ganglia [*see Figure 1*].

Dementia is not a presenting or early feature of idiopathic PD, but dementia occurs in up to 30% of patients in advanced stages of disease.[35,36] It is more common in patients with the akinetic-rigid subtype of parkinsonism. Dementia is frequently preceded by depression or drug-induced hallucinations. Patients with parkinsonism and dementia typically have mixed pathologies, including senile dementia of the Alzheimer type and diffuse cortical Lewy bodies (i.e., Lewy body dementia).[36]

Depression affects as many as 50% of patients with PD and may develop at any stage of the illness, irrespective of disease severity.[37] Depression may be difficult to recognize because overt emotionality may be lacking and the psychomotor retardation of depression may closely resemble the hypokinetic aspects of parkinsonism. Anxiety often accompanies depression. Anxiety and dysphoria can occur episodically in relation to the wearing off of levodopa. Depression can be induced or aggravated iatrogenically by polypharmacy and poorly managed motor symptoms. Conversely, emerging depression may adversely affect motor symptoms. Personality changes in the form of apathy, lack of assertiveness, and indecisiveness are also common. It is important to rule out hypothyroidism and hypogonadism with low testosterone levels in men, which may not only contribute to the negative symptoms of PD but may make depression resistant to treatment.

Sleep disorders are common in PD.[38] A variety of problems, including insomnia and sleep fragmentation, can interfere with both the duration and quality of sleep. In addition, rapid eye movement sleep–related behavioral disorders (e.g., nocturnal vocalizations and bursts of motor activity) and restless legs syndrome contribute to sleep disruption. Nighttime reemergence of parkinsonian motor signs and involuntary movements (e.g., myoclonic jerks and periodic leg movements) may also disrupt sleep.[38] Vivid dreams and hallucinations, which may be side effects of antiparkinsonian therapy, may also contribute to sleep disruption.[39] In addition, sleep apnea and other sleep disturbances often occur in older PD patients. Daytime drowsiness and frequent napping may be typical signs of sleep disruption or an adverse effect of dopaminomimetic therapy, particularly dopamine agonists.

Other nonmotor disturbances in PD include orthostatic hypotension, constipation, sexual and urinary dysfunction, and seborrhea. All of these result from autonomic dysfunction.

Treatment

The goals of treatment in PD are to maintain function by controlling primary disability with symptomatic therapy and to minimize secondary disability (e.g., deconditioning, contractures, accelerated arthritis) with a consistent program of physical exercise.[40] Other goals include maintaining drug efficacy, avoiding drug-induced dyskinesias, preventing psychiatric complications, and slowing the progression of the disease. Goals still on the horizon include addressing currently unresponsive symptoms such as speech, balance disturbances, and autonomic dysfunction and eliminating common side effects such as nausea, orthostatic hypotension, and daytime sedation.

Levodopa Since 1969, when Cotzias demonstrated that oral administration of the dopamine precursor levodopa could alleviate parkinsonism,[41] levodopa therapy has been the mainstay of treatment. It greatly improves the quality of life and the lifespan of patients with PD. Although levodopa is toxic to dopamine neurons in vitro, it has not been shown to be toxic in vivo.[42] In a randomized, double-blind, placebo-controlled study of carbidopa-levodopa in early PD, clinical data suggested that treatment with levodopa for 40 weeks either slows the progression of PD or at least has a prolonged effect on disease symptoms; whereas neuroimaging studies suggested that either levodopa accelerates the loss of nigrostriatal dopamine nerve terminals or its pharmacologic effects modify the dopamine transporter.[43] Long-term levodopa administration clearly can kindle motor fluctuations and dyskinesias in PD.[44,45]

Dopamine agonists Concerns about side effects with long-term levodopa use have spurred interest in treating PD with dopamine agonists (see below). Several double-blind placebo-controlled studies have now established that compared with carbidopa-levodopa treatment, starting PD treatment with

Table 2 Carbidopa-Levodopa Preparations

Preparation	*Levodopa Dose Equivalency*	*Available Strengths (mg)*	*Initial Dosage*	*Comments*
Carbidopa-levodopa IR	100 mg (anchor dose)	10/100 25/100 25/250	25/100; 0.5–1 tablet t.i.d.	—
Carbidopa-levodopa CR	150 mg	25/100 50/200	50/200; one tablet b.i.d or t.i.d	Increased bioavailability with food; splitting the tablet negates the CR properties
Carbidopa-levodopa-entacapone	120 mg	12.5/50/200 25/100/200 37.5/150/200	25/100/200; one tablet b.i.d or t.i.d.	Do not split tablets

CR—controlled release IR—immediate release

dopamine-agonist monotherapy will delay the onset and reduce the severity of motor fluctuations.[46-48] A randomized, controlled comparison of initial PD treatment with pramipexole or levodopa found that initial treatment with pramipexole resulted in lower incidences of dyskinesias and wearing-off (i.e., shortened duration of therapeutic effect of individual drug doses), whereas initial treatment with levodopa resulted in lower incidences of freezing, somnolence, and edema and provided for better symptomatic control.[49] Of interest, a comparison of controlled-release carbidopa-levodopa (e.g., Sinemet CR) with regular (immediate-release) carbidopa-levodopa found that the incidence of dyskinesia was not significantly lower with the controlled-release formulation, which suggests that there are fundamental differences in the long-term consequences of dopamine receptor stimulation between levodopa and dopamine agonists.[50]

Initiating treatment The major determinants in the choice of initial therapy in PD are age of onset, the presence of dementia, the level of existing polypharmacy, and cost.[45,51] In cognitively intact patients with no significant medical problems, we favor initiation of dopamine-agonist monotherapy in sufficient doses to adequately control motor symptoms. This typically means giving higher doses than when dopamine agonists are used in combination with levodopa. Although symptoms such as orthostasis, dizziness, and nausea are more common with dopamine agonists than with levodopa, these can be avoided in most cases by slow titration. A common mistake with dopamine-agonist monotherapy is the failure to push the dose high enough to maintain adequate symptom control, leading to the premature addition of levodopa.

Most, if not all, patients with PD will need levodopa therapy at some point. When to introduce levodopa depends on the patient's ability to maintain function on dopamine-agonist monotherapy. Some patients resist starting levodopa for fear of its side effects. These patients should be advised against compromising their quality of life for the sake of avoiding levodopa therapy. In addition, they should be reassured that when levodopa is added, its dose is limited to that necessary to complement the effect of the dopamine-agonist, which remains the dominant component of therapy.

Still controversial is whether dopamine agonists provide a neuroprotective effect.[45] This hypothesis is currently being tested in a number of clinical trials in Europe and the United States.

Demented patients and those on multiple other medications are particularly prone to developing sedation, orthostasis, and drug-induced psychiatric symptoms. Initiation of therapy in this setting is aimed at reducing the incidence of central nervous system symptoms. To this end, in these patients we favor starting treatment with levodopa, with or without levodopa augmentation strategies (see below). Dopamine-agonist augmentation is introduced later as needed. In demented patients, anticholinergics and amantadine are to be avoided as much as possible to minimize CNS side effects. In cognitively intact patients, these agents may be given to minimize the use of levodopa and to control tremor and dystonic symptoms.

Levodopa formulations Levodopa is customarily given in combination with carbidopa, a peripheral dopa decarboxylase (DDC) inhibitor that blocks peripheral breakdown of levodopa, thus augmenting the bioavailability of levodopa while minimizing the side effects associated with peripheral conversion of levodopa to dopamine (notably, nausea). Carbidopa-levodopa is available in immediate-release formulations (10 mg carbidopa/100 mg levodopa, 25 mg/100 mg, and 25 mg/250 mg) and in controlled-release formulations (25 mg/100 mg, 50 mg/200 mg) [*see Table 2*]. Immediate-release carbidopa-levodopa is also available in an orally disintegrating form (Parcopa) that can be taken without water.

Carbidopa supplements (25 to 200 mg/day) are occasionally used to pretreat selected patients who have persistent nausea, presumably in response to inadequate plasma and carbidopa levels. For patients with persistent nausea, antiemetics such as trimethobenzamide and domperidone (available in Canada and Europe) may be well-tolerated and effective temporary measures. Because of its high cost, ondansetron is not a practical choice for long-term outpatient management. Other antiemetics, such as the dopamine receptor antagonists prochlorperazine and metoclopramide, should be avoided because they may significantly worsen parkinsonian symptoms.

Initiating treatment with either a regular or a controlled-release formulation of carbidopa-levodopa is acceptable. Although regular carbidopa-levodopa is better absorbed on an empty stomach, many experts recommend that early in treatment it be taken with meals to minimize nausea. In contrast, the absorption and bioavailability of the controlled-release formulations are increased when taken with meals.[52] The side effects of carbidopa-levodopa can be controlled by starting with a small dose (e.g., one-half tablet of carbidopa-levodopa, 25 mg/100 mg b.i.d.) and then increasing the dose as tolerance to the nausea develops. Dose adjustments should be made slowly because the full response to each increase in dose evolves over weeks. In the early stages of the disease, a typical daily dose should not exceed 300 to 400 mg/day of levodopa (as carbidopa-levodopa). Higher and more frequent doses may be necessary in patients with more advanced disease who experience wearing-off and other motor fluctuations.

Compared with immediate-release carbidopa-levodopa, controlled-release carbidopa-levodopa provides the convenience of one or two fewer daily doses and smaller oscillations in plasma levodopa levels, which results in a decrease in motor fluctuations in patients who experience mild to moderate wearing-off.[50,52] The bioavailability of levodopa in the controlled-release formulations is about 70% of that in the immediate-release formulations. The bioavailability of carbidopa in controlled-release formulations is about 50% that of immediate-release formulations. If controlled-release carbidopa-levodopa is selected as initial therapy, the initial dose is half of a 50 mg/200 mg tablet taken twice daily. Splitting the tablet negates the controlled-release properties; we do not recommend initiating therapy with controlled-release 25 mg/100 mg formulations because of the high incidence of nausea compared with immediate-release therapy. We prefer that patients start taking doses at breakfast and lunch only, maintaining 5- to 6-hour intervals between doses, rather than adopt a strict twice-daily schedule. The goal is to build a plateau of plasma levodopa levels early in the day and let the patient "ride" this plateau the rest of the day. Eventually, the patient will need late-afternoon and evening doses. Typical schedules of the various formulations of carbidopa-levodopa vary at different stages of disease and with different types of motor response abnormalities [*see Table 3*]. As the disease progresses and the level of motor-response abnormality increases, we rely less on controlled-release carbidopa-levodopa formulations and more on immediate-release formulations or on dopamine-agonist–dominant treatment.

Table 3 Strategies for the Use of Carbidopa-Levodopa Formulations

Time	Dosage (Tablets)				
	Monotherapy (CR 50 mg/200 mg)	Early Fluctuations		Late Fluctuations

CR—controlled release IR—immediate release

Levodopa augmentation One strategy for levodopa augmentation is the use of monoamine oxidase (MAO) inhibitors. MAO-B enzyme activity is one of the major catabolic pathways for dopamine in the CNS. Blocking its activity increases the intrasynaptic half-life of dopamine, leading to reduced motor fluctuations and tremor. Selegiline is a selective and irreversible MAO-B inhibitor that has a weak antiparkinsonian effect when used alone and a moderate effect when used as an adjunct to carbidopa-levodopa.[53] Selegiline is available as a 5 mg capsule or tablet. The usual dose is 5 mg with breakfast and lunch. In contrast to the nonselective MAO inhibitors (MAO-AB) and the MAO-A inhibitors, dietary tyramine restrictions are not necessary with selegiline. Insomnia is a significant side effect of selegiline, particularly when the drug is taken after midday. Older persons and those with significant but stable cardiac disease may benefit from daily doses as low as 2.5 mg. The dose should be reduced or the drug withdrawn if refractory hyperdopaminergic side effects occur (e.g., worsening dyskinesias, hallucinosis, confusion). A single European report citing increased mortality in elderly patients using selegiline[54] is inconsistent with all previous studies and with the long-term experience with selegiline in the Parkinson Study Group in North America.

Another levodopa augmentation strategy consists of blocking the activity of the enzyme catechol-O-methyltransferase (COMT). Together, COMT and DDC activity account for approximately 85% (10% and 75%, respectively) of the peripheral breakdown of levodopa.[55] Inhibition of COMT activity with tolcapone or entacapone can decrease oscillations in plasma levodopa levels. Both short-term and long-term administration of these agents slow the elimination of carbidopa-levodopa, thus increasing the area under the curve of plasma levodopa by 10% to 15% without changing the peak plasma level or the time to reach this peak.[55]

A number of double-blind, placebo-controlled studies have shown that this leads to a clinically important reduction in motor fluctuations and an increase in the time that the medication dose is effective ("on" time) of 1 to 2 hours a day.[56] In patients treated with tolcapone, the daily dose of carbidopa-levodopa may need to be decreased by 10% to 30% to avoid dyskinesias or other hyperdopaminergic side effects. In patients treated with entacapone, we generally wait until after the first few weeks of treatment to see whether any reduction in the dose of carbidopa-levodopa becomes necessary. Tolcapone is available in 100 and 200 mg tablets and is taken three times a day. Entacapone is available in 200 mg tablets and is administered as a single tablet with each dose of carbidopa-levodopa. Entacapone is now available in combination with carbidopa-levodopa (Stalevo 50 mg/100 mg/150 mg), which offers some convenience in reducing the number of pills taken.

COMT inhibitors can worsen levodopa-induced dyskinesias and cause nausea and diarrhea. Tolcapone carries a small risk of hepatotoxicity (including fatal hepatic necrosis) that has prompted a black-box warning from the Food and Drug Administration; for that reason, it is necessary to obtain informed consent before initiating therapy and to monitor liver function during therapy.[57] Rare cases of rhabdomyolysis associated with tolcapone use have also been described. Entacapone causes orange urine discoloration. Both agents can cause piloerection. Although the clinical antiparkinsonian effect of tolcapone appears to be more robust than that of entacapone, we favor initiating treatment with entacapone because of its greater safety.

There is little information comparing COMT inhibitors with dopamine agonists. Trials comparing tolcapone with the dopamine agonists bromocriptine and pergolide have been conducted, but those trials did not have sufficient power to detect clinically relevant differences between the agents.[58] Unlike dopamine agonists, COMT inhibitors are not effective for monotherapy, nor have they been shown to decrease the incidence of dyskinesias when introduced early in the course of treatment.

Dopamine agonists Dopamine agonists require neither transformation nor facilitated transport across the blood-brain barrier; they act directly on postsynaptic dopamine receptors. The available agents are the ergot alkaloids bromocriptine and pergolide and the newer nonergot alkaloids pramipexole and ropinirole [*see Table 4*].[46,48] The nonergot alkaloids are approved for early PD monotherapy and as adjuncts to carbidopa-levodopa in patients with advancing disease. Accumulating data indicate that pergolide may also be an effective monotherapeutic agent in PD.[48] However, pergolide has been associated with rare cases of cardiac valve dysfunction, most commonly tricuspid regurgitation.[59]

In a few head-to-head comparisons, the newer agents proved to be slightly superior to bromocriptine. There is no obvious advantage among the other three agents. Nonergot alkaloids are thought to cause less nausea and orthostatic hypotension than the ergots, but this difference appears to be clinically marginal. The new-

er agents offer no advantage over the old agents in terms of CNS side effects (e.g., confusion, hallucinations, and sleep disturbances). In fact, pramipexole has been associated with episodes of somnolence during the daytime—so-called sleep attacks—that have led to automobile accidents in patients.[60] This has led to the FDA's issuing a warning. There have been a few similar reports with ropinirole. Although the ergot alkaloids appear to be less likely to cause such episodes, we warn all our patients about this potential danger.

Amantadine and anticholinergics Some physicians prefer to treat early, mild PD with less potent agents, such as amantadine or anticholinergic agents, to delay the introduction of levodopa. There are no data to indicate that this levodopa-sparing maneuver prevents the emergence of dyskinesias.

Amantadine is particularly helpful in the treatment of drug-induced dyskinesias and thus may be especially valuable in later stages of the disease. Amantadine is available in 100 mg tablets and capsules and in 50 mg/5 ml syrup; the usual dosage is 200 to 400 mg/day in two or three divided doses. The mechanism of action of amantadine is unclear. In vitro, it can enhance dopamine transmission, it has anticholinergic effects, and it acts as a weak glutamate antagonist.[61] The side effects of amantadine are edema, erythema, and livedo reticularis. In older patients, it may aggravate confusion and psychosis. Amantadine needs to be used with caution and in smaller doses in patients with renal insufficiency.

Anticholinergics have long been used in PD, particularly for their effects on tremor, rigidity, and dystonia. They have limited effects on akinesia, bradykinesia, posture, and gait. Their major drawbacks, particularly in elderly patients, are memory impairment, hallucinations, visual blurring, aggravation of glaucoma, constipation, urinary hesitancy, and dry mouth. The last side effect can be exploited as a treatment for the drooling (sialorrhea) that affects many patients with PD. Specifically, patients with significant sialorrhea may benefit from glycopyrrolate (1 to 2 mg b.i.d.), which is an anticholinergic with low CNS penetrability. Other available anticholinergic agents include ethopropazine (50 to 200 mg/day), trihexyphenidyl (1 to 10 mg/day) and benztropine (1 to 4 mg/day). Tolerance of these agents decreases with advancing age. Of these agents, ethopropazine is a less potent antiparkinsonian agent but is more likely to be tolerated by elderly patients. In the United States, ethopropazine can be obtained through compounding pharmacies.

Treatment of advanced disease and its complications Clinical management of PD becomes increasingly complex as the disease advances and patients experience worsening gait and postural instability, increased freezing, falls, and the emergence of motor fluctuations and dyskinesias. Equally disabling are drug-induced confusional spells, hallucinations, and psychosis. Referral to a movement-disorder specialist is indicated when disease progresses to this point.[62]

Motor fluctuations Wearing off of levodopa's clinical antiparkinsonian benefit after 3 to 4 hours is the earliest sign of motor fluctuations. Giving antiparkinsonian drugs before rather than with meals or in a slurry (liquid levodopa) helps to bypass the erratic and partial drug absorption that contributes to this problem. Similarly, first-pass metabolism is avoided through the use of the orally disintegrating formulation of carbidopa-levodopa. Immediate-release carbidopa-levodopa can be combined with the controlled-release formulation to provide a better bal-

Table 4 Dopamine Agonists for Parkinson Disease

Class	*Agent*	*Dose Equivalent to Levodopa Anchor Dose**	*Starting Dosage*	*Titration Schedule†*	*Typical Maintenance Dosage for Single-Agent Therapy*	*Typical Maintenance Dosage As Adjunct to Levodopa*	*Comments*
Nonergot alkaloids	Pramipexole	1 mg	0.125 mg t.i.d.	Increase to 0.25 mg t.i.d. after 1 wk, then increase weekly in increments of 0.25 mg t.i.d.	Maximum dosage 1.5 mg t.i.d.	Maximum dosage 1.5 mg t.i.d.	Renal metabolism; dose adjustments needed in renal insufficiency; occasionally associated with sleep attacks
	Ropinirole	5 mg	0.25 mg t.i.d.	Weeks 1–4, increase weekly in increments of 0.25 mg t.i.d. to a dosage of 1 mg t.i.d.; after week 4, increase in weekly increments of 1.5 mg/day to a dosage of 9 mg/day, then of 3 mg/day to maximum dosage of 24 mg/day	12–24 mg/day	3–16 mg/day	Hepatic metabolism; potential drug-drug interactions; occasionally associated with sleep attacks
Ergot alkaloids	Bromocriptine	2 mg	1.25 mg b.i.d. or t.i.d.	Increase by 2.5 mg/day every 2–4 wk	7.5–15 mg/day	3.75–7.5 mg/day	Rare reports of pulmonary and retroperitoneal fibrosis; relative incidence of sleep attacks not well studied
	Pergolide	1 mg	0.05 mg/day, t.i.d. at mealtimes	Every 2–5 days	3–4.5 mg/day	1.5–3 mg/day	Rare reports of valvular heart disease; fewer reports of sleep attacks compared with nonergot agents

*100 mg immediate-release levodopa; see Table 2.
† Because of lower tolerance, some patients will require slower titration.

ance between prompt and sustained antiparkinsonian responses [*see Table 2*]. Dopamine agonists and selegiline have a longer half-life than carbidopa-levodopa, and combination therapy that includes one of these agents produces a smoother clinical response than carbidopa-levodopa alone in patients who experience motor fluctuations.

Another strategy involves shortening the dosing intervals. However, regimens that involve dosing more frequently than every 4 hours are difficult to manage clinically; such regimens should probably be undertaken in specialty movement-disorder clinics.[62]

Neuropsychiatric symptoms Depression in patients with PD typically responds well to conventional antidepressants (e.g., tricyclics, selective serotonin reuptake inhibitors [SSRIs], venlafaxine, and bupropion). Short-acting rather than long-acting SSRIs are preferred, because there are reports that fluoxetine, a long-acting SSRI, may produce extrapyramidal symptoms (EPS). Although all SSRIs are probably effective in PD, we find that citalopram (10 to 30 mg/day), sertraline (50 to 150 mg/day), and paroxetine (10 to 30 mg/day) are particularly well tolerated. Limited experience with bupropion (50 to 200 mg/day) and sustained-release venlafaxine (37.5 to 150 mg/day) suggests that these agents are also well tolerated and may be less sedating. Concerns about the potential for hyperserotoninergic reaction (delirium with myoclonus and hyperpyrexia) stemming from the combination of selegiline and SSRIs in PD appear to have been grossly exaggerated.[62]

In patients who fail to respond to antidepressant medication, it is important to rule out other causes of refractory depression, such as hypothyroidism. Patients with PD who suffer from refractory depression or are intolerant of oral antidepressants are candidates for electroconvulsive therapy (ECT). In addition to alleviating depression, ECT may also improve parkinsonian motor symptoms.[63]

Patients with PD may undergo slow but profound drug-induced personality changes, which may be expressed as erratic, temperamental, unreasonable, and demanding behaviors; self-centeredness; and apparent disregard for the needs of others. These may be a prelude to depression or psychotic symptoms that are either drug induced or secondary to emerging dementia. Drug-induced psychosis is typified by visual hallucinations with retention of insight. Auditory hallucinations suggest coexisting psychotic depression or dementia, but they may be a side effect of anticholinergic medications.[64] In many instances, disturbing cognitive and psychiatric symptoms will cease with elimination of anticholinergics or amantadine. Some patients, however, require reduction in doses or elimination of drugs, typically in the following order: selegiline, nocturnal doses of dopamine agonists or controlled-release carbidopa-levodopa, and regular carbidopa-levodopa. If the patient improves after only a modest adjustment in polypharmacy, the impact on the parkinsonian motor symptoms will range from negligible to positive. If the patient requires a drastic reduction in antiparkinsonian therapy, the resulting aggravation of motor symptoms is likely to be intolerable.[64] Levodopa drug holidays are no longer recommended, because several reports indicate that they are potentially dangerous and provide no significant long-term benefit.

When the reduction in antiparkinsonian polypharmacy has intolerable consequences, an antipsychotic drug may be necessary. Conventional antipsychotics are poorly tolerated because of associated EPS and worsening of parkinsonism. Atypical antipsychotics have a higher ratio of serotonin 5-HT_{2a} to dopamine D_2 blockade and, compared with conventional antipsychotics, a lower incidence of EPS. Of the atypical antipsychotics, clozapine has been shown to be more effective than placebo in the treatment of drug-induced hallucinations in PD in two double-blind, placebo-controlled studies.[65] Clozapine may have additional beneficial effects on tremor, dystonia, and dyskinesias. Associated side effects include dizziness, orthostatic hypotension, sialorrhea, and confusion. Although most PD patients tolerate small doses of clozapine (12.5 to 75 mg in the evening), its use has been tempered by the 1% risk of agranulocytosis, which requires frequent monitoring of the leukocyte count.

The atypical antipsychotic quetiapine appears to be the first-line drug for the treatment of all psychotic symptoms in PD. It is not associated with hematologic or other serious toxicity and has a low incidence of EPS across the therapeutic spectrum. In a series of open-label studies, it was shown to be effective and well tolerated in PD.[65] The median range of effective doses is 50 to 75 mg/day, with most of the dose administered at night. This dose is significantly less than that typically used in schizophrenia (400 to 600 mg/day). The side effects are similar to those of clozapine except for the lack of hematologic toxicity or sialorrhea. If neuropsychiatric symptoms are not well controlled with quetiapine, the patient is switched to clozapine.

Risperidone is the second oldest atypical antipsychotic. In small doses (0.25 to 1 mg/day), it is an effective antipsychotic in PD patients who have drug-induced hallucinations. In a few open-label studies, however, it appeared to aggravate motor symptoms in many patients over a period of weeks to months.[65] This worsening was typified by increasing akinesia, decreased walking, and other signs of EPS. Olanzapine is not well tolerated by patients with PD.[66] All atypical antipsychotics carry warnings of potential hyperglycemia; monitoring of blood glucose levels is recommended.

Treatment of dementia in PD with the dual cholinesterase inhibitor rivastigmine has been studied. In a 24-week, placebo-controlled study, rivastigmine use was associated with moderate improvements in PD-associated dementia; however, it was also associated with higher rates of nausea, vomiting, and tremor.[67]

Neuroprotective therapy Slowing the progression of PD through neuroprotective therapy is a major focus of current research.[68] Epidemiologic studies suggest that the long-term use of cyclooxygenase inhibitors or of estrogen replacement in postmenopausal women may delay or prevent the onset of PD through yet unclear mechanisms. Coffee drinking has also been associated with a reduced incidence of PD, as has cigarette smoking. Current treatment strategies involve interrupting the cascade of biochemical events that leads to death of dopaminergic cells [*see Table 5*]. The first such clinical trial in PD was the large multicenter Deprenyl and Tocopherol Antioxidative Therapy of Parkinsonism (DATATOP) study, in which selegiline monotherapy delayed the need for levodopa therapy by 9 to 12 months in newly diagnosed patients.[69] Most evidence indicates that this delay resulted from a mild symptomatic effect of selegiline. Long-term follow-up of the DATATOP cohort revealed that patients who remained on selegiline for 7 years experienced slower motor decline compared with those who were changed to placebo after 5 years. Interestingly, patients in the 7-year patient group were more likely to develop dyskinesias but less likely to develop freezing gait. A metabolite of selegiline, desmethylselegiline, has been shown in laboratory studies to have power-

Table 5 Selected Neuroprotective Treatments for Parkinson Disease

Pathogenetic Factor	*Intervention*	*Specific Agents*
Oxidative stress	Antioxidants	Vitamin E, vitamin C, iron chelators
	MAO-B inhibitors	Selegiline, rasagiline
Mitochondrial dysfunction	Bioenergetic agents	Coenzyme Q10
Excitotoxicity	Antiglutamatergic agents	NMDA receptor antagonists
Inflammation	Anti-inflammatory agents	COX-2 inhibitors
Neuronal dysfunction	Trophic factors	Glial cell line–derived neurotrophic factor
Apoptosis	Antiapoptotic agents	Dopamine agonists, caspase inhibitors, minocycline, propargylamines

COX—cyclooxygenase MAO—monoamine oxidase NMDA—*N*-methyl-D-aspartate

ful neuroprotective effects. Clinical trials to test this agent are now in progress.

In another pilot study, coenzyme Q10, an antioxidant and a cofactor of complex I of the mitochondrial oxidative chain, appeared to delay progression of early disability in PD.[70] A large multicenter trial is now under way. Other potentially neuroprotective agents under investigation are acetyl-levo-carnitine and creatine monohydrate. A large controlled study of the antiglutamatergic agent riluzole was prematurely discontinued after a futility analysis revealed little effect on progression of symptoms.[71] As noted, dopamine agonists are also being studied for a neuroprotective role, based on their ability in vitro to decrease dopamine turnover, scavenge free radicals, and interfere with proapoptotic cell signals. Other promising agents include nitric oxide synthase inhibitors, antiapoptotic agents such as Jun N-terminal kinase inhibitors, and the antibiotic minocycline.[71] Minocycline can inhibit microglial activation in vitro and interrupt apoptosis by inhibiting caspase 1 and 3, which are involved in the enzymatic processing of α-synuclein.

Surgical treatment The past decade has witnessed a renaissance in the surgical treatment of PD and other movement disorders. This has been motivated first by the fact that after 5 or more years of pharmacologic treatment, many patients develop significant drug-induced motor fluctuations and dyskinesias. Second, major advances in understanding the pathophysiologic basis of parkinsonism have provided a clearer rationale for the effectiveness of surgical procedures and guidance for targeting specific structures, such as the GPi and the STN [*see Figure 2*].

The selection of suitable patients for surgery is critical, because in general, patients with atypical PD do not benefit from surgery. Candidates for surgery must have the following: (1) a clear diagnosis of idiopathic PD, (2) a good initial response to levodopa, and (3) significant intractable symptoms of PD or (4) drug-induced dyskinesias and wearing-off. The major contraindications to surgery are atypical PD, dementia, major psychiatric illness, and substantial medical comorbidities. Age is not a contraindication, but older patients derive less benefit from surgery. Patients with clinical manifestations such as unresponsive features, postural instability and falling, hypophonia, micrographia, drooling, and autonomic dysfunction are unlikely to benefit from surgery. In general, the benefits of surgery are unlikely to exceed the best benefits of antiparkinson medication. The major benefit of surgery is the elimination of dyskinesias and "off" periods (i.e., periods when medication is ineffective) and production of a stable "on" state. The decision for surgery should be made by a movement disorder neurologist who is part of a team that includes a neurosurgeon with fellowship training in functional neurosurgery, a psychiatrist, a neuropsychologist, and trained technicians.

Use of procedures that involve the creation of surgical lesions (e.g., pallidotomy or thalamotomy) has decreased greatly since the introduction of deep brain stimulation. In deep brain stimulation, a lead wire is surgically implanted in the GPi or STN and connected to a pulse generator that is implanted subcutaneously, generally on the chest wall near the clavicle. The patient can activate the system by passing a small handheld magnet over the generator. This system was approved by the FDA in August 2004 for patients with PD.

The major advantages of deep brain stimulation are that it is less invasive than the creation of surgical lesions and that the system may be adjusted to best effect after implantation. Although the choice between STN and GPi as targets for deep brain stimulation has shifted toward the STN, the available evidence suggests that both sites are effective for all the cardinal features of PD, as well as for dyskinesias and motor fluctuations. Several clinical trials are now under way to compare these two targets. Although bilateral surgery is generally necessary for patients with advanced disease and those with significant bilateral manifestations, unilateral stimulation is appropriate for patients with asymmetrical disease. Postoperative reductions in drug dosages appear to be easier with STN than GPi approaches.

The mechanism of action of deep brain stimulation remains controversial. Because both ablation and stimulation of a given target have a similar clinical effect, it was assumed that stimulation caused a functional blockade. With both approaches, it is probable that the remaining motor systems in the brain stem, thalamus, and cortex are able to compensate more effectively for the abnormal activity associated with the parkinsonian state. Whatever the mechanism, it is clear that these approaches can offer impressive results in properly selected patients with PD, as well as in patients with other movement disorders.

Although deep brain stimulation can be very effective, serious complications occur in 1% to 2% of patients who receive the device.[72] Even in the best hands, approximately 15% of patients require a second operation to treat complications or improve efficacy.

Although neurotransplantation of dopamine-producing fetal cells once seemed promising, the results from two large con-

trolled clinical trials have proved considerably disappointing.[73] The first study showed only modest benefit in patients younger than 60 years, and it showed no benefit in those older than 60 years. Moreover, a number of patients developed dyskinesias, which occurred when the patients were off medication. The second study showed similar findings with regard to benefit and the development of dyskinesias. Because of this, as well as the considerable obstacles to obtaining sufficient fetal tissue and the opposition to the use of fetal tissue on ethical grounds, this approach is now viewed as purely investigational. Conceivably, other sources of replacement dopaminergic cells (e.g., carotid body cells, stem cells, or encapsulated, genetically engineered cells capable of producing levodopa, dopamine, or trophic factors) may prove more successful. An open-label trial of direct infusion of glial cell–derived neurotrophic factor (GDNF) to the putamen in a small number of patients with PD raised hopes for this approach; however, in a subsequent randomized, double-blind trial of GDNF administered through an implanted intracerebroventricular catheter, patients showed no improvements in parkinsonism.[74]

OTHER FORMS OF PARKINSONISM

Pathologic studies reveal that the error rate in the clinical diagnosis of PD can be as high as 25%, which suggests that a number of other entities can closely mimic this syndrome [*see Table 1*]. Most important in the differential diagnosis are drug-induced parkinsonism, degenerative disorders with parkinsonlike features, vascular parkinsonism, and normal-pressure hydrocephalus. Scenarios under which an alternative diagnosis should be considered include the following: recent exposure to drugs or toxins; a history of, or significant risk factors for, cerebrovascular disease; symmetrical symptoms or abrupt onset of symptoms; early dementia; prominent postural instability from the outset; and cerebellar or pyramidal signs or autonomic dysfunction.

Drug-Induced Parkinsonism

Drug-induced parkinsonism (DIP) closely resembles clinical PD, except that the rest tremor is generally less prominent and more symmetrical in DIP than in PD. Postural tremor is also more prominent in DIP. DIP is commonly caused by the use of dopamine blockers such as neuroleptics and antiemetics.[75] Other drugs with different or unknown mechanisms include lithium carbonate and, to a lesser extent, SSRIs, divalproex, and selected calcium channel blockers used in Europe. Among the dopamine blockers, the most common offending agents are conventional antipsychotics and metoclopramide.

Atypical antipsychotics can also cause parkinsonism in a dose-dependent manner, with risperidone and olanzapine being more frequent offenders than clozapine and quetiapine. In parkinsonism induced by atypical antipsychotics, onset is delayed and there is less tremor than in DIP caused by typical antipsychotics. The most prominent features of DIP caused by atypical antipsychotics are increased akinesia and ataxia. This condition is often missed in the setting of chronic illnesses such as dementia and PD with dementia, because the delayed deterioration in the patient's condition is assumed to be secondary to the progression of the underlying disease.

DIP can also be induced by the long-term administration of such antihypertensive agents as reserpine, which depletes presynaptic dopamine stores, and α-methyldopa, which can inhibit the synthesis of dopamine by blocking the transport of levodopa through the blood-brain barrier.

Exposure to certain toxins can also lead to a parkinsonian state [*see Table 1*]. Any young adult presenting with parkinsonism should be questioned about the use of street drugs, because mistakes in the illicit synthesis of certain narcotics can result in their contamination with MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), which may cause an irreversible parkinsonian syndrome.

DIP is treated by stopping the offending agent. Symptoms usually resolve within days or weeks. When DIP persists despite withdrawal of a drug that is not known to produce permanent neuronal damage, presumably the drug exposure simply exposed a parkinsonian disorder that was in the process of developing. In DIP precipitated by atypical antipsychotics, neuroleptics can be substituted for the offending drug, if necessary. In patients who need to continue using the offending agent and whose symptoms are not incapacitating, DIP can be alleviated by anticholinergics, amantadine, and dopaminomimetics.

Vascular Parkinsonism

Patients with vascular parkinsonism exhibit an akinetic-rigid lower-body parkinsonism with gait and balance problems that include a short-stepping gait (marche à petits pas).[76] Upper body rigidity and tremor are less prominent than in idiopathic PD, and action tremor is more common than rest tremor. Most patients report an acute to subacute onset of symptoms and have a history of cerebrovascular disease, diabetes mellitus, or hyperlipidemia. Accompanying neurologic findings in vascular parkinsonism that are typically absent in idiopathic PD include upper motor neuron signs, frontal release signs, pseudobulbar palsy, and dementia. Other diseases that occasionally produce a similar picture include normal-pressure hydrocephalus, chronic subdural hematoma, inflammatory vasculitides, the antiphospholipid syndromes, and hyperhomocysteinemia. Rare entities such as leukodystrophies and demyelinating disorders can present similarly. The diagnosis is made on the basis of the clinical picture, the presence of risk factors, and evidence on magnetic resonance imaging of multiple strokes, a hypertensive lacunar state, or a multifocal or diffuse microangiopathy [*see Figures 5a and c*]. A postmortem examination is necessary for definitive diagnosis, given the absence of definite disease markers.

No satisfactory therapeutic options are available for vascular parkinsonism. Response to dopaminomimetic agents is limited; anticholinergics and amantadine frequently cause confusion and delirium.

Multiple-System Atrophy

The multiple-system atrophies (MSAs) are a clinically diverse group of neurodegenerative disorders of unknown etiology characterized by varying degrees of parkinsonism and corticospinal, cerebellar, and autonomic dysfunction[77] [*see Figures 5a and b*]. Widespread degeneration is typically found in the basal ganglia, spinal cord, brain stem, and cerebellum. A unique and distinctive pathologic feature of the MSAs is the presence of α-synuclein–positive glial cytoplasmic (and to a lesser extent neuronal) inclusions in the absence of Lewy bodies. The role of α-synuclein–positive (and ubiquitin-positive) inclusions in the pathophysiology of these illnesses remains unclear.

Clinical features The average age of onset of MSAs is 50 years (range, 33 to 76 years). Median survival is 6 years. Men are affected more often than women. The presentation is highly varied and may begin with signs of parkinsonism (46%), cerebellar dysfunction (< 25%), or autonomic dysfunction. The signs of au-

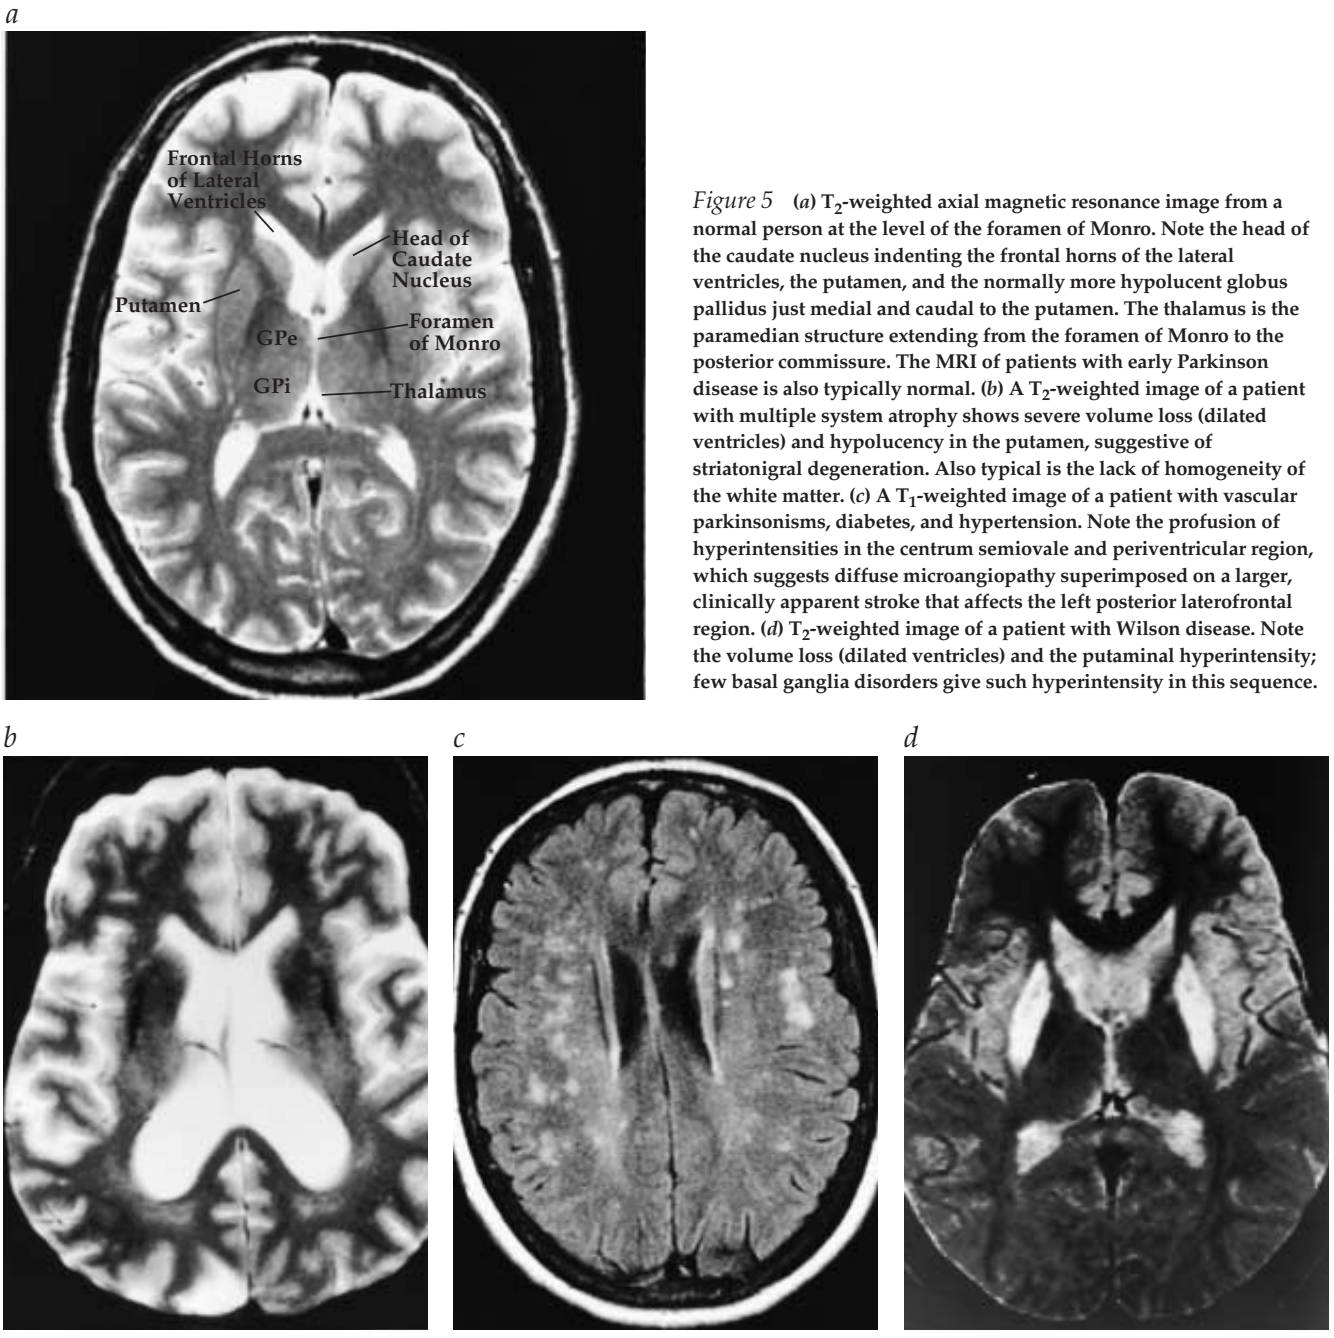

Figure 5 **(*a*) T_2-weighted axial magnetic resonance image from a normal person at the level of the foramen of Monro. Note the head of the caudate nucleus indenting the frontal horns of the lateral ventricles, the putamen, and the normally more hypolucent globus pallidus just medial and caudal to the putamen. The thalamus is the paramedian structure extending from the foramen of Monro to the posterior commissure. The MRI of patients with early Parkinson disease is also typically normal. (*b*) A T_2-weighted image of a patient with multiple system atrophy shows severe volume loss (dilated ventricles) and hypolucency in the putamen, suggestive of striatonigral degeneration. Also typical is the lack of homogeneity of the white matter. (*c*) A T_1-weighted image of a patient with vascular parkinsonisms, diabetes, and hypertension. Note the profusion of hyperintensities in the centrum semiovale and periventricular region, which suggests diffuse microangiopathy superimposed on a larger, clinically apparent stroke that affects the left posterior laterofrontal region. (*d*) T_2-weighted image of a patient with Wilson disease. Note the volume loss (dilated ventricles) and the putaminal hyperintensity; few basal ganglia disorders give such hyperintensity in this sequence.**

tonomic failure include orthostatic hypotension, urinary symptoms, constipation, impotence, and loss of sweating. Parkinsonism occurs in about 90% of patients at some time during the illness.[78] Autonomic symptoms are the initial feature in less than half of patients, but they develop later in virtually all patients. A high percentage of patients with MSA have upper motor neuron signs (e.g., spasticity and Babinski signs).[78]

MSAs have been grouped into three broad categories: striatonigral degeneration (MSA-P), olivopontocerebellar atrophy (MSA-C or OPCA), and Shy-Drager syndrome. Patients with relatively pure parkinsonism are designated as having striatonigral degeneration. Those who express a combination of parkinsonism and other signs, such as ataxia, upper motor neuron and corticobulbar involvement, myoclonus, oculomotor abnormalities, peripheral neuropathy, and deafness, fit into the grouping of OPCA. The OPCAs are a markedly heterogeneous group that includes both hereditary and sporadic forms of the disease. If parkinsonian features are associated with prominent signs of autonomic failure, a diagnosis of Shy-Drager syndrome is justified.

Treatment In general, the parkinsonian features of the MSAs respond only modestly to antiparkinsonian medications. The efficacy of dopaminomimetic therapy is often limited by orthostatic hypotension. Treatment of orthostatic hypotension in patients with MSAs (as well as in those with PD and other disorders associated with symptomatic orthostatic hypotension) includes simple measures such as changing position slowly, increasing salt and fluid intake, and avoiding overheated rooms, large meals, and alcohol. Other measures include wearing support stockings, sleeping in the reverse Trendelenburg position,

raising the hematocrit if it is below 32%, and adjusting other drug therapies that may affect blood pressure. Because blood pressure tends to be higher in the afternoon, patients can learn to conduct most activities of daily living in the afternoon. If these measures fail, pharmacologic strategies to deal with the autonomic insufficiency may be effective, including the use of vasopressors such as midodrine.

Other symptoms, such as impotence, urinary urgency and incontinence, and autonomic storms with profound diaphoresis, are more difficult and sometimes impossible to treat pharmacologically. Impotence occasionally responds to yohimbine or to the more contemporary agents sildenafil, vardenafil, and tadalafil. Penile implants may help but should not be pursued until orthostatic changes are well controlled. Constipation can be treated with high-dose fiber, hydration, bisacodyl, senna concentrate, or lactulose. Urinary urgency and frequency may respond to oxybutynin, tolterodine tartrate, and hyoscyamine sulfate; incontinence requires intermittent catheterization, adult diapers, or both. Gastroparesis can be improved with metoclopramide—which may, however, exacerbate parkinsonian symptoms—or with erythromycin ethylsuccinate, erythromycin lactobionate, or domperidone (available in Canada and Europe); all are taken before meals.

Disorders Associated with Primary Tau Pathology

Tau is a microtubule-associated phosphoprotein that promotes tubulin polymerization and the stabilization of microtubules in neurons. Disorders of tau protein lead to neurodegeneration by causing the intraglial and intraneuronal accumulation of tau protein–positive neuropil threads and secondary neuronal damage in the form of achromatic neurons and tangles. These tau protein inclusions are thought to cause neurotoxic damage to gray and white matter, particularly in basal ganglia and the frontotemporal cortex. Several mutations in the gene that codes for tau protein on chromosome 17 have been identified. Most of these are associated with familial frontotemporal dementia [*see 11:XI Alzheimer Disease and Other Dementing Illnesses*]. Linkage disequilibrium studies suggest that progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD) may be autosomal recessive conditions associated with polymorphisms that map to the *tau* gene in chromosome 17.[79] For instance, a missense mutation in exon 13 of the *tau* allele R406W has been linked to a dominantly inherited form of PSP in Europe but not to 31 unrelated individuals with PSP or CBD in the United States.[80,81] Pathologically, these conditions share overexpression of the same tau protein haplotype in the affected regions of brain.

Progressive supranuclear palsy PSP is perhaps the most common of the so-called Parkinson-plus syndromes. Like PD, PSP begins in the sixth or seventh decade of life; unlike PD, it progresses to death in 5 to 10 years, mostly from complications of aspiration.[82] Early on, nonspecific complaints of visual impairment, dizziness, and unsteadiness are common. Later in the disease course, more specific complaints of slowness, falls, and deterioration of speech and swallowing begin to appear. Tremor is distinctly uncommon. A staring look (because of partial lid retraction) with a furrowed brow, deep facial lines, and a hyperextended head provides an image distinct from the masked facies and flexed posture of PD [*see Figure 6*]. Supranuclear control of voluntary vertical gaze is impaired first, followed by difficulties with accommodation (blurring of vision) and, eventually, impairment of horizontal eye movements. Parkinsonian features can be prominent, whereas the characteristic oculomotor findings may be absent early on, leading to diagnostic confusion. The rest of the examination reveals prominent axial rigidity and dystonia, dysarthria, and upper motor neuron signs with loss of fine motor dexterity and gait imbalance. Patients complain of a tendency to "fall like a tree" without warning. In more advanced stages, appendicular dystonia and cerebellar signs develop. A significant number of patients progress to dementia similar to that seen in patients with CBD. Widespread degeneration in the brain stem, basal ganglia, and cerebellum is present in varying degrees. Although most patients respond to high doses of antiparkinsonian medications initially, response to treatment is mediocre at best compared with that in PD.

Corticobasal degeneration CBD is almost as common as PSP, but it may tend to be missed because it often presents as an atypical dementia with few of the characteristic movement abnormalities that may be associated with PSP.[82,83] The syndrome typically begins in the sixth decade of life and presents as a varied but striking unilateral syndrome with rigidity, dystonia, slowness, and apraxia, with or without cortical sensory loss.[84] Symptoms worsen until the patient becomes totally incapacitated. MRI and gross examination of biopsy specimens reveal prominent focal cortical loss in the contralateral parietal and frontal areas. Histologic examination reveals gliosis and swollen (ballooned) achromatic neurons and neuronal loss. There are also white-matter abnormalities consisting of swollen and demyelinated axons, and the neuropil has a spongiform appearance. In addition to affecting the cortex, these changes affect the subthalamic nucleus, globus pallidus, striatum, thalamus, and several cerebellar nuclei. Treatments are generally ineffective.

Parkinsonism and Dementia

A number of disorders (e.g., Alzheimer disease, Creutzfeldt-Jakob disease, and frontotemporal dementia [Pick disease]) present with dementia and variable degrees of extrapyramidal features. For example, 20% of patients with Alzheimer disease exhibit mild rigidity and bradykinesia. As many as 40% of PD patients have some Alzheimer disease pathology.[36]

Patients with parkinsonism and dementia typically present with an akinetic-rigid form of parkinsonism without tremor. The progression of disability is more rapid, and management is more difficult than in nondemented patients because of the high incidence of drug-induced cognitive side effects. In these patients, central dopaminomimetic toxicity can present in many ways, including sleep disruption (with daytime sleepiness), personality changes, depression and mental dullness, episodic confusion, hallucinations, and disruptive behaviors.[64]

Diffuse Lewy body disease is a form of dementia with prominent parkinsonian features that is recognized with increasing frequency.[85] In some families with diffuse Lewy body disease, patients with pure Lewy body PD are found. Pathologically, Lewy bodies are found in the cortex and brain stem. Many of these patients also exhibit Alzheimer disease pathology, which makes it difficult to distinguish these patients from those with a PD–Alzheimer disease overlap syndrome. Clinically, an action tremor may precede other parkinsonian features, and dementia is often heralded by levodopa-induced sedation, myoclonus, and hallucinations. Early on, the response to levodopa can be substantial, making it difficult to differentiate diffuse Lewy body

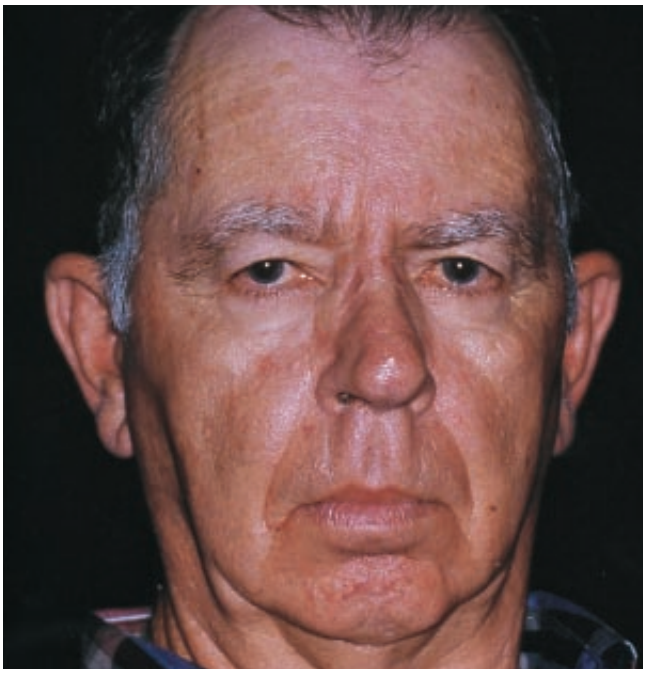

Figure 6 **Face of a patient with progressive supranuclear palsy. Note the intense leonine expression and deep facial furrows, in contrast to the passivity of expression in Parkinson disease. Patients with progressive supranuclear palsy typically have a surprised or staring expression.**

disease from PD. The progression of symptoms of diffuse Lewy body disease appears to be intermediate, as compared with the progression of symptoms in the PD and PD–Alzheimer disease subgroups.

Hyperkinetic Disorders

Hyperkinetic movement disorders encompass a variety of involuntary movements (dyskinesias) that may occur in isolation, in combination, and even in the setting of parkinsonism. Hyperkinesias have a wide spectrum of severity, ranging from barely detectable (e.g., restlessness or fidgetiness) to violent (e.g., hemiballismus) and from straightforward to complex and emotionally laden (e.g., focal tics and coprolalia in Tourette syndrome). When dyskinesias occur in combination, it is important to determine which one is predominant, because this will help guide the diagnostic workup and suggest potential therapies.

Chorea is perhaps the most common form of dyskinesia.[83] The term chorea, which means dance, refers to arrhythmic, involuntary movements that are typically sudden and brief and seem to flow from one part of the body to another. When combined with slower, writhing movements or dystonic posturing, the dyskinesia is sometimes referred to as choreoathetosis. Hemiballismus is a unilateral, large-amplitude, violent form of chorea that affects the proximal limbs more than the distal limbs. The most common cause of hemiballismus is a vascular lesion of the subthalamic nucleus.

Examples of other quick, involuntary movements that may be confused with chorea include myoclonus, tics, and dystonic tremors. Myoclonic jerks are lightning fast but lack the rhythmic flow of activity seen in chorea. Although patients with myoclonic jerks commonly lose motor control and drop objects, this rarely happens to patients with chorea or tics. Unlike chorea and myoclonus, motor tics can be readily suppressed.

Dystonic movements tend to be slower and the contractions are more sustained (lasting seconds or longer), as compared with chorea and tics. At first, dystonia may be present only with voluntary movement (action dystonia); later, dystonia may occur spontaneously. The dynamic contractions often lead to postural deformities such as those in spasmodic torticollis. Early on, dystonic movements may respond to sensory tricks, such as holding the chin lightly to prevent the neck from moving. Tremor associated with dystonia tends to have a jerking, irregular quality that is different from the oscillatory quality of most other tremors. Chorea, myoclonus, tremor, and dystonic contractions are perceived by patients as involuntary. In contrast, tics are often perceived as voluntary responses to underlying urges.

CHOREA

Etiology

Chorea has been described in at least 150 somatic illnesses and as a reaction to numerous drugs and toxins. From a medical standpoint, the more important causes of chorea are postinfectious, immunologic, vascular, metabolic, endocrine, and drug-induced processes [*see Tables 6 and 7*]. Systemic illnesses that may cause chorea include inflammatory disorders such as systemic lupus erythematosus and periarteritis nodosa, as well as infectious or parainfectious processes such as streptococcal infection, diphtheria, pertussis, toxoplasmosis, and AIDS. Cerebrovascular disorders that cause chorea are associated with asymmetrical neurologic signs and a stepwise or stuttering course that is consistent with the lacunar state.

The most important pediatric entities associated with chorea are Sydenham chorea, Wilson disease, torsion dystonia, Tourette syndrome, and, in rare instances, Huntington disease. Rare disorders of intermediary metabolism can also lead to chorea, but their associated findings, such as myoclonus, encephalopathy, and mental subnormality, tend to be more prominent than the chorea [*see Table 8*]. Disorders associated with chorea that may also present in adulthood include Wilson disease, Huntington disease, and familial calcification of the basal ganglia (Fahr disease).

Treatment

Regardless of etiology, chorea can usually be treated with so-called dopamine depletors (e.g., reserpine, tetrabenazine) and dopamine blockers. Dopamine depletors are preferred because they tend to produce fewer extrapyramidal side effects than dopamine blockers and do not carry the risk of tardive dyskinesia.[86] Potentially disabling side effects of reserpine include parkinsonism, acute dystonia, and postural hypotension. Reserpine is typically started at low doses (0.10 to 0.25 mg/day); doses are increased as tolerated (usually weekly) until the chorea is controlled or side effects supervene.

HUNTINGTON DISEASE

Epidemiology, Etiology, and Pathogenesis

Huntington disease is a uniformly fatal autosomal dominant disorder with high penetrance that is characterized by progressive motor, emotional, and cognitive dysfunction. Onset is typically in midlife, although it ranges from 3 to 70 years of age. Huntington disease is recognized worldwide and has a prevalence of 10 cases per 100,000 population.

Table 6 Selected Causes of Chorea

Developmental and Age-Related
- Cerebral palsy
- Kernicterus
- Senile chorea
- Oral-lingual-buccal dyskinesias of aging

Hereditary
- Disorders of intermediary metabolism
- Lesch-Nyhan syndrome and its variants
- Wilson disease
- Hallervorden-Spatz disease
- Ataxia-telangiectasia
- Tuberous sclerosis
- Huntington disease
- Choreoacanthocytosis
- Familial calcification of the basal ganglia

Cerebrovascular
- Basal ganglia infarction or hemorrhage
- Arteriovenous malformation
- Polycythemia vera
- Hemoglobin sickle cell disease

Immunologic
- Systemic lupus erythematosus
- Antiphospholipid syndrome
- Periarteritis
- Behçet syndrome
- Henoch-Schönlein purpura

Nutritional
- Beriberi, pellagra
- B_{12} deficiency in infants

Infectious
- Sydenham chorea (poststreptococcal)
- Scarlet fever
- Diphtheria
- Pertussis
- Typhoid fever
- Viral encephalitis
- Postvaccinial
- Neurosyphilis
- Mononucleosis
- Legionnaires disease
- Bacterial endocarditis

Metabolic
- Hyponatremia
- Hypocalcemia
- Hypoglycemia
- Hypomagnesemia
- Hepatic encephalopathy
- Renal encephalopathy
- Porphyria

Endocrine
- Hyperthyroidism
- Hypoparathyroidism and hyperparathyroidism
- Pseudohypoparathyroidism
- Chorea gravidarum (in pregnancy)
- Addison disease

Miscellaneous
- Multiple sclerosis
- Sarcoidosis

Huntington disease is one of a group of neurologic disorders caused by an increase in the number of repeats of the DNA trinucleotide, CAG, that encodes glutamine; thus, these disorders are characterized by expanded numbers of glutamine residues [*see 11:X Inherited Ataxias*].[87] Like the other trinucleotide repeat disorders, Huntington disease exhibits anticipation (a tendency toward earlier onset in successive generations), a preponderance of unstable repeats from the paternal chromosome, and a correlation between the number of repeats and the severity of disease and age of onset.[87]

Huntington disease is caused by the *HD* gene, an expanding and unstable polyglutamine repeat in the short arm of chromosome 4.[88] Normal persons have up to 34 CAG repeats, whereas nearly all patients with Huntington disease have more than 40 repeats. Individuals with 34 to 39 repeats are thought to have unstable and dynamic so-called premutations that may lead to higher numbers of repeats—and, hence, clinical disease—in their progeny.[87]

The *HD* gene encodes a protein named huntingtin that is widely distributed in neural and nonneural tissue. The role of this protein in the pathogenesis of the illness is unknown, but patients with Huntington disease, as well as experimental mice expressing the mutation, have intranuclear huntingtin-positive and ubiquitin-positive inclusions in the affected brain regions.[89] This has led to speculation that abnormalities in the intracellular degradation of these proteins mediate the process of apoptotic neuronal death in patients with Huntington disease.[90,91]

Clinical Features

A diagnosis of Huntington disease can be made on clinical grounds alone in patients who present with chorea and have a positive family history. Dementia and emotional symptoms (e.g., depression, irritability) may precede and typically overshadow the motor symptoms, accounting for the greatest disability and hardship. The clinical course can be as long as 20 years. In the early stages of the disease, physical examination usually reveals focal choreatic movements (e.g., increased blinking or grimacing) that progress and eventually involve multiple body parts.[92] The chorea typically peaks within 10 years and is gradually replaced by muscle restlessness, hypertonia and dystonia, and tremor or myoclonic jerks.

Other movement abnormalities in Huntington disease include bradykinesia and slow, saccadic eye movements. Gross motor coordination and gait become impaired, clumsiness increases, and patients move with a wide-based, slow gait and irregular, lurching steps. Fine motor coordination and, eventually, speech become severely affected. Swallowing abnormalities can lead to aspiration pneumonia. Patients progress to a nearly mute, akinetic state. In 6% to 10% of cases, Huntington disease may present as parkinsonian features rather than as chorea (Westphal variant). The Westphal variant typically presents early (i.e., onset occurs in persons younger than 20 years) and is more likely to exhibit paternal inheritance.

Laboratory Tests

The diagnosis of Huntington disease can be confirmed with genetic testing. For issues related to genetic counseling and presymptomatic testing, the reader is referred to a review of these important issues.[93] It is not necessary to test persons for whom there is genetic or pathologic confirmation of the disease in other family members. Ancillary diagnostic measures include MRI to look for selective atrophy of the caudate nucleus, a typical finding that may be hard to detect.

Treatment

Treatment of Huntington disease should involve a multidisciplinary team that can provide social, medical, neuropsychiatric, and genetic guidance to patients and families throughout the course of the illness. Symptomatic treatment can alleviate chorea, although this is not typically the most disabling aspect of the illness; indications to treat chorea include interference with activities of daily living and social embarrassment. Dopamine blockers are at best moderately effective, and they may aggravate the nonchoreatic movement abnormalities of Huntington disease, such as bradykinesia and dystonia. Atypical antipsychotic agents such as risperidone and olanzapine are better tolerated and may also help in controlling chorea. The treatment of depression in Huntington disease is similar to that in PD.

Experimental treatments include the use of glutamate antagonists (e.g., lamotrigine) as neuroprotective agents meant to block neuronal apoptosis.[94] A more novel strategy is inhibition of the protease caspase-1, with the intention of modulating the presumably abnormal intracellular degradation process that leads to the accumulation of intracellular inclusions.[90]

Table 7 Selected Drug- and Toxin-Induced Movement Disorders*

Chorea
- Antipsychotic neuroleptic drugs
- Antiparkinsonian drugs
- Noradrenergic stimulants
- Anabolic steroids
- Oral contraceptives
- Tricyclic antidepressants

Myoclonus
- Psychiatric medications
  - Selective serotonin reuptake inhibitors
  - Tricyclic antidepressants
  - Monoamine oxidase inhibitors
  - Lithium carbonate
  - Clozapine
  - Dopamine blockers (tardive syndrome)
  - Methaqualone
  - Buspirone
  - Benzodiazepine withdrawal
- Narcotics
  - Morphine and its derivatives
  - Fentanyl
- Toxins
  - Bismuth
  - Mercury
  - Methyl bromide
  - Strychnine
  - Marijuana
  - Aluminum
  - Tetraethyl lead
  - Oven cleaner
  - Tetanus toxoid
- Anticonvulsants
  - Phenytoin
  - Valproic acid
  - Carbamazepine
- Anesthetics
  - Etomidate
  - Enflurane
  - Isoflurane
  - Midazolam
- Cardiac medications
  - Calcium channel blockers
  - Antiarrhythmics (flecainide, propafenone)
- Antibacterial and antiviral agents
  - Penicillins
  - Monobactams
  - Isoniazid
  - Acyclovir
  - Vidarabine
- Miscellaneous
  - Dopamine agonists
  - Metoclopramide
  - Physostigmine
  - Antihistamines
  - Cimetidine

*Drug-induced parkinsonism, tremor, and dystonia are discussed in the text.

DYSTONIA

Dystonia is a term used to describe both a constellation of signs and a series of hyperkinetic disorders. Among movement disorders, dystonia is one of the more common and also one of the most frequently misdiagnosed and untreated. The worldwide prevalence is not certain because of underreporting, but taking all forms of dystonia into account, it probably exceeds 300 million, a prevalence equal to that of multiple sclerosis.[95]

Classification

The dystonias can be classified according to the age at onset, the region of the body involved, and the etiology. Using an etio-

Table 8 Differential Diagnosis of Myoclonus

Medical Causes of Myoclonus
- Metabolic disorders
  - Hyponatremia
  - Hypoglycemia
  - Nonketotic hyperglycemia
  - Hepatic failure
  - Renal failure
  - Dialysis disequilibrium syndrome
  - Mitochondrial defects
  - Multiple carboxylase deficiency
- Viral encephalopathies
  - Herpes simplex encephalitis
  - Arbovirus encephalitis
  - Human immunodeficiency virus
  - Encephalitis lethargica
  - Subacute sclerosing panencephalitis
  - Postinfectious encephalitis
- Malabsorption syndromes
  - Celiac disease
  - Whipple disease
- Paraneoplastic syndromes

Physical Encephalopathies
- Posthypoxia (Lance-Adams)
- Heatstroke
- Electric shock

Neurologic Causes of Myoclonus
- Focal/diffuse CNS damage
  - Stroke
  - Thalamotomy
  - Hypoxia (Lance-Adams)
  - Tumors
- Essential myoclonus
  - Hereditary (autosomal dominant)
  - Sporadic
  - Palatal myoclonus
- Epileptic myoclonus (childhood seizures without encephalopathy)
  - Epilepsia partialis continua
  - Idiopathic stimulus-sensitive myoclonus
  - Myoclonic absences in petit mal epilepsy
  - Childhood myoclonic epilepsies
- Progressive myoclonic epilepsy (seizures with encephalopathy; onset age variable)
  - Lennox-Gastaut syndrome
  - Baltic myoclonic epilepsy (Unverricht-Lundborg disease)
  - Lafora myoclonic epilepsy
  - Adult ceroid lipofuscinosis (Kuf disease)
  - Neuronal ceroid lipofuscinosis (Batten disease)
  - Storage diseases
    - Lipidoses
      - GM_2 gangliosidosis
      - Tay-Sachs disease
      - Krabbe disease
    - Sialidosis (cherry-red spot myoclonus)
- Defects of oxidative phosphorylation
  - Myoclonic epilepsy and myopathy with ragged red fibers
  - Mitochondrial encephalopathy lactic acidosis strokelike episodes
- Progressive myoclonic ataxias (prominent ataxia; onset age, encephalopathy, and seizures are variable)
  - Friedreich ataxia
  - Ataxia-telangiectasia
  - Dyssynergia cerebellaris progressiva
  - Spinocerebellar ataxias
  - Dentatorubral-pallidoluysian atrophy
- Basal ganglia degenerations
  - Wilson disease
  - Torsion dystonia
  - Hallervorden-Spatz disease
  - Huntington disease
  - Multiple system atrophy
  - Cortical basal ganglia degeneration
- Primary dementias
  - Creutzfeldt-Jakob disease
  - Alzheimer disease
  - Diffuse Lewy body disease

logic scheme similar to that used for PD, the dystonias may be divided into primary, secondary, and dystonia-plus syndromes and heredodegenerative disorders with dystonic manifestation.

Primary dystonias Primary dystonias include syndromes in which dystonia is the principal clinical manifestation of the disease. Although no pathology has been identified, the basal ganglia are strongly implicated. Fluorodeoxyglucose PET scans in patients with primary dystonias reveal increased metabolism in the GPi, the cerebellum, and the supplementary motor area. These abnormalities have been interpreted as representing increased (or abnormal) drive in the direct striatopallidal pathway that inhibits GPi. This results in decreased inhibition (or modulation) of thalamocortical input, which leads to overactivity in the frontal lobe planning centers (e.g., supplemental motor area, dorsolateral prefrontal cortex) and underactivity in the motor executive areas such as the primary motor cortex.[95]

The major primary dystonia is dystonia type 1 (DYT1), an autosomal dominant hereditary disorder that can present as either generalized or focal dystonia.[96] A high proportion of DYT1 occurs in Ashkenazi Jewish families, but the disorder is also found in non-Jewish families. The disease has a penetrance of about 30% and is caused by a gene located on chromosome 9q34. The *DYT1* gene codes for the protein torsin A and is adjacent to the gene *DQ1,* which encodes for the related protein torsin B.[96] Torsin A and torsin B form part of a larger group of adenosine triphosphatase (ATPase)–associated proteins (AAA family) that either have ATPase activity or that bind to adenosine triphosphate (ATP), forming oligomeric complexes with other proteins. These complexes are involved in a variety of processes, including cell signaling, folding and unfolding of other proteins, and recovery and protection from stress by penetration of degraded proteins.[96] How these proteins relate to dystonia itself remains unclear, but the role of these complexes in providing recovery and protection from stress opens the possibility that these genes confer susceptibility to a so-called second hit; such a two-stage process might account for the 30% penetrance of the gene and perhaps some of the secondary (e.g., posttraumatic) forms of dystonia.

Dystonia-plus syndromes Dystonia-plus syndromes refer to those in which the patient exhibits neurologic findings in addition to dystonia. Perhaps the most interesting and treatable of these is dopamine-responsive dystonia (DRD), which is dominantly inherited but is more common in women. DRD is associated with multiple mutations in the gene for guanine triphosphate cyclohydrolase I, the rate-limiting enzyme in the synthesis of the tyrosine hydroxylase cofactor tetrahydrobiopterin.[97] Tyrosine hydroxylase is the rate-limiting enzyme for dopamine synthesis. DRD typically presents in childhood, beginning in the legs and then spreading to the arms. Marked diurnal fluctuations are common. Some patients present later in life with parkinsonian symptoms instead of dystonia. The hallmarks of DRD are an excellent response to low doses of levodopa and, in many patients, slowly evolving features of PD. DRD may be misdiagnosed as athetoid cerebral palsy, spastic paraplegia, or parkinsonism. Although rare, DRD and its other phenotypic forms are so responsive to levodopa that a trial of levodopa is warranted in all suspected cases. DRD appears to be a purely biochemical disorder with no degenerative change in the brain. An interesting form of dystonia-plus syndrome is myoclonic dystonia, which has been linked to polymorphism in the D_2 dopamine receptors.[98]

Heredodegenerative dystonias The heredodegenerative dystonias (dystonias with demonstrable and progressive neuropathology) include DYT3, which is an X-linked form of dystonia-parkinsonism found in men in certain Philippine families; women carriers are mildly affected. The disease is sometimes called by its Filipino name, Lubag.[99] Other examples of heredodegenerative dystonias are rapid-onset dystonia parkinsonism,[100] dystonia-associated trinucleotide repeat disorders (e.g., Huntington disease), Machado-Joseph disease (spinocerebellar ataxia type 3 [SCA 3]), and dentatorubropallidoluysian atrophy (DRPLA) [*see 11:X Inherited Ataxias*]. A few metabolic disorders associated with prominent dystonia include Wilson disease, GM1 and GM2 gangliosidosis, glutaric acidemia, and neuroacanthocytosis. Mitochondrial disorders with dystonic manifestations include Leigh disease and Leber disease.

Secondary dystonias Secondary dystonias are caused largely by drugs, trauma, or other environmental factors. They include levodopa-induced dystonia, acute and tardive dystonia associated with dopamine receptor blockers, dystonia associated with cerebral palsy (athetoid cerebral palsy), cerebral trauma, cerebral hypoxia, and peripheral nerve injury. Dystonia can also be associated with infectious and postinfectious states and with toxic exposure to manganese, cyanide, and 3-nitropropionic acid.

Clinical Features

Dystonic signs include involuntary muscle contractions, which typically occur first with voluntary movement (action dystonia) and later at rest and which result in twisting of body parts and abnormal postures. Dystonia is sometimes accompanied by a coarse, irregular, jerking tremor (dystonic tremor) or by a typical postural tremor. Cocontraction of antagonist muscles is a fundamental feature of dystonia that distinguishes it from chorea, tics, and other dyskinesias. Dystonia is also associated with so-called overflow phenomena, which involve the abnormal spread of activation to muscles other than those required for the intended movement. The most common forms of dystonia are the focal dystonias, which may affect (1) the eyelids (blepharospasm), causing them to close involuntarily; (2) the neck and shoulders (cervical dystonia), causing the neck to twist to the side (torticollis), forward (anterocollis), or backward (retrocollis); (3) the lower face and jaw (oromandibular dystonia); and (4) the larynx (spasmodic dysphonia), causing the voice to have a strained and discontinuous quality as a result of involuntary closure of the vocal cords. Focal dystonia may affect the hand and forearm during the performance of specific activities, such as handwriting (writer's cramp), typing, or playing a musical instrument (musician's cramp), or during almost any other activity that involves repetitive actions of the hands (occupational dystonia). The focal dystonias that occur in adults are often misdiagnosed as psychiatric or orthopedic problems, as compared with generalized dystonia, which begins in childhood. In children, generalized dystonia begins as an action dystonia of the foot. Later, dystonia occurs at rest; eventually, it causes postural abnormalities as it spreads first ipsilaterally and then to the limbs contralateral to the initially affected foot.

Treatment

Treatment of dystonia is strictly symptomatic and consists of medical and surgical therapies. In general, high doses of anticholinergics, sometimes in combination with neuroleptics or

dopamine depletors, are used to treat generalized dystonia.[101] Stereotactic surgery (pallidotomy and thalamotomy) has been used successfully to treat medically refractory cases.[102] The best therapeutic outcomes in idiopathic torsion dystonia (especially DYT1) appear to be in patients treated with deep brain stimulation of the GPi; this procedure has been approved by the FDA for this purpose. The neurosurgery literature shows substantial response to deep brain stimulation in generalized dystonias—a response that is much greater than that achieved by medical management.[103] Early referral of these patients to a movement disorder specialist is indicated so that this intervention can be considered.

The focal dystonias generally respond poorly to drugs, but they respond dramatically to botulinum toxin injections of the affected muscle group. Botulinum toxin acts by blocking the release of acetylcholine at the neuromuscular junction, resulting in dose-dependent weakness, which alleviates the spasmodic contraction without producing paralysis. Repeat injections are required every 2 to 5 months.

WILSON DISEASE

Epidemiology and Etiology

Wilson disease, or hepatolenticular degeneration, is an autosomal recessive disorder of copper metabolism with a prevalence of one per 30,000 population.[104] Although relatively rare, it is clinically important because it is treatable and mimics other movement disorders. The gene for Wilson disease, localized in chromosome 13, encodes a 7.5 kb protein transcript that is highly expressed in the liver and brain.[105] The protein belongs to a class of ATP-dependent copper-transporting ATPases. Multiple mutations of the Wilson disease gene give rise to the same phenotype. Most victims are compound heterozygotes who have different mutations in each allele. This complicates the molecular diagnosis of Wilson disease and limits screening to family members of known patients.[106,107]

Pathogenesis

In Wilson disease, reduced hepatic incorporation of copper into ceruloplasmin and reduced biliary copper excretion eventually lead to exhaustion of hepatic storage sites; spillover of copper into plasma; and pathologic deposition of copper in the brain (primarily in the basal ganglia), cornea (producing Kayser-Fleischer rings), kidney (causing tubular dysfunction), bone marrow (causing anemia and thrombocytopenia), and musculoskeletal system (causing arthritis and osteoporosis).[104] Acute crises (acute encephalopathy with seizures, hemolytic crisis, and acute tubular damage) are caused by the sudden dumping of large quantities of copper into the bloodstream iatrogenically (see below) or after liver infarction or acute hepatitis.

Figure 7 **Kayser-Fleischer rings in a young boy with Wilson disease.**

Clinical Features

The age at presentation in Wilson disease ranges from 3 to 60 years, with a peak onset at around 16 years. In one large study, 54% of patients presented with neurologic manifestations, 31% presented with hepatic dysfunction, and as many as 33% had psychiatric manifestations.[104] Most patients who present with liver abnormalities are female and do so typically between 8 and 16 years of age; males present more commonly with neurologic manifestations. The presentation can vary from acute fulminant hepatic failure to low-grade insidious cirrhosis. Wilson disease may be the most common cause of chronic liver dysfunction in children; all children with that presentation should be investigated for the disorder.

Important hematologic manifestations of Wilson disease include hemolytic anemia, thrombocytopenia (found in 50% of all patients with hematologic presentations), and neutropenia (30% of all patients with hematologic presentations). Other systemic manifestations include pancreatic exocrine abnormalities, hypoparathyroidism, polyarthritis, renal stones, and cardiomyopathy from myocardial copper accumulation.

The neurologic manifestations of Wilson disease are myriad and include a variety of movement disorders, such as dystonia (65% of patients), rigidity or parkinsonism (52%), postural and gait abnormalities (42%), and tremor (32%). The most common neurologic presentation, however, is dysarthria (97%), which is sometimes accompanied by abnormal facial expressions (the classic risus sardonicus).

The pleomorphic psychiatric and behavioral manifestations of Wilson disease include irritability, impaired work performance, depression, and mood changes. Affective disorders that mimic bipolar illness and psychotic symptoms also occur. Cognitive problems may start with poor school performance and culminate in dementia. Given the extreme variability of the neuropsychiatric manifestations of Wilson disease, it is important to consider this diagnosis in virtually all patients with movement disorders that do not have a readily demonstrable etiology, especially younger patients who manifest psychiatric disturbances.

Laboratory Findings

In about 80% of patients with Wilson disease, the diagnosis can be made by demonstrating a decrease in serum ceruloplasmin (Wilson disease, 0 to 200 mg/L; normal, 200 to 400 mg/L). Patients with normal ceruloplasmin levels are presumed to be heterozygotes. The serum copper level (bound plus unbound) is also decreased (Wilson disease, 3 to 10 μmol/L; normal, 11 to 24 μmol/L). Measurement of 24-hour urinary copper excretion may be more sensitive than measurement of serum copper levels for detecting Wilson disease. In patients with Wilson disease, 24-hour urinary copper excretion is 100 to 1,000 μg/24 hr (normal, ≤ 40 μg/24 hr), but this result is also found in other disorders that produce cholestasis. When measurement of ceruloplasmin or copper is not conclusive, demonstration of increased hepatic copper content on liver biopsy is the definitive test (Wilson disease, 200 to 3,000 μg/g dry liver; normal, ≤ 50 μg/g dry liver).

Almost all patients who have neurologic involvement have the classic ophthalmologic findings of Kayser-Fleischer rings, or sunflower cataracts [*see Figure 7*]. Kayser-Fleischer rings represent copper deposits in the basement membrane of the cornea, the detection of which may require a slit-lamp examination. Neuroimaging studies reveal loss of brain volume, with ventricular dilatation in more than 95% of neurologically affected persons, as well as in some who are neuropsychiatrically intact. MRI shows a unique hyperintense signal on T_2-weighted images of the lenticular nucleus, as well as on images of the thalamus, midbrain pons, and dentate gyrus of patients with more advanced disease [*see Figure 5d*]. T_1-weighted images may reveal white-matter lesions.

Treatment

Treatment of Wilson disease has to be undertaken cautiously to prevent acute encephalopathy or hepatic toxicity induced by a rapid mobilization of copper. We favor obtaining an MRI before initiating treatment, even in asymptomatic patients. Treatment consists of lowering dietary copper and reducing copper absorption with zinc acetate or zinc sulfate (150 mg/day) or potassium sulfide (20 mg t.i.d.).[108] To mobilize tissue copper deposits, it is necessary to use copper chelation with penicillamine (1 to 3 g/day orally). Chelation therapy needs close monitoring for patients to achieve an initial 24-hour copper urinary excretion level of 1.2 to 2.0 g/day. Penicillamine therapy is poorly tolerated in as many as 30% of patients because of idiosyncratic allergic side effects, including autoimmune conditions. In contrast to penicillamine, zinc therapy is well tolerated. Zinc can increase plasma amylase, lipase, and alkaline phosphatase levels; reports of immunosuppressive effects are rare. In patients who cannot tolerate penicillamine or in those who worsen as therapy is initiated, alternative copper-chelating agents are trientine (with or without lower doses of penicillamine), dimercaprol, and cobalt chloride (now rarely used).[109] Other strategies to minimize tissue damage from copper deposition include free-radical scavengers such as mercaptodextran. When there is evidence of progressive disease despite optimal dietary and pharmacologic therapy or when hepatic failure occurs, autologous liver transplantation is the most definitive therapy.[110]

The neurologic symptoms of Wilson disease generally respond poorly to therapy. Anticholinergics may be given to treat dystonia and tremor; dopaminomimetics may be given to treat rigidity. Psychiatric symptoms (i.e., anxiety and depression) are treated with standard therapies. Improvement in neuropsychiatric and other symptoms may take months to as long as 2 years after initiation of chelation therapy.

TOURETTE SYNDROME

Etiology

Tourette syndrome is an autosomal dominant disorder for which sib pair studies have identified at least two regions in the genome with high probability (LOD scores > 2) of containing the gene or genes responsible for this complex illness.[111] Tourette syndrome has a broad range of clinical manifestations that is influenced by gender as well as variable penetrance. The diagnostic criteria include multiple motor and vocal tics that appear before age 21 and last longer than 1 year. The symptoms must be of sufficient severity to warrant a medical diagnosis, and the disturbance cannot be associated with other neurologic or drug-induced conditions. A family history is important and may include individuals affected by a single motor tic, obsessive-compulsive symptoms (OCS), and perhaps attention-deficit disorder (ADD). The male-to-female ratio for Tourette syndrome is more than 4:1.[112] Learning disabilities, sleep disorders, and a variety of poorly defined behavioral syndromes may also be present.[113]

Pathogenesis

The pathogenesis of Tourette syndrome is unknown, but clinical pharmacologic evidence and limited autopsy studies suggest that it may be mediated by hyperdopaminergic innervation of the corpus striatum. Morphometric studies using brain MRI scans and metabolic studies using PET scans suggest the presence of anatomic and functional abnormalities in cortico-striato-pallido-thalamic circuits that project to the prefrontal cortex and cingulate gyrus. Surgical interruption of these circuits (e.g., anterior tractotomy and cingulotomies) may be of value in treating OCS and, to a lesser extent, tics, in carefully selected cases.

A still undetermined subgroup of Tourette syndrome (and OCS) cases have been linked to a poststreptococcal syndrome associated with circulating antibodies that presumably cross-react with neurons in the striatum and cause dysfunction in these circuits. This syndrome forms part of a broader category of pediatric autoimmune neurologic disorders associated with streptococcal infections (PANDAS). The onset of symptoms is often temporally linked with a history of pharyngitis and tends to be more abrupt than in regular Tourette syndrome. Symptoms tend to fluctuate wildly. There is no associated carditis or nephritis. Successful treatment with plasma exchange has been reported, but this and other proposed treatments are still experimental.

Clinical Features

Tics, both motor and vocal, are a prominent feature of Tourette syndrome. A tic is a brief, rapid, repetitive, and seemingly purposeless stereotyped action that may involve a single or several muscle groups. Both motor and vocal tics can be simple (e.g., nose twitching, coughing, and grunting) or complex (self-mutilation and coprolalia). Tics can be associated with brief focal sensory experiences (sensory tics), which may precede, accompany, or follow the movements or vocalization. In general, tics are the least disabling aspect of Tourette syndrome and may not require treatment. During school years, ADD and its behavioral accompaniments (impulsivity and irritability) and learning deficits tend to be the most disabling and disruptive features. OCS begins during early adolescence and can be quite disabling. It responds less reliably to clomipramine and standard SSRIs than does obsessive-compulsive disorder without Tourette syndrome. Sleep disorders are frequent but poorly understood.

Treatment

The treatment of Tourette syndrome is challenging and should be undertaken by specialists. When the symptoms are complex (e.g., tics, OCS, and ADD), pediatricians and neurologists may need to work in concert with psychiatrists who can provide guidance and treatment of the behavioral symptoms. Tics generally respond to dopamine blockers (e.g., fluphenazine, haloperidol, pimozide, olanzapine).[114] Some children may be particularly intolerant of the side effects of these drugs, which range from acute dystonia and motor restlessness (akathisia) to daytime sedation and school phobias. The atypical neuroleptic risperidone may also be effective. Other treatments for tics include clonidine (0.1 to 0.4 mg/day, either as a pill or as a transdermal patch) and clonazepam (0.5 to 4.0 mg/day).

Tremor

The term tremor describes a number of unrelated movements that share one major characteristic: oscillation of a limb or body part. Parkinsonian rest tremor and cerebellar tremor are examples.

ENHANCED PHYSIOLOGIC TREMOR

Physiologic tremor is typically not clinically apparent, except when exaggerated by stress, anxiety, or stimulants. Stage fright and other forms of situational anxiety are well-recognized and readily treatable examples of stress-enhanced physiologic tremor. Other causes of endogenous epinephrine release that may enhance physiologic tremor are pheochromocytoma and hypoglycemia. Drugs that may enhance physiologic tremor include beta-adrenergic agonists (e.g., exogenous epinephrine, isoproterenol, terbutaline, and theophylline), lithium, tricyclic antidepressants, stimulants, valproate, steroids, thyroid hormones, and caffeine. Withdrawal of certain drugs, such as alcohol, opiates, and benzodiazepines, and muscle fatigue from excessive exercise can cause enhanced physiologic tremor.

Treatment

Treatment includes eliminating or reducing tremor-enhancing drugs when possible, using beta-adrenergic blockers, controlling anxiety, and treating any associated endocrinopathy. Situational anxiety can be controlled by taking propranolol (20 to 60 mg) 1 hour before the triggering event or situation.

ESSENTIAL TREMOR

Essential tremor has a frequency of 6 to 8 Hz, is of central origin, and commonly follows an autosomal dominant pattern of inheritance.[115] Unlike patients with PD, patients with essential tremor may lack other parkinsonian features and may exhibit isolated head titubation and voice tremor. The latter gives speech a quivering, shaky quality. Essential tremor is exacerbated by the same factors that enhance physiologic tremor.

Treatment

Characteristically, essential tremor responds rapidly, albeit briefly, to alcohol (as blood alcohol level falls, however, the rebound effect may worsen the tremor). More practically, it also responds to beta-adrenergic blockers. Propranolol is usually an effective long-term treatment; other helpful beta blockers include metoprolol, timolol, atenolol, and sotalol. Primidone can be effective at doses of 50 to 500 mg/day, which are lower than those required for anticonvulsant therapy. Other drugs that may be beneficial include benzodiazepines (especially clonazepam), phenobarbital, and clonidine. Anticonvulsants such as gabapentin and topiramate have also proved to be helpful. In particularly refractory cases, clozapine can be considered. Stereotactic neurosurgery (ventrolateral thalamotomy or deep brain stimulation) is very effective in severe, medically refractory essential tremor. It is less effective in cerebellar tremor.

MYOCLONUS

Clinical Features

Myoclonus is a sudden, brief, shocklike, involuntary jerk. Myoclonic jerks may be considered fragments of epilepsy; they have electroencephalographic characteristics that are similar to focal epileptic discharges. Positive myoclonus consists of an active muscle contraction; negative myoclonus consists of a sudden lapse in contraction, which is clinically indistinguishable from asterixis. Specialized electrophysiologic testing can localize myoclonic discharges to the somatosensory cortex, the brain stem (the reticular activating system), and, in rare instances, the spinal cord. Like seizures, myoclonic discharges represent a nonspecific sign of CNS irritation with a broad differential diagnosis [*see Table 8*].[116]

Myoclonic jerks can be focal, segmental, or generalized. When focal, they suggest a focal pathology, which can range from epilepsy to focal encephalitis [*see Table 8*]. They can be spontaneous, stimulus sensitive (reflex), or related to ongoing activities (action). When generalized, they can be associated with epilepsy or with a host of static and progressive encephalopathies. To narrow the differential diagnosis, it is important to look for signs of encephalopathy, dementia, retinal pathology, hearing loss, myopathy, neuropathy, and ataxia.

Differential Diagnosis

In the differential diagnosis of myoclonus, it is important to first consider toxic etiologies and intercurrent medical illness before considering a primary disorder of the CNS.[116,117] An important element of the differential diagnosis is whether the myoclonus is epileptic or nonepileptic.[118,119] The age at onset is also extremely important, because the more common progressive forms of epilepsy that result from degenerative processes tend to occur in the pediatric age group.

Laboratory Tests

Basic laboratory screening should include a routine hemogram, blood chemistries, and a toxicologic screen. Brain imaging and electroencephalography are indicated when the cause of the myoclonus is not immediately apparent. When clinically indicated, specialized metabolic studies should be considered to rule out systemic inflammatory disorders, endocrinopathies, disorders of copper metabolism (e.g., Wilson disease and Menke disease), selected enzyme deficiencies, and lysosomal storage disorders [*see Table 8*]. A subgroup of these disorders, such as some disorders of mitochondrial oxidative phosphorylation (see below) and some of the SCAs, can now be diagnosed with genetic tests.

Treatment

Treatment of myoclonus is strictly symptomatic. Commonly used drugs include clonazepam (2 to 12 mg/day), sodium valproate (600 to 3,000 mg/day), primidone (500 to 1,500 mg/day), and, in Europe, piracetam (6 to 20 mg/day). SSRIs and 5-hydroxytryptophan (with carbidopa) may help specific forms of myoclonus (reticular reflex myoclonus) but tend to aggravate most other forms of myoclonus. Another special case is palatal myoclonus, which responds to trihexyphenidyl (6 mg/day). Treatment of epileptic syndromes associated with the above myoclonic disorders is beyond the scope of this chapter.

MYOCLONUS IN GENERAL MEDICAL PRACTICE

In general medical practice, the most common form of myoclonus results from metabolic disorders, in which negative myoclonus, or asterixis, tends to dominate the clinical picture [*see Table 8*]. Etiologies of myoclonus also include viral encephalitis, which typically presents as positive and negative myoclonus. Examples include encephalitides associated with herpes simplex virus and arbovirus, as well as those associated with postinfectious syndromes (e.g., subacute sclerosing panencephalitis and encephalitis lethargica).

Other common forms of myoclonus observed in general medical practice are drug-induced myoclonus and myoclonus sec-

ondary to drug withdrawal. Drugs that induce myoclonus include lithium carbonate, tricyclic antidepressants, and SSRIs. Coadministration of SSRIs and MAO-A or MAO-AB inhibitors can cause a hyperserotoninergic syndrome that is typically heralded by myoclonus and changes in mental status. Antimicrobial agents occasionally associated with myoclonus include penicillins and cephalosporins [*see Table 7*]. In anesthesia, ultra–short-acting nonbarbiturate hypnotics (e.g., etomidate) can also cause myoclonus. Patients with PD who are taking levodopa occasionally develop myoclonus.

Overdose or intoxication with anticonvulsants, antihistamines, or hypnosedatives can cause myoclonus, with or without generalized seizures. Other drugs include antineoplastics, such as chlorambucil, NSAIDs in patients with renal failure, and bismuth. Extended exposures to the following toxins are also associated with myoclonus: methyl bromide, organic mercury, tetraethyl lead (gasoline), strychnine, and DDT. Withdrawal from alcohol, benzodiazepines, or opiates is also commonly associated with myoclonus. Finally, myoclonus can be a sequela of such global cerebral insults as trauma, hypoxia-ischemia (post-hypoxic myoclonus), heatstroke, and electrocution.[120]

Dementing disorders associated with myoclonus include prion-associated disorders, such as Creutzfeldt-Jakob disease. In addition, a small percentage of patients with Alzheimer disease (10% to 15%) and a larger percentage of patients with diffuse Lewy body disease experience myoclonus. In these disorders, myoclonus may evolve from a focal to a more generalized form.

Several additional disorders represent uncommon primary genetic disorders with complex associated symptom clusters [*see Table 8*]. Beyond controlling myoclonic jerks and seizures, therapy for these conditions is very limited.

Drug-Induced Movement Disorders

Drug-induced movement disorders are an important group of iatrogenic and mostly reversible conditions that are occasionally encountered in general clinical practice. The frequency of drug-induced movement disorders depends on the nature of the compound, the age of the affected person, and other risk factors.

Most drug-related movement disorders are associated with agents that directly or indirectly affect central dopaminergic transmission. These include CNS stimulants, the dopamine precursor levodopa, direct-acting dopamine agonists, and central dopamine receptor blockers. Movement disorders produced by these compounds can be acute; subacute; or delayed, as in the case of tardive dyskinesia or tardive dystonia. The mechanisms of acute and subacute movement disorders appear to be idiosyncratic extensions of the intended action of the compound. The mechanism of tardive syndromes is more obscure.

Approximately one third of patients with tardive dyskinesia experience remission within 3 months of stopping neuroleptic therapy. In most patients, the movements gradually remit within 5 years. Patients at risk for permanent tardive dyskinesia include the elderly, the edentulous, and those with underlying organic cerebral dysfunction. Patients with affective illnesses appear more likely to develop tardive dyskinesia than patients with schizophrenia.

ACUTE DRUG-INDUCED MOVEMENT DISORDERS

Acute dystonia may be provoked by central dopamine blockers such as lithium, calcium channel blockers, and SSRIs. Young men are most vulnerable to these reactions. Acute dystonia can be readily treated with the parenteral administration of anticholinergics (benztropine or diphenhydramine) or benzodiazepines (lorazepam or diazepam). Other acute drug-induced movement disorders include dyskinesias; stereotyped behaviors in response to neuroleptics; and tics, which may occur in response to such CNS stimulants as methylphenidate, dextroamphetamine, and pemoline.

SUBACUTE DRUG-INDUCED MOVEMENT DISORDERS

Probably the most common subacute drug-induced movement disorder is neuroleptic-induced akathisia.[119] Akathisia is a state of motor restlessness that involves an irresistible need to move. Movement tends to alleviate the symptoms temporarily. The restlessness is thought to be mediated by mesolimbic dopamine receptor blockade. Symptomatically, this may be related to restless legs syndrome [*see 11:XIII Disorders of Sleep*]. Therapy consists of removing the offending agent. When this is not possible, symptoms can be alleviated with benzodiazepines, anticholinergics, beta blockers, or, in some cases, dopamine agonists.

TARDIVE MOVEMENT DISORDERS

Clinical Features

Tardive movement disorders are primarily caused by long-term exposure (longer than 3 months) to central dopamine blockers.[121] The movements are most often choreatic and are referred to as tardive dyskinesia. Initially, the cranial musculature is affected (in particular, the mouth, lips, and tongue); later, the trunk and limbs are affected. In a fully developed case, a person may experience head nodding, pelvic rocking, and fine movements of the fingers and toes. In rare instances, tardive dyskinesia can affect the diaphragm and cause respiratory distress.

In tardive dystonia, dystonic contractions are more often axial than appendicular. Other tardive syndromes include tardive akathisia, tardive tics, and even tardive tremor.[122]

Treatment

The best treatment of tardive dyskinesia is prevention. Neuroleptics should be used judiciously, for as short a period as possible. Atypical neuroleptics pose a significantly lower risk of causing tardive dyskinesia than do conventional neuroleptics, for which the risk ranges from 13% to 20%. The lower risk associated with atypical neuroleptics may be attributed to their higher affinity for mesolimbic D_4 and D_3 dopamine receptors rather than striatal D_2 dopamine receptors. Atypical neuroleptics include clozapine, risperidone, olanzapine, quetiapine, and aripiprazole.

When withdrawal of the agent that causes tardive dyskinesia is not possible, replacing traditional neuroleptics with atypical neuroleptics should be considered.[122] If the patient is also taking stimulants and anticholinergics, eliminating them may alleviate dyskinesias.

Reserpine is the treatment of choice for choreatic tardive dyskinesia. The initial dosage of reserpine should be 0.125 mg/day; the dosage can be increased slowly up to 6 mg/day, as needed. Elderly patients are less likely to tolerate reserpine because of orthostatic hypotension. Long-term use of reserpine is associated with an approximate 15% incidence of depression.

Another treatment strategy consists of stimulating γ-aminobutyric acid (GABA) release with baclofen (40 to 80 mg/day),

clonazepam (1 to 8 mg/day), or valproic acid (1 to 3 g/day). GABAergic strategies are particularly helpful in patients with tardive dystonia, who can also benefit from anticholinergic therapy and botulinum toxin injections that target the muscles most affected. Buspirone (40 to 60 mg/day) has proved helpful in some cases. Vitamin E was not helpful in tardive dyskinesia in a multicenter, double-blind, placebo-controlled study.[122]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XVI ACUTE VIRAL CENTRAL NERVOUS SYSTEM DISEASES

Donald H. Gilden, m.d.

Viral infections of the central nervous system produce aseptic meningitis, encephalitis, and sometimes vasculopathy. Although nearly all the viruses discussed in this chapter are capable of producing meningitis and encephalitis, each virus typically causes one of these diseases. Viruses that most often cause acute aseptic meningitis include the enteroviruses (i.e., coxsackievirus, echovirus, and nonparalytic polioviruses) and the influenza and parainfluenza viruses (especially mumps virus). Herpes simplex virus type 2 (HSV-2) and, rarely, HSV type 1 (HSV-1) cause recurrent meningitis. Viruses that primarily produce acute encephalitis include the herpesviruses (i.e., HSV-1, varicella-zoster virus [VZV], and Epstein-Barr virus [EBV]), the togaviruses (i.e., St. Louis encephalitis virus, the California encephalitis virus group, the equine encephalitis viruses, Powassan virus, and Colorado tick fever virus), the arenaviruses (lymphocytic choriomeningitis [LCM] virus), and the adenoviruses.

The time of year that an infection manifests itself may be a clue for identifying the causative virus [*see Table 1*]. For example, enterovirus infections occur in the summer and account for most cases of aseptic meningitis. Mumps and other parainfluenza virus infections, as well as influenza virus infection, most often present in the winter, although they may occur at any time of year. Togavirus infection occurs in the late summer and autumn (the mosquito and tick season); LCM infection presents in the early winter (when mice come indoors); and chickenpox (varicella) occurs predominantly in the spring. All HSV infections occur year-round.

Approach to Viral Aseptic Meningitis and Encephalitis

DIAGNOSIS

Clinical Features

Aseptic meningitis is associated with headache, fever, and stiff neck. Irritability and alterations in state of consciousness may occur, although these symptoms are more common in encephalitis. Patients may suffer sore throat, photophobia, abdominal discomfort, focal paresthesias, diplopia, and nausea and vomiting. An erythematous maculopapular rash may result from enterovirus (echovirus or coxsackievirus) infection; a vesicular eruption suggests coxsackievirus or a herpesvirus infection. Stretching the irritated nerve roots may elicit pain. For example, in the recumbent patient, the Kernig sign is pain produced by attempts to extend the leg after flexion of the thigh. The Brudzinski sign is flexion of the thighs when the head is passively flexed onto the chest. These signs of meningeal irritation appear more often in nonviral and bacterial meningitis, however.

Clinical symptoms and signs of viral encephalitis include insomnia, lethargy, mental status changes, seizures, aphasia, and hemiplegia. Focal deficit is most common in HSV and VZV encephalitis and less common in cytomegalovirus (CMV) and EBV encephalitis. Brain imaging is usually normal but may reveal effacement [*see Figure 1a*] and an increase in water content [*see Figure 1b*], which is indicative of brain swelling.

Diagnostic Tests

Clinical symptoms and signs alone usually cannot establish a specific diagnosis of viral meningitis or encephalitis, and nonviral causes of meningitis and encephalitis can be confused clinically with viral infections [*see Table 2*].

Careful examination of the cerebrospinal fluid is the mainstay of diagnosis of viral meningitis or encephalitis. Characteristically, the CSF is clear and features a predominantly mononuclear pleocytosis and normal glucose content. Initially, the CSF may contain polymorphonuclear leukocytes. The CSF cell count is usually below 100/mm^3; it may be higher with enteroviral infections, however, and the CSF may contain thousands of mononuclear cells after mumps and LCM virus infections. The CSF protein concentration is usually normal or mildly elevated. Bacteria are not found on Gram stain, and CSF cultures are sterile. A mild depression in the CSF glucose content develops in approximately one third of patients with meningitis caused by mumps or LCM virus; this drop in CSF glucose level occurs less often after enterovirus infection. In rare instances, the CSF glucose content is depressed in aseptic meningitis caused by HSV or VZV.

Most important is that a mononuclear pleocytosis with hypoglycorrhachia (low CSF glucose content) occurs in some nonviral forms of meningitis and requires prompt treatment. Such nonviral forms include tuberculous (TB) or fungal menin-

Table 1 Important Clinical Features of the Major Virus Infections of the Nervous System

Virus	*Seasons*	*Major Acute Presentation*	*Brain Imaging*
Herpes simplex virus type 1	All	Encephalitis	Medial temporal lobe
Varicella-zoster virus	All*	Localized herpes zoster, postherpetic neuralgia, encephalitis with focal deficit	Multifocal pale and hemorrhagic infarction
Enterovirus	Summer	Aseptic meningitis	Normal; possible effacement
HIV	All	Aseptic meningitis, subacute encephalitis	Atrophy; diffuse white matter attenuation
Arthropod-borne encephalitis	Summer and fall	Encephalitis	Normal; possible effacement

*Although chickenpox (varicella) occurs mostly in the spring, zoster develops at any time of the year.

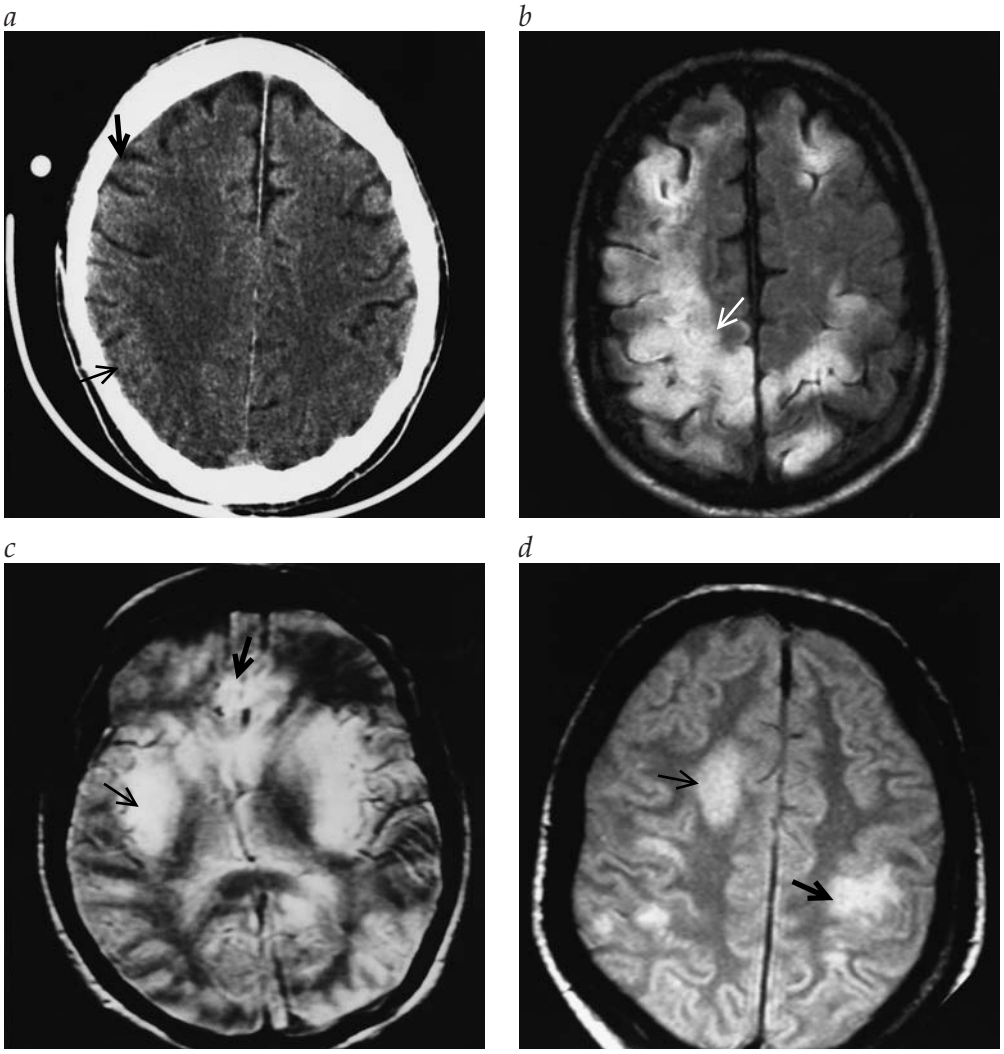

Figure 1 **(*a*) CT changes that occur in most viral encephalitides. Computed tomography scan of the brain demonstrates relative effacement of sulci posteriorly in both hemispheres (thin arrow), compared with normal sulcal spaces anteriorly (thick arrow). (*b*) MRI changes that occur in most viral encephalitides. T_2-weighted inversion recovery (fluid-attenuated inversion recovery [FLAIR]) MRI brain scan of the same patient demonstrates areas of increased signal in both hemispheres, with the increased signal being greater on the right and even more so posteriorly (arrow), reflecting increased water content in mildly swollen brain. (*c*) Herpes simplex virus encephalitis. T_2-weighted MRI brain scan demonstrates bilateral involvement of temporal lobes. The exaggerated signal does not extend beyond the insular cortex (thin arrow) but does involve the cingulate gyrus (thick arrow). (*d*) Varicella-zoster virus encephalitis. Proton-density brain MRI scan shows multiple areas of infarction in both hemispheres, particularly involving white matter (thin arrow) and extending to gray-white–matter junctions (thick arrow).**

gitis and carcinomatous or lymphomatous meningitis; those CSF findings also occur in about 30% of cases of sarcoid meningitis. Furthermore, viral aseptic meningitis may be mimicked by granulomatous meningitis (i.e., TB, fungal, sarcoid, and toxoplasmic meningitides), leptospiral infection (e.g., Lyme disease), *Brucella* infection, *Mycoplasma* pneumonia, sulfonamide or nonsteroidal anti-inflammatory drug toxicity, and various vasculitides.

Laboratory methods that are used to identify the causative agent of viral meningitis and encephalitis include polymerase chain reaction (PCR) detection of viral RNA or DNA in the CSF, the culturing of virus from the CSF, the detection of antigen or antibody in the CSF, serologic tests (e.g., enzyme immunoassays and Western blot assay), and brain biopsy [*see Table 3*].

NONSPECIFIC TREATMENT OF VIRAL CNS INFECTIONS

Bed rest is indicated for patients with viral CNS infection. If a patient has recently traveled to an area endemic for highly contagious agents that are spread by direct patient contact (e.g., Ebola virus), isolation procedures should be followed until the cause of the illness is established. Most other agents that cause viral meningitis and encephalitis present no special dangers to medical personnel, provided antiviral precautions for blood products are followed, or to others. The patient's airway can be protected by repeated suctioning and, if necessary, by endotracheal intubation or tracheostomy. Nutritional support is important, but only conscious patients with intact brain stem function should receive oral feedings. All others should be fed by parenteral or nasogastric techniques. Patients should be monitored closely for

secondary infections, especially of the urinary tract and lungs. Passive range-of-motion exercises and use of foot boards or Styrofoam boots will minimize contractures. Frequent turning decreases the risk of bedsores. Patients with encephalitis may develop the syndrome of inappropriate antidiuretic hormone secretion and become water intoxicated, which can lead to deepening coma and, sometimes, seizures. Serum and urine electrolyte levels and urine output should be monitored frequently. Encephalitis is treated by restricting fluid intake and, in rare instances, with hypertonic saline solution. Headache is a frequent problem and can be treated with acetaminophen, ibuprofen, and codeine; occasionally, meperidine (50 mg every 4 to 5 hours) is used. Most viruses are thermolabile, and modest temperature elevation may serve as a natural defense mechanism; but fever can be treated with acetaminophen if necessary. Specific viruses that cause aseptic meningitis, encephalitis, or both may also require particular treatment regimens.

Table 3 Viral Diagnosis of Aseptic Meningitis Syndrome and Encephalitis

Virus	*Tissue Culture*	*Antigen/Antibody Detection in CSF**	*PCR*

Viruses That Cause Meningitis or Encephalitis

ENTEROVIRUSES

Enteroviruses are the most common cause of viral aseptic meningitis. Most, but not all, cases of enterovirus infection occur in children. Epidemics are common. The Picornaviridae family comprises nearly 70 distinct serotypes. Enterovirus infections are acquired primarily by the fecal-oral route and occasionally by the respiratory route. Fever is often biphasic. The first phase is associated with constitutional and gastroenterologic symptoms. After resolution of these symptoms, the fever may reappear with other signs and symptoms of meningeal irritation. Almost all patients with enterovirus meningitis are immunocompetent. In agammaglobulinemic persons, however, enterovirus infection may result in a chronic meningitis or meningoencephalitis that lasts years, and the outcome is often fatal.[1] The CSF contains between 50 and 1,000 cells, which are predominantly mononuclear. Elevated CSF protein levels are common. The CSF glucose content is usually normal, but hypoglycorrhachia has been reported.[2] The optimal time to culture virus from the CSF is 8 to 18 days after infection; PCR amplification of the conserved region of enterovirus is possible.[3] Enterovirus antibodies appear in the CSF at the end of the second week and persist longer than 1 month.

In rare instances, enteroviruses cause focal encephalitis. In addition, enterovirus infections have been associated with ataxia, opsoclonus and myoclonus,[4] and parkinsonism. In the 1998 enterovirus 71 epidemic in Taiwan, the main neurologic complication was rhombencephalitis. Myoclonic jerks were the most common initial symptoms, and magnetic resonance imaging usually showed evidence of brain stem involvement.[5] Enteroviral infections may lead to myelitis and, occasionally, neuropathy (e.g., cranial nerve palsies). Since the eradication of poliovirus in Brazil, enterovirus 71 has emerged as a cause of persistent flaccid paralysis[6]; acute pulmonary edema is common in enterovirus 71 encephalomyelitis.[7] Chronic progressive echovirus and coxsackievirus meningoencephalitides in hypogammaglobulinemic and agammaglobulinemic persons have been treated successfully with immunoglobulin.[8]

Table 2 Nonviral Causes of Meningitis and Encephalitis

Behçet syndrome
Brucella infection

Syphilis
Systemic lupus erythematosus
Toxoplasmosis
Tuberculosis
Uveomeningoencephalitis (Vogt-Koyanagi-Harada syndrome)†
Whipple disease
Sulfonamides and nonsteroidal anti-inflammatory drugs‡

*Many cases are found to be herpesvirus infections when studied by polymerase chain reaction.
†This may be viral if not autoimmune.
‡These agents mimic granulomatous meningitis.

POLIOVIRUS

Although immunization has nearly eradicated encephalomyelitis caused by type 1 poliovirus, a case of encephalomyelitis with oral-facial dyskinesias and quadriplegia was attributed to type 3 poliovirus on the basis of positive stool cultures and high neutralizing serum titers.[9]

In the past, immunization against polio was accomplished with an oral vaccine, which contained attenuated live virus. Rare reports of oral vaccine–associated polio led to a recommendation by the Advisory Committee on Immunization Practices that as of January 1, 2000, only inactivated poliovirus vaccine (IPV) should be used for routine childhood polio vaccination in the United States. The current schedule involves a total of four doses of IPV: the first two doses are administered at 2 months and 4 months of age, the third dose is administered at 6 to 18 months of age, and the final dose is administered at 4 to 6 years of age.[10]

MUMPS

Aseptic meningitis is a common complication of mumps virus infection. Widespread vaccination against mumps has dramatically reduced the incidence of mumps and, consequently, of mumps meningitis. Mumps vaccine contains attenuated virus, however, and outbreaks of mumps meningitis have been traced to the use of incompletely attenuated mumps virus strains.

Mumps virus is a paramyxovirus that is transmitted by respiratory droplets. After the initial mucosal infection, viremia can lead to involvement of many organs, including the heart and, in particular, the glands. The association of aseptic meningitis with parotitis, pancreatitis (abdominal pain and increased serum amylase levels), or oophoritis (abdominal pain and ovarian tenderness on pelvic examination) is a clue that mumps virus is the causative agent. One study revealed that aseptic meningitis may develop in as many as 23% of patients with mumps, whereas encephalitis occurs in only one in 6,000 cases. Months of persistent pleocytosis[11] and a low CSF glucose content or chronic encephalomyelitis[12] may follow mumps meningitis. Mumps meningoencephalitis is rarely fatal. Because mumps virus replicates in ependymal cells, aqueductal stenosis and hydrocephalus may ensue months to years after an otherwise benign case of aseptic meningitis.

INFLUENZA VIRUS

Influenza is another myxovirus that causes neurologic disease. Acute encephalitis develops during the height of influenza epidemics. Mental and motor deficits (including ataxia) and a CSF lymphocytic pleocytosis, in association with rising complement-fixing and hemagglutination-inhibiting antibody titers to influenza virus, provide presumptive evidence of influenza encephalitis. In seven patients with CNS disease who had recently been infected with influenza virus, PCR assay of the CSF for influenza virus was helpful in making the diagnosis.[13] During the winter of 1998 to 1999, an outbreak of encephalitis/encephalopathy in Japan was associated with influenza. Of 202 cases analyzed, 148 were confirmed virologically.[14] Seizures were the most frequent presenting feature; mental status changes were common. Many patients experienced multiple-organ failure; the mortality was 31.8%. Thrombocytopenia and severely elevated transaminase levels indicated a poor prognosis.

NIPAH VIRUS

Nipah virus is a paramyxovirus that is found in the respiratory tract of Malaysian pigs and that can cause human disease [*see 7:XXXI Viral Zoonoses*]. Outbreaks of encephalitis from Nipah virus have occurred in Malaysia and Singapore.[15]

HERPES SIMPLEX VIRUS TYPE 2

HSV-2 Aseptic Meningitis

HSV-2 aseptic meningitis is the main neurologic complication of HSV-2 infection. HSV-2 causes genital herpes. In the United States, HSV-2 is the third most common cause of aseptic meningitis, accounting for approximately 5% of all cases. Unlike viral meningitides that have a seasonal association, HSV-2 meningitis occurs at any time of year. The typical symptoms and signs are headache, fever, stiff neck, and a marked lymphocytic pleocytosis of the CSF. Meningitis may be preceded by genital or pelvic pain, and the astute clinician who suspects HSV-2 meningitis will ask about recent symptoms of pelvic inflammatory disease or penile lesions. The workup for suspected HSV-2 meningitis should include a careful search for vesicular lesions over the external genitalia and a pelvic examination for lesions in the vagina or on the cervix. The cause of aseptic meningitis in one patient with recurrent dermatomal skin lesions was shown to be HSV-2.[16] PCR has also revealed that the primary agent causing benign recurrent lymphocytic meningitis is HSV-2.[17] Occasionally, HSV-1 is the culprit, as evidenced by the detection by PCR of HSV-1 DNA in the CSF of patients with benign recurrent lymphocytic meningitis.[18] HSV-2 meningitis is self-limited; antiviral treatment is not required.

HSV-2 Encephalitis

HSV-2 encephalitis is a rare disease; it occurs most often in newborns and, in rare instances, in immunocompromised adults. In both of these populations, CNS infection by HSV-2 is diffuse, unlike the focal medial-temporal and orbital-frontal lesions observed in cases of HSV-1 infection. Nevertheless, seizures, alterations in state of consciousness, and focal neurologic deficits—common clinical features of HSV-1 encephalitis—also characterize HSV-2 encephalitis. AIDS predisposes a person to HSV-2 encephalitis, which may occur in association with CNS infection by such other opportunistic agents as cytomegalovirus. HSV-2 encephalitis is treated with 15 to 30 mg/kg/day of acyclovir. After 10 to 14 days of intravenous acyclovir treatment, AIDS patients with HSV encephalitis may require indefinite maintenance on famciclovir or valacyclovir to prevent further reactivation of the disease.

HERPES SIMPLEX VIRUS TYPE 1

HSV-1 Encephalitis

Unlike most viral encephalitides, HSV-1 encephalitis is focal. HSV replication in the medial temporal lobe and orbital surface of the frontal lobe, with accompanying inflammation, produces the characteristic clinical picture.

Clinical features Fever, headache, lethargy, irritability, and confusion are typical. Seizures (major motor, complex partial, focal, and even absence attacks) affect approximately 40% of patients. If the dominant temporal lobe is involved, aphasia and focal motor or sensory deficits develop. Progressive hemorrhagic necrosis and temporal lobe edema may lead to uncal herniation, the most common features of which are tachycardia, hyperventilation, flexor (and later extensor) posturing, and a dilated pupil (usually on the side of the herniated temporal lobe).

Because HSV infection becomes latent and periodically reactivates to produce recurrent herpes labialis, the misconception exists that HSV encephalitis is usually protracted or chronic. Although survivors of HSV encephalitis may have a permanent seizure disorder, mental changes, aphasia, or motor deficit, the onset of neurologic disease is usually acute or subacute, as in other viral encephalitides, and early treatment is crucial to a favorable outcome. Before acyclovir became available for treatment, approximately two thirds of patients with HSV encephalitis died.

CSF findings The CSF is usually abnormal in HSV encephalitis. The CSF opening pressure is often elevated and may be very high if there is brain swelling and impending temporal lobe herniation. CSF examination is usually performed in the first few days of illness, before significant brain swelling develops, to decrease the potential for herniation after lumbar puncture. The

electroencephalogram and imaging studies may demonstrate features highly suggestive of HSV encephalitis, often obviating subsequent lumbar punctures. CSF pleocytosis is observed in more than 90% of patients, although its absence at initial evaluation does not rule out HSV encephalitis. The CSF cell count ranges from 4 to 755/mm^3, and more than 200/mm^3 may be present weeks after the onset of disease. The predominant cell type is mononuclear. Although red blood cells (RBCs) are unusual in other viral encephalitides, in HSV encephalitis they are often present in the CSF, which may also be xanthochromic; this presumably reflects the hemorrhagic nature of brain lesions. Instead of attributing the presence of RBCs in CSF to a so-called traumatic tap, the astute clinician may use this finding to support the presumptive diagnosis of HSV encephalitis.

The majority of patients with HSV encephalitis have elevated CSF protein. In rare instances, hypoglycorrhachia occurs. Increased levels of antibody to HSV, suggestive of recent infection, may be found in serum and CSF; increased CSF-to-serum ratios of anti-HSV antibody may help in making the diagnosis of HSV encephalitis. Unfortunately, increased antibody titers are not usually detected until 2 weeks or longer after the onset of disease; thus, their practical value lies more in retrospective presumptive diagnosis than in identifying acute encephalitis. Although HSV can often be isolated from cerebral biopsy or autopsy material, the isolation of HSV from CSF during acute disease is unusual. PCR detection of HSV-1 DNA in the CSF is both sensitive and specific and has become the gold standard in suspected cases of HSV encephalitis.[19] Nonetheless, clinicians should be aware that PCR may be negative for HSV in the first few days of illness with HSV encephalitis.[20]

Electroencephalography Early in the course of the disease, background disorganization with generalized or focal slowing occurs, predominantly over the involved temporal region. Within days, widespread, periodic, stereotyped sharp-wave and slow-wave complexes develop, usually at regular intervals of 2 to 3 seconds.[21] Bilateral periodic complexes appear if both sides of the brain are involved. Although these features can be seen in other CNS disorders (e.g., tumor, abscess, syphilis, infarct), their presence in the clinical setting of fever and rapidly progressive neurologic disease provides strong presumptive evidence for HSV encephalitis.

Imaging studies Computed tomographic scanning shows hypodense lesions involving the medial temporal regions. An important diagnostic clue is a sharp transition from the hypodense temporal lesion to the normal basal ganglia.[22] Edema and mass effect occur in 80% of cases, and contrast enhancement appears in more than 50% of cases.

MRI reveals a decrease in T_1 and an increase in T_2 signal [*see Figure 1c*], and the signal abnormality includes a larger area of brain than is usually found with CT scanning. Unlike with CT scanning, MRI of the temporal lobes is not subject to artifact from the petrous and sphenoid bones, which often obscure the temporal fossa. A comparison between CT and MRI in four cases of HSV encephalitis showed that temporal lobe inflammation was obvious on MRI days before changes were visible on CT.[23]

Differential diagnosis Other viral and bacterial infections, cerebral abscess, tumor, and stroke can mimic the clinical features of HSV encephalitis. A focal area of decreased density and increased vascularity that extends into subcortical areas is consistent with the cerebritis that heralds frank abscess formation and helps distinguish evolving abscess from HSV encephalitis. Ring-enhancing lesions characteristic of cerebral abscess or tumor are not seen in the first few days of HSV encephalitis. Glioma and infarct are not likely to be associated with fever, and brain imaging reveals that they are not restricted to the medial temporal lobe.

Treatment Patients with HSV encephalitis should be treated with intravenous acyclovir, 15 to 30 mg/kg/day in three divided doses for at least 10 days. Early institution of acyclovir has reduced the mortality—which ranged between 60% and 70%—to slightly lower than 30%.[24] Generally, early treatment (before coma ensues) is associated with a more favorable outcome. Acyclovir appears to be safe; only mild hematologic, hepatic, and renal function abnormalities have been reported, although relapses after acyclovir therapy have been documented.[25]

Cerebral edema may be the most frequent cause of death resulting from HSV encephalitis. Treatment involves reducing the total fluid intake to between one half and two thirds of that required for maintenance and elevating the patient's head to 30°. Edema is treated by intubation and hyperventilation to bring the partial pressure of carbon dioxide to 25 mmol/L. This reduces increased intracranial pressure (ICP) by constricting the intracranial vasculature. After 24 hours, hyperventilation is less effective. Steroids and osmotic agents may also control brain swelling. The benefits of a short course of steroids in instances of cerebral edema and impending herniation probably outweigh the small risk of potentiating HSV infection. Dexamethasone is administered intravenously at an initial dose of 10 mg, then 4 to 8 mg every 4 to 5 hours for the next 3 days. Incipient herniation may be managed with osmotic diuretics. Mannitol is given in repeated doses of 0.25 to 2.0 g/kg. The serum osmolality should be monitored closely and kept below 310 mOsm/L. The effectiveness of mannitol decreases with repeated use, and rebound increases in ICP may occur.

Anticonvulsants are used to treat seizures. For initial seizures, diazepam may be administered intravenously in doses of 2 mg/min for a maximum total dose of 15 to 20 mg; alternatively, lorazepam may be administered intravenously in doses of 2 mg/min for a maximum total dose of 5 to 10 mg. These treatments are followed by fosphenytoin, which is administered in a loading dose of 20 mg/kg at 150 mg/min. Blood pressure and electrocardiographic monitoring should be employed during treatment with fosphenytoin. Maintenance doses of phenytoin average between 300 and 400 mg/day. Therapy should be guided in accordance with blood levels, side effects, and the presence or absence of seizures. Anticonvulsants should be continued for several months after the acute illness. There are no controlled studies of the prophylactic use of steroids or anticonvulsants in HSV encephalitis.

HSV Neuropathy (Zosteriform Eruption)

Pain and sensory loss in a dermatomal distribution may accompany a zosteriform eruption. The syndrome is usually characterized by a prodrome of diffuse neuralgia, often with malaise and fever, followed within a few days by vesicular eruption.[26] Most reports describe lesions on the face in one or more areas served by the trigeminal nerve, but zosteriform eruptions attributed to HSV have also been described on the trunk, extremities,

and genitalia. A long-standing report of recurrent sciatica associated with HSV is particularly interesting because it identifies a form of sciatica that can be treated with antiviral agents.[27] A first episode may be confused with herpes zoster, but recurrent episodes of dermatomal neuralgic pain and zosteriform eruptions are usually caused by HSV-2.[16]

Although HSV neuropathy is well documented as a clinical entity, more information is needed to know the exact type of HSV responsible for each disease. Clinicians attribute herpes lesions above the neck to the reactivation of HSV-1, whereas lesions below the waist are attributed to the reactivation of HSV-2. Future DNA analysis of herpes isolates by PCR with primers specific for HSV-1 or HSV-2 will identify whether herpes neuropathy is caused primarily by HSV-1 or HSV-2.

Most accounts of HSV neuropathy were made before the development of acyclovir or famciclovir. Because antiviral treatment will probably reduce the number of days that patients have pain and rash, treatment with famciclovir (500 mg three times daily) for 7 to 10 days is reasonable. Neither HSV-1 nor HSV-2 can be eradicated by antiviral therapy. Rather, resolution of acute disease is followed by a return of the herpesvirus to the latent state with the potential for future reactivation.

VARICELLA-ZOSTER VIRUS

VZV causes chickenpox (varicella) in childhood and becomes latent in the ganglia of the cranial nerves, the dorsal root, and the autonomic nervous system. Reactivation decades later produces shingles (herpes zoster), the most common cause of virus-induced neurologic disease in adults.

Herpes Zoster

Herpes zoster is characterized by pain and vesicular rash on an erythematous base in one to three dermatomes (localized zoster). Most herpes zoster cases reflect VZV reactivation from ganglia. In rare instances, cases of herpes zoster are clustered in time, supporting the notion that herpes zoster can be acquired by exogenous reinfection. More than a half-million persons in the United States develop herpes zoster each year. Fewer than 10% of cases of herpes zoster are recurrent. Although chickenpox occurs primarily in the spring, herpes zoster occurs at any time of year. There is no sex bias. Herpes zoster is eight to 10 times more common in persons older than 60 years, and approximately 50% of persons 80 years of age or older have had herpes zoster once. A continuing increase in the number of elderly persons will result in greater herpes zoster–associated morbidity and mortality. Herpes zoster and its attendant complications [*see Figure 2*] are also more common in immunocompromised persons, especially persons with AIDS. Before the AIDS era, herpes zoster occurred most often in bone marrow transplant recipients and patients with leukemia, particularly those who had received radiation therapy; herpes zoster developed at the irradiated site. In my experience, long-term, low-dose steroid therapy also predisposes patients to the serious complications of VZV reactivation, including postherpetic neuralgia (PHN), disseminated herpes zoster, and herpes zoster encephalitis.

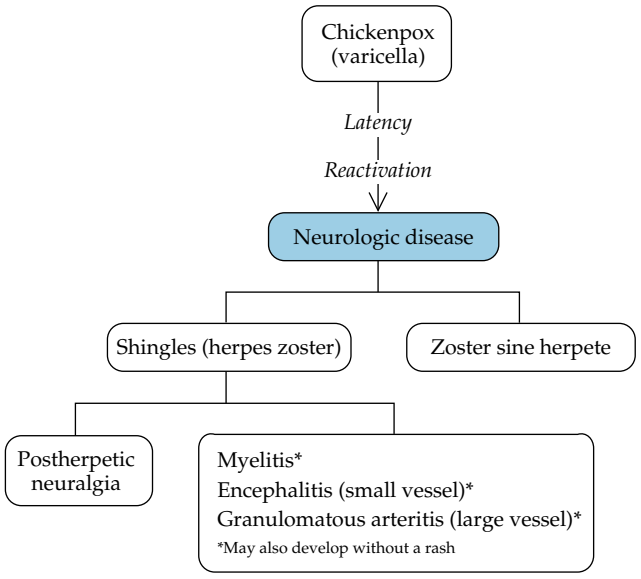

Figure 2 **The neurologic complications of varicella-zoster virus reactivation.**

Clinical features Herpes zoster pain is severe, deep, burning, and jabbing and usually lasts 4 to 6 weeks. Examination reveals hyperesthesia (allodynia) in a dermatomal distribution with mixed hypopigmentation and hyperpigmentation. Except for its shorter duration, acute herpes zoster pain does not differ from the pain of PHN. Herpes zoster may involve any dermatome. The trunk, represented by 12 pairs of thoracic ganglia, is the most frequently involved site. The face, which is supplied by the trigeminal nerve, is involved more often than any single thoracic dermatome, however.

Trigeminal distribution of herpes zoster most frequently occurs in the ophthalmic branch. Cranial neuropathies often occur weeks or months after cutaneous signs, perhaps because of microinfarction of cranial nerves from occlusion of the vasa vasorum. The blood supply of the cranial nerves is part of the carotid circulation. Because trigeminal afferent nerves innervate the large extracranial and intracranial blood vessels, virus can also spread along ganglionic afferent fibers to small vessels supplying cranial nerves, in a manner similar to that proposed to explain the pathogenesis of VZV-induced granulomatous arteritis. Peripheral facial weakness, an abnormality of the cranial nerves, is often associated with vesicles in the ear (herpes zoster oticus); the combination of these conditions constitutes the Ramsay Hunt syndrome.

Herpes zoster in cervical or lumbosacral dermatomes may be associated with muscle weakness. The incidence of herpes zoster paresis in patients with zoster varies from as low as 0.5% to as high as 31%. Bladder and bowel dysfunction are often associated with a sacral distribution of herpes zoster.

Treatment of acute herpes zoster Valacyclovir (1,000 mg three times daily for 7 days) and famciclovir (500 mg three times daily for 7 days) appear to be equally effective in clearing skin lesions and reducing pain. Both drugs are safe and well tolerated. Because it is easier for patients to take medication three times daily instead of five times daily, valacyclovir and famciclovir are preferred over acyclovir. In combination with antiviral therapy, steroids may reduce the use of analgesics and the time to uninterrupted sleep and to resumption of usual activities.[28]

Complications of herpes zoster infection PHN, defined as pain persisting longer than 4 to 6 weeks after the appearance of herpes zoster rash, is the most common complication of herpes

zoster. Age is the most important factor in predicting the development of PHN. The incidence of PHN is 46.9% in patients 60 years of age and older who have contracted acute herpes zoster[29] and varies from zero to 15% in patients younger than 60 years; most of these cases occur in patients between 50 and 60 years of age. PHN is slightly more common in women than in men, but in both sexes, it occurs more often after ophthalmic-distribution zoster.

Analgesics are used to reduce the pain of PHN; if possible, narcotics should be avoided. Gabapentin, beginning with 300 mg daily and gradually increased to a maximum of 3,600 mg daily, provides some relief. Starting with 25 mg at night, amitriptyline can be gradually increased to 150 mg daily. Side effects include postural hypotension, confusion, and urinary retention. Carbamazepine may help, but doses in excess of 600 mg daily are often required, and side effects of sleepiness, confusion, and unsteadiness, particularly in the elderly, may be intolerable. Carbamazepine should be started at doses of 100 mg daily and gradually increased by 100 mg every third day until pain decreases. Lidocaine skin patches are often helpful, as is topical application of triethanolamine salicylate (Aspercreme) or Flex-All 454 if the agent is applied alternatively throughout the day and before sleep. Transcutaneous electrical nerve stimulation units, nerve blocks, and rhizotomy do not usually provide long-term relief.

Studies linking PHN with VZV persistence provide a rationale for treatment with high-dose, perhaps intravenous, acyclovir for more than 10 days to reduce the virus burden.[30] Further studies are needed to determine whether antiviral agents, with or without steroids, initiated at the onset of herpes zoster prevents PHN and whether short-term, high-dose antiviral agents effectively treat PHN.

Zoster Sine Herpete

Prolonged radicular pain without rash may indicate zoster sine herpete. This nosologic entity was verified in two men, aged 62 and 66 years, who developed radicular pain that persisted for years. The pain did not differ from that of PHN. VZV DNA, but not HSV DNA, was found in the blood mononuclear cells of one man and in the CSF of both men 5 to 8 months after the onset of pain.[31] Treatment with intravenous acyclovir, 10 to 15 mg/kg every 8 hours for 14 days, followed by oral acyclovir, relieved pain in both patients. A remarkable case of zoster sine herpete characterized by prolonged pain in a trigeminal distribution, sensory loss, and tumor was shown to be caused by an active VZV ganglionitis.[32]

VZV Vasculopathy

CNS disease is the most alarming complication of herpes zoster. Two conditions predominate: multifocal (small-vessel) vasculopathy, which occurs primarily in immunocompromised patients; and unifocal (large-vessel) vasculopathy, which occurs in immunocompetent patients.

It is important to recognize that syndromes of large-vessel and small-vessel vasculopathy are not always distinct. Both types of syndromes may be involved in a given patient, and together they can produce waxing and waning neurologic symptoms and signs. Therefore, the designation VZV unifocal or multifocal vasculopathy rather than VZV encephalitis seems appropriate because the symptoms and signs seen clinically and on brain imaging indicate vasculopathy rather than encephalitis. Prompt recognition of a unifocal or multifocal vasculopathy after zoster or varicella should lead to improved diagnosis and rapid treatment.

VZV multifocal vasculopathy Multifocal vasculopathy is the most common form of CNS involvement caused by VZV. Disease develops in the setting of cancer, immunosuppression, or AIDS. Neurologic disease is subacute, and death is common. Herpes zoster small-vessel multifocal vasculopathy presents as headache, fever, vomiting, mental changes, seizures, and focal deficit. Brain imaging reveals large and small ischemic or hemorrhagic infarcts—often both—of cortex and subcortical gray and white matter [*see Figure 1d*]. Deep-seated white-matter lesions often predominate and are ischemic or demyelinative. The demyelinative lesions are smaller and less coalescent than those seen in progressive multifocal leukoencephalopathy. The CSF shows a mild to moderate pleocytosis (predominantly mononuclear), normal or mildly elevated concentrations of CSF protein, and a normal CSF glucose content—findings that do not differ significantly from those associated with herpes zoster without vasculopathy. Treatment of herpes zoster vasculopathy includes intravenous acyclovir at a dosage of 15 to 30 mg/kg/day for 10 days. Longer treatment may be necessary in severely immunocompromised patients.

VZV unifocal vasculopathy The salient feature of this form of VZV-induced CNS disease is an acute focal deficit that occurs weeks or months after an episode of herpes zoster in a contralateral trigeminal distribution. Stroke results from a necrotizing arteritis, primarily of large cerebral arteries. One comprehensive review showed that most patients with large-vessel vasculopathy were older than 60 years and that there was no sex bias.[33] The mean onset of neurologic disease was 7 weeks, and the longest interval between the onset of herpes zoster and the onset of neurologic disease was 6 months. Transient ischemic attacks and mental symptoms were common. Twenty-five percent of patients died. The majority of patients had CSF pleocytosis, usually fewer than 100/mm^3 (predominantly mononuclear), oligoclonal bands, and increased CSF IgG. Besides contralateral hemiplegia, ipsilateral central retinal artery occlusion and posterior circulation involvement have been described. Angiographic examination has revealed focal constriction and segmental narrowing, primarily in middle cerebral, internal carotid, and anterior cerebral arteries. Microscopic examination has revealed a necrotizing arteritis (primarily involving the intima and adventitia), inflammation with multinucleated giant cells, VZV antigen, Cowdry type A inclusions, and herpesvirus particles. Most herpes zoster–associated granulomatous angiitis infarcts are pale,[34] but hemorrhagic infarction also occurs. Afferent trigeminal ganglionic fibers to both intracranial and extracranial blood vessels provide an anatomic pathway for the spread of virus.

No definitive treatment is available for large-vessel herpes zoster vasculopathy. Nevertheless, because productive virus infection is found in arteries, patients should receive intravenous acyclovir (to kill persistent replicating virus) and steroids (for their anti-inflammatory effect).

The neurologic features of VZV vasculopathy are protean. Neurologic disease often occurs months after zoster and sometimes without any history of zoster rash. MRI scanning, cerebral angiography, and examination of CSF with virologic analysis are needed to confirm the diagnosis. VZV DNA is not always present in the CSF of patients with VZV vasculopathy, but the diagnosis can be confirmed by finding anti-VZV antibody in CSF in

conjunction with reduced serum-to-CSF ratios of VZV IgG compared with the normally high serum-to-CSF ratios of albumin or total IgG. When VZV vasculopathy develops months after zoster, antiviral treatment is often effective.

In addition to causing vasculopathy, VZV may cause disease at multiple levels of the neuraxis, involving the central and peripheral nervous systems in the absence of rash. Cases include encephalomyeloradiculoneuropathy; mixed small-vessel and large-vessel vasculopathy; acute, chronic, and recurrent neuropathy[35]; and myelopathy.[36] In some of these cases, patients have responded well to treatment with intravenous acyclovir, underscoring the value of aggressive testing for VZV in unusual cases of CNS disease or neuropathy.

Overall, VZV is a neurotropic virus that infects CNS blood vessels of various calibers, producing protean multifocal or unifocal neurologic disorders. Diagnosis requires recognition of the diversity of syndromes that can be caused by VZV, a high index of suspicion, and extensive testing for VZV DNA and antibody in CSF. Finally, nearly all CNS disease caused by VZV infection entails stroke, and infarction may follow zoster or varicella. Disease is not a primary encephalitis but is instead the result of unifocal or multifocal infarction that develops secondary to productive virus infection within large and small cerebral arteries. Rarely, VZV is associated with disseminated encephalomyelitis, a CNS complication of chickenpox.[37]

EPSTEIN-BARR VIRUS

EBV causes infectious mononucleosis and has been implicated as a cause of nasopharyngeal carcinoma and Burkitt lymphoma. EBV is ubiquitous. Primary infection of most humans usually occurs in childhood or adolescence. By 30 years of age, more than 90% of adults have antibody to EBV. Despite the prevalence of EBV infection, neurologic disease is rare. The most common presentation is meningoencephalitis, which is often associated with acute cerebellar ataxia. More serious meningoencephalopathy, presenting as athetosis and chorea or as stupor and coma, has been described. In a fascinating case of acute demyelinating encephalopathy after EBV infection, a patient presented with behavioral abnormalities, visual illusions, and a seizure.[38] EBV mononucleosis may also be followed by recurrent aseptic meningitis. Chronic active EBV infection has been associated with calcification in the basal ganglia.[39] EBV-associated cranial neuropathies, including acute autonomic neuropathy, have been described.[40,41] In a comprehensive study of four patients with EBV myeloradiculitis and encephalomyeloradiculitis, none of the patients died or had brain swelling, but residual neurologic deficits were evident.[42] A case of myeloradiculitis in an immunocompetent 72-year-old woman who was seronegative for EBV was proved to be caused by EBV by the detection of EBV DNA in both serum and CSF; quantitative PCR revealed an EBV DNA load not detected in healthy subjects who had latent infection or were not infected.[43] Detection of EBV DNA in CSF and reductions in the ratio of EBV antibody in serum to EBV antibody in CSF have been used to diagnose infection in the peripheral nervous system and CNS.[41,42,44] There is no specific treatment for EBV infection.

CYTOMEGALOVIRUS

CMV produces neurologic disease, primarily in infants, as part of the clinical spectrum of congenital CMV infection. Although most congenital CMV infections are asymptomatic, many carriers develop sensorineural hearing loss and intellectual handicaps. Other neurologic complications of congenital infections include microcephaly, seizures, hypotonia, and spasticity. Lethargy and coma may follow a severe case of CMV meningoencephalitis.

In immunocompetent adults, the most common neurologic complication of CMV infection is the Guillain-Barré syndrome. The association was made on the basis of the following findings: the isolation of CMV from buffy coat of blood, the development of CMV IgM antibodies in serum,[45] and the demonstration of a fourfold or greater alteration in complement-fixing antibody to CMV in 21 of 92 patients with acute polyneuritis.[46] CMV infection has also been associated with acute brachial plexopathy.[47]

Until the AIDS era, CMV infection of the CNS was rare. There were a few cases of CMV encephalitis in immunocompetent adults, characterized by mental status changes and pyramidal signs. Because the natural history of CMV encephalitis in immunocompetent persons is not known, no treatment protocols have been established. However, two patients with presumptive CMV encephalitis, verified by the isolation of CMV from CSF and urine, were treated with vidarabine and responded well.[48] In contrast to the rare occurrences of CMV infection in the immunocompetent adult, CMV infections in the immunocompromised population, particularly AIDS patients, are common. CMV has emerged as an important cause of encephalitis, myelitis, and polyradiculitis. CMV encephalitis was first documented in renal transplant[49] and bone marrow transplant recipients; an interesting case of CMV vasculitis and retinitis in a lymphoma patient receiving multiple cytotoxic and anti-inflammatory drugs has been reported. In AIDS patients, CMV is the most common opportunistic infectious agent found in the nervous system. Complications include retinitis, encephalitis,[50] progressive myelitis, and polyradiculopathy. CMV encephalitis is usually subacute and is characterized by headache, seizures, progressive dementia, and diffuse weakness. Thus, neurologic deficit may be diffuse, focal, or both.

Like other herpesviruses, CMV can establish a latent infection in persons with intact immune systems. The lymphoid system is the most likely site for viral latency. The source of CMV encephalitis may be circulating lymphocytes. Perhaps because of the ill-defined clinical picture, the diagnosis of CMV encephalitis has been made at autopsy in most cases. The CSF may show a neutrophilic or mononuclear pleocytosis, elevated protein concentration, and depressed glucose content, but these findings are hardly specific, particularly in immunosuppressed patients. MRI may show enhancement in the ventricular ependyma, a finding that is highly suggestive of CMV ventriculitis or encephalitis. Focal disease has been attributed to CMV vasculitis or foci of demyelination. Characteristic owl-eyed cytomegalic inclusions and CMV-specific antigens have been found in the CNS and blood vessels of AIDS patients with subacute encephalopathy. Complicating the picture, however, is the additional presence of HIV or HSV-2. Thus, the attribution of specific symptoms and signs to CMV is difficult. The organism can occasionally be isolated from the CSF of AIDS patients.

Of particular interest is the occurrence in AIDS patients of a CMV polyradiculopathy. Disease often begins insidiously as a cauda equina syndrome with paresthesias and distal weakness (which is usually asymmetrical), incontinence, and sacral-distribution sensory loss. CSF pleocytosis is usually present; either polymorphonuclear leukocytes or mononuclear cells may predominate; CSF protein concentration may be elevated; hypoglycorrhachia may be present; and, occasionally, CMV is isolated

from CSF. Postmortem examination reveals inflammation, necrosis, and focal vasculitis of nerve roots, with typical CMV intranuclear and intracytoplasmic inclusions.[51]

Ganciclovir and foscarnet demonstrate high activity against CMV, although formal trials have not been performed to establish dosage or treatment length. Measurement of viral load in the CSF by PCR is a potential way to assess therapeutic efficacy. CMV infections of the nervous system are currently best treated with intravenous ganciclovir, 5 mg/kg every 12 hours for 2 weeks, followed by maintenance therapy of 5 mg/kg of ganciclovir daily. Patients may need maintenance therapy for life to prevent relapse. Oral ganciclovir has been approved by the Food and Drug Administration for maintenance therapy in AIDS patients. The recommended maintenance dosage is 1,000 mg three times daily with food or 500 mg six times daily (every 3 hours) with food. The main side effect of ganciclovir is neutropenia. The drug should be stopped if the total white blood cell count falls below 750/mm^3.

HUMAN HERPESVIRUS TYPE 6

Human herpesvirus type 6 (HHV-6) causes encephalitis primarily in bone marrow and stem cell transplant recipients[52]; it may present as limbic encephalitis.[53] Diagnosis is confirmed by PCR amplification of HHV-6 DNA in CSF. Not enough cases have been reported to know whether antiviral therapy is effective.

PAPOVAVIRUS BK

The papovavirus BK virus is a relative of JC virus, the cause of progressive multifocal leukoencephalopathy. Like JC virus, BK virus is most commonly found in immunosuppressed patients.[54] On the basis of the development of IgM antibody and PCR results that are positive for viral DNA in CSF, papovavirus BK has also been shown to cause encephalitis in an immunocompetent patient.[55]

HIV

HIV infects the meninges early and persists in the CNS after primary infection. Aseptic meningitis affects 5% to 10% of HIV-infected patients just before seroconversion or after a mononucleosis-like syndrome that is characterized by headache, fever, altered mental status, and focal or generalized seizures. HIV infection is verified by the presence of p24 antigen in serum or the CSF; proof of infection is aided by evidence of seroconversion 1 or 2 months later. Acute meningoencephalitis is usually self-limited, although slowly progressive HIV encephalitis with mental status changes and motor deficit may follow [*see 7:XXXIII HIV and AIDS*].

ARTHROPOD-BORNE ENCEPHALITIS VIRUSES

Arthropod-borne viruses include the virus families Togaviridae (alphaviruses and flaviviruses), Bunyaviridae, and Orbiviridae—all RNA viruses. Humans are infected through mosquito or tick bites. Mosquitoes are infected by biting infected horses or birds. Human infection occurs in the summer and early fall. Human epidemics often follow epidemics in horses, the migration of infected birds, and the infection of rodents. Typical symptoms and signs of infection include headache, photophobia, myalgia, fever, lethargy, confusion, and seizures. Tremor and focal deficit may develop. The CSF pattern is the same as in aseptic meningitis. A specific diagnosis can be verified by the following means: virus isolation from CSF, the production of encephalitis in suckling mice inoculated with infected CSF, the development of a cytopathic effect in tissue culture cells inoculated with infected CSF, the detection of virus-specific antibody in CSF, the presence of virus-specific IgM during acute disease, or a rising titer of virus-specific IgG in sera during the acute and convalescent stages of the disease.

In the United States, the most common vector-borne viral (arbovirus) infection is St. Louis encephalitis (SLE), followed by Western equine encephalitis (WEE), California virus encephalitis, and Eastern equine encephalitis (EEE) [*see 7:XXXI Viral Zoonoses*]. SLE is transmitted mostly by mosquitoes. Nervous system infections usually produce encephalitis, although aseptic meningitis occurs in about 15% of cases. Prominent opsoclonus and tremulousness[56] and brain stem involvement have been described. Nearly all SLE cases are self-limited, although approximately 3% to 4% of cases are fatal.

In 1999, an outbreak of encephalitis accompanied by severe weakness and axonal neuropathy occurred in New York. Initial serologic analysis attributed disease to SLE virus in five of six patients. More extensive molecular analysis identified the virus responsible as a Kunjin/West Nile–like flavivirus, part of the Japanese encephalitis virus serogroup.[57] West Nile virus has now spread to the central and western United States. Although most human cases of West Nile virus infection are acquired through bites from infected mosquitoes, infection may also be transmitted by infected blood products or transplanted organs.[58]

The neurologic complications of West Nile virus infection are protean. Patients have presented not only with meningoencephalitis but also with rhombencephalitis,[59] opsoclonus-myoclonus cerebellar ataxia,[60] unilateral brachial plexopathy with meningoencephalitis,[61] and Guillain-Barré syndrome.[62] As with other arbovirus infections, deep-seated lesions in the basal ganglia and thalamus are often seen on brain MRI.[63] PCR examination of the CSF often reveals West Nile virus RNA.[64]

The bunyaviruses are transmitted by mosquitoes and cause California encephalitis. La Crosse virus is the most common and causes encephalitis primarily in school-age children; hyponatremia is common.[65] Although encephalitis is usually mild, 50% of victims have seizures, and focal deficits and focal EEG abnormalities are seen in 20% to 40% of patients. EEE is more serious; more than 50% of patients die, and mental, visual, auditory, speech, and motor deficits remain in more than 80% of survivors. MRI often reveals focal increases in signal intensity in the basal ganglia and thalamus[66] that distinguish EEE from HSV encephalitis. WEE has a case-fatality rate of approximately 10%; it is more severe in infants and children and may produce transient parkinsonism.[67] Powassan encephalitis is caused by a flavivirus transported by ticks. Almost total ophthalmoplegia in a virologically verified case of Powassan encephalitis has been reported.[68] Orbivirus infection causes Colorado tick fever. There is no specific treatment for arbovirus encephalitis.

ADENOVIRUSES

Adenoviruses are large DNA viruses that usually cause outbreaks of acute respiratory illness, keratoconjunctivitis, and, occasionally, pneumonia. Different adenovirus serotypes produce meningoencephalitis. Although the incidence of CNS disease after adenovirus infection is unknown, the mortality after CNS infection ranges from 26% to 38%.[69] A fascinating case of subacute focal encephalitis in an immunocompromised man from whom type 32 adenovirus was isolated from the brain has been described.[70]

ARENAVIRUSES

The arenaviruses are RNA viruses endemic in rodents. Human infection, which occurs mostly in South America and Africa, produces various hemorrhagic fevers that are often fatal [*see 7:XXXI Viral Zoonoses*]. In the United States, the most common arenavirus infection is produced by LCM virus. Infection is acquired from mice or pet hamsters or through occupational exposure in laboratory personnel working with the virus. Most cases present as aseptic meningitis, but fatal meningoencephalitis also occurs. LCM preceded by a lupuslike syndrome that included rash and the presence of a circulating anticoagulant has been described.[71] In 2005, a cluster of fatal cases of meningoencephalitis in solid organ transplant recipients was associated with LCM infection.[72] As with mumps, orchitis and parotitis may develop concurrently with CNS disease[73]; profound mononuclear pleocytosis and hypoglycorrhachia are also produced. A specific diagnosis can be made by observing the development of choriomeningitis in weanling or adult mice inoculated intracerebrally with infected CSF or the development of LCM-specific antibody in the serum or CSF of infected humans.

HEPATITIS C VIRUS

Acute disseminated encephalomyelitis has been reported in a patient who had received multiple blood transfusions.[74] T_2-weighted MRI revealed symmetrical multifocal changes in the gray matter and white matter of the brain, with some gadolinium enhancement. Hepatitis C virus (HCV) infection was verified by a high titer of IgM antibody to HCV and a strongly positive reaction for HCV RNA. Treatment with high-dose dexamethasone led to a dramatic improvement.

GLOBAL MOBILITY AND DISEASE SPREAD

Although some new viruses that cause encephalitis have been found only in the Far East or South America, it is worth emphasizing that the globe can be circled in 24 hours. Thus, every viral infection in the world could travel anywhere in the world within one incubation period.[75] Over 500 million people cross international boundaries on commercial aircraft every year, about 70 million work legally or illegally in other countries, and 50 million are refugees or displaced persons.[76] This global mobility represents an enormous and steadily increasing opportunity to transport infectious agents or their vectors.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XVII CENTRAL NERVOUS SYSTEM DISEASES DUE TO SLOW VIRUSES AND PRIONS

Francisco González-Scarano, m.d.

There are a number of central nervous system diseases whose common elements include a long incubation period and a progressive clinical course leading to severe neurologic dysfunction or death. The term slow virus infection was at one time used to describe all these diseases, and most of them are in fact caused by viruses. One group, however, is now believed to be caused by abnormally configured proteins known as prions. This chapter reviews the more common of these diseases: HIV-associated dementia (HAD or HIVD), human T cell lymphotropic virus type I (HTLV-I)–associated myelopathy, Creutzfeldt-Jakob disease (CJD), progressive multifocal leukoencephalopathy (PML), and subacute sclerosing encephalitis (SSPE), which is associated with a variant of measles virus.

HIV-Associated Dementia

The primary neurologic syndromes associated with HIV infection are among the more complex and enigmatic complications of HAD. HIV can involve both the peripheral and the central nervous systems. Dementia is the most common of a number of primary neurologic consequences of HIV infection of the CNS; motor dysfunction (e.g., rigidity, spasticity, and ataxia) is also frequently encountered. HAD (also known as AIDS dementia complex [ADC]) is associated with cognitive and motor dysfunction and, in untreated patients, it follows a progressive course that can lead to a nearly vegetative state.[1] HIV has also been associated with spinal cord degeneration (vacuolar myelopathy), which results in the severe motor and sensory symptomatology characteristic of spinal cord involvement. HAD is more common than vacuolar myelopathy and was clinically diagnosed in up to 30% of HIV-infected patients before the development of highly active antiretroviral therapy (HAART). Aggressive treatment of the systemic disease has decreased the incidence of this HIV complication, but the prevalence may be rising as patients with HIV infection and AIDS live longer. In addition, a more subtle form of this complication—namely, minor cognitive and motor disorder (MCMD), which has a similar neuropathology—has been identified in patients whose systemic disease is well controlled.[2] Autopsy studies have detected neuropathologic changes in a greater percentage of patients, but frequently, there is discordance between the clinical syndrome and the pathologic findings (see below).

The peripheral nervous system is also a target for HIV, and distal sensory polyneuropathy (DSPN) is now more common than HAD. Some antiretroviral drugs, chiefly the dideoxynucleosides, are also associated with polyneuropathy; the correct diagnosis of the underlying cause of the polyneuropathy is often dependent on the patient's response to medication withdrawal. There is no generally used test that definitively distinguishes between DSPN and drug-induced neuropathy.[3,4]

PATHOGENESIS

The enigmatic pathogenesis of HAD [*see Figure 1*] may represent a new paradigm for the development of neurologic problems from a viral infection. First, there is discordance between the extensive clinical findings and the neuropathologic substrate. Second, the most prominently infected cells are brain macrophages and microglia rather than neurons or neuroglia.[5] Third, neurons appear to undergo apoptotic cell death in spite of the absence of viral infection.

Most investigators believe that the abnormalities associated with HAD result from the secretion of neurotoxins from chronically infected microglia.[3,5] Among the putative toxins are proinflammatory cytokines such as tumor necrosis factor–α (TNF-α) and platelet-activating factor.[6] Some investigators have also proposed that certain viral proteins, such as gp120 (one of the external or envelope proteins), tat (a viral transactivator), and vpr, can directly injure neurons when secreted by infected cells.[7,8] All these substances have been shown to mediate deleterious effects in cultured neurons of several mammalian species, but there is no conclusive proof that any of them are present in the HIV-infected CNS in levels sufficiently high to lead to comparable damage.

Alternatively, a low-level infection of neuroglia and neurons could mediate HAD. Conventional techniques (e.g., immunohistochemistry and in situ hybridization) have yielded mostly negative results regarding infection of oligodendrocytes and neurons. Astrocytes could be responsible for some of the viral burden, but infection of these cells is generally restricted (i.e., it results in little production of new virus).[9,10]

An interesting finding is that chemokine receptors, which are among the components of the HIV cellular receptor complex, are present in many cells besides microglia (where they would be expected to be found because these cells can be infected with HIV). Chemokine receptors may provide a bridge through which the virus can interact with neurons and astrocytes, although this function has to be considered speculative at this point.

DIAGNOSIS

Clinical Features

Neurologic problems—including cranial neuropathies, meningoencephalitis, and, rarely, coma—develop in some patients who are clinically ill with acute HIV infection [*see 7:XXXIII HIV and AIDS*]. Although the primary HIV syndrome is self-limited, seeding of the CNS during that period of high viremia may result in chronic asymptomatic mononuclear meningitis in some patients.

HAD generally occurs in the later stages of HIV infection, when low levels of $CD4^+$ T cells and a compromised immune system have led to opportunistic infections involving other organ systems. Initially, HAD may present as mild cognitive impairment that is detectable only by the administration of a battery of neuropsychological tests by psychologists who have experience with this particular condition.[11,12] Such mild cognitive

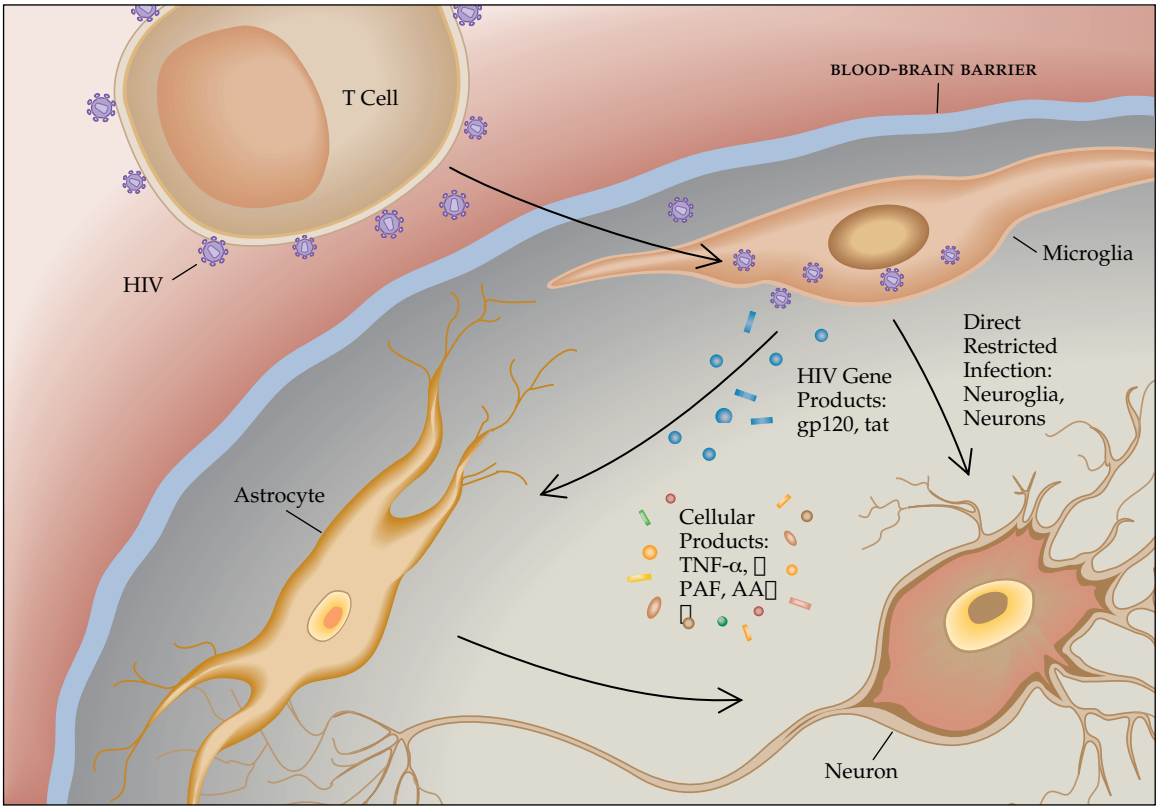

Figure 1 **The enigmatic pathogenesis of HIV-associated dementia (HAD). HIV enters the nervous system early in infection, carried in the plasma, monocytes, or T cells from the peripheral blood. HIV can then infect perivascular macrophages and perhaps also microglia, both of which express the primary HIV receptor, the $CD4^+$ molecule. The infected macrophages may cause disease by releasing cytokines (e.g., tumor necrosis factor–α [TNF-α], platelet-activating factor [PAF]), other inflammatory mediators (e.g., arachidonic acid [AA]), and viral proteins (e.g., gp120, tat), some of which may be toxic to neural cells (astrocytes, oligodendrocytes, neurons). Infected and uninfected macrophages and microglia fuse together to form multinucleated giant cells, the hallmark neuropathology of HAD [*see Figure 2*].**

deterioration may not interfere with job performance or activities of daily living.

HAD is a subcortical dementia, and psychomotor slowing, apathy, and such motor symptoms as ataxia and paralysis can precede memory loss and the deterioration of language function. In its end stages [*see Table 1*], persons with HAD may be nearly vegetative. Antiretroviral therapy can arrest or, in some instances, reverse the symptoms of HAD.

MCMD has been recognized more recently and is particularly worrisome because it may occur in patients who have been adequately treated with antiretroviral therapy. Although its pathologic substrate (see below) is similar to that of HAD, the symptoms of MCMD are more subtle and evidently less progressive than those of HAD.

The diagnosis of HAD depends on the exclusion of other causes of dementia in an HIV-infected patient. Cerebrospinal fluid abnormalities (i.e., elevated protein and decreased cell count) are characteristic of HIV infection but are not specific for HAD. The presence of HIV in the CSF is also not diagnostic of HAD, because both cell-free and cell-associated virus can be cultured from the CSF of persons who do not manifest CNS symptoms. However, there may be a rough correlation between the level of viral RNA in the CSF and the incidence of HAD. Magnetic resonance imaging studies have indicated that HAD is associated with global atrophy of the brain, but a high degree of brain atrophy is present in many persons with AIDS. Furthermore, metabolic abnormalities detectable with magnetic resonance spectroscopy point to neuronal destruction, but these cannot be used diagnostically.

Pathologic Features

The major neuropathologic findings associated with HAD are (1) multinucleated giant cell encephalitis (MGCE) [*see Figure 2*], (2) HIV leukoencephalopathy (myelin pallor and other white-matter changes), and (3) astrocytosis and perhaps neuronal dropout. MGCE, which is the most specific neuropathologic finding in HAD, is present in approximately 25% of persons who have been diagnosed clinically and is characterized by macrophage/microglial syncytia that may contain HIV-specific nucleic acid and antigens. These neuropathologic findings of encephalitis are characteristically more prominent in the perivascular regions, the basal ganglia, and other subcortical areas. Myelin pallor—which, as the name implies, is defined by decreased uptake of histochemicals by the CNS white matter—is present in 33% of patients with HAD; however, it is a less specific finding than MGCE and may be caused by alterations of the blood-brain barrier rather than by oligodendrocyte pathology.

The most striking feature of the neuropathology of HAD is the discordance between the histologic findings and the clinical disease. For example, in one study, neither MGCE nor diffuse pallor was present in 50% of the patients, and even in cases with morphologic changes, the abnormalities were frequently rela-

tively unimpressive.[13] This implies that the symptoms associated with HAD, although clearly associated with viral infection of macrophages and microglia, are ultimately the result of a process in which a mild infection of one cell type is amplified by unknown mechanisms.

TREATMENT

There is increasing evidence that successful treatment of HIV infection brings improvement in HAD,[2] although some studies suggest that HAART has less of an effect on HAD than it has on other conditions associated with AIDS.[12] Recent findings have suggested that antiretroviral regimens that include CSF-penetrating drugs are more effective at inducing clinical improvements in patients with MCMD or HAD.[14] These findings imply that the CNS viral load is directly responsible for cognitive dysfunction in patients with AIDS. The CNS may also be a reservoir for virus that has not been eliminated by HAART.

HTLV-I Myelopathy/Tropical Spastic Paraparesis

The entity known as HTLV-I–associated myelopathy (HAM), which was initially described in Japanese patients, is the same disease as tropical spastic paraparesis (TSP), which occurs in some Caribbean islands. Epidemiologic studies have firmly established the association between HTLV-I infection and the development of this slowly progressive neurologic syndrome. However, HAM/TSP is a relatively rare complication of HTLV-I, with an incidence roughly comparable to that of adult T cell leukemia, another rare condition associated with HTLV-I.

DIAGNOSIS

HAM/TSP is characterized by the development of signs of spinal cord dysfunction, including paraparesis and urinary incontinence. Sensory changes are less common. The diagnosis is based on the exclusion of space-occupying lesions by MRI of the spinal cord in the setting of HTLV-1 seropositivity. Additionally, the T_2-weighted images (T_2 refers to the spin-spin, or transverse, relaxation time) may demonstrate areas of increased signal intensity in the spinal cord and, occasionally, above the foramen magnum; these findings may resemble the radiologic findings associated with multiple sclerosis, although these entities are clearly distinct. The CSF of patients with HAM may demonstrate high levels of protein, and most patients have oligoclonal bands and an elevated IgG index, which are indicative of intrathecal antibody synthesis. Cells resembling those of adult T cell leukemia may also be present in the CSF. Patients with HAM/TSP will usually have a progressive course, leading to lower limb paralysis and, possibly, arm involvement. HAM/TSP is rarely fatal, however.

Table 1 Stages of HIV Dementia (AIDS Dementia Complex)

Stage	*Characteristics*
0 (normal)	Normal mental and motor function
0.5 (subclinical)	Minimal or equivocal symptoms; no impairment of work; can perform tasks of daily life; few, if any, neurologic signs; and normal motor function
1 (mild)	Mild but unequivocal evidence of functional and intellectual impairment, although able to perform all but the most demanding tasks of work or daily life; ambulatory without assistance
2 (moderate)	Incapacitated for work but able to perform basic tasks of daily life; may need unilateral assistance for walking (cane)
3 (severe)	Major intellectual dysfunction, with slowing of mental processes or severe motor disability, requiring bilateral assistance for ambulation
4 (end stage)	Nearly vegetative, with minimal intellectual and social comprehension; nearly mute and paraparetic or paraplegic

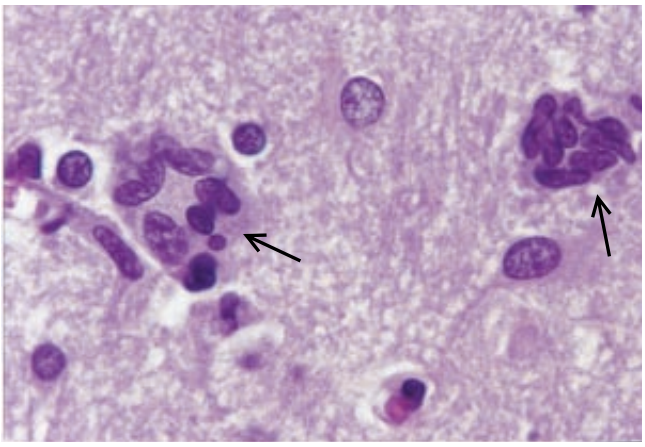

Figure 2 **Pathology of HIV-associated dementia (HAD). Multinucleated giant cells (arrows) formed by the fusion of HIV-infected microglia or macrophages are the most specific finding in HIV dementia. Fusion occurs through the interaction of the HIV glycoproteins with the cell receptors for the virus. Other pathologic changes (not shown) include astrocytosis and myelin pallor.**

Autopsy studies have revealed low levels of HTLV-I in the spinal cord of HAM/TSP patients, indicating that direct cytolysis by virus infection is probably not the cause of the myelopathy.[15] The pathogenesis is generally thought to be, at the very least, associated with infiltration of the spinal cord by $CD8^+$ T cells, as well as possibly with antibodies against the viral protein tax.[16,17] In one series of studies, these antibodies were linked to molecular mimicry of a neuronal protein.[17]

TREATMENT

Because of the lack of evidence that direct viral infection mediates HAM, most therapeutic trials have been directed toward reduction of the immune attack on the CNS. To date, there is no established therapy for HAM/TSP, but some patients show improved neurologic function when treated with interferon alfa (IFN-α).[18]

Transmissible Spongiform Encephalopathies

The spongiform encephalopathies, a group of neurologic disorders of humans and other mammals, are characterized by (1) subacute, progressive deterioration of neurologic function involving several regions of the neuraxis (cognitive and motor dysfunction are most common, although other systems may also be involved); (2) spongiform neuropathologic changes in the affected areas of the CNS; (3) experimental transmissibility to either the same or a related species, with long incubation periods,

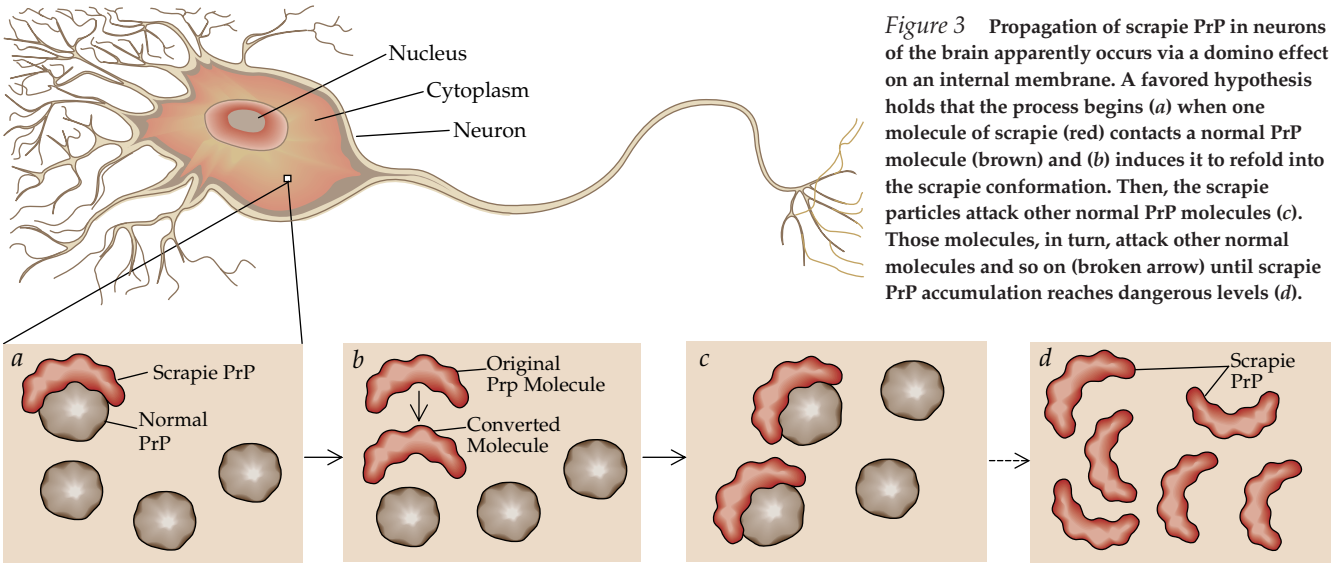

Figure 3 **Propagation of scrapie PrP in neurons of the brain apparently occurs via a domino effect on an internal membrane. A favored hypothesis holds that the process begins (*a*) when one molecule of scrapie (red) contacts a normal PrP molecule (brown) and (*b*) induces it to refold into the scrapie conformation. Then, the scrapie particles attack other normal PrP molecules (*c*). Those molecules, in turn, attack other normal molecules and so on (broken arrow) until scrapie PrP accumulation reaches dangerous levels (*d*).**

typically many months or years; and (4) no evidence of conventional transmissible agents such as viruses.

In humans, the spongiform encephalopathies include both sporadic and genetic forms of CJD, Gerstmann-Sträussler syndrome (GSS), kuru disease (a spongiform encephalopathy associated with ritual endocannibalism of the Fore tribe in the remote highlands of New Guinea), and familial fatal insomnia (FFI), as well as others. Parallel diseases in other species are sheep scrapie, transmissible mink encephalopathy, and chronic wasting disease in deer and elk in the United States.[19,20] Spongiform diseases have been experimentally transmitted to mice and hamsters from sheep tissues, to monkeys and chimpanzees from human tissues, and accidentally to dairy cows (bovine spongiform encephalopathy [BSE], or mad-cow disease) perhaps by dietary supplementation with processed organs from infected sheep. Although there are species barriers to infection, the spongiform diseases are generally considered to be caused by similar processes.

CJD and scrapie had been described for many years when transmission of the human form of the disease was first accomplished by intracerebral inoculation of primates with CNS tissues from patients dying of kuru.[19,21] Kuru disappeared with the cessation of cannibalistic practices, and human-to-human transmission of CJD and other spongiform encephalopathies is now limited to rare cases of accidental transplantation of an organ from a diseased person and parenteral exposure to CJD tissues through contaminated instruments; in new-variant CJD (nvCJD), transmission may be possible by blood transfusion (see below).[22]

PRION HYPOTHESIS OF PATHOGENESIS

Initially championed by Prusiner and colleagues and now widely accepted, the prion hypothesis provides a model for the transmission of CJD and other spongiform encephalopathies. The hypothesis is based on the unquestionable presence of a protease-resistant pathogenic form of an endogenous protein (prion protein, or PrP) in the brains of all affected species.[23,24] The natural form of the protein, PrP^{c}, is a glycosylated protein of unknown function containing lengthy coils (α-helices). In the brains of affected mammals, PrP^{c} appears to misfold into a structure with a high concentration of β-pleated sheets, a protein conformation that promotes the formation of crystals [*see Figure 3*]. The misfolded protein (PrP^{Sc}, or scrapie PrP) is deposited in amyloid fibrils, or plaques, in the diseased brain. Together with the spongy appearance of the diseased brain [*see Figure 4*], these proteinaceous deposits are characteristic of the neuropathology of all the spongiform encephalopathies, although the extent and regional location of the deposit varies from condition to condition.

Evidence supporting PrP involvement in the spongiform diseases includes experiments in which mice were genetically engineered to delete (knock out) the *PrP* gene. These mice became resistant to scrapie-infected brain and did not develop any spongiform changes, even after high concentrations of scrapie-infected tissue were injected intracerebrally. In contrast, transgenic mice that were engineered to express the *PrP* gene from other species, including humans, became particularly susceptible to the diseased brain harvested from the species supplying the transgene.[25] Because there are species barriers to the transmission of spongiform change, these latter experiments suggest that the transgene is responsible for promoting the disease process. A synthetic form of the PrP^{Sc} has been used to induce scrapie in susceptible transgenic mice that overexpressed the endogenous PrP.[26]

How does a protein devoid of nucleic acid function act as an infectious agent and encode its own replication in diseased brain? One scheme proposes that a misfolded PrP^{Sc} serves as a seed, which combines with PrP^{c} from normal tissue [*see Figure 3*]. This interaction induces PrP^{c} to change at least a portion of its α-helical structure into a structure composed primarily of β-pleated sheets. Because the β-pleated sheet–rich PrP^{Sc} is less soluble, the reaction is driven in a single direction. The initial aggregate then expands through the recruitment of additional PrP^{c} molecules, producing an insoluble deposition that is presumably injurious to neurons and neuroglia. This theory has been reviewed recently.[25]

In this mechanism, the source of the seed PrP^{Sc} in spontaneously occurring spongiform encephalopathy is unknown. In a condition such as BSE, in which the disease appears to be transmitted by feeding diseased sheep tissues to cows, the seed protein would have to have been ingested and transmitted to the

brain from peripheral tissue. The spleen and other lymphoid organs are known to harbor scrapie infectivity; therefore, circulating lymphoid cells in the CNS are prime candidates for this neuroinvasion. Extensive epidemiologic surveys have not supported a role for blood transfusion in the transmission of sporadic CJD; however, a case of a patient who developed nvCJD after a blood transfusion has raised the suspicion that blood transfusion may serve as a mechanism of transmission in certain instances.[22]

CREUTZFELDT-JAKOB DISEASE

Diagnosis

The diagnosis of CJD is often based on clinical findings. The most important feature is a dementia that progresses over weeks to months, rather than years, which is more typical of the dementia in Alzheimer disease. Therefore, rapid cognitive deterioration should alert a clinician to the potential diagnosis of CJD. In addition, patients may complain of insomnia, fatigue, and visual problems. In some instances, persons with CJD may be cortically blind. Neurologic examination shows evidence of pyramidal tract involvement and occasional muscle atrophy. Myoclonus (a jerky reaction, particularly prominent after a startle) is an important physical finding, but its absence does not rule out CJD. Other findings may include cerebellar ataxia and seizures.

No single test other than brain biopsy can confirm the diagnosis of CJD, but this is cumbersome to perform because of the need for special treatment of instruments. A combination of laboratory tests and imaging have made the diagnosis less dependent on biopsy. Specifically, examination of the CSF for an abnormal protein (14-3-3 protein), particularly in laboratories with specific expertise, can be useful.[27,28] The electroencephalogram may demonstrate characteristic triphasic forms. Importantly, new imaging modalities such as diffusion-weighted MRI are being used with increasing frequency to demonstrate the persistent edema and cortical involvement characteristic of CJD. Typical findings are a well-defined gyral pattern of restricted diffusion.[29]

Treatment

CJD is uniformly fatal, usually within 2 years of onset. In vitro studies suggest a possible therapeutic role for antimalarial agents and phenothiazines,[30] but clinical studies have not been conclusive. A recent large study reviewed the parameters associated with longer and shorter survival.[31]

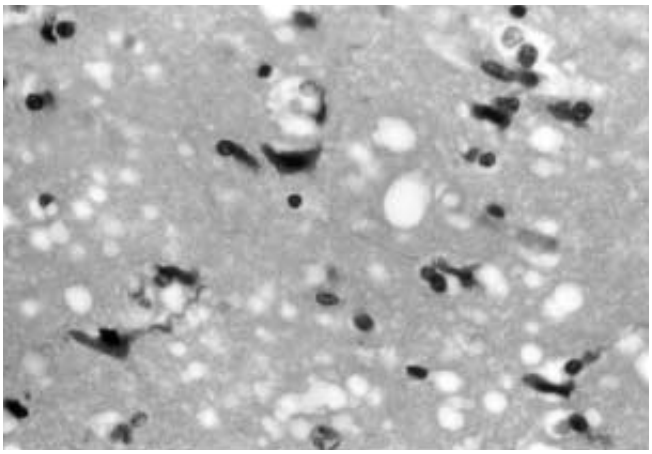

Figure 4 **Spongiform change is characteristic in the brain of a patient with Creutzfeldt-Jakob disease.**

NEW-VARIANT CJD

Bovine spongiform encephalopathy, a spongiform encephalopathy that occurred primarily in the United Kingdom, is associated with the consumption of protein supplements derived from ruminant tissue by cows. Aggressive management of potentially infected herds has reduced the incidence of BSE. However, nvCJD, appearing in young adults and with characteristic neuropathologic findings, has been temporally associated with the appearance of BSE in the United Kingdom. Reliable diagnostic criteria for nvCJD have been formulated.[32] Because there are insufficient epidemiologic data to rule out potential transmission of nvCJD through blood products, the Food and Drug Administration recommends that persons who lived in the United Kingdom for more than 6 months between 1980 and 1996 and persons suspected of nvCJD not donate blood or blood products. Current epidemiologic estimates suggest that the United Kingdom epidemic will be less widespread than initially predicted by some experts; the number of new cases appears to have reached a plateau in 2003 and 2004.[33] No cases of nvCJD have been reported in individuals who have continuously resided in the United States[34]; however, the CDC reported in 2002 the occurrence of nvCJD in a 22-year-old Florida resident who was born and raised in the United Kingdom.[35]

The nvCJD is distinguished from sporadic CJD by the wide difference in patients' ages (i.e., patients with nvCJD are much younger), the clinical presentation with neuropsychiatric abnormalities, and MRI changes in the basal ganglia. The nvCJD cases are also exclusively homozygous for methionine at a specific codon (129) of the PrP protein, whereas the cases of spontaneous CJD are more reflective of the population,[36] although homozygosity at codon 129 is associated with a worse prognosis.[31]

GENETIC DISEASES ASSOCIATED WITH PRP MUTATIONS

In humans, the spongiform diseases include, in addition to spontaneous or accidentally transmitted CJD, genetic forms of CJD and even rarer conditions, such as GSS and FFI.[37,38] In GSS, which is transmitted as an autosomal dominant trait, the affected persons develop ataxia, followed by dementia; patients with FFI are unable to sleep. All these conditions can be transmitted to susceptible nonhuman primates by inoculation of diseased tissues. Remarkably, these conditions have been associated with mutations in the *PrP* gene, and in one series of experiments, mice engineered with the *GSS* gene mutation developed spongiform changes.[37] The mutations on the *PrP* gene are thought to be involved in promoting the conversion to a misfolded, insoluble state.

The existence of diseases that are simultaneously genetic and infectious and the association of mutations in the *PrP* gene with these diseases provide strong evidence in support of the prion hypothesis, although the hypothesis initially met with considerable skepticism because it violated the central dogma of molecular biology.[39] Recent experiments with PrP in transgenic animals, as well as other prion models in primitive eukaryotes, have established that protein-only transmission of phenotypes occurs in nature.

Progressive Multifocal Leukoencephalopathy

PML is a disease of the brain white matter—characterized by dementia and progressive motor deterioration—that is caused by

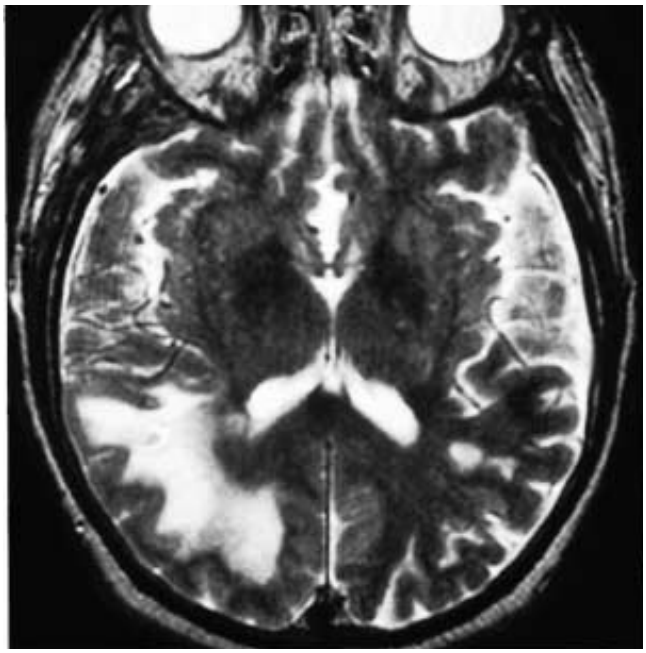

Figure 5 **Magnetic resonance imaging in progressive multifocal leukoencephalopathy. T_2-weighted MRI of a patient with progressive multifocal leukoencephalopathy (PML) demonstrates characteristic changes in the subcortical white matter of the right occipitoparietal region (increased intensity). As is typical of this disease, the abnormalities respect the gray matter–white matter junction, which accounts for the outline of the cortical sulci.**

a papovavirus-related DNA virus, referred to as JC virus. Other symptoms of PML include loss of vision and incontinence. PML was first described in patients with immunodeficiency caused by hematologic malignancies or by therapy for the prevention of transplant rejection. PML remained a very rare condition, however, until the appearance of AIDS. Before the widespread use of HAART, epidemiologic studies indicated that between 1% and 5% of HIV-infected persons would eventually develop PML. In many HIV-infected persons, the development of PML heralds the onset of immunodeficiency and is the AIDS-defining illness; in others, it is a complication associated with other opportunistic infections. Since the widespread availability of HAART, the incidence of PML has dropped considerably in HIV patients.

PATHOGENESIS

Oligodendrocytes, which are the cells responsible for the manufacture and maintenance of myelin, are the principal target of JC virus. Therefore, oligodendroglial cytolysis and apoptosis are the principal pathogenic mechanisms in PML, and they lead to the characteristic severe demyelination. The initial event in the development of PML appears to be the rise of a microscopic focus of oligodendroglial infection, from which virus spreads centrifugally to involve large segments of the white matter. Astrocytes, as well as some oligodendrocytes, demonstrate bizarre morphologic changes similar to those associated with some CNS tumors. There is little involvement of the gray matter or neurons in PML, and any involvement that does occur may reflect death of adjacent oligodendrocytes, perhaps through the recruitment of microglia and macrophages and concomitant inflammatory reaction.[40]

JC Virus and Its Role in the Pathogenesis of PML

JC virus is related to, but clearly distinct from, other polyomaviruses.[41] A large percentage of the adult population in the United States (70% to 90%) have antibodies against JC virus, indicating that this is a common infection, but no diseases have been attributed to the primary infection.

The evidence of widespread infection and the isolation of JC virus from the urine of some immunosuppressed patients are consistent with the hypothesis that PML represents the reactivation of a latent DNA virus. The reservoir organ has not been identified, however. The absence of JC virus DNA in the brains of normal persons suggests that JC virus remains latent in other tissue. Lymphocytes, lymphoid organs, and kidneys have been considered prime candidates because JC virus has been detected in these tissues by PCR or has been isolated from these tissues.[42,43] However, the JC virus isolated from the peripheral tissue of nonimmunosuppressed persons (the archetypal virus) differs from that isolated from patients with PML in the regions responsible for the regulation of viral expression.[44] One intriguing hypothesis, which may explain these findings, is that the archetypal virus is modified by deletion or duplication and is thus converted into a neurotropic form that is carried into the brain in infected B cells. The development of PML in two patients with multiple sclerosis who were treated with a combination of immunomodulators reinforced the hypothesis that JC virus is normally latent in many individuals.[45]

DIAGNOSIS

The diagnosis of PML should be considered in any person with a subacute, progressive illness involving motor function and cognition in the setting of known or presumed immunodeficiency (e.g., AIDS or malignancy). Most cases exhibit features of white-matter involvement, including ataxia, visual defects, and weakness. In rare cases, PML occurs in otherwise healthy persons. PML should be strongly suspected if MRIs show confluent areas of increased signal intensity in the T_2-weighted images [*see Figure 5*]. These areas, which respect the boundaries between gray matter and white matter, may be hypointense in the T_1-weighted images (T_1 refers to the spin-lattice, or longitudinal, relaxation time). The CSF is usually normal in PML; CSF pleocytosis, when present, is usually mild.

Pathologic examination of PML-diseased brain shows dramatic changes in the subcortical white matter. Traditionally, the definitive diagnosis of PML required a brain biopsy. However, biopsy has been largely superseded by the use of PCR to detect JC virus in the CSF.[46,47] The frequency of false positive reactions is low, and it has been estimated that CSF PCR has a sensitivity and specificity greater than 90%.[47]

TREATMENT

Improved outcomes in PML have been reported in AIDS patients treated with HAART.[48] Adjunctive treatment with cidofovir may also be beneficial, although the evidence for this is anecdotal.[49]

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a rare sequela of measles infection (one per 100,000 cases). SSPE can also result from vaccination with a live, attenuated strain of measles, but the rate of development is at least 10 times less than that associat-

ed with wild-type measles infection. A similar disorder, progressive rubella paraencephalitis, is caused by rubella virus.

SSPE presents as a progressive encephalitis that develops several years after measles infection. The condition appears to result from a mutation in the measles virus that affects virus packaging, so the virus can spread only by fusion between adjacent infected and uninfected cells. This may explain viral persistence despite a strong humoral response.

Clinical features of SSPE include cognitive changes, loss of vision, seizures, and, characteristically, myoclonus. MRI may show hyperintensity of white and gray matter, and the CSF may show elevated titers of antimeasle antibody.[50]

A recent report suggested that because of the rarity of measles in the United States, SSPE often goes unrecognized, particularly in immigrant children.[51] There is no established therapy for SSPE, and its outcome is nearly always fatal

I CANCER EPIDEMIOLOGY AND PREVENTION

Alfred I. Neugut, m.d., ph.d., f.a.c.p.
Frederick P. Li, m.d.

An estimated 1,368,000 new cases of invasive cancer and 553,000 cancer deaths will occur in the United States in 2004.[1] An additional 1,000,000 cases of superficial squamous cell and basal cell carcinomas will also be diagnosed, but these rarely result in death. After heart disease, cancer is the leading cause of death in the United States, accounting for one in four deaths.[1] Overall age-adjusted cancer mortality has declined since the early 1990s, reversing the rising cancer mortality of preceding decades.[2] The number of cancer deaths has also reached a plateau despite a growing elderly population, who are at higher risk for cancer. Similar trends have been reported in Europe.[3] Worldwide, cancer control will also become increasingly important as life expectancy improves because of lower infant mortality and fewer deaths from infectious diseases.

Morbidity and mortality from many forms of cancer can be controlled through primary or secondary prevention. Primary prevention can be defined as risk modification to lower cancer occurrence. Secondary prevention refers to the use of screening tests to detect cancers at earlier stages. Chemoprevention—the use of medications to inhibit or reverse the carcinogenic process—is being studied as another approach to reduce cancer rates. Chemoprevention has been effective in reducing the incidence of breast cancer in women, the occurrence of second cancers in patients with oral cancers, and colorectal cancers in susceptible patients.[4-6]

Environmental Carcinogens

Up to 90% of all cancers in the United States may be primarily the result of environmental factors.[7] This conclusion is based on evidence that incidence rates of specific cancers change over time, differ substantially among populations, and can be altered by migration. Environment encompasses a person's way of life, including occupation, diet, tobacco use, alcohol consumption, and sun exposure. Alterations of the environment may be sufficient to prevent most cancers, but heredity also exerts an influence on the multistage development of human cancers.

Conclusive evidence regarding the etiologic role of specific environmental factors is difficult to obtain in studies of humans because (1) the time between a carcinogenic exposure and diagnosis of a resultant cancer is usually years or decades, (2) the amount of exposure to a carcinogen can rarely be quantified accurately in retrospect, and (3) most carcinogens induce cancer in only a small proportion of exposed persons.[8] The role of complex dietary factors in cancer development is particularly difficult to study for these reasons. However, data are available from large epidemiologic studies that employ a prospective study design, careful measurement of dietary intake, and bioassays as dosimeters of nutrients consumed. Evidence suggests that obesity and diets characterized by high caloric intake, increased consumption of red meat and animal fat, and decreased consumption of fruits and vegetables increase the risk of cancers of the breast, the colon, lung, pancreas, oral cavity, and other organs. However, the specific ingredients in the diet that elevate or lower cancer risk have been difficult to identify.[8]

Clinicians often discover the link between an unusual carcinogenic exposure and exceptional risk of a rare cancer. Carcinogens that have been identified in this way include the hormone diethylstilbestrol and the industrial chemicals bis(chloromethyl)-ether and vinyl chloride. Most cancers, however, arise as a result of fairly common exposures that may produce only moderate elevations in risk. To detect these associations, epidemiologists strive for large study populations, accurate exposure measurement, informed judgments regarding the relevant temporal relation between exposure and cancer diagnosis, and recognition of confounding (extraneous) causes of the cancer under study.[9] Despite inherent difficulties in studying human populations, epidemiology remains the most useful method for studying carcinogenic effects in humans. A causal relation between a suspected carcinogen and cancer is strengthened by corroborating studies that provide plausible biologic mechanisms.

Certain physical, chemical, and biologic agents have been identified as carcinogens.[8] These agents may act on a single organ or at multiple sites [*see Table 1*]. Ultraviolet radiation from sunlight can cause cutaneous melanoma, basal cell carcinoma, and squamous cell carcinoma, whereas ionizing radiation can induce leukemias, sarcomas, and carcinomas at various sites.[10] Several dozen chemicals are known to be carcinogenic in humans; they induce leukemias, lymphomas, and carcinomas of diverse organs, particularly of the lung and upper airway. Many more chemical compounds can induce cancer in laboratory animals, but evidence linking these compounds to cancer in humans is insufficient or inconsistent. Strong evidence of viral oncogenesis in humans has been found for hepatitis B and C viruses in patients with liver cancer, human papillomavirus in cervical and anal cancers, Epstein-Barr virus in nasopharyngeal cancer and in some lymphomas, and human herpesvirus type 8 in Kaposi sarcoma.[11,12] The discovery that *Helicobacter pylori* causes gastric adenocarcinoma and certain lymphomas represents the first time a bacterium has been linked to the etiology of malignancy, and this is significant because it suggests that antibiotics may be used for the prevention and treatment of certain malignancies.[13,14]

During the past 10 years, biomarkers have been used increasingly to enhance exposure assessment, gain insights into disease mechanisms, and identify host susceptibility. Epidemiology has traditionally employed a quantitative approach rather than mechanistic steps to the understanding of disease causation. With the advent of modern molecular techniques, molecular epidemiologists can investigate the molecular pathogenesis of cancer. Biomarkers used in cancer epidemiology may be broadly classified into categories according to study design and may include markers of internal dose, biologically effective dose, early biologic effects, susceptibility, and disease.[15] Examples of common biomarkers include DNA adducts, polymorphisms in metabolic genes, and cytogenetic alterations and mutations in cancer cells.[16-19] Validated biomarkers can be useful for exposure assessment when traditional tools are not effective for identifying susceptible and exposed persons. For example, insulinlike growth factor–1 (IGF-1) and its main binding protein, IGFBP-3, have been investigated as potential risk markers for a variety of common cancers.[20-23] Studies show that high circulating IGF-1 and low IGFBP-3 concentrations are correlated with an increased risk of cancers of the

Chemicals and Naturally Occurring Compounds	Aflatoxins, naturally occurring	Liver
	4-Aminobiphenyl	Bladder
	Arsenic	Lung, skin, bladder
	Asbestos	Lung, mesothelioma of pleura and peritoneum, larynx
	Benzene	Acute myelocytic leukemia
	Benzidine	Bladder
	Beryllium	Lung
	Bis(chloromethyl)ether	Lung
	Cadmium	Prostate, respiratory tract, genitourinary tract
	Chromium compounds	Lung
	Erionite	Mesothelioma
	Ethylene oxide	Leukemia
	Mustard gas	Pharynx, lung
	2-Naphthylamine	Bladder
	Nickel compounds	Lung, nasal sinuses
	Radon	Lung
	Silica	Lung
	Sunlight (UV)	Skin, melanoma, eye
	Tetrachlorodibenzo-*p*-dioxin	Lymphoma, sarcoma
	Vinyl chloride	Liver (angiosarcoma)
Medicines and Hormones	Azathioprine	Lymphoma, skin, liver
	Busulphan, treosulfan	Leukemia
	Chlorambucil	Leukemia
	Cyclophosphamide	Bladder, leukemia
	Cyclosporine	Lymphoma
	Estrogens	Endometrium, liver
	Ionizing radiation	Myelogenous leukemia, breast, thyroid, lung, other
	Melphalan	Leukemia
	Methoxsalen with psoralen plus ultraviolet A therapy (PUVA)	Basal cell and squamous cell skin cancers
	Nitrosourea	Leukemia
	Phenacetin	Renal pelvis, bladder
	Tamoxifen	Endometrium
	Thiotepa	Leukemia
Infectious Agents	Epstein-Barr virus	Nasopharynx, lymphomas (Burkitt, Hodgkin, non-Hodgkin)
	Helicobacter pylori	Stomach
	Hepatitis B and C viruses	Liver
	Human herpesvirus type 8	Kaposi sarcoma, MALT lymphoma
	Human T cell lymphotropic virus type I	Adult T cell leukemia/lymphoma
	Human papillomavirus types 16 and 18	Cervix, anus
	Opisthorchis viverrini	Liver
	Schistosoma haematobium	Bladder
Mixtures	Alcohol	Liver, esophagus, pharynx, larynx
	Betel quid	Mouth
	Coal tars	Skin, lung
	Involuntary smoking	Lung
	Mineral oils	Skin
	Salted fish	Nasopharynx
	Shale oils	Skin
	Soot	Skin, lung
	Tobacco	Lung, mouth, pharynx, larynx, esophagus, stomach, pancreas, bladder, kidney, renal pelvis, cervix
	Wood dust	Nasal sinuses

colon, prostate, and lung, as well as premenopausal breast cancer. IGF-1 appears to promote tissue growth and prevent apoptosis, whereas IGFBP-3 modulates IGF-1 availability and induces apoptosis via an IGF-independent mechanism.[24]

TOBACCO

Tobacco is by far the major cause of lung cancer worldwide, particularly in developing nations.[25,26] In the United States, 30% of all cancer deaths are attributed to tobacco use.[27] Tobacco use is associated primarily with squamous cell and small cell carcinomas of the lung, as well as with pulmonary adenocarcinomas. Increased tobacco consumption in the United States and elsewhere has been followed by a rise in lung cancer rates several decades later. A series of reports from the Surgeon General have summarized data from individual epidemiologic studies.[28] At least nine large prospective studies of up to 1,000,000 persons each and 50 case-control studies worldwide have consistently shown that cigarette smoking increases the risk of lung cancer. This increased risk is related to the dose of smoking as measured by years of tobacco use, amount of tobacco consumed daily, tar and nicotine content of the cigarettes, and depth of inhalation of cigarette smoke. Programs that promote reductions in tobacco use among adolescents and young adults, if addressed to these age groups, can prove effective because most smokers become addicted to cigarettes at an early age.[29,30] With smoking cessation, the risk decreases, although more than a decade is required to return to the low cancer risk level of nonsmokers; thus, both prevention and early cessation of tobacco use are important.[31]

Cigarette smoking and alternative methods of tobacco use increase the risk of laryngeal and oral cancers.[28] Fewer lung cancers develop in pipe and cigar smokers than in cigarette smokers, but pipe and cigar smokers are at high risk for oral mucosal cancers, including lip cancer in pipe users.[32] Use of smokeless tobacco also places individuals at high risk for cancer of the oral mucosa.[28] Long-term exposure to environmental tobacco smoke (passive smoking) has been associated with a 30% increased risk of lung cancer in nonsmokers and is estimated to account for 3,000 cases of lung cancer in the United States each year. The Third National Health and Nutrition Examination Survey reported in 1996[33] that 88% of a large population sample of nonsmokers had detectable levels of serum cotinine, a surrogate measure of tobacco exposure. Furthermore, the effects of passive smoking have been demonstrated in pet dogs that are at increased risk of certain malignancies only when their owners smoke.[34]

The causal effect between tobacco use and cancers of the lung and the head and neck is well established; however, tobacco also plays a major carcinogenic role in other organs of the upper aerodigestive tract. Notable among these is the esophagus, for which cigarette smoking is the major risk factor for cancer, particularly squamous cell carcinoma of the esophagus. Over the past three decades, there has been an increasing incidence of adenocarcinoma in the lowest third of the esophagus that is associated with a condition known as Barrett esophagus. Currently, this malignancy constitutes approximately 50% of esophageal cancers. Although associated with tobacco use, Barrett esophagus generally has been more closely linked to gastroesophageal reflux disease (GERD).[35-37]

Alcohol consumption increases the risk of cancers of the oral cavity and the head and neck, as well as cancers of the esophagus, but the risk is greatly increased when alcohol consumption is associated with tobacco use. Cigarette smoking and alcohol consumption are independent risk factors for oral cancer, and

their combined use results in a synergistic effect that has been associated with a 13-fold increase in risk in some studies.[38,39]

Tobacco also plays a significant etiologic role in renal cell carcinoma, bladder cancer, pancreatic cancer, cervical cancer, and gastric cancer. In each of these, the relative risk ranges between 1.5 and 3. Some studies have suggested that cigarette smoking is an etiologic factor in cancer of the colon and rectum, although this remains controversial.[40-42] Also controversial is the role of tobacco use in the development of breast cancer in women.[43]

Reduction in tobacco use is clearly the most important approach to cancer prevention. Physicians see approximately 85% of smokers in their offices at least once a year and can effectively help their patients to stop smoking by using structured, short-term counseling techniques administered by the physicians themselves or their office staff. Smoking-cessation efforts employ behavior modification techniques that have been successful with other addictive disorders; nicotine substitutes (e.g., patch or gum) have also been effective for selected patients. Relapse rates within the first year after cessation are high, and often many attempts to quit are required.[27] In men, the prevalence of smoking decreased from 52% to 27% between 1965 and 1995, and the incidence of lung cancer has declined since rates peaked in 1984.[2] In women, smoking prevalence has decreased from 34% to 23%, whereas lung cancer incidence has yet to decline.[2]

Policy approaches to tobacco control include restrictions on advertising that targets young people, aggressive antismoking education at the elementary school level, limits on government subsidies to tobacco growers, and taxation to raise prices of tobacco and tobacco products. Many communities have legislation requiring smoke-free workplaces, restaurants, and other facilities.[44] In 1998, a master settlement agreement was signed by 46 state attorneys general, a coalition of trial lawyers, and representatives of the five largest tobacco manufacturers in the United States. The settlement requires the tobacco companies to reimburse the states over $200 billion over 25 years for the cost of providing health care services to people with tobacco-related diseases.[45] It also prohibits targeting of youths by banning cartoon characters in advertising, sponsorship of certain events, and use of certain promotional tactics, such as the targeting of adolescents. Additional lawsuits at the state level, including a successful suit in Florida, have found tobacco companies liable for cancer and other diseases in smokers.[46]

In 1997, the Food and Drug Administration proposed extending its jurisdiction to the advertising and sale of tobacco products.[47] However, in 1998 the United States Court of Appeals ruled that the FDA does not have jurisdiction to regulate tobacco, and in 2000 the United States Supreme Court upheld that decision.[48]

DIET

Unusual geographic clustering has been observed for certain cancers of the digestive tract. Exceptionally high mortality rates are found for esophageal cancer in southern Africa and in parts of China and for stomach cancer in eastern Asia and eastern Europe. In the United States, nearly one fifth of all cancers arise in the digestive tract, most often in the colon or rectum. For unknown reasons, cancers of the right colon have become more common, whereas sigmoid colon and rectal cancers have diminished. Death rates from stomach cancer in the United States have declined sharply over the past 60 years, possibly because of improvements in food preservation and decreased consumption of salted, pickled, and smoked foods.[49] Incidence rates of certain digestive tract cancers change when people migrate and, as a result, modify their diets. For example, Japanese who migrate to the United States have a decline in stomach cancer rates, but their colon cancer rates rise within one generation to the levels found in the American-born white population.[49,50] Within the United States, colon cancer rates differ among subpopulations. Mormons and Seventh-Day Adventists, who tend to consume less meat, have lower rates of large bowel cancer. Mexican Americans have low rates of bowel cancer but high rates of stomach cancer.

Despite epidemiologic evidence implicating diet in digestive tract cancer, the roles of specific dietary elements remain uncertain. Suspected dietary factors in large bowel cancer include excess consumption of animal fat and red meat and excess total caloric intake.[51-53] Consumption of multivitamins containing folic acid may reduce colon cancer risk.[54,55] Although low fiber consumption has been suggested to increase colorectal cancer risk, a randomized trial and other recent studies did not show any benefit of a high-fiber, low-fat diet on the recurrence of colorectal adenomas.[56-58]

Recommended dietary changes to reduce cancer risk include controlling caloric intake, decreasing fat consumption to less than 30% of total daily caloric intake, and increasing consumption of fresh fruits and vegetables.[52] These dietary modifications may also reduce the risk of cardiovascular disease.

In general, despite widespread public interest and concern regarding the role of diet in cancer etiology, specific recommendations regarding appropriate dietary recommendations remain elusive. A major contribution in this regard is a monograph published by the World Health Organization that summarizes much of the current knowledge regarding the association between diet and cancer prevention.[59] Generally, a diet high in fresh fruits and vegetables and low in red meat seems most prudent. Much interest currently focuses on caloric consumption, physical activity, and energy utilization and how these factors contribute to obesity and cancer risk [*see* Obesity and Physical Inactivity, *below*]. Very recently, attention has focused on early-life patterns of food and caloric consumption and their role in establishing future cancer risk.

Numerous randomized trials have been undertaken to clarify the relationship between diet and cancer. Antioxidant vitamins, minerals such as selenium and calcium, low-fat diets, and other dietary patterns have been assessed as possible risk-lowering factors. Results have differed across these studies, and many studies are ongoing. The Alpha-Tocopherol, Beta-Carotene Cancer Prevention Trial randomized 29,133 Finnish male smokers to receive vitamin E, β-carotene, both, or a placebo to determine whether these supplements lowered the risk of lung cancer. Ironically, the study showed an 18% increased risk of lung cancer in patients who received β-carotene.[60] A postintervention follow-up study concluded that smokers should avoid β-carotene supplements.[61] These results suggest that dietary interventions may be harmful, and careful investigation is needed to determine their role in cancer prevention.[62]

OBESITY AND PHYSICAL INACTIVITY

Two risk factors for cancer that have come under increased study in recent years have been obesity and physical inactivity, which are related to energy intake and consumption. A study by Calle and colleagues demonstrated that obesity, which has been associated most notably with breast cancer, may be linked to a larger number of cancers than had previously been suspected, including colon, rectum, prostate, pancreas, kidney, and others.[63] Although the physiologic mechanisms linking obesity to hor-

monally related cancers (e.g., breast cancer and prostate cancer) are well elucidated, the biologic underpinnings between obesity and other cancers are not obvious.

Physical inactivity, which frequently accompanies obesity, has been implicated as a risk factor in many chronic diseases and is currently being assessed for its contribution to cancer risk. A Canadian study showed that physical inactivity, high energy intake, and obesity are associated with an increased risk of rectal cancer; the study further suggested that these three factors may have a synergistic effect that further increases cancer risk if they are all present.[64]

Increased physical activity, either on an occupational or on a recreational basis, has been shown to be a protective factor for a number of malignancies, including colorectal and breast cancer.[65,66] Whether this represents a surrogate for a healthy lifestyle, a confounder for obesity, or other physiologic mechanisms again remains unclear. Nonetheless, randomized trials are under way to assess its efficacy as a modifiable intervention for cancer prevention in persons at high risk for developing certain cancers.

INFECTIOUS AGENTS

Infectious agents have been known to cause cancer since 1911, when Peyton Rous discovered the Rous sarcoma virus. However, recent findings have made it clear that infectious agents are responsible for a larger portion of the cancer burden in the United States and around the world than was previously suspected. This is a cause for optimism because it suggests the preventive and management strategies developed for controlling infectious diseases, including sanitation, vaccination, antibiotics, and antivirals, may be applicable to cancer prevention.

Hepatitis B virus (HBV) infection is an established risk factor for the development of liver cancer in certain patient populations. Cancers of the liver, primarily hepatocellular carcinoma (HCC), are relatively rare in the United States, but the rates are rising.[67] HCC occurs largely in patients with cirrhosis caused by chronic hepatitis, hemochromatosis, and use of exogenous androgenic steroids. It also may occur as a result of occupational exposure to vinyl chloride and the subsequent development of angiosarcoma of the liver. Liver cancer is a leading cause of cancer death in certain developing nations, particularly in Africa and Asia. The major risk factor for liver cancer in these patients is chronic HBV infection, which is often acquired during infancy or early childhood. The risk of liver cancer is increased as much as 200-fold in HBV carriers. Hepatitis B vaccination decreases the risk of infection and subsequent occurrence of HCC. Since initiation of widescale hepatitis B vaccination in Taiwan, HCC rates have fallen by 25% or more.[68] In the United States, however, the rising incidence of hepatitis C virus (HCV), which causes hepatoma and for which a vaccine does not yet exist, poses an increasing problem.

Squamous cell carcinoma of the uterine cervix has been linked to human papillomavirus (HPV)[69-71] and has been studied in relation to sexual behavior. Incidence of the disease is increased in prostitutes and in other women who have multiple sexual partners, in women who have first coitus at an early age, and in women with a history of venereal disease. Cohort and case-control studies have demonstrated that HPV is associated with both in situ and invasive cervical carcinoma. HPV DNA has been found in up to 95% of cervical cancers. Furthermore, progression of cervical intraepithelial neoplasia is associated with high levels of HPV DNA within the cervical tissues. This finding has prompted two advances in the prevention and early detection of cervical cancer. First, the presence of HPV in the genital mucosa of women is now being used as a means for cervical cancer screening.[72] This technique has proved to be inexpensive and effective and has a high enough sensitivity and specificity for use in poor countries where the more commonly used Papanicolaou smear is not routinely available. Women are able to swab themselves; the swab is tested for the presence of HPV DNA, and its presence is then used to select those women for further testing where routine gynecologic care is not feasible.[73] A second major advance linked to the viral etiology of cervical cancer is the development of a vaccine for HPV. A randomized, multicenter trial found the vaccine to be effective; however, the vaccine must undergo further testing before it can be widely distributed.[74]

Another virus of interest as a carcinogen is Epstein-Barr virus (EBV). This DNA virus has been associated with a number of different malignancies, including nasopharyngeal carcinoma, Burkitt lymphoma, and possibly Hodgkin disease.

Particularly since the early 1980s, with the onset of AIDS and the HIV era, interest has focused on finding retroviruses or RNA viruses associated with cancer. This has been of particular interest because many of the oncogenic viruses found in rodent and animal studies (e.g., SV40 or Rous sarcoma virus) are RNA viruses. A major breakthrough in this regard was the discovery that human herpesvirus type 8 (HHV-8), a retrovirus, was the etiologic agent for Kaposi sarcoma.[75] Kaposi sarcoma, which classically occurs in elderly men of Mediterranean descent, became more widespread as a cancer commonly found in AIDS patients. Chang and Moore found HHV-8 to be the virus responsible for Kaposi sarcoma in both the AIDS-associated and the classic forms of the disease.[72] HHV-8 has been found to be responsible for other lymphomas as well.

Human T cell lymphotropic virus type I (HTLV-I) infection has been linked to the development of an aggressive form of leukemia, adult T cell leukemia/lymphoma.[76] This disease has an unusual geographic distribution, with clusters in Japan and the Caribbean. Spatial and temporal clusters of leukemia and Hodgkin disease have also been reported, but no etiologic agent has been found, and these clusters may be the result of chance. HIV type 1 (HIV-1) has been identified as the cause of AIDS. Patients with AIDS are at high risk for Kaposi sarcoma, Hodgkin disease, non-Hodgkin lymphoma (NHL), and other cancers.

In recent years, the incidence of NHL has increased in adolescents and adults. Both inherited and acquired immunodeficiency appear to be associated with an elevated risk for NHL. Organ transplant recipients are at high risk for NHL and carcinomas of the skin.[77] These neoplasms may appear within several weeks after renal or cardiac transplantation and therefore differ from most environmentally induced cancers that arise many years after exposure to carcinogens. The transplant-associated lymphomas have a predilection for the central nervous system. Immunosuppressive therapy with azathioprine and cyclosporine has been implicated as a risk factor in transplant recipients, although the transplanted cells per se may also have a carcinogenic influence. Epstein-Barr virus has been associated with nasopharyngeal cancer, Burkitt lymphoma, NHL, and Hodgkin disease.[11]

Evidence accrued over the past 20 years has established *H. pylori* as a causal agent in gastric cancer. This discovery is significant because it represents the first time a bacterium has been found to be associated with cancer etiology. *H. pylori* is a widely prevalent infection that increases the risk of gastric adenocarcinoma and gastric lymphoma of mucosa-associated lymphoid tissue (MALT) lymphomas.[13,14] The treatment of *H. pylori* infection with antibiotics

has resulted in cures of MALT tumors. Furthermore, a recent randomized trial from China has demonstrated that early treatment of *H. pylori* with antibiotics can decrease the subsequent incidence of gastric cancer in persons at high risk for that disease.[78]

In some parts of the world, such as the Middle East, a large number of cases of bladder cancer are attributable to chronic schistosomiasis, a parasite.

OCCUPATIONAL CARCINOGENS

Asbestos induces lung cancer and mesothelioma and is a major cause of cancers of the respiratory tract. Asbestos is estimated to cause several thousand cancer cases, primarily lung cancer, each year in the United States.[8] Asbestos is virtually indestructible and is widely used throughout industrialized environments. Mesothelioma has been reported to develop after a single identifiable exposure to asbestos. In contrast, lung cancer develops chiefly in workers who have been heavily exposed to asbestos, such as asbestos manufacturers, pipe fitters, and shipyard workers. Concerns have also been raised regarding low-level asbestos exposure associated with decaying insulation in older homes and buildings.[79] The carcinogenic effect of asbestos appears to be related to the long, needlelike physical configuration of the fiber. There are concerns that other fibers, such as certain fiberglass insulation materials, might pose a cancer risk.[80] Smoking and exposure to asbestos appear to act synergistically in producing cancer. The combination of smoking and occupational exposure to asbestos increases lung cancer risk about 60-fold.

Bladder cancer has been reported in workers exposed to certain aromatic amines in the dye, rubber, leather, tanning, and organic chemical industries. This has been found to be true for kidney cancers, as well.

Other occupational carcinogens include polycyclic aromatic hydrocarbons, such as those found in cigarette smoking. These are also derived from combustion of petroleum and its by-products in diesel engines or in other similar settings.

Certain miners, such as uranium miners, can be exposed to unusual carcinogens such as radon. Radon is inhaled and increases the risk of lung cancer. Studies have shown that there is a dose-response relationship associated with mining and that an interactive effect with cigarette smoking increases the risk of lung cancer in these miners.[81] Other types of miners, such as coal miners, may also have an increased risk of lung cancer.

CARCINOGENS AFFECTING THE REPRODUCTIVE SYSTEM

Breast cancer is the most common neoplasm in women in the United States and accounts for 30% of all new cancers diagnosed in women in 2004.[1] The cumulative incidence of breast cancer in American women is 9% by 74 years of age. The highest rates worldwide are observed in the industrialized countries of North America and Europe. Rising breast cancer rates in Japan and other newly industrialized nations, as well as in Asian immigrants to the United States, suggest environmental influences.[7,82]

Studies have focused on hormonal factors and the influence of obesity, exercise, diet, and parity in promoting carcinogenesis in the breast and female reproductive organs.[83-89] Risk of breast cancer increases with early menarche, nulliparity, older age at first birth, and late menopause. Available data suggest a slight increase in breast cancer risk with prolonged use of oral contraceptives in women younger than 35 years but not in older women.[83] Prolonged use of postmenopausal hormone replacement therapy has been shown to increase the risk of breast cancer, and the addition of progesterone appears to exacerbate this effect.[84,90]

In addition, oophorectomy reduces the incidence of breast cancer by about 50%. Taken together, these observations support a unified hypothesis that breast cancer development is promoted by prolonged exposure to cyclic ovarian secretion of estrogens and progesterone.

A higher risk of breast cancer has been found in women with benign lesions having histologic evidence of proliferation and atypia. Because most of the known risk factors for breast cancer cannot be modified easily, chemopreventive strategies are being explored for women at high risk for cancer. A large randomized trial has determined that tamoxifen substantially reduces the incidence of breast cancer in women at high risk and reduces the rate of contralateral breast cancer in breast cancer patients.[4]

Use of conjugated estrogens during menopause appears to retard the progression of osteoporosis and reduce menopausal symptoms.[90] However, these agents may promote endometrial cancer, and newer drugs, such as raloxifene, are under study in clinical trials.[91] Little is known about environmental causes of carcinoma of the ovary and endometrium. These malignant tumors have some risk factors in common with breast carcinoma, including increased risk with nulliparity and perhaps with obesity and high socioeconomic class.

Multiple primary adenocarcinomas of the breast, ovary, and endometrium have been reported in individuals and in families.[8] The risk of both ovarian and endometrial cancer may be lower in women who have used oral contraceptives. For women who were exposed in utero to diethylstilbestrol, the risk that adenocarcinoma of the vagina will develop in their early adult years is 1 in 1,000. Otherwise, this cancer is extraordinarily rare.[8]

In the past 25 years, age-adjusted incidence rates for prostate cancer in the United States have more than doubled.[1] Prostate cancer is estimated to account for 29% of all incident cancers in males in the United States. Much of the increase in incidence can be explained by the widespread use of prostate-specific antigen (PSA) for early cancer detection.[92] Clinical prostate cancer is much more common in the United States than in Japan. In both countries, however, a large proportion of elderly men have in situ malignant changes in the prostate. Prostate cancer incidence and mortality have risen more rapidly in African Americans, whose age-adjusted mortality for prostate cancer is more than double that of whites (54.8 versus 23.7 per 100,000 from 1990 to 1996).[1] Benign prostatic hyperplasia, a common condition in men older than 60 years, does not appear to be strongly associated with prostate cancer risk.

Environmental influences have been examined as an explanation for the rising incidence of prostate cancer and the higher frequency of advanced prostate cancer in the United States, even in the Asian-American population. Dietary and hormonal influences have been examined in relation to prostate cancer, but their role is still unclear. Evidence suggests that a slightly increased risk of prostate cancer is associated with increased consumption of saturated fat and red meat; vitamins A and D and β-carotene may decrease the risk.[92]

IATROGENIC CAUSES

In more than 50 patients treated with cyclophosphamide for cancer and other serious diseases, bladder cancer developed after cyclophosphamide-induced cystitis.[93] A second drug, phenacetin, is associated with cancer of the renal pelvis and bladder.[94]

Ionizing radiation can induce all major forms of leukemia except chronic lymphocytic leukemia.[8] Studies have provided evidence for and against the association between electromagnetic radiation and risk for leukemia; current evidence tends not to

support this association.[95] A high incidence of acute myeloid leukemia has been reported in cancer patients treated with alkylating agents (i.e., melphalan, cyclophosphamide, chlorambucil, and the nitrosoureas) or epipodophyllotoxins.[96] In several large studies, the cumulative leukemia risk at 10 years of follow-up was approximately 5%; the leukemogenic effect of these drugs diminishes with longer follow-up. Clinically, the risk of secondary leukemia needs to be weighed against the benefit of treatment. Alternative nonleukemogenic therapies should be sought; antimetabolites, such as cytarabine, fluorouracil, and methotrexate, do not appear to be carcinogens. Patients who undergo bone marrow transplantation are at higher risk for new solid cancers for at least 10 years after transplantation.[97]

MISCELLANEOUS ENVIRONMENTAL CAUSES

Ionizing radiation has been recognized as a human carcinogen for a century. This has been a major etiologic factor for cancer following the atomic bomb in Japan, as well as in various occupational settings. Approximately 3% to 5% of all cancers can be attributed to ionizing radiation, including high-dose therapy for cancer and other diseases.[8] Radiation can induce brain tumors, cancers of the skin and thyroid, sarcomas of bone and soft tissue, and cancers of other sites.[10] Cancer of the skin of the scrotum occasionally develops in workers topically exposed to soot and mineral oils. Chemical exposures and viruses have been studied as etiologic agents in brain tumors, Hodgkin disease, and multiple myeloma, but definitive results are scanty. Although several reports have suggested an association between electromagnetic radiation and leukemia and brain cancer, more definitive studies have demonstrated no evidence of an association.[95] Studies have examined the role of herbicides and defoliants, including Agent Orange, which was heavily used during the war in Vietnam. Agent Orange contains dioxins, which are potent animal carcinogens, although no definitive evidence has been found for increased cancer risk in Vietnam War veterans.[98] Excesses of soft tissue sarcoma and NHL have been reported in workers exposed to dioxins through their manufacture or use in farming for long periods.[8]

Inherited Factors That Predispose to Cancer

Until recently, hereditary factors received little attention in epidemiologic studies of cancer. Interest in hereditary influences emerged with the understanding that genetic alterations underlie the process of transformation of a normal cell into a cancer cell. The basis of cancer is the loss of normal genetic control of cellular processes. At the molecular level, cancer is a disorder of genes, particularly oncogenes and tumor suppressor genes. Among the estimated 50,000 genes in the human genome, only a small fraction seem to be essential for cancer development. Genetic alterations can alter regulation of cell replication, DNA repair, apoptosis, and immune surveillance against tumor cells. Inherited traits can interact with environmental carcinogens. For example, sunlight increases skin cancers in genetically susceptible Celts and other light-skinned populations. Patients with albinism or xeroderma pigmentosum have a defect in excision repair of UV-damaged DNA and develop multiple skin cancers in exposed areas. Epidemiologic studies can help define the influences of both environmental carcinogens and host factors in cancer development.[99]

Hereditary factors in cancer development have been identified in studies of families with a history of cancer. Virtually every form of cancer manifests a tendency to aggregate in families. Close relatives of a cancer patient are at increased risk for the same form of cancer and perhaps other cancers. The excess site-specific cancer risk is usually two to three times above the age- and sex-specific population rate. However, germline (inherited) mutations in some cancer genes can increase the likelihood of cancer development to nearly 100%. These potent cancer genes are rare in the population but serve as important models for studies of carcinogenesis.[100]

HIGH-PENETRANCE GENETIC FACTORS

Risk Factors for Retinoblastoma

A paradigm of hereditary cancers in humans is retinoblastoma. Approximately one third of this childhood cancer occurs in an autosomal dominant pattern with high penetrance. Carriers of a mutated retinoblastoma gene (*Rb-1*) have more than a 10,000-fold excess risk of this eye tumor, as well as a marked increase in risk of second cancers (sarcomas, melanoma, and brain tumors).[101] The *Rb-1* gene is a tumor suppressor. Loss or inactivation of both alleles of the gene abolishes its tumor suppressor function and leads to tumor development. In hereditary retinoblastoma, one abnormal allele has been inherited from a parent. However, this eye tumor develops only after the second normal allele has been inactivated through a somatic (acquired) mutation or other mechanism. Although inherited mutations in the *Rb-1* gene are rare, somatic mutations in the gene are active in the genesis of many forms of cancer, including carcinomas of the breast, the lung, and other sites. The Rb-1 protein interacts with the transcription factors and cyclins that regulate progression through the cell cycle. The *Rb-1* gene can also be inactivated through binding by the transforming proteins of several oncogenic viruses; this protein-protein interaction is one molecular mechanism of viral oncogenesis.

Risk Factors for Familial Neoplasms

An increasing number of genetic diseases are associated with a high risk of cancer [*see Table 2*].[100] Neoplasia is the primary manifestation of some cancer genes, such as the *Rb-1* gene. Carriers of these genes can often be identified by a family history of the same cancer in multiple relatives affected at unusually early ages. In other genetic disorders, such as neurofibromatosis, cancer is a less common manifestation of the underlying genetic disease. The finding of a predisposing genetic disorder should alert the physician to the possibility of early diagnosis of associated cancers through periodic surveillance.

Risk Factors for Colorectal Cancer

Colorectal cancer tends to develop within certain families. In the dominantly inherited disorder adenomatous polyposis coli (APC), colonic polyps arise in adolescence, and the lifetime risk of colon cancer is nearly 100%. The APC tumor-suppressor gene was isolated in 1991 and shown to be the inherited mutation in all polyposis families. In contrast, familial colon cancer without multiple polyposis may be caused by germline mutations in one of the DNA repair genes: *MSH2*, *MLH1*, *MSH6*, *PMS1*, or *PMS2*.[102,103] Their phenotypes include familial colorectal cancer and hereditary nonpolyposis colorectal cancer, which accounts for 5% to 10% of these cancers in the United States.[104]

Risk Factors for Reproductive Cancers

A family history of breast cancer is one of the most consistent risk factors of the neoplasm, particularly in women who have multiple relatives with bilateral premenopausal disease. Heredi-

Table 2 Common Hereditary Cancers and Syndromes Due to Germline Mutations in Predisposing Genes

Gene	*Type*	*Locus*	*Familial Neoplasms and Syndromes*
BRCA1	Tumor suppressor	17q	Hereditary breast and ovarian cancer
BRCA2	Tumor suppressor	13q	Hereditary breast and ovarian cancer
hMSH2	Mismatch repair	2p	Hereditary nonpolyposis colon cancer (also endometrium, brain, urinary tract, other)
hMLH1	Mismatch repair	3p	Hereditary nonpolyposis colon cancer (also endometrium, brain, urinary tract, other)
hPMS1	Mismatch repair	2q	Hereditary nonpolyposis colon cancer (also endometrium, brain, urinary tract, other)
hPMS2	Mismatch repair	7p	Hereditary nonpolyposis colon cancer (also endometrium, brain, urinary tract, other)
NF1	Tumor suppressor	17q	Neurofibromatosis-1 (neurofibroma, sarcoma)
NF2	Tumor suppressor	22q	Neurofibromatosis-2 (acoustic neuroma, brain)
RB1	Tumor suppressor	13q	Hereditary retinoblastoma and other second cancers
APC	Tumor suppressor	5q	Adenomatous polyposis coli (colon, brain)
p53	Tumor suppressor	17p	Li-Fraumeni syndrome (sarcoma, breast, brain, leukemia)
MEN1	Tumor suppressor	11q	Multiple endocrine neoplasia type I (pituitary, parathyroid, pancreas)
MEN2A	Oncogene	10q	Multiple endocrine neoplasia type IIA/B (thyroid, parathyroid, pheochromocytoma)
WT1	Tumor suppressor	11p	Hereditary Wilms tumor
VHL	Tumor suppressor	3p	Von Hippel–Lindau syndrome (hemangioblastoma, renal cell carcinoma)
TSC1	Tumor suppressor	9q	Tuberous sclerosis 2 (kidney, brain)
TSC2	Tumor suppressor	16p	Tuberous sclerosis 2 (kidney, brain)
CDKN2	Tumor suppressor	9p	Hereditary melanoma
ATM	DNA repair	11q	Ataxia-telangiectasia (breast in heterozygote, lymphoma in homozygote)
PTEN	Tumor suppressor	10q	Cowden disease (breast, thyroid, skin)

tary breast cancer accounts for approximately 5% of all breast cancers in the United States. Studies have identified at least five genes predisposing to inherited breast cancer. Clinically, the most important is the *BRCA1* gene, located on chromosome 17q.[105] A second breast cancer gene, *BRCA2*, has been found on chromosome 13q.[106] *BRCA1* and *BRCA2* account for most of the hereditary breast cancers in young women; carriers of *BRCA1* are also predisposed to ovarian cancer of early onset. Women who are carriers of the *BRCA1* mutation have a 50% to 85% probability of developing breast cancer by 70 years of age, and their risk for ovarian cancer is 20% to 50%.[107] Corresponding figures for breast and ovarian cancers associated with inherited *BRCA2* mutations may be lower. The frequency of inherited *BRCA1* and *BRCA2* mutations varies widely among populations; it appears to be higher among Ashkenazi Jews, approximately 2% of whom carry mutations of *BRCA1* or *BRCA2*.[107]

Another susceptibility gene for breast cancer is the *p53* tumor-suppressor gene, the inherited defect in most families with dominantly inherited Li-Fraumeni syndrome. The *PTEN* gene, which is associated with Cowden disease, also confers an increased risk for benign and malignant breast tumors, as well as brain, prostate, and thyroid neoplasms.[108] Breast cancer genes might include the ataxia-telangiectasia gene, on chromosome 11q. Ataxia-telangiectasia is a rare autosomal recessive disease in which homozygotes develop neurologic, neoplastic, and other disorders in childhood.

Prostate cancer has a hereditary component, with male relatives of prostate cancer patients exhibiting a twofold increased risk. Hereditary prostate cancer, which accounts for 5% to 10% of all cases, is primarily associated with early onset disease. Major susceptibility loci for hereditary prostate cancer were recently mapped on chromosome 1 and the X chromosome.[109,110]

Other High-Penetrance Genetic Factors

Inherited susceptibility plays a role in other common forms of human cancers, including endocrine and brain tumors, skin cancer, kidney cancer, melanoma, and the hematologic neoplasms. Familial forms of these cancers account for a small fraction of incident cases. Within affected families, however, the inherited cancer gene is an exceptionally potent oncogenic influence that can lead to cancer among multiple relatives.

LOW-PENETRANCE GENETIC FACTORS

In addition to highly penetrant cancer-susceptibility genes, many low-penetrance genetic variants (polymorphisms) may interact with environmental agents and other genes to modify cancer risk.[18,111] These polymorphisms are associated with only moderate increases in risk, but they can occur at high frequency in the population and contribute to the development of substantial numbers of cancers.[16,17,19] Unfortunately, the effects of these variants are often small and difficult to measure in heterogeneous populations. For example, rare *HRAS1* alleles in the H-*ras*-1 oncogene are reportedly associated with increased breast cancer risk, but new results based on improved analytical methods have failed to support the finding.[111,112] Inconsistent results in studies of low-penetrance cancer genes might also be the result of small sample sizes and misclassification of carcinogenic exposures.[113] Characterization of the role of genetic variants in cancer development can help identify susceptible populations to individualize cancer-prevention efforts.

Polymorphisms in genes that encode for proteins involved in metabolism of steroid hormones or carcinogens might alter cancer risks. Variants in the cytochrome *P-450* genes are associated with increased risk of lung, esophageal, and head and neck cancers. The genes *GSTM1* and *GSTT1* produce glutathione transferases that are involved in the deactivation of tobacco carcinogens.[16] Certain variants in these genes are associated with increased risk of bladder cancer and lower survival rate for patients with lung cancer.[16] A combination of genetic variants in both cytochrome *P-450* genes and *GSTM1* may produce gene-gene interactions that further increase cancer risks.[17] Polymorphisms of the *NAT1* and *NAT2* genes may affect susceptibility to cancers of the urinary bladder, colon and rectum, breast, head and neck, and lung.[18,19] Individuals with the slow *NAT1* and *NAT2* acetylator phenotypes may be prone to bladder cancer, whereas those with fast acetylator phenotypes may be predisposed to colorectal cancer.[19]

Before familial cancers are attributed to genetic susceptibility, chance association and shared exposures to environmental carcinogens should be excluded. Inherited predisposition can be identified through detection of laboratory markers of host susceptibility and by segregation and linkage analysis of the pedigree. With the increasing identification of cancer-susceptibility genes, genetic testing of individuals is becoming more widespread. Analysis of the *Rb-1* gene has been used for a decade to detect carriers in families with retinoblastoma. In affected families, surveillance of newborns for early cancer can reduce loss of vision. As genes for more common cancers have been found, ethical and social issues have become more complex [*see 3:VIII Genetic Diagnosing and Counseling*]. Careful consideration must be given to the costs and benefits of genetic testing.[114]

Screening and Early Detection

The recommendations of the American Cancer Society, the National Cancer Institute, and the United States Preventive Services Task Force for the prevention and early detection of cancer have received wide attention. These guidelines are intended primarily for asymptomatic patients at average risk of cancer. They do not apply to symptomatic patients, who should be managed by the usual standards of medical practice. Patients considered to be at increased risk because of family history or environmental exposures should seek a physician's recommendations for establishing an appropriate early-detection program.

Data are incomplete regarding the costs, risks, and benefits of cancer screening in the general population. A few large randomized studies have been completed for specific cancers, such as breast cancer. These studies have found that periodic mammography reduces breast cancer mortality by 25% to 30% in women 50 to 70 years of age [*see CE:V Adult Preventive Health Care*]. Data are scanty and uncertain for younger and older women. To be useful, a screening test must detect preclinical cancers that are less likely to be lethal after treatment than if they are allowed to progress to clinical detection. False positive results of screening tests lead to unnecessary workups and treatment for indolent tumors and increase medical, psychological, and financial costs.[115] Identifying high-risk populations through risk evaluation, including genetic testing, can help channel scarce resources to susceptible persons.

The American Cancer Society has made specific recommendations for the early detection of asymptomatic carcinoma of the colon and rectum, cervix and other pelvic organs, breast, and prostate [*see Table 3*].[116] However, because of the lack of convincing evidence of benefit from screening for lung cancer, periodic chest x-rays and sputum cytology are not recommended, nor are CT scans. PSA is being increasingly used for prostate cancer detection. Serum PSA levels correlate with the clinical stage of

Table 3 American Cancer Society Recommendations for Early Cancer Detection[113]

Tissue	*Test or Procedure*	*Sex*	*Age (years)*	*Frequency*
Breast	Breast self-examination (BSE)	Female	Early 20s	Should be informed about benefits and limitations and then may choose to do BSE or not
	Breast clinical physical examination	Female	20–39	Every 3 yr
			40	Every year
	Mammography	Female	40	Every year
Colorectal*	Fecal occult blood test	Male, female	50	Every year
	and/or			
	Flexible sigmoidoscopy	Male, female	50	Every 5 yr
	or Colonoscopy	Male, female	50	Every 10 yr
	or Double-contrast barium enema	Male, female	50	Every 10 yr
Cervix	Papanicolaou smear Pelvic examination	Female	Papanicolaou smear and pelvic examination every year for women who are or have been sexually active for 3 yr or have reached 21 yr of age; after 30 yr of age, after three or more consecutive satisfactory normal annual exams, the Pap test may be performed every 2 to 3 yr at the discretion of the physician	
Endometrium	Endometrial tissue sample	Female	Women at very high risk beginning at 35 yr of age	Should be informed about potential benefits and limitations of screening
Prostate	PSA/DRE	Male	50	Every year Annual PSA/DRE testing should be limited to men with life expectancy of at least 10 yr and men at high risk (those of African descent or with familial risk should initiate testing at 45 yr of age); the benefits and limitations should be discussed with the clinician, but if the clinician is asked to make the decision, the ACS recommends testing
Skin	Skin	Male	20–40	Every 3 yr
		Female	> 40	Every year
General	Health counseling and cancer checkup	Male	20–40	Every 3 yr
		Female	> 40	Every year

*These guidelines are intended for individuals at standard risk. Patients with a family history or other factors that indicate elevated risk should consult their physicians for recommended screening guidelines.

DRE—digital rectal examination PSA—prostate-specific antigen

prostate cancer and the volume of the cancer in the gland[117]; evidence of its efficacy is minimal, and the National Cancer Institute currently recommends informed decision making between the physician and the patient. A large randomized trial, the Prostate, Lung, Colorectal, Ovary (PLCO) trial, is currently in progress to assess screening tests for each of these cancers.[118]

The current screening guidelines can be expected to evolve with the accrual of knowledge and technological advances. For example, the technical quality of mammograms and their interpretation are critical factors in their usefulness. Mammographic detection of cancer is more problematic in the dense breast tissue of younger women, whose tumor growth rates are generally more rapid. After analyzing the same body of evidence from randomized mammographic studies, expert committees have reached different conclusions regarding routine mammographic screening of asymptomatic women 40 to 49 years of age. The American Cancer Society, the National Cancer Institute, and other groups have recommended that women begin receiving annual mammograms once they reach 40 years of age, but the National Institutes of Health consensus panel did not make this recommendation.[119] Of several methods available for colorectal cancer screening, colonoscopy was found to be superior to both double-contrast barium enema and sigmoidoscopy in two studies.[120,121] New screening methods, such as magnetic resonance imaging of the breast and spiral computed tomography of the lungs, may further enhance the sensitivity and specificity of screening tests.[122]

Clinicians can help prevent and detect cancer at early stages. They can prevent environmental cancers by counseling patients to avoid tobacco use, asbestos exposure, and unnecessary exposure to ionizing radiation. A brief medical and family history can reveal an unusual predisposition to cancer and a need for closer medical surveillance. In the course of the physical examination, attention to signs of early cancer can lead to curative treatment.

II MOLECULAR GENETICS OF CANCER

Daniel A. Haber, m.d., ph.d.

Cancer as a Genetic Disease

The uncontrolled clonal expansion of a cell, which often leads to invasion of surrounding tissues and metastatic spread, produces cancer. The initial genetic alterations in this cell that trigger its aberrant proliferation are followed by the accumulation of additional mutations among its progeny. Finally, a selection process occurs by which subclones with enhanced growth properties become dominant within the tumor—so-called tumor progression. A clear histologic and molecular genetic evolution from precancerous lesions to frankly malignant and invasive cancer has been defined for some tumors (e.g., colon and bladder cancers); in many cancers, however, this process may not be clinically evident. The genes that are altered in the development and progression of cancer are still being intensively investigated. In many cases, identification of these genes has led to major insight into the normal physiologic mechanisms that control cell proliferation. The products of these genes are engaged in basic cell cycle regulation, transmission of growth signals, regulation of cellular differentiation and cell death, and establishment of cellular immortality. Disruption of these genes typically occurs in somatic cells destined to become cancerous. However, in rare cases, mutations may be passed on in the germline, resulting in genetic predisposition to cancer (i.e., familial cancer syndromes).

Environmental factors are also thought to contribute to the development of cancer. Interactions between environmental factors and subtle genetic variations that distinguish individuals may conceivably constitute an important determinant of cancer risk within the general population.[1] In some cases, there is a direct link between the effect of the carcinogen on DNA and specific mutations in the *p53* tumor suppressor gene (e.g., exposure to tobacco or to the fungal toxin aflatoxin). In other cases, more indirect effects may increase the risk of developing cancer (e.g., exposure to such potent carcinogens as asbestos or more subtle exposure, such as occurs with prolonged treatment with estrogen). Exposure to ionizing radiation is another cause of cancer. The incidence of leukemias and various solid tumors in atomic bomb survivors provided data for classic studies of radiation dosage and its consequences. More recent data derive from cases of late complications of radiation therapy or cases involving the administration of radiomimetic chemotherapy drugs to patients as treatment for an initial malignancy.

Finally, viral infection has been linked to the development of specific cancers. Cancer-virus linkages include cervical carcinoma with specific subtypes of human papillomavirus; hepatocellular carcinoma with chronic hepatitis B virus infection; nasopharyngeal carcinoma and lymphomas with Epstein-Barr virus in immunosuppressed hosts; the rare acute T cell leukemia with acute transforming human T cell lymphotrophic virus type I; and, potentially, Kaposi sarcoma with human herpesvirus 8. Such cases, it should be noted, represent exceptions to the rule; most human cancer does not result from viral infection. However, much of our understanding about the human genes involved in cancer was originally derived from the study of viruses that cause tumors in chickens and rodents. The misappropriation by these viruses of cellular genes involved in cellular proliferation led to the identification of oncogenes and provided the first clue to the genetic events that cause cancer in humans.

Oncogenes and Proto-oncogenes

ACTIVATING OR GAIN-OF-FUNCTION MUTATIONS

Cancer-causing genes, or oncogenes, were discovered when researchers found that specific genes of chicken and rodent retroviruses can transform normal mammalian cells in culture. These viral transforming genes proved to be activated homologues of mammalian genes (proto-oncogenes) that had been stolen from the host cell during viral evolution for their ability to stimulate cellular proliferation.[2] Primary human cancers, although not caused by viral infection, were found to harbor similar activated alleles of proto-oncogenes. Among the first oncogenes discovered were those that encoded proteins directly involved in the transmission of cellular proliferation signals. These include receptors for growth factors that are constitutively activated, as though responding to the continuous presence of a growth factor (e.g., platelet-derived growth factor receptor or epidermal growth factor receptor), and downstream signaling molecules (i.e., molecules that are activated in response to growth factor signaling) that normally shuttle between an on and off state but are mutated in cancer cells to a permanently on position (e.g., H-*ras*, K-*ras*, and N-*ras*). The mechanisms by which these normal cellular proto-oncogenes are activated in human cancers include point mutations, gene amplification, and chromosomal translocations [*see Table 1 and Figure 1*]. Because they result in novel or altered functional properties for the encoded protein and are genetically dominant over the second normal allele, these mutations are commonly referred to as gain-of-function mutations.

Point Mutations

Point mutations that are capable of activating a gene product are unusual and reflect specific functional properties of the protein itself. For instance, only specific alterations in three codons of ras family proteins lead to constitutive activation of ras signaling.[3] Presumably, other mutations are functionally silent or lead to inactive proteins and thus are not selected during malignant transformation. Similarly, specific amino acid changes in growth factor receptors or other signaling molecules confer an active, growth-inducing effect or prevent downregulation by appropriate physiologic signals. Of particular interest are mutations in the *ret* gene, which codes for a growth factor receptor and is the only proto-oncogene found to be mutated in the germline of patients predisposed to cancer. Amino acid substitutions within distinct functional domains of the protein cause multiple endocrine neoplasia type IIA or type IIB or medullary thyroid cancer, whereas inactivating mutations cause Hirschsprung disease, a developmental defect affecting colonic innervation.[4] This striking link between different mutations in the *ret* gene and distinct cancer and developmental syndromes presumably results from different functional properties that are mediated by the various domains of the ret protein, as well as from different ret-associated pathways that may be activated in different tissue types.

Table 1 Selected Oncogene Mutations in Human Cancer[95]

Gene	*Activation Mechanism*	*Protein Properties*	*Cancer Types*	*Germline Mutations*
K-*ras*	Point mutation	p21 GTPase	Pancreatic, colorectal, lung (adenocarcinoma), endometrial, other carcinomas	ND
N-*ras*	Point mutation	p21 GTPase	Myeloid leukemia	ND
H-*ras*	Point mutation	p21 GTPase	Bladder	ND
EGFR (*erb B)*	Amplification	Growth factor (EGF) receptor	Gliomas, squamous and other carcinomas	ND
NEU (erb B2)	Amplification	Growth factor receptor	Breast, ovarian, gastric, other carcinomas	ND
c-*myc*	Chromosome translocation, amplification	Transcription factor	Burkitt lymphoma, SCLC, other carcinomas	ND
N-*myc*	Amplification	Transcription factor	Neuroblastoma, SCLC	ND
L-*myc*	Amplification	Transcription factor	SCLC	ND
bcl-2	Chromosome translocation	Antiapoptosis protein	B cell lymphoma (follicular type)	ND
CYCD1	Amplification, chromosome translocation	Cyclin D, cell cycle control	Breast and other carcinomas, B cell lymphoma, parathyroid adenomas	ND
bcr-abl	Chromosome translocation	Chimeric nonreceptor tyrosine kinase	CML, ALL (T cell)	ND
ret	Chromosome translocation, point mutation	GNDF-receptor tyrosine kinase	Thyroid (papillary type) Thyroid (medullary type)	Yes (MEN2)
CDK4	Amplification, point mutation	Cyclin-dependent kinase	Sarcoma	Yes (familial melanoma)
MET	Point mutation	HGF-receptor tyrosine kinase		Yes (hereditary renal cancer, papillary type)
SMO	Point mutations	Transmembrane signaling molecule in sonic hedgehog pathway	Basal cell skin	ND
β-CAT	Point mutation, in-frame deletion	Transcriptional coactivator, links E-cadherin to cytoskeleton	Melanoma, colorectal	ND
HST	Amplification	Growth factor (FGF-like)	Gastric	ND
PML-RAR-α	Chromosome translocation	Chimeric transcription factor	APL	ND
W2A-PBX1	Chromosome translocation	Chimeric transcription factor	Pre-B ALL	ND
MDM-2	Amplification	p53-binding protein	Sarcoma	ND
gli	Amplification	Transcription factor	Sarcoma, glioma	ND
TTG	Chromosome translocation	Transcription factor	T cell ALL	ND

ALL—acute lymphocytic leukemia APL—acute promyelocytic leukemia CML—chronic myelogenous leukemia EGF—epidermal growth factor FGF—fibroblast growth factor GDNF—glial cell line–derived neurotrophic factor GTPase—guanine trinucleotide phosphatase HGF—hepatocyte growth factor ND—not determined SCLC—small cell carcinoma of the lung

Gene Amplification and Chromosomal Translocations

In addition to amino acid substitutions resulting in an activated gene product, proto-oncogenes may be converted to their oncogenic forms by gross chromosomal alterations. Gene amplification—the overreplication of large chromosomal fragments—is a common mechanism for aberrant overexpression of specific genes in tumors.[5] Amplified genes, which occasionally may number as many as hundreds of copies of normally diploid genes, may reside on small extrachromosomal elements (double minute chromosomes) or may be integrated within a single chromosomal location, detectable as a large homogeneously staining region. In cancer cells, the loss of cellular genes that normally contribute to the maintenance of genomic integrity (e.g., *p53*) may facilitate aberrant chromosomal events, including gene amplification, and thus the accumulation of additional genetic lesions. Among the best-known oncogenes that are amplified in cancer cells is N-*myc*. This gene codes for a transcription factor that plays a physiologic role in stimulating cellular proliferation and is commonly amplified in the pediatric cancer neuroblastoma; patients have a poor clinical prognosis.[6] Overexpression of a proto-oncogene may also result from a chromosomal translocation or rearrangement, which removes the cellular gene from its physiologically regulated promoter and brings it under the control of a foreign and more active promoter.[7] In Burkitt lymphoma, for instance, the chromosomal locus containing the c-*myc* gene is rearranged such that the upstream (i.e., a region that is located to the 5′ side of a gene) negative regulatory regions of c-*myc* are lost; expression of the gene is directed by the strong immunoglobulin heavy-chain enhancer, which is constitutively active in B lymphocytes.[8,9] Deregulation of c-*myc* expression in these cells is thus a potent force driving cellular proliferation.

The first specific chromosomal translocation identified in human cancer was the Philadelphia chromosome, which underlies chronic myeloid leukemia (CML). The fusion of chromosomes 9 and 22 leads to the joining of two unrelated genes, the c-*abl* gene, which encodes a tyrosine kinase and is located on chromosome 9, and the gene *bcr* (for breakpoint recombination), located on chromosome 22.[10] A chimeric protein with novel transforming properties is formed from this specific chromosomal rearrangement. Uncommon variants of CML, in which a Philadelphia chromosome is not evident by cytogenetic analysis, may have complex genetic rearrangements, resulting in a *bcr-abl* translocation that can be detected only with molecular markers. The accelerated or blast phase of CML is often associated with duplication of the Philadelphia chromosome, suggesting that increased copies of this aberrant gene confer a dose-dependent transforming effect. The *bcr-abl* fusion also demonstrates a striking cell-type specificity: the classic chromosomal breakpoint is associated with myeloid proliferation, whereas a variant breakpoint, resulting in a subtle alteration in the chimeric protein, leads to a pediatric lymphoid leukemia that has a poor prognosis.[11] The importance

of the *bcr-abl* translocation as the initiating genetic event in CML is supported by a mouse model, in which transgenic expression of a bcr-abl chimeric protein in hematopoietic cells is sufficient to trigger both myeloid and lymphoid proliferation.[12] The recent discovery of an effective inhibitor of the bcr-abl kinase, imatinib mesylate (formerly STI571), has led to dramatic responses in CML and has revolutionized treatment of this leukemia[13] [*see* Rational Drug Design and Small Molecules, *below*].

Chromosomal translocations that generate novel chimeric proteins have been linked to other types of leukemia.[14] In acute promyelocytic leukemia (APL), a chromosomal rearrangement joins a novel gene, *PML*, to the gene for the retinoic acid receptor–α (*RAR*-α). Although the precise functional properties of the chimeric molecule, PML-RAR-α, are unknown, this translocation underlies the dramatic responsiveness of this leukemia to treatment with all-*trans*-retinoic acid, which has revolutionized the clinical care of patients with APL.[15] A novel chromosomal translocation product, TEL-AML1, that underlies a common and treatment-responsive form of pediatric acute lymphoblastic leukemia has also been identified.[16]

The ability to grow leukemic cells in culture long enough to allow cytogenetic analysis has facilitated the characterization of chromosomal translocations in leukemias. However, specific chromosomal translocations have also been observed in solid tumors. Among the most noteworthy are Ewing sarcoma and the family of peripheral neuroepithelial tumors (PNETs). These once disparate tumors are now defined by a chromosomal translocation fusing the *EWS* gene to a number of transcription factors

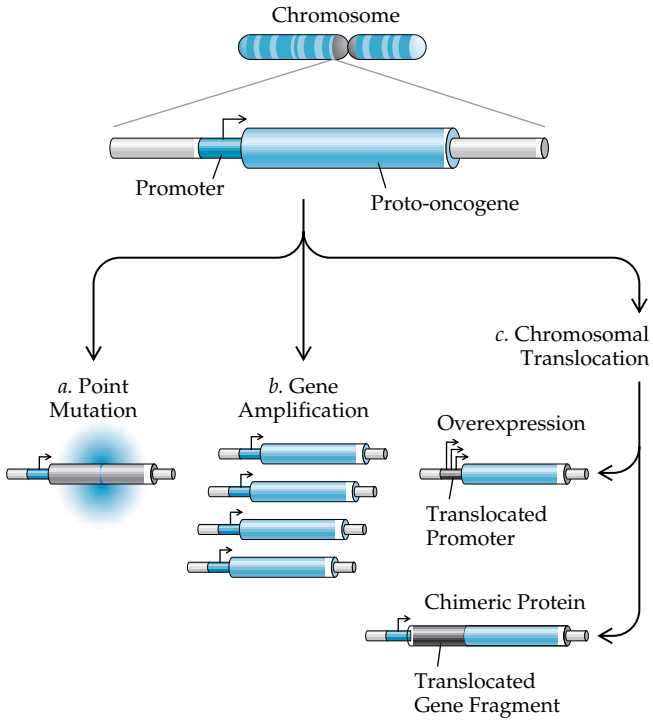

Figure 1 **Mechanisms of activation of proto-oncogenes. Cellular genes may be activated in cancer as a result of (*a*) point mutations that alter the amino acid sequence, encoding a protein that may be constitutively activated; (*b*) amplification of the cellular gene, resulting in higher levels of protein expression; or (*c*) chromosomal translocations that lead to the juxtaposition of a strong promoter and cause increased protein expression or that produce a novel chimeric protein, derived from gene fragments normally present on different chromosomes.**

of the *ETS* gene family (the most common chimeric protein is EWS-FLI1).[17] This chimeric product presumably acts directly on target promoters to direct the expression of genes that induce cellular proliferation. Identification of the *EWS* translocations allowed the molecular grouping of a class of tumors whose proliferation is driven by similar genetic alterations and that respond to similar chemotherapeutic regimens.

IN VITRO AND MOUSE MODELS OF ONCOGENE FUNCTION

The detection of gain-of-function mutations in proto-oncogenes provides strong evidence that these genetic alterations contribute to malignant transformation. However, the timing of these mutations during the initiation and progression of cancer may be variable. With the single exception of c-*ret*, mutations in proto-oncogenes are not observed in the germline of patients with familial cancer syndromes, presumably because they are likely to have adverse consequences on normal development. Chromosomal translocations appear to constitute the initiating event for malignant transformation in some leukemias and solid tumors; in other cancers, mutations in proto-oncogenes are thought to contribute to the progression of cancer once it has developed. Two model systems, transgenic mice and primary cell culture, have proved to be of great value in investigating the functional properties of oncogenes. Transgenic mice are generated by the injection of recombinant DNA plasmids into a fertilized egg.[18] These plasmids may contain an oncogene whose expression is directed by a tissue-specific promoter. A fraction of the mouse progeny will demonstrate the predicted expression of the transgenic construct. Although expression of some oncogenes in appropriate tissues may trigger malignant growth, in other cases, cancer develops only after the mating of mice expressing different oncogenes. The simultaneous expression of two different oncogenes may induce malignant growth.[19] The function of dominant oncogenes is also being tested via transformation of primary rodent cells in vitro. Whereas established cell lines often require little stimulus to become tumorigenic, primary cultured cells, such as those derived from baby rat kidneys or mouse embryo fibroblasts, are transformed only after the introduction of combinations of potent oncogenes.[20] The combination of c-*myc* and activated H-*ras*, for instance, is effective in transforming primary cells, but neither oncogene is sufficient by itself.

In addition to their role in validating the transforming potential of activated proto-oncogenes, these functional assays in the study of DNA tumor viruses have provided important insight into the link between oncogenes and another class of cancer genes, tumor suppressors. Unlike retroviruses that have activated versions of cellular proto-oncogenes incorporated into their own genomes, DNA tumor viruses, such as adenovirus, SV40, and papillomavirus, encode original viral proteins capable of transforming rodent, monkey, or human cells. Introduction of SV40 T antigen into transgenic mice leads to the development of tumors in virtually any tissue to which its expression is directed. Similarly, the combination of adenoviral proteins E1A and E1B has transforming potential, as shown in primary cell transformation assays. A major discovery regarding the etiology of cancer was the finding that the transforming genes derived from these three unrelated DNA tumor viruses have the same function—namely, the inactivation of the cellular tumor suppressor genes *p53* and *RB1*.[21] Cancer thus arises from both the gain of proliferative signals and the loss of genes that inhibit cellular proliferation.

Tumor Suppressor Genes

REVERSION OF TUMORIGENICITY

Formerly referred to as anti-oncogenes, tumor suppressors constitute a family of cellular genes whose inactivation during tumorigenesis promotes malignant growth [*see Table 2*]. Their initial discovery arose from three convergent lines of investigation: analysis of the functional properties of normal versus cancer cells, epidemiologic studies of pediatric cancer, and molecular genetic analysis of chromosomal losses in tumors. Among the earliest discoveries was that fusion of a malignant cell to a nonmalignant cell resulted in a hybrid cell that had lost its malignant properties [*see Figure 2*].[22] This unexpected finding indicated that the malignant state was recessive and suggested that genes in the nonmalignant cell could restore normal growth control to a malignant cell that had presumably lost genetic information. These experiments were followed by the demonstration that individual chromosomes isolated from normal cells were capable of reverting the tumorigenicity of cancer cells.[23] The molecular cloning of specific tumor suppressor genes then made it possible to show that recombinant DNA plasmids containing these genes were capable of suppressing malignant growth.

THE KNUDSON MODEL AND LOSS-OF-FUNCTION MUTATIONS

Most cancers arise during adulthood; presumably, the fact that the incidence of cancer rises with increasing age is a reflection of the accumulation of genetic damage in aging stem cells. Pediatric cancers, although rare, typically develop in early stem cells, such as the renal stem cells that give rise to Wilms tumor, the primitive neuroectodermal cells that are transformed in neuroblastoma, and the retinoblasts that may produce the eye tumor retinoblastoma. A striking feature of these pediatric tumors is the existence of families in which approximately half the children develop specific types of tumors. Within these cancer-prone families, the tumors that arise are frequently bilateral or multicentric at presentation and develop earlier than in corresponding cases arising sporadically within the general population. By using Poisson distribution to determine the probability of developing cancer as a function of age in familial versus sporadic pediatric cancers, Alfred Knudson proposed the model that now forms the foundation of human cancer genetics [*see Figure 3*].[24]

The Knudson model predicts that children with familial tumors have inherited an initial genetic hit (i.e., a distinct genetic alteration) and require only one additional, rate-limiting genetic hit to initiate tumorigenesis. In contrast, children with sporadic tumors need to acquire two independent genetic hits within the

Table 2 Mutations in Selected Tumor Suppressor Genes and Candidate Tumor Suppressor Genes in Cancer[95]

Gene	*Function of Protein Product*	*Cancers with Somatic Mutations*	*Germline Mutations*
RB1	Transcriptional regulator, E2F1 binding	Retinoblastoma, osteosarcoma, SCLC, breast, prostate, and bladder	Familial retinoblastoma
TP53	Transcription factor	~50% of all cancers (rare in some cancer types—e.g., prostate carcinoma, neuroblastoma)	Li-Fraumeni syndrome
p16	Cyclin-dependent kinase inhibitor	~20%–25% of many different cancer types (e.g., breast, lung, pancreatic, bladder)	Familial melanoma, familial pancreatic carcinoma
APC	Regulates β-catenin function, ?microtubule binding	Colorectal mutations, rare or absent in most other cancers	Familial adenomatous polyposis, Gardner syndrome, Turcot syndrome, familial desmoid disease
MSH2, MLH1, PMS1, PMS2	DNA-mismatch repair	Colorectal, endometrial, gastric	Hereditary nonpolyposis colorectal cancer
WT-1	Transcription factor	Wilms tumor	WAGR and Denys-Drash syndromes
NF-1	p21ras-GTPase, ?microtubule binding	Melanoma, neuroblastoma	Neurofibromatosis type 1
NF-2	Juxtamembrane link to cytoskeleton	Schwannomas, meningiomas, ependymomas	Neurofibromatosis type 2
VHL	?Regulator of protein stability	Renal (clear-cell type), hemangioblastoma	von Hippel–Lindau disease
BRCA1	?DNA repair, complexes with Rad51, transcriptional regulation	Ovarian (~10%), rare in breast	Inherited breast and ovarian carcinoma
BRCA2	DNA repair, binds to Rad51	Not known	Inherited breast (female and male), pancreatic, and ?ovarian carcinoma
MEN1	Not known	Parathyroid adenomas, pituitary adenomas, endocrine tumors of pancreas	Multiple endocrine neoplasia type I
PTCH basal	Transmembrane receptor for sonic hedgehog; negative regulator of smoothened protein	Basal cell skin, medulloblastoma	Gorlin syndrome, hereditary cell syndrome
PTEN	Tyrosine phosphatase	Glioma, breast, prostate, head and neck, squamous cell, follicular thyroid cancer	Cowden disease
DPC4	Downstream signaling in TGF-β pathway	Pancreatic, mutations rare in others (e.g., colon, gastric)	Not known
E-CAD	Transmembrane cell-cell adhesion molecule	Diffuse type gastric and lobular breast; rare mutations in others (e.g., endometrial and ovarian)	Not known
α-CAT	Links E-cadherin to the cytoskeleton	Some prostate and lung, ?others	Not known
DCC	?Transmembrane receptor for netrin cell guidance molecule	Mutations in some colorectal and other carcinomas, gliomas, neuroblastomas, germ cell tumors, AML	Not known
TGF-βII R	Transmembrane receptor for TGF-β	Colorectal and gastric, ?others	Not known

AML—acute myeloid leukemia SCLC—small cell lung cancer TGF-β—transforming growth factor–β WAGR—Wilms tumor, aniridia, genitourinary abnormalities, mental retardation syndrome

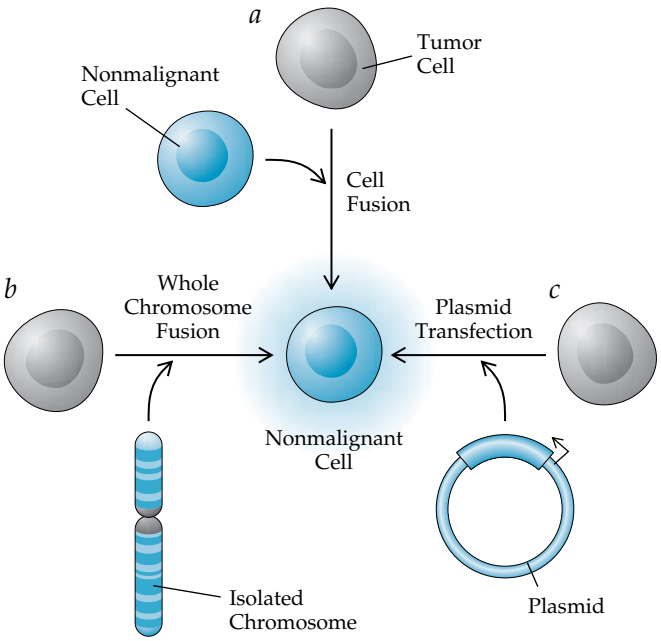

Figure 2 **Reversion of tumorigenicity by tumor suppressor genes. The observation that malignant properties of cultured cells can be reversed by introduction of normal DNA indicates that in many cases, these properties result from the loss of genetic material. These experiments include (*a*) cellular fusion of a malignant cell with a nonmalignant cell, resulting in loss of malignant growth properties; (*b*) introduction of a specific chromosome into the malignant cell, with the same result; and (*c*) insertion of a cloned individual gene (tumor suppressor) into the malignant cell, leading to loss of the malignant phenotype.**

same cell, an unlikely event that explains the less frequent, unilateral presentation and later onset of sporadic cancers. Subsequent genetic studies in two of the tumors studied by Knudson identified these so-called genetic hits as the sequential inactivation of the two alleles of a critical tumor suppressor gene: *RB1* in retinoblastoma[25] and *WT1* in Wilms tumor.[26] The Knudson model also explains the paradox that tumor suppressor gene mutations are loss-of-function or recessive mutations [*see Table 2*], yet familial cancer presents as an autosomal dominant trait. Although loss of a single allele of a tumor suppressor gene may be functionally silent in the presence of a normal second allele, the frequency of spontaneous mutations is sufficiently high to ensure that at least one cell within the target tissue is likely to lose the second allele and initiate malignant transformation [*see Figure 3*].

Tumor suppressor genes were identified by the application of cytogenetic and molecular genetic tools to these functional and epidemiologic observations. Whereas the initial mutation that inactivates one allele of a tumor suppressor gene is typically a point mutation within the gene itself, loss of the second allele commonly results from a gross chromosomal deletion or rearrangement.[27] This second hit may be readily identified by karyotype analysis, but more commonly it requires molecular analyses to detect the loss of polymorphic markers closely linked to the targeted gene. Polymorphic markers (such as restriction fragment length polymorphisms) are genetic variations that may be used to identify a chromosome inherited from either parent [*see Figure 4*]. Loss of a polymorphism derived from either parent (so-called loss of heterozygosity [LOH]) is an indication that a neighboring tumor suppressor gene has been inactivated in a cancer. Such allelic losses, which may be mapped across all chromosomes for a given tumor type, have been most effective for isolating individual tumor suppressor genes, typically with positional cloning strategies.

CELL CYCLE PROGRESSION AND THE RB1 PATHWAY

The first tumor suppressor identified was the *RB1* gene, which is involved in the pediatric eye tumor retinoblastoma.[25] In many ways, *RB1* remains the prototype for this class of genes, and its intimate connection to the basic mechanism of cell cycle progression illustrates the close connection between normal cellular proliferation and malignant transformation. As predicted by the

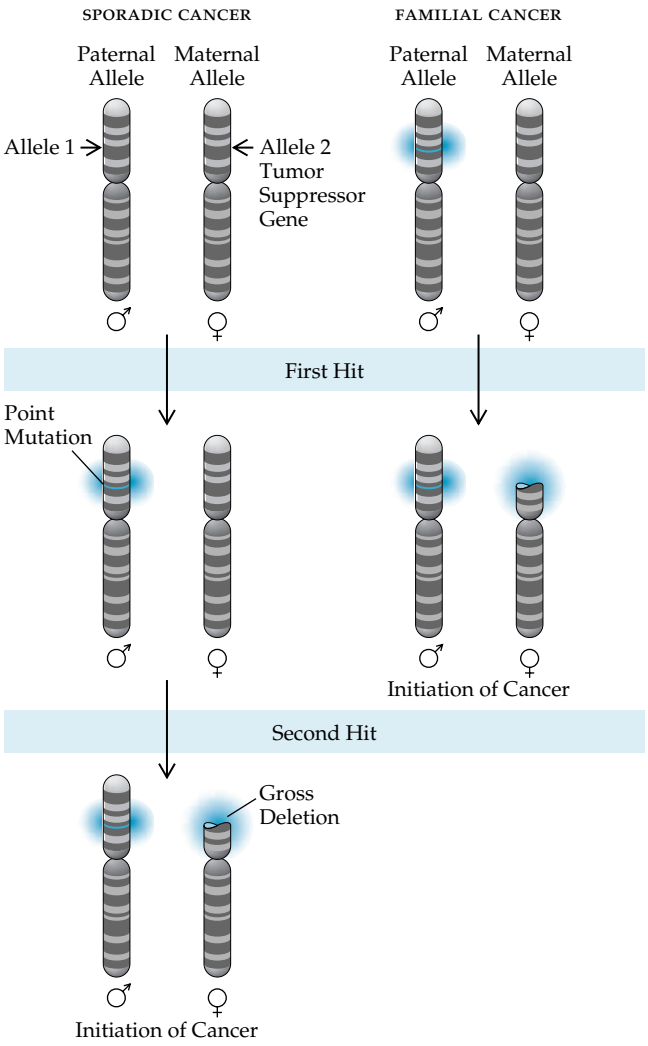

Figure 3 **The Knudson two-hit model of tumor initiation. As currently formulated, the model predicts that inactivation of both alleles of a tumor suppressor gene are required and rate-limiting for the initiation of cancer. In sporadic cancer, the inactivation of these two alleles within the same cell depends on two independent rare genetic events. In contrast, persons who have one mutated tumor suppressor gene allele in their germline, either inherited from one parent or as a result of a de novo germline mutation, require only one genetic event (i.e., loss of the second allele) for tumor initiation. This single mutation may occur in any cell within the target organ, which explains the high frequency of cancer, its earlier onset, and frequent multicentric presentation in persons with genetic predisposition to cancer.**

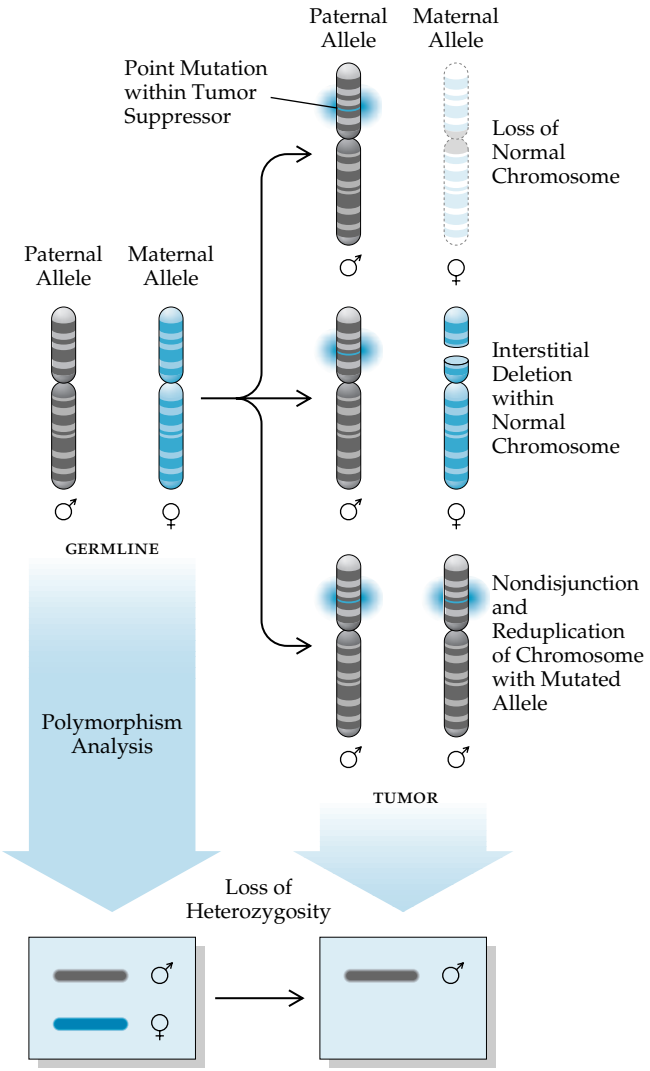

Figure 4 **Allelic losses in tumors and loss of heterozygosity (LOH). The loss of genetic material that accompanies tumor development has been used to map the chromosomal location of tumor suppressor genes. Whereas the initial genetic hit typically results from a point mutation within a tumor suppressor gene, the second gene inactivation event is commonly the result of a gross chromosomal loss. This may include loss of the entire normal chromosome, a small deletion that removes a chromosomal segment containing the gene, or a duplication of the chromosome carrying the mutant allele, with loss of the normal chromosome. These chromosomal events can be mapped using restriction fragment length polymorphisms or other molecular methods that distinguish maternally inherited alleles from paternally inherited alleles. The identification of chromosomal loci that are subject to LOH in specific cancers has formed the starting point for the cloning of cancer predisposition genes.**

Knudson model,[24] one allele of *RB1* is inactivated in the germline of children with familial retinoblastoma; their tumors demonstrate LOH, indicating somatic loss of the remaining allele. Children with sporadic retinoblastoma constitute 90% of cases; in these children, both *RB1* alleles are inactivated within a single somatic cell. Children harboring a mutation in one *RB1* allele are also prone to osteosarcomas, although they do not show increased susceptibility to other types of cancers in which somatic loss of *RB1* has been demonstrated (e.g., lung cancer). This illustrates a central paradox in cancer genetics: a gene expressed in all normal tissues is rate limiting for the initiation of cancer in only selected organs; in other organs, it appears to be just one of many genetic alterations that contribute to the malignant state. Current explanations for this paradox include potential differences in the genetic wiring of different cell types, as well as differences in compensatory mechanisms that may be activated after the loss of a tumor suppressor gene (e.g., the triggering of cell death).

The protein encoded by *RB1* is a nuclear phosphoprotein that binds to products of a gene family called *E2F*, which in turn associate with proteins of the *DP* gene family.[28] The E2F-DP complexes play a critical role in activating transcription of genes required for DNA synthesis; binding to RB1 suppresses this effect, essentially blocking cells in the G_1 phase of the cell cycle. During normal cellular proliferation, a cell cycle–regulated kinase complex containing cyclin D and cyclin-dependent kinase 4 (CDK4) phosphorylates RB1, causing its release from E2F-DP; this in turn allows cells to enter the DNA synthesis (S) phase of the cell cycle. Although the physiologic inactivation of RB1 through hyperphosphorylation is transient and reversible, mutational inactivation of RB1, common to many different tumor types, ensures a continued drive for cellular proliferation. Similarly, oncogenic DNA viruses encode proteins that specifically and irreversibly inactivate the *RB1* gene product, including the E1A protein of adenovirus, T antigen of SV40, and E7 protein of papillomavirus. *RB1* itself is a member of a gene family, with two closely related genes called *p107* and *p130*. Why *RB1* is frequently targeted by mutations in human cancers, whereas these similar genes are not mutated, is still unknown. A better understanding of subtle differences in the physiologic function of these gene family members may explain this striking specificity.

Understanding the normal regulation of *RB1* has provided important insight into other cancer genes that play a role in cell cycle regulation [*see Figure 5*]. Cyclin D, a gene whose expression leads to the hyperphosphorylation and inactivation of RB1, is commonly amplified and overexpressed in breast cancer. In contrast, *p16-INK4a*, the gene for an inhibitor of CDK4 that favors the active, hypophosphorylated form of RB1, is deleted in a wide variety of tumors. Germline mutations of *p16-INK4a* are a cause of familial melanoma.[29] Finally, mutations in the kinase gene *CDK4* that make the encoded protein insensitive to inhibition by p16-INK4a, favoring inactivation of RB1, have also been demonstrated in human cancers and in melanoma kindreds. A striking feature of mutations in these different components of the cell cycle pathway is that they appear to be mutually exclusive. A single tumor typically has an abnormality in only one of these genes—evidence that these mutations are functionally equivalent and that no further growth advantage is conferred by the accumulation of additional mutations in components of the same pathway.[30]

GENOMIC STABILITY GENES: *P53* AND *BRCA1*

Although the *RB1* tumor suppressor gene is a central component of cell cycle regulation, *p53* plays a critical role in the maintenance of genomic integrity—hence its popular designation as "guardian of the genome."[31] p53 is normally expressed at low levels in all cells. However, genetic injuries, such as those that occur through ionizing radiation, trigger the stabilization and activation of p53 protein. p53 functions as a transcription factor, directing expression of p21, an inhibitor of the cyclin-dependent kinases that regulate the cell cycle [*see Figure 6*].[32] Activation of p53 leads to arrest in the G_1 phase of the cell cycle, enabling cells to repair DNA damage before proceeding into S phase and

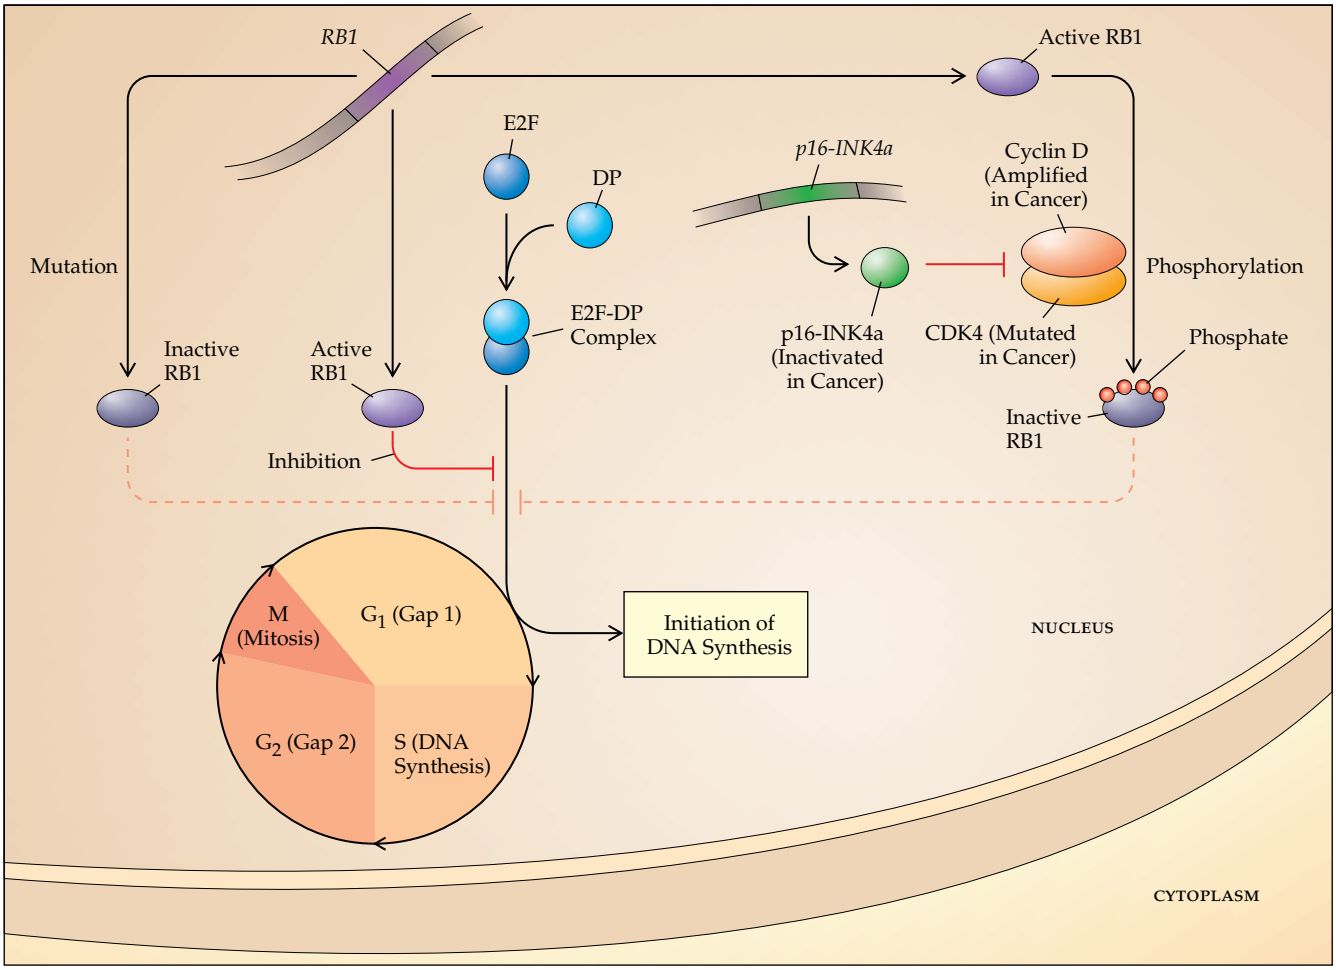

Figure 5 **The retinoblastoma gene (*RB1*) cell cycle pathway. Cellular division in mammalian cells is triggered by a critical checkpoint between G_1 phase and DNA synthesis (S phase). The E2F-DP protein complex, which activates genes required for DNA synthesis, is directly inhibited by the product of the *RB1* tumor suppressor gene. Normal cell cycle progression requires the reversible inactivation of RB1 protein by phosphorylation induced through cyclin D and CDK4. Mutations in RB1 prevent its normal inhibition of cell cycle progression, contributing to deregulated cellular division. Amplification of cyclin D, activating mutations in CDK4, and inactivation of the CDK4 inhibitor p16-INK4a are other mechanisms by which the RB1 pathway is disrupted in human cancers.**

DNA replication. In other cells, activation of p53 causes activation of multiple effectors, leading to apoptosis—a suicide program in cells whose DNA may have been irreparably damaged. Not surprisingly, mutations of p53 are common in human cancers, being demonstrable in about 50% of cases.[33] Most mutations are amino acid substitutions within the DNA-binding domain of p53, resulting in its misfolding and binding to heat shock proteins. The rate of protein turnover is greatly slowed for these mutant p53 molecules. This explains the paradox that high levels of p53 protein in tumor specimens are commonly taken as evidence of a mutation in p53.

The constellations of *p53* mutations in tumors have also provided an important correlation with the presumed mechanism of carcinogenesis. For example, specific *p53* mutations in liver cancers have been found in a population living in a region of China where there is exposure to high levels of the potent fungal liver carcinogen aflatoxin, and the panel of mutations observed in lung cancer are correlated with those induced by the polycyclic carcinogens in tobacco. In contrast, *p53* mutations detected in colorectal carcinoma are frequently seen at nucleotides that are susceptible to methylation, which appears to be a common mechanism for spontaneous mutations.[34]

Deletion of *p53* in the mouse has minimal effect on normal development but leads to greatly enhanced tumor formation.[35] This effect is more subtle in mice lacking one *p53* allele; mice missing both alleles rapidly succumb to tumors. Overexpression of some *p53* mutants may disrupt the normal formation of p53 tetramers, a so-called dominant-negative or dysfunctional phenotype, resulting in an intermediate level of tumor formation. In humans, loss of one *p53* germline allele is responsible for the multicancer phenotype known as Li-Fraumeni syndrome.[36] Families affected by this rare autosomal dominant trait demonstrate a highly penetrant predisposition to different types of cancer, including sarcomas, breast cancer, brain tumors, and leukemia. The mechanism whereby inactivation of p53 function leads to the development of cancer is thought to be loss of a checkpoint that monitors integrity of the genetic material before DNA replication. p53 also plays a critical role in triggering cellular suicide in response to inappropriate growth signals, such as those induced by the loss of other tumor suppressors or activation of proto-oncogenes. In some cancers, such as those arising in Li-Fraumeni syndrome, loss of *p53* initiates tumorigenesis; in others, such as colorectal

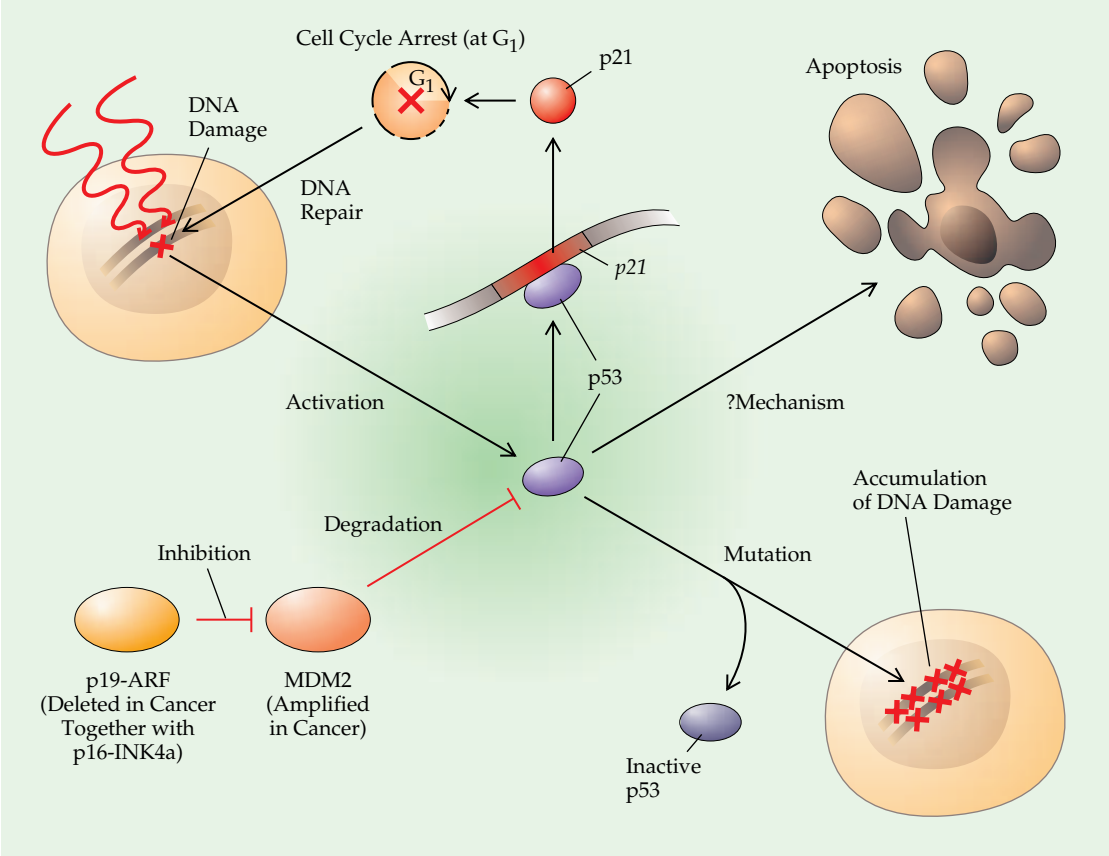

Figure 6 **The p53-DNA damage response pathway. p53 is activated after DNA damage, resulting in either of two cellular responses: induction of the CDK inhibitor p21, which leads to a G_1-phase cell cycle arrest, allowing time to repair DNA damage before cellular division; and programmed cell death (apoptosis), whereby the damaged cell undergoes suicide. In tumors with mutations of p53, DNA damage is not adequately repaired, leading to the accumulation of mutations and genetic rearrangements. Two cellular genes regulate p53 activation: *MDM2* and *p19-ARF*. MDM2 induces the normal degradation of p53 protein, and amplification of *MDM2* in some tumors results in loss of p53 function. p19-ARF inhibits the effects of MDM2 and contributes to the activation of p53 in response to DNA damage. *p19-ARF* is commonly deleted in human cancers, along with its neighboring gene, *p16-INK4a*.**

cancer, inactivation of *p53* is a late genetic event important in the progression of the malignant phenotype.

Like RB1, p53 is specifically targeted by viral oncogene products, including the E1B protein of adenovirus, T antigen of SV40, and the E6 protein of papillomavirus. Thus, DNA tumor viruses combine a dual strategy: inducing cellular proliferation by inactivating RB1 while disrupting the ability of p53 to trigger cell death in response to this aberrant proliferation signal.[37] Cellular proteins have also been found to regulate *p53* function. Among them is MDM2, a protein that is induced by p53 and that itself enhances p53 degradation, providing a critical negative feedback loop [*see Figure 6*]. The fact that p53 and MDM2 are part of a common cellular pathway is supported by mutually exclusive alterations in human cancers: osteosarcomas result from either a mutation inactivating p53 or amplification of the *MDM2* gene, leading to overproduction of the gene product.[38] Mice lacking both alleles of *MDM2* die in very early embryonic development, unless they also lack *p53*, in which case they develop normally to adulthood—evidence that MDM2 is critical to prevent unopposed activity by p53 during normal development.[39]

Activation of p53 in response to ionizing radiation occurs through the DNA damage response kinase ATM (ataxia-telangiectasia mutated) and its downstream kinases, CHK1 and CHK2.[40] Phosphorylation of p53 appears to reduce binding by MDM2 and lead to increased p53 protein stability and enhanced activity. A second important regulator of p53 is the *p19-ARF* gene. This gene is unusual in that it overlaps with the *p16-INK4a* gene but is encoded by a different codon reading frame.[41] p19-ARF interacts with MDM2 to regulate the turnover of p53; its role in human cancer is suggested by the frequency with which tumors contain genomic deletions that inactivate both p16-INK4a and p19-ARF. Activation of *p53* through the p19-ARF pathway is thought to be triggered primarily by aberrant proliferation signals associated with induction of E2F, a transcriptional regulator of p19-ARF.[42] Thus, DNA damage and aberrant oncogenic proliferation signals may activate p53 through distinct but complementary pathways. Of note, two long-overlooked gene family members of *p53*, *p73* and *p63*, have some of the same functional properties of *p53* in vitro; their possible role in human cancer is still under investigation.[43,44]

Although *p53* has been the most intensively studied tumor suppressor gene implicated in genomic stability, additional disease-associated genes appear to function in similar or parallel pathways. The ataxia-telangiectasia gene, *ATM*, is responsible for an autosomal recessive trait characterized by cerebellar degeneration, immunologic dysfunction, and cancer predisposi-

tion; as noted above, it functions upstream of *p53* and is required for *p53* to be activated after ionizing radiation.[45,46] Two other genes that may function in genomic stability are *BRCA1* and *BRCA2*.[47,48] The products of these genes, responsible for predisposition to breast and ovarian cancer, appear to interact with other proteins active in chromosomal recombination and repair.[49] Although the precise functional properties of the *BRCA1* and *BRCA2* gene products are currently unknown, mutations in these genes may trigger malignant transformation by preventing cells from repairing DNA damage. Other genes involved in the repair of chromosomal damage are associated with tumor-prone syndromes, including Fanconi anemia and the Nijmegen breakage syndrome.[50]

TUMOR SUPPRESSORS INVOLVED IN SIGNALING AND DIFFERENTIATION

The identification of tumor suppressor genes implicated in cancer predisposition syndromes led to the discovery of key components of cellular differentiation pathways. The *WT1* gene encodes a transcription regulator that is specifically expressed in podocytes of the developing glomerulus. Mutations in *WT1* cause Wilms tumor, an embryonic kidney cancer, and germline mutations lead to genitourinary developmental defects. The genes that are normally regulated by WT1 appear to be involved in proliferation and differentiation.[51] The von Hippel–Lindau gene (*VHL*) is frequently mutated in adult renal cell cancers and in the germline of persons with a syndrome that includes both benign and malignant vascular tumors. The function of the VHL protein appears to involve regulation of protein degradation pathways, particularly that of the transcription factor hypoxia inducible factor.[52] The *APC* gene is a key target in colorectal cancer: germline mutations cause familial polyposis coli, a syndrome characterized by the development of numerous colonic polyps with a very high risk of malignant transformation; somatic mutations constitute the earliest step in the development of colorectal cancer.[53] APC normally binds β-catenin, leading to its inactivation. β-Catenin is an important cofactor for the LEF/TCF family of transcription factors, which mediate signaling by the *WNT* gene family; the latter is involved in key developmental pathways. Inactivation of APC therefore disrupts WNT function, resulting in abnormal developmental signals in the colonic epithelium. The *SMAD* genes, active in signaling by transforming growth factor–β (TGF-β), are mutated in pancreatic tumors.[54] In the basal cell nevus syndrome, PTCH, a receptor for another growth factor called hedgehog, is mutated, conferring predisposition to skin cancer.[55] Other tumor suppressor genes linked to cellular signaling pathways are the *NF1* gene, which is responsible for neurofibromatosis (von Recklinghausen disease) and whose gene product normally downregulates the proto-oncogene *ras*[56]; the *NF2* gene, which is frequently mutated in mesotheliomas and schwannomas and which encodes a structural protein that may be involved in cellular adhesion and proliferation[57]; and the *PTEN* gene, which is implicated in a large number of different cancers and in the breast cancer predisposition syndrome known as Cowden disease. *PTEN* encodes a phosphatase thought to catalyze the removal of key phosphate moieties from specific target proteins.[58] PTEN negatively regulates the phosphoinositide 3-kinase pathway implicated in the regulation of proliferation and apoptosis. In sum, the genes whose disruption leads to human cancer are critical links in the pathways for normal cell differentiation and proliferation.

Microsatellite Instability and DNA Mismatch Repair

The use of short, repetitive stretches of nucleotides (microsatellites)—which are highly variable from person to person—to trace different alleles within tumor specimens led to a startling discovery: in some cases, microsatellites differ in size between tumors and normal cells of the same patient. This observation suggested that the tumors had inactivated genes that are required to correct errors in the replication of these short, repetitive stretches of DNA.[59] Inactivation of DNA mismatch repair genes, which are highly conserved from bacteria to humans, leads to the accumulation of errors during DNA replication that can be detected with randomly positioned microsatellite markers. When replication errors occur within critical genes, however, they may be detrimental and may trigger malignant proliferation. The members of the mismatch repair gene family that are most commonly targeted by mutations in human cancers are called *MSH2* and *MLH1*. Mutations in these genes result in loss of function; however, mismatch repair genes differ from classic tumor suppressors in that their inactivation initiates cancer indirectly (i.e., by increasing the frequency of mutations in other genes). Reintroduction of a normal mismatch repair gene copy after secondary mutations have arisen would presumably occur too late to reverse the malignant phenotype. Potential targets for mismatch repair genes have been identified. Among the most striking is the TGF-β receptor, which contains a short, repetitive stretch within its coding sequence.[60] Colorectal tumors, in which mutation of a mismatch repair gene triggers microsatellite instability, may have mutations within this specific sequence of the TGF-β receptor gene, thus disrupting an important pathway for the regulation of cellular proliferation in colonic epithelium. Germline mutations in mismatch repair genes are associated with a multicancer phenotype, called Lynch syndrome, or hereditary nonpolyposis colorectal cancer, which includes predisposition to cancers of the colon, ovary, and endometrium.[61] In addition, approximately 10% of sporadic colorectal cancers demonstrate microsatellite instability (so-called RER^+), suggesting that disruption of mismatch repair also contributes to colorectal cancer in the absence of familial predisposition [*see Figure 7*].[62]

Tumor Progression

THE ACCUMULATION OF GENETIC LESIONS

A genetic lesion within a single rate-limiting gene is required to initiate malignant transformation. However, the progression of the malignant phenotype requires the acquisition of additional mutations that confer an added growth advantage and are therefore selected during expansion of the malignant clone [*see Figure 8*]. A given gene may be rate limiting for transformation in one cell type but may play a secondary role in another. The most intensely studied model of tumor progression is colorectal cancer, for which Kinzler and Vogelstein correlated histologic progression from polyp to carcinoma with the accumulation of genetic events.[63] The inactivating mutation of the *APC* gene is associated with the development of epithelial hyperplasia; activating mutations in H-*ras* and changes in DNA methylation are correlated with progression to adenomatous polyps; changes in one or more genes residing on chromosome 18q denote the transition to high-grade adenomas; and finally, inactivation of p53 accompanies the evolution to malignant carcinoma [*see Figure 9*]. The preneoplastic lesions that lead to colorectal cancer are readily defined because they occur within the colonic mu-

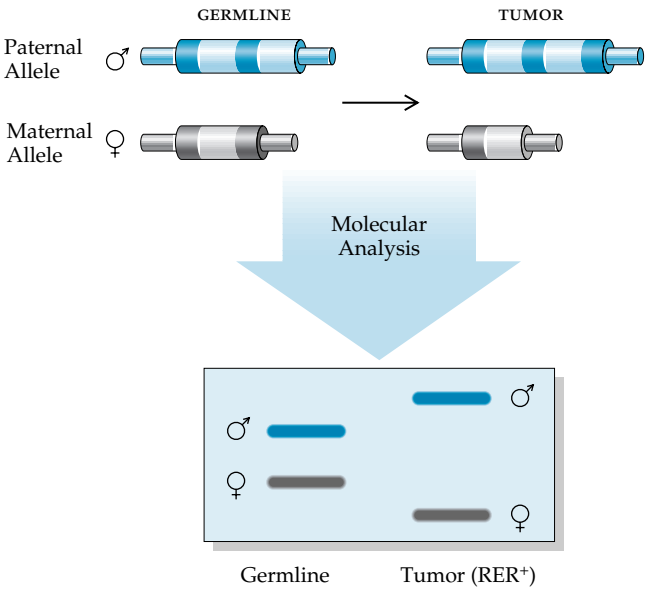

Figure 7 **Microsatellite instability and DNA mismatch repair. Microsatellites are short repeated sequences of DNA that are distributed throughout the genome and are highly variable, facilitating the distinction between maternally inherited alleles and paternally inherited alleles. Unlike tumors showing LOH, which have loss of one allele compared with the germline, tumors that have microsatellite instability (RER$^+$) demonstrate altered lengths for microsatellite markers. This results from errors in DNA mismatch repair. When microsatellite sequences are present within the coding region of a gene, such errors lead to mutations and loss of gene function.**

cosa and are accessible to colonoscopic biopsy. Other models of tumor progression are under study, including esophageal, head and neck, and bladder cancers.

CELL DEATH AND IMMORTALITY

The initial cellular proliferation drive that occurs in a transforming event is often accompanied by an increase in cell death or apoptosis, a compensatory mechanism that prevents the rapid growth of a cancer. Inactivation of the *p53* tumor suppressor is the most common genetic lesion that abrogates the cell death response, allowing cancer cells to rapidly increase in number. Another gene involved in the regulation of apoptosis is *BCL2,* which encodes a mitochondrial protein that prevents triggering of the protease cascade required for cellular suicide.[64] The role of *BCL2* in human cancer is best illustrated in follicular B cell lymphoma, an indolent tumor in which a chromosomal translocation brings the *BCL2* gene under the control of the immunoglobulin gene enhancer.[65] The increased expression of *BCL2* in these lymphoid cells prevents their programmed cell death, resulting in the increased cell mass that characterizes this slow-growing lymphoma. Mouse models that recreate this chromosomal rearrangement also demonstrate a striking increase in lymphocyte numbers, analogous to the human lymphoma. *BCL2* is part of a large gene family, with some members exhibiting proapoptotic effects and others antagonizing programmed cell death.[64] A proapoptotic member of the *BCL2* family, *BAX,* contains a repetitive nucleotide sequence that is targeted by mutations in tumors with microsatellite instability.[65,66] Thus, overexpression of antiapoptotic *BCL2* gene family members or inactivation of proapoptotic genes may contribute to the malignant phenotype.

Whereas proliferation and apoptosis constitute immediate and opposing cellular responses to mutations in proto-oncogenes and tumor suppressors, cellular immortality refers to the unlimited cellular lifespan required for tumor formation. Somatic cells are programmed to undergo only a limited number of cell divisions, after which they enter a state called senescence. This is most readily apparent in vitro, where cultured primary cells reach the end of their programmed lifespan, enlarge, and permanently cease to divide.[67] The molecular mechanisms underlying cellular senescence are not well understood, but roles for the *p16-INK4a, p53,* and *p19-ARF* tumor suppressor genes have been suggested in mouse models. Primary cells that are driven to proliferate by oncogenic transformation bypass senescence and enter crisis, or massive cell death, as they approach the end of their lifespan. The small number of cells that survive crisis are capable of an infinite number of cell divisions, essentially becoming immortal cell lines. These in vitro studies have provided a model to study the biological clock of normal somatic cells, one of the most potent safeguards against malignant transformation and one that must be overcome by all cancer cells destined to grow past their prescribed lifespan.

The cellular biological clock is linked to telomeres, the ends of chromosomes that are necessary to maintain chromosomal integrity. Telomeres are composed of a stretch of repeated nucleotides.[68] Because DNA polymerase fails to copy the extreme ends of chromosomes—a problem caused by its requirement for annealed primers to initiate DNA replication—telomeres shrink

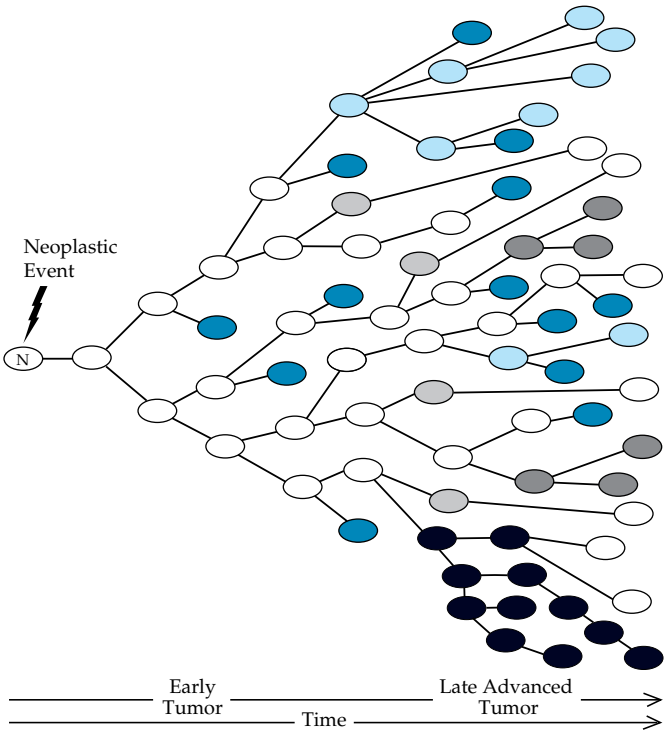

Figure 8 **After an initiating, rate-limiting, neoplastic genetic event, the proliferation of cancer cells is driven by selective growth advantages conferred by cumulative mutations. Continued cellular division and loss of genes required to maintain genomic stability facilitates the occurrence of mutations. Properties such as loss of cell death, invasiveness, angiogenesis, and drug resistance characterize the progression in the phenotype of tumor cells. The colors indicate the clonal descendants of individual cells.**

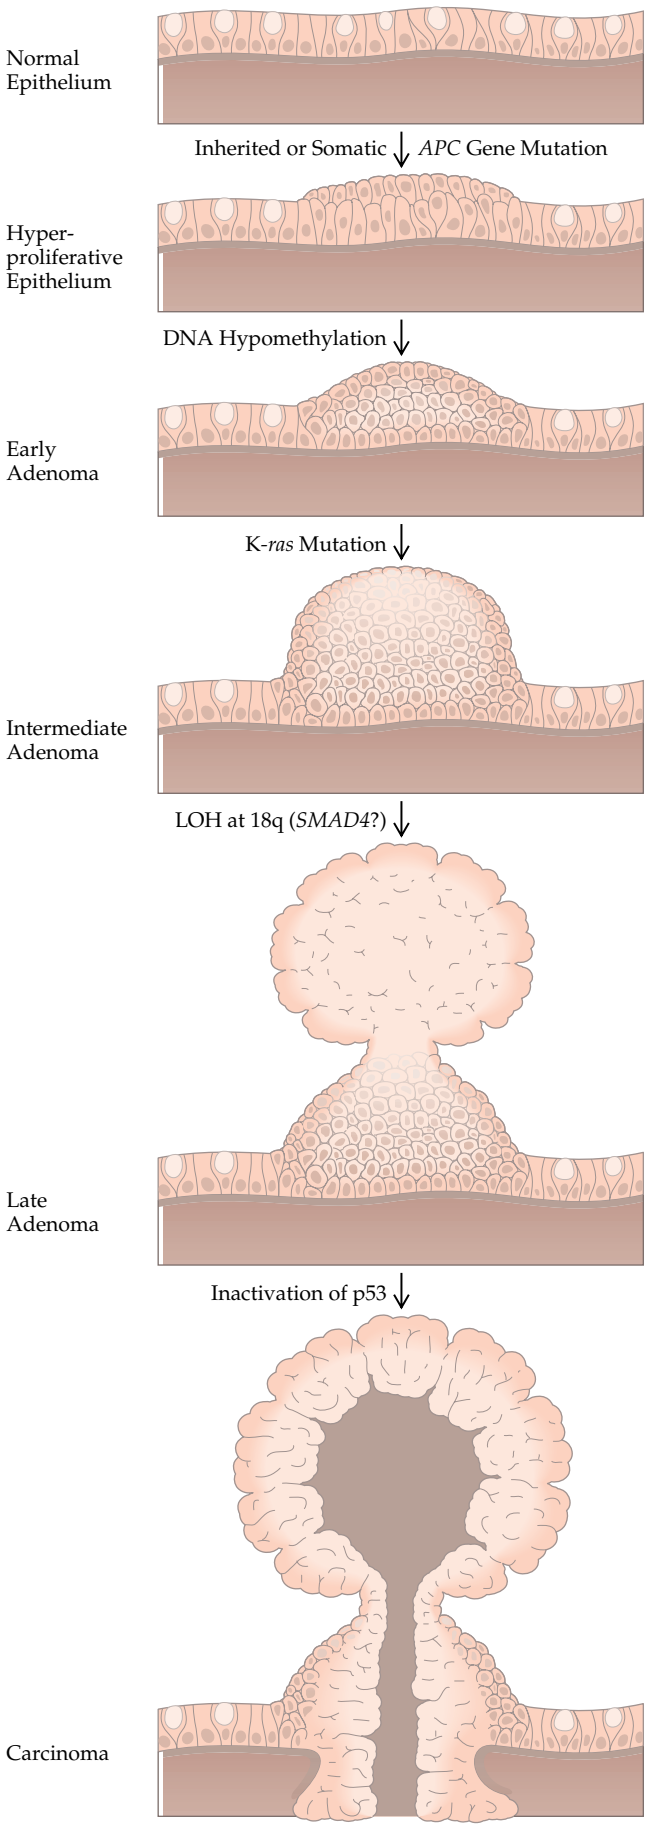

with every cell division. Cellular senescence is well correlated with the shortening of telomeres to less than the size required to maintain the integrity of chromosomes. In contrast to somatic cells that have a finite lifespan, germ cells and hematopoietic stem cells preserve the length of their telomeres with an enzyme called telomerase. A ribonucleoprotein with reverse transcriptase activity, telomerase uses an RNA template to add the appropriate nucleotide repeats to the ends of telomeres, thus matching the progressive shortening that accompanies cell division [*see Figure 10*].[69,70] This physiologic mechanism for circumventing senescence has been adapted by human tumors, most of which express high levels of telomerase. By analogy, cultured cells that emerge from crisis and have become immortal also express telomerase, validating this in vitro model of malignant transformation. The isolation of the catalytic subunit of telomerase, called hTERT, has allowed analysis of its expression pattern at the single-cell level; this analysis has shown that hTERT is commonly induced at the earliest stages of malignant transformation.[71] The fact that hTERT encodes a unique reverse transcriptase has also stimulated interest in the design of specific inhibitory agents.

METASTASIS AND ANGIOGENESIS

The accumulation of mutations driving cellular proliferation and the acquisition of an infinite lifespan provide the essential components for malignant transformation, but it is tissue invasion and metastasis that constitute the most visible and life-threatening properties of cancer. Cancer cells invade normal neighboring tissues, penetrating the epithelial basement membrane and the lining of endothelial cells and traveling through either the bloodstream or lymphatic chains to distant organs, where they exit the vasculature and establish independent sites of growth. Unfortunately, the genetic events responsible for these complex characteristics of human cancer are not well defined, and current animal models have been of only limited relevance. Cancer cells are known to secrete enzymes, such as matrix metalloproteinase-2 (MMP2), that are capable of digesting the basement membrane, facilitating tissue invasion and seeding of the bloodstream.[72] Expression of specific membrane-bound proteins, such as avb3αvβ3 integrin, appears to anchor MMP2 to the surface of tumor cells. Systemic administration of metalloproteinase inhibitors in combination with chemotherapeutic drugs is being investigated in clinical trials. Cell adhesion molecules have also been implicated in metastasis, possibly explaining in part the apparent predilection of certain tumors for specific metastatic sites. Among the best-characterized molecules is the cell surface protein CD44; alternative pre-mRNA splicing produces variants of CD44 transcripts, yielding different protein isoforms. Specific CD44 variants are present at high levels in metastatic tumor cells and may play a role in facilitating invasiveness.[73] Reduced ex-

Figure 9 **Genetic alterations during colorectal cancer progression. This model, proposed by Bert Vogelstein and commonly known as the "Vogelgram," links histologic features in the progression of colorectal cancer to specific genetic lesions. Mutation of the familial polyposis gene *APC* constitutes the initiating event for familial colorectal cancer and most cases of sporadic colorectal cancer. Additional genetic lesions are associated with polyps of increasing severity, whereas loss of *p53* commonly marks the transition to invasive colorectal cancer. The progression of other tumor types may be driven by the loss of different tumor suppressor genes or by a different cumulative order in the inactivation of the same genes, including *p53*.**

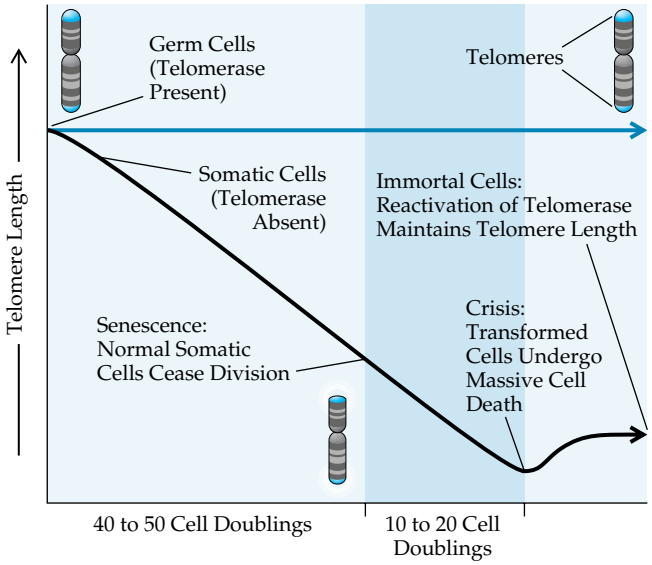

Figure 10 **Cellular senescence and the activation of telomerase. Normal cellular division requires the maintenance of telomeres at the ends of chromosomes. In germ cells programmed for an eternal lifespan, this telomere maintenance results from the activity of the enzyme telomerase. Growth of somatic cells in culture results in progressive shortening of telomeres, until such time as cellular division ceases and senescence is reached. Cells driven to proliferate past that point by the expression of transforming genes continue to shrink their telomeres until they reach crisis, a point at which chromosomes become unstable and massive cell death results. In small numbers of cells, telomerase may be activated at the time of crisis, producing immortal cell lines capable of indefinite growth in vitro. The majority of human cancers express high levels of telomerase, suggesting that a similar selection pressure in vivo contributes to their unlimited growth potential.**

pression of E-cadherin and α5β1 integrin in tumor cells has also been correlated with increased tumor cell migration and tumorigenicity. Additional comparisons between primary and metastatic tumors will probably reveal genetic changes that underlie the progression of the malignant phenotype.

A critical property required for the growth of cancers beyond a minimal size is the recruitment of blood vessels.[74] Tumors vary in their degree of vascularization; and even within a given tumor, certain areas may become hypoxic and frankly necrotic as they outgrow their blood supply. Some of the angiogenic peptides secreted by tumors are the same as certain peptides released during physiologic wound healing, including vascular epidermal growth factor and platelet-derived growth factor. However, in mouse models, certain primary tumors may also release substances that are thought to prevent their distant metastases from recruiting blood vessels—a phenomenon that might be explained as essentially preventing competition for nutrients. This discovery led Folkman and colleagues to isolate two antiangiogenic peptides called angiostatin and endostatin.[75-77] Both of these substances are unusual in that they appear to be breakdown products of other proteins—namely, plasminogen and type XVIII collagen. Their effect in mouse models is striking—they cause the necrosis of established tumors [*see Figure 11*]. In human trials to date, however, angiostatin and endostatin have not demonstrated the effects they show in mouse studies. Recent studies have focused on inhibition of other angiogenic growth factors, including vascular endothelial growth factor. The identification of short peptides that recognize specific markers within tumor endothelial cells has fostered another novel therapeutic approach that entails the designing of chemotherapeutic agents directly targeted at the tumor vascular supply.[78]

RESISTANCE TO CHEMOTHERAPEUTIC DRUGS

Surgical resection constitutes the primary treatment modality for most solid tumors. Chemotherapy and radiation therapy are effective in the treatment of tumors with known metastatic spread; in the so-called adjuvant setting, where residual microscopic tumor deposits are suspected on the basis of the clinical stage of the tumor; and, occasionally, in the preoperative setting, where initial systemic treatment may be required to make a large tumor surgically resectable. Many chemotherapeutic agents are derived from naturally occurring compounds; they include alkylating agents that chemically cross-link DNA, nucleotide analogues that inhibit enzymes required for DNA synthesis, and inhibitors of the mitotic spindle. Chemotherapeutic agents that directly damage DNA are typically administered by short-term infusion, whereas nucleotide analogues that are thought to be effective only during the S phase are given by continuous infusion to maximize the potential exposure of cycling tumor cells. In general, tumors with a high mitotic rate are thought to be more responsive to chemotherapy than those with a smaller fraction of proliferating cells. Chemotherapeutic agents are commonly administered in combination; the specific drugs to be combined are chosen on the basis of their pharmacologic properties, the spectrum of drug sensitivity displayed by different tumor types, and the need to avoid overlapping toxicities to such organs and tissues as bone marrow, intestinal epithelium, kidney, and nervous system. Attempts at in vitro testing of tumors for drug sensitivity have been limited by the fact that only a small fraction of cells from a tumor can be cultured, and these may not adequately represent the heterogeneity of the primary tumor. Radiation therapy entails targeting ionizing radiation, which causes double-stranded breaks in DNA, to specific anatomic sites infiltrated by cancer. Exposure of normal tissues is minimized by the use of multiple converging beams of radiation, together with protective blocks. In some cancers, such as localized rectal and anal cancers, the combined use of chemotherapy and radiation therapy has been particularly effective.

Resistance of cancer to the effects of chemotherapy may be intrinsic, as commonly seen in melanoma, hepatocellular carcinoma, and renal cell carcinoma, which are typically refractory to many agents. In these cases, drug resistance may reflect properties of the tissue from which the cancers arose, such as the need of normal renal tubular cells to be protected from naturally occurring toxins to which they may be exposed. In other cases, cancers that are initially highly sensitive to chemotherapy may become resistant, either during a course of treatment or, more commonly, at the time of disease recurrence. This acquired form of drug resistance presumably results from mutations that confer a selective advantage to a subset of tumor cells, analogous to other genetic events that contribute to tumor progression. A number of molecular mechanisms conferring resistance to specific chemotherapeutic agents have been defined using in vitro models. A well-studied example is the drug methotrexate, which specifically inhibits the enzyme dihydrofolate reductase (DHFR), required for DNA synthesis. Tumors may become drug resistant by acquiring defects in the intracellular transport of methotrexate; by mutations in the *DHFR* gene, resulting in an enzyme that fails to bind methotrexate; or by amplification of the *DHFR* gene itself, which increases the amount

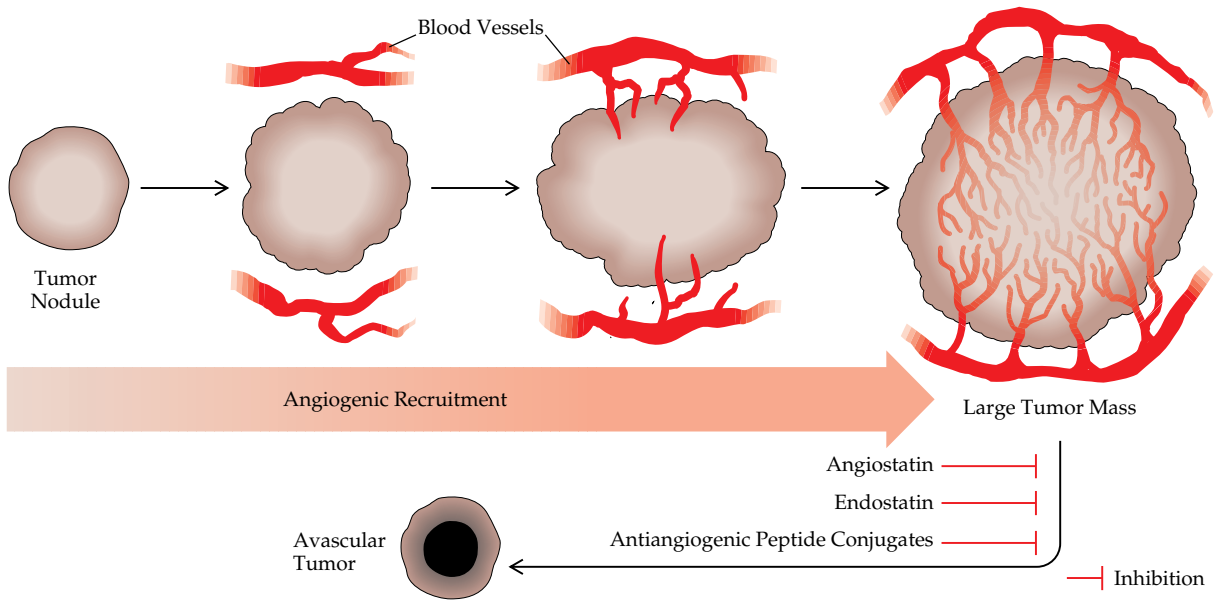

Figure 11 **Tumor angiogenesis and its inhibitors. Among the most important properties of tumors is their ability to recruit blood vessels, providing nutrients that allow their growth beyond a minimal size. Angiogenic recruitment depends on the secretion by tumors of endothelial growth factors. It may be inhibited by peptides, such as angiostatin and endostatin, as well as by drug conjugates using small peptides that target endothelial membrane proteins.**

of protein made and thus acts to titrate and overcome the intracellular drug concentration.[79]

Although drug-specific resistance mechanisms may contribute to some cases of chemotherapeutic drug resistance, most cancers appear to acquire resistance to a broad range of agents, including some to which they have had no prior exposure. This multidrug-resistance phenotype was reproduced in cell culture, and this led to the discovery of the multidrug-resistance (*mdr*) gene family. These genes encode adenosine triphosphate (ATP)–dependent pumps that span the cell membrane and appear to be involved in the transport of large organic compounds.[80] Other gene family members include the gene for cystic fibrosis and a prokaryotic gene that may contribute to quinine resistance in malaria. The most intensively studied gene implicated in resistance to cancer chemotherapy is *mdr*-1, whose gene product is capable of exporting a wide range of organic compounds, including anthracyclines and vinca alkaloids. The molecular mechanisms underlying drug specificity by mdr-related transporters is unknown. In addition, other drugs, such as cyclosporine and verapamil, are capable of noncompetitively blocking the export of chemotherapeutic agents by mdr-1 and are being included in chemotherapeutic regimens undergoing testing in clinical trials. The strong link between *mdr*-1 overexpression and resistance to chemotherapy that is evident in vitro has not been generally confirmed in the clinic, and the contribution of this gene to most cases of clinical drug resistance is still unknown. However, in some cancers, such as multiple myeloma, repeated exposure to anthracyclines and vinca alkaloids does appear to be correlated with increased expression of *mdr*-1 and resistance to chemotherapy,[81] and *mdr*-1 expression appears to be a marker for poor-prognosis acute myelogenous leukemia.[82]

New insight into resistance to chemotherapeutic agents comes from a better understanding of the mechanism of action of these agents. DNA injury mediated by chemotherapeutic agents and ionizing radiation triggers activation of p53, leading to programmed cell death, or apoptosis [*see Figure 12*]. The realization that exposure to chemotherapeutic agents initiates an active cellular suicide program, rather than simply causing

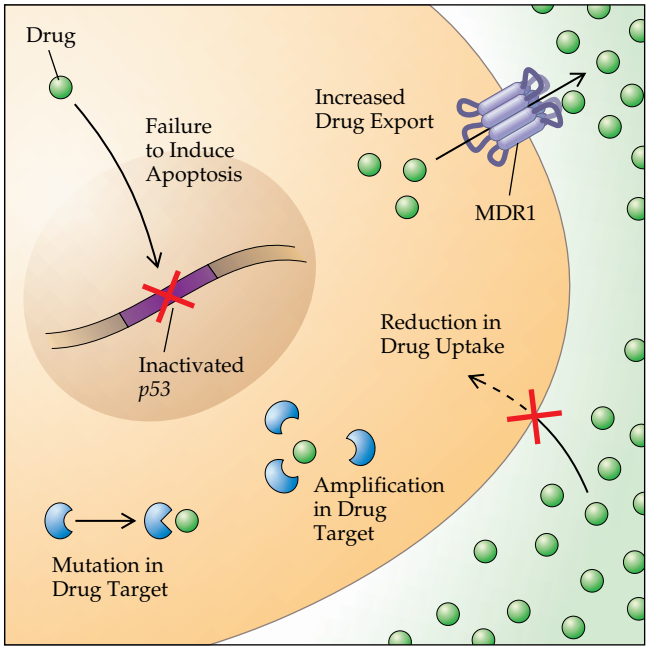

Figure 12 **Mechanisms of resistance to chemotherapeutic agents. The resistance of cancers to chemotherapeutic drugs may be intrinsic, reflecting properties of their tissue of origin, or it may be acquired, a consequence of mutations selected during tumor progression and previous drug treatments. Mechanisms include mutations in the *p53* gene, which preclude the physiologic cellular apoptotic response to DNA injury mediated by these drugs; decreased drug uptake; increased drug export by MDR1-related proteins; a compensatory amplification in the amounts of the cellular drug target; or a mutation in the target that renders it resistant to the effects of the drug.**

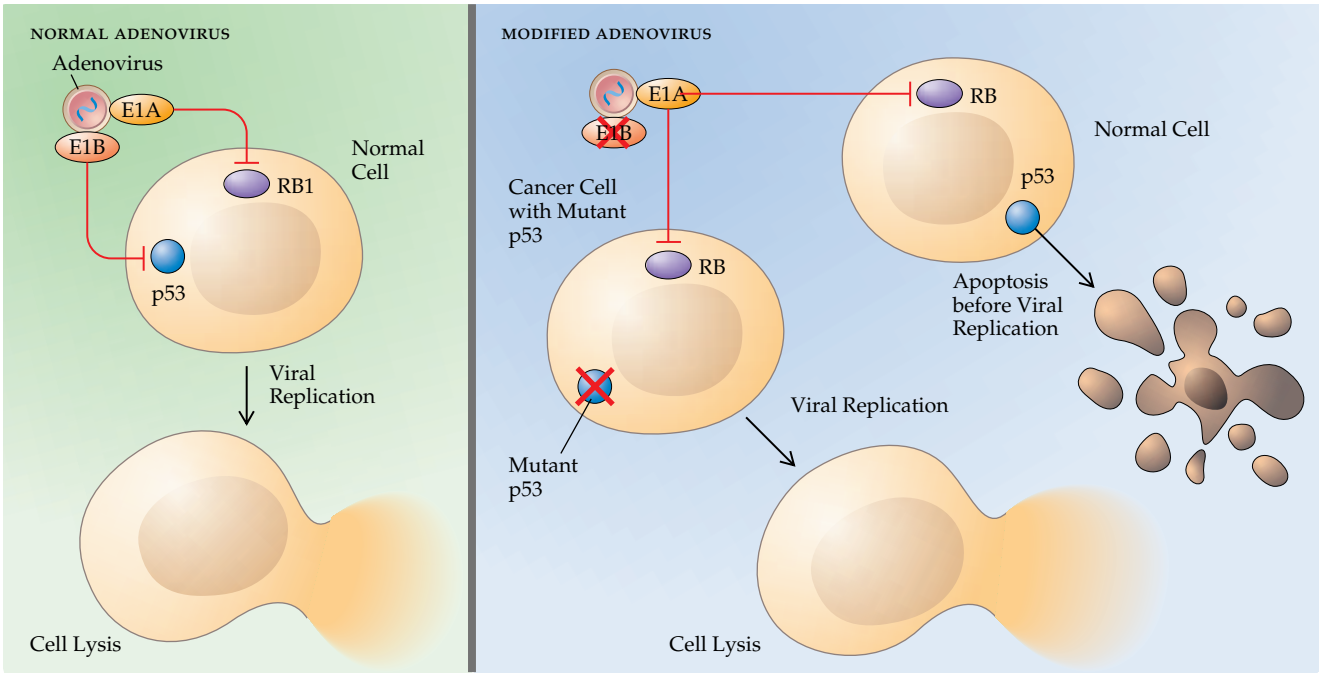

Figure 13 **Specific killing of cells with mutant p53 using a modified adenovirus. The common cold virus adenovirus encodes two genes, *E1A* and *E1B*, that inactivate the cellular tumor suppressor genes *RB1* and *p53*. Loss of RB1 leads to cellular replication, whereas loss of p53 prevents the cellular apoptotic response to viral infection and aberrant cellular replication. Cellular lysis results from unimpeded viral replication. The modified adenovirus produced by Frank McCormick and collaborators lacks the *E1B* gene and therefore can only lyse cancer cells in which the cellular *p53* gene has been mutated. The presence of intact p53 in surrounding normal cells leads to their apoptosis following viral infection, preventing widespread infection of normal tissue.**

cell death through massive DNA damage, raised the possibility that these apoptotic pathways may be disrupted in drug-resistant cancer cells. In a rodent model system, cells driven to proliferate by expression of oncogenes undergo apoptosis after treatment with chemotherapeutic agents or radiation.[82,83] However, inactivation of *p53* in these cells is associated with resistance to these therapeutic agents. Loss of *p53* is a common feature of human cancers, and a number of studies have suggested a correlation between inactivation of *p53* and resistance to chemotherapeutic agents, as well as a more aggressive clinical course.[34] The possibility of using genetic lesions in tumors to enhance, rather than diminish, the selective killing of human cancer cells is being intensively investigated. A promising approach has been the development of a modified adenovirus, capable of replicating and inducing lysis only in cells whose *p53* genes have been inactivated, leading to the specific killing of cancer cells [*see Figure 13*].[84] Selective tumor cell lysis by this modified adenovirus may also reflect other factors, such as viral infectivity[85] and the host immune response to viral infection. A second adenovirus that selectively replicates in human tumor (retinoblastoma) cells, but not normal cells, has been reported.[86]

Expression Profile Analysis and New Therapeutic Targets

MICROARRAYS

The development of high-density microarray technologies has made it possible to scan all expressed human genes simultaneously in an unbiased search for differences between clinical specimens. Whereas traditional experimental approaches have favored the study of individual genes within well-characterized cellular pathways, expression profiling aims at a global analysis of all the mRNA transcripts expressed in a tissue or tumor [*see Figure 14*]. A number of technical platforms have been developed, including oligonucleotide arrays, in which multiple short stretches of nucleotides representing each gene are attached to a chip,[87] and cDNA arrays, in which longer clones representing each gene may be fixed onto a glass slide.[88] A single chip or slide can carry markers for as many as 10,000 genes or more, making it possible to measure their relative levels of expression in a single hybridization, using labeled RNA derived from clinical material. Laser-directed scanning is then used to identify the hybridization signal for each gene. Complex algorithms are required to quantify the signal and to cluster expression patterns that may be correlated with a clinical phenotype. A different strategy, known as serial analysis of gene expression, involves direct nucleotide sequencing of multiple expressed tags derived from cellular transcripts.[89]

An important clinical application of expression profile analysis has involved its ability to distinguish tumors that are histologically similar but differ in their clinical prognoses. For instance, a cluster of gene expression patterns has been used to distinguish large-cell lymphomas with favorable prognoses from those with adverse prognoses,[90] and to identify primary breast cancers with different clinical outcomes.[91] As these studies are confirmed prospectively and as the assays themselves become more broadly available, molecular profiling may eventually become critical in making appropriate treatment decisions. Furthermore, such studies may lead to a new appreciation of similarities and differences between tumor types that is based on shared genetic pathways and mutations, rather than tissue type or histologic appearance—so-called molecular tax-

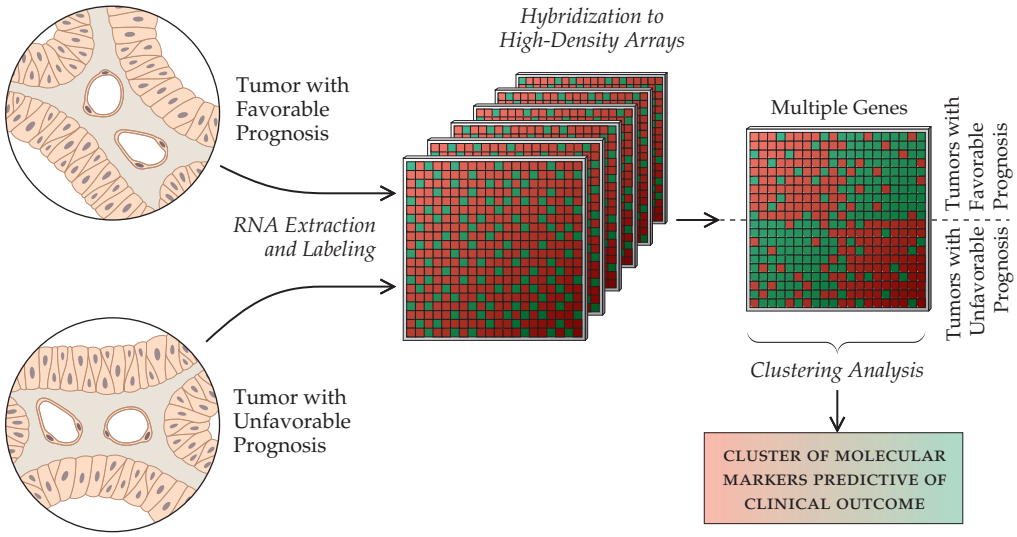

Figure 14 **Analysis of expression profiles using high-density microarrays. This strategy is designed to allow simultaneous quantitation of all messenger RNA transcripts within a tissue. For instance, tumor specimens representing different types of cancer or cancers with different clinical behavior can be compared. Total cellular mRNA is isolated from frozen tumor specimens. The RNA is labeled as a probe and hybridized to high-density microarrays carrying markers for approximately 10,000 genes. The hybridization signal for each gene is detected and compared with different clinical specimens. Complex data mining and bioinformatics approaches are required to identify clusters of expression patterns that may be correlated with different clinical measures.**

onomy.[92] Finally, expression profile analysis may lead to the discovery of novel markers expressed by different types of cancer. Some of these may encode secreted proteins that may prove important in early detection, whereas others may constitute novel chemotherapeutic drug targets.

RATIONAL DRUG DESIGN AND SMALL MOLECULES

The concept of therapeutic approaches based on common drug targets is best illustrated by the success of imatinib mesylate (Gleevec), a small-molecule inhibitor of specific protein kinases [*see Figure 15*].[13] Imatinib was initially identified by its ability to inhibit the binding of ATP to the kinase domain of the platelet-derived growth factor receptor (PDGFR); it was subsequently found to also inhibit the Abelson kinase (ABL) and the c-Kit kinase. The effectiveness of imatinib in treating CML is derived from the underlying chromosomal translocation that results in the chimeric protein bcr-abl [*see* Gene Amplification and Chromosomal Translocations, *above*]. Constitutive activation of the abl kinase by this rearrangement is essential for malignancy, and CML cells are extremely sensitive to disruption in this signaling pathway. bcr-abl thus provides an ideal drug target, because its function is essential for leukemic cell survival, whereas inhibition of abl in normal cells has few consequences. A very high frequency of complete remission induced by imatinib in chronic-phase CML has been reported, with very few side effects.[13] A remarkable coincidence is the effectiveness of imatinib in a histologically unrelated solid tumor, which is also dependent on a protein targeted by this drug. Gastrointestinal stromal tumors (GISTs) are rare tumors characterized by c-*kit* mutations that cause constitutive activation of the c-Kit kinase. Although GIST is typically refractory to standard chemotherapy, dramatic responses have been observed in patients treated with imatinib.[93] Similarly, cases of chronic myelomonocytic leukemia, in which the underlying genetic lesion involves rearrangement and activation of PDGFR, are also responsive to imatinib.[94] Thus, the rational design of small-molecule inhibitors directed at proteins that are critical components of cellular pathways may lead to novel and effective treatments of different types of cancer.

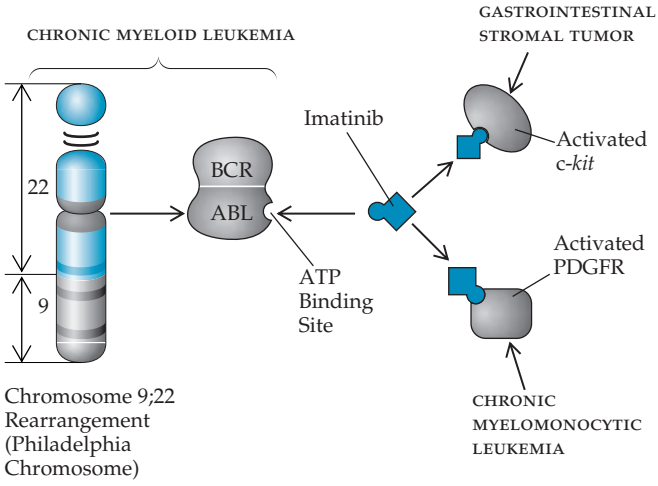

Figure 15 **Effectiveness of imatinib mesylate in targeting oncogenic proteins in diverse tumor types. Imatinib disrupts the binding of adenosine triphosphate (ATP) to the catalytic domain of three kinase proteins: platelet-derived growth factor receptor (PDGFR), ABL, and c-Kit. Tumor types in which activation of these kinase proteins is critical to tumor growth include chronic myeloid leukemia, in which the BCR-ABL chimeric fusion protein is derived from the rearrangement of chromosomes 9 and 22 (Philadelphia chromosome); gastrointestinal stromal tumor (GIST), containing activating mutations of c-*kit*; and chronic myelomonocytic leukemia (CMML), in which rearrangement of the PDGFR gene leads to its activation. In these three different malignancies, treatment with imatinib leads to rapid and sustained clinical responses.**

Clinical Implications of Genetic Analysis

The molecular genetic analysis of human cancer has elucidated mechanisms that underlie malignant transformation and the progression from early premalignant lesions to invasive carcinomas. The pace of discovery will probably accelerate as novel, high-throughput techniques facilitate the identification of genetic differences between normal cells and cancer cells. The emerging challenge will be the application of this molecular information to the clinical management of human cancer.[95] Although this field is still in its infancy, a number of approaches are under active investigation. Early diagnosis of malignancy currently relies on radiographic monitoring, such as mammography and chest x-ray; testing for secreted markers, such as prostate-specific antigen and CA125; and invasive procedures, including cystoscopy and colonoscopy. Molecular markers in cells that are sloughed in sputum, urine, or stool may eventually provide accurate and effective screening approaches.[96-99] Genetic lesions in malignant cells have also been used to facilitate diagnosis in cases in which histologic analysis is not definitive and to detect minimal residual disease that is undetectable by standard methods.[100,101] Analysis of tumors for genetic lesions that confer prognostic significance has already become standard in the management of many leukemias.[14-16] Molecular markers associated with response to chemotherapy, as well as the likelihood of metastatic spread, may eventually guide the treatment of solid tumors. Eventually, an understanding of the aberrant molecular pathways that drive cellular proliferation, angiogenic recruitment, and metastatic spread in different types of cancer may lead to the development of more specific and effective treatment regimens.

The appropriate use of germline mutation analysis may identify persons at increased risk for specific cancers who may benefit most from close monitoring.[102] In some cases, patients at high risk for developing cancer may benefit from prophylactic surgery. This is well established in carriers of *APC* mutations with familial polyposis coli, in whom prophylactic colectomy prevents the development of colorectal cancer.[103] Similarly, prophylactic thyroidectomy is commonly recommended in patients with multiple endocrine neoplasia.[104] More recently, prophylactic oophorectomy after completion of childbearing has been recommended for *BRCA1* and *BRCA2* mutation carriers, because it reduces the risk of both ovarian and breast cancers in these patients.[105,106] However, genetic predisposition to cancer in the general population is thought to result primarily from common genetic variations associated with a moderate increase in cancer risk (so-called low penetrance mutations), rather than from rare mutations that are associated with an extremely high risk of cancer.[107] The appropriate clinical options are less clear for individuals who carry such low-penetrance mutations in cancer susceptibility genes; although the effects of these mutations are apparent in population studies, their consequences are difficult to predict for any individual carrier. For instance, the *APC* I1307K mutation, which is present in 6% of the Ashkenazi Jewish population, appears to be associated with a twofold increase in risk of colorectal cancer.[108] The 1100delC mutation in the cell cycle checkpoint gene *CHK2*, which is present in 1% of the general population, has been linked to a similar increase in breast cancer risk.[109] Taken together, these and other genetic variants that will emerge from population genetics studies are likely to be important in targeting screening and chemopreventive options to individuals at increased risk for developing cancer.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III TUMOR IMMUNOLOGY

Robert F. Todd III, m.d., ph.d.
Bruce G. Redman, d.o.

The development of cancer represents a failure of immune surveillance, because the immune system has the capacity to recognize tumor-associated antigens and develop specific T cell responses to those antigens. The ability to intervene and enhance the immune system to achieve a beneficial antitumor response remains an area of intense clinical research. Considerable progress has been made in expanding our knowledge of the targets for an immune response and about the full repertoire of cellular and humoral constituents involved in the generation of an effective antitumor response. Tumor cells display a variety of mechanisms by which they evade immune detection and destruction and render the immune response ineffective. With a more complete understanding of these escape mechanisms, clinical investigators are devising strategies to enhance the development of a robust immune response in the tumor-bearing host (active tumor immunity) or, alternatively, by the adoptive transfer of activated effector cells or tumor-specific antibodies into the tumor-bearing host (passive tumor immunity). Several strategies hold promise for substantial therapeutic benefit. Finally, antibodies that recognize tumor-associated antigens can aid in the pathologic diagnosis of cancer and facilitate the staging of cancer in vivo and the detection of recurrent cancer.

Overview of the Immune Response

The cellular and humoral arms of the immune response feature lymphocytes and antibodies, respectively, but extend beyond those elements. The cellular response consists of multiple components, including different subsets of lymphocytes (helper T cells, cytotoxic T cells, B cells, and natural killer [NK] cells) and antigen-presenting cells (APCs) that include blood monocytes, tissue macrophages, and dendritic cells. Different components of the immune system communicate with one another by direct cell-to-cell interaction via various adhesion molecules and receptors on the cell surface or through secreted chemicals (usually proteins) called cytokines that circulate and bind to specific receptors on effector cells. Cytokines can be either immune stimulatory or immune inhibitory; examples of cytokines include interleukins and interferons.

The cellular and soluble constituents of the immune response work in concert to recognize foreign (nonself) antigens (e.g., proteins, glycoproteins, and glycolipids) that are expressed by or secreted from tumor cells. The afferent limb of the immune response (immune recognition) subsequently triggers a highly specific response by the effector limb, in which other immune cells and their soluble products attack tumor cells bearing the same antigens recognized by the afferent limb. The success or failure of the afferent limb in recognizing tumor cells and of the effector limb in attacking them is influenced by a variety of mitigating factors.

The identification of the cellular constituents of the immune response and knowledge of their functions have been aided by the development of monoclonal antibodies created by immunization of mice against human immune cells. Each monoclonal antibody recognizes a single glycoprotein antigen that reflects the expression of a unique cell surface receptor. By convention, these receptors and the cells that express them have been assigned a cluster designation (CD) number (e.g., CD3, CD4, CD8).

Host Immune Response to Cancer

The existence of a host immune response to cancer is supported by the following observations:

1. Histologic analysis of excised human and animal tumors has demonstrated varying degrees of immune cellular infiltration (lymphocytes and APCs), which suggests the recruitment of these cells in response to neoplastic proliferation. When analyzed, the activity of these tumor-infiltrating lymphocytes is often found to be specific for the autologous tumor, with little to no activity against unrelated tumor targets. Accompanying this mononuclear infiltration of tumors is the elaboration of various cytokines that are associated with an ongoing immune response. T cells that exhibit specific reactivity against autologous tumor have been isolated from patients with melanoma, breast cancer, ovarian cancer, and colorectal cancer.[1]
2. Long-term remissions are induced in small numbers of patients who receive some form of immunologic therapy for their advanced cancers.
3. There are documented (albeit infrequent) reports of spontaneous remissions in patients with melanoma and renal cell carcinoma that are believed to be immune mediated.

The possible existence of immune surveillance mechanisms that prevent the development of cancer is supported by the finding that immunodeficient individuals and patients undergoing long-term treatment with immunosuppressive drugs are at greater risk for cancer than the general population. Experimental evidence that directly links immune mechanisms to the defense against cancer comes from classic experiments in which immunized mice rejected chemically induced syngeneic tumors.[2] Naive syngeneic mice (i.e., mice not previously exposed to tumor) were protected against tumor growth by immunization with killed tumor cells administered before challenge with viable tumor cells [*see Figure 1*]. The specificity of this immune response was demonstrated by the lack of protective effect of prior immunization with killed cells from an unrelated tumor. The important role of lymphoid cells in this immune response was demonstrated by the protective effect of spleen cells from a tumor-bearing mouse administered to a naive host (adoptive transfer of immune cells) before tumor challenge with live tumor cells. In these experiments, the cytotoxic T cell population ($CD8^+$ T cells) within the spleens of tumor-bearing mice demonstrated unique protective activity upon transfer. Transfer of helper T cells ($CD4^+$ T cells), B cells, or serum-derived antibodies did not confer protection in this model. The results of these classic experiments, in which syngeneic tumors could be rejected in naive hosts receiving prior immunization or by adoptive transfer of immune cells, support the existence of tumor-associated antigens in animal models and form the basis of much of the experimental work in human tumor immunology.

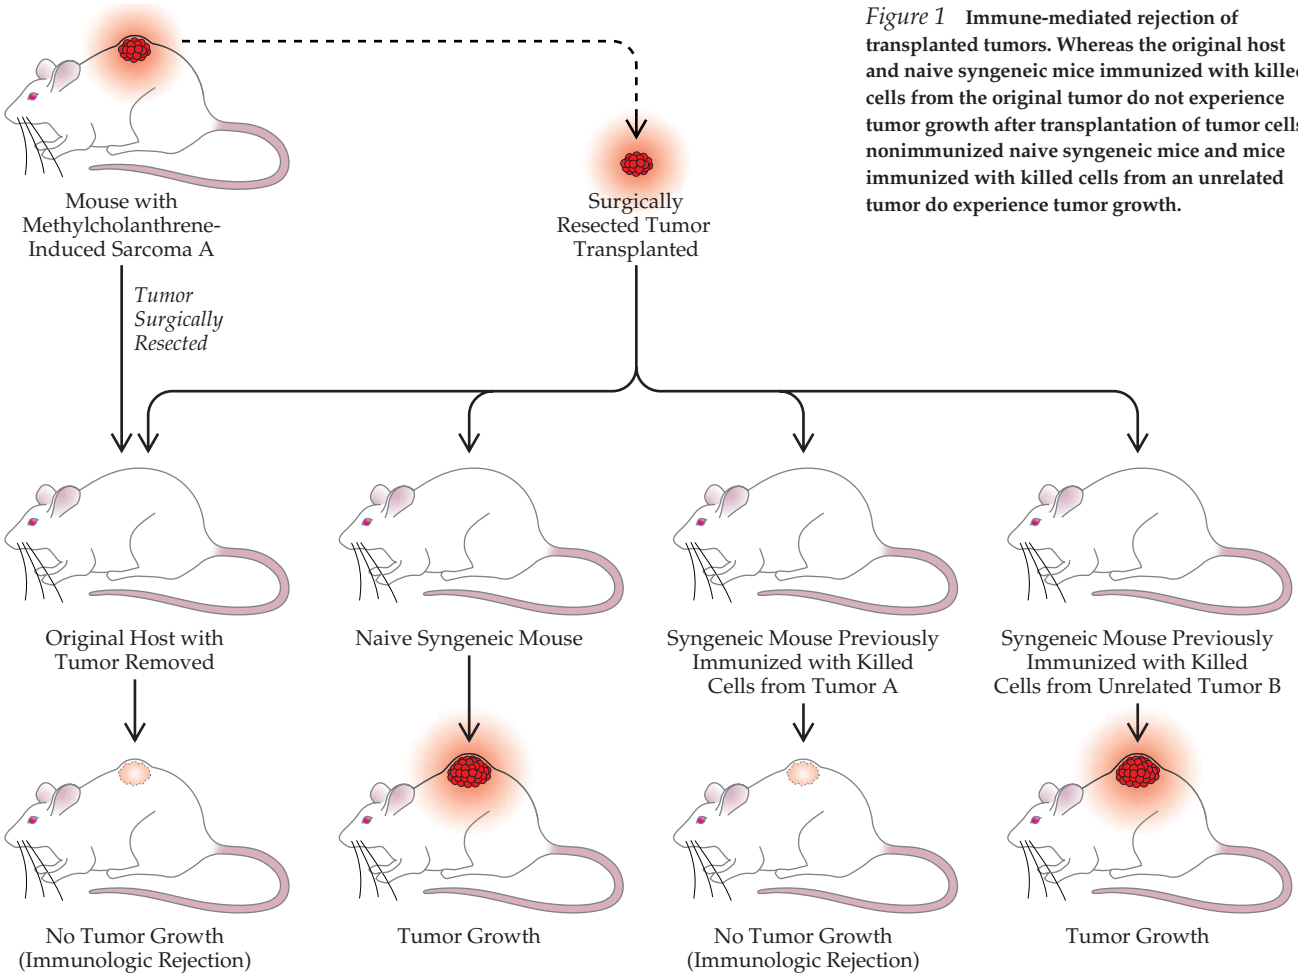

Figure 1 **Immune-mediated rejection of transplanted tumors. Whereas the original host and naive syngeneic mice immunized with killed cells from the original tumor do not experience tumor growth after transplantation of tumor cells, nonimmunized naive syngeneic mice and mice immunized with killed cells from an unrelated tumor do experience tumor growth.**

Targets for Immune Response to Cancer

The ability to immunize naive animals against cancer led to the concept of tumor-specific or tumor-associated antigens that serve as the target of an inducible effector response. The development of strategies to enhance this immune response against cancer has depended upon the further identification and characterization of these tumor-related antigens.[3] The work of many investigators over the past decade has confirmed the existence of at least five classes of potential tumor-associated antigens that are recognized by and stimulate T cells: oncoviral proteins, tumor-associated antigens, mutated or overexpressed oncogene or tumor-suppressor gene antigens, differentiation (or lineage-specific) antigens, and abnormal posttranslational modification of self-proteins.

ONCOVIRAL PROTEINS

Oncoviral proteins represent cellular antigens encoded by the genomes of oncogenic viruses. Examples of oncoviral proteins include the human papillomavirus E6 (HPV-E6) and HPV-E7 antigens, found in cervical carcinoma; and the Epstein-Barr virus (EBV) EBNA-1 antigen, found in Burkitt lymphoma and nasopharyngeal carcinoma.

TUMOR-ASSOCIATED ANTIGENS

Tumor-associated antigens (also referred to as tumor-testis antigens) are proteins that are normally expressed during the course of embryonic development and in the human adult testis; they become abnormally expressed by the cancer cells of adult individuals. Examples of tumor-associated antigens include the MAGE-1 and MAGE-3 proteins, which are expressed by a variety of tumor cells, including melanoma, glioma, and breast carcinoma.

MUTATED OR OVEREXPRESSED ONCOGENE OR TUMOR-SUPPRESSOR GENE ANTIGENS

Mutated or overexpressed oncogene or tumor-suppressor gene antigens represent the protein products of mutated or overexpressed cellular oncogenes or tumor-suppressor genes found in a variety of tumor cells. Examples of this class of tumor-associated antigens are $p21^{ras}$ (expressed in a number of carcinomas), the p210 product of the *bcr-abl* translocation found in chronic myelogenous leukemia, the cyclin-dependent kinase 4 (CdK4) and β-catenin proteins found in melanoma, the HER-2/neu protein found in breast carcinoma and other cancers, the caspase-8 protein expressed in certain squamous cell carcinomas, and the p53 tumor-suppressor gene product found in multiple tumors.

DIFFERENTIATION ANTIGENS

Differentiation (or lineage-specific) antigens are proteins that are normally expressed in a tissue-specific fashion by normal cells but are coexpressed by tumor cells derived from the normal

host tissue. Examples of differentiation antigens are tyrosinase, GP100, MART-1 antigens coexpressed by normal melanocytes and melanoma cells, and cell membrane immunoglobulin in a specific B cell clone.

ABNORMAL POSTTRANSLATIONAL MODIFICATION OF SELF-PROTEINS

Self-proteins that have undergone abnormal posttranslational modification represent mutated forms of normal protein products; these modified self-proteins give rise to unique tumor-associated carbohydrate epitopes. An example of this class of tumor antigens is the MUC-1 antigen (featuring underglycosylated mucin), which is expressed by breast and pancreatic carcinomas.

In addition to the antigens that may be the targets of a T cell–directed immune response, there are other antigens that may be recognized by T cells as well as by antibodies resulting from deliberate immunization against these antigens. These targets of an antibody-mediated immune response include (1) tissue-specific differentiation antigens that, like the lineage-specific antigens, represent protein products shared between tumor cells and the tissues from which they are derived (e.g., CD20 and the surface immunoglobulin [Ig] idiotype, which are expressed by B cell lymphomas; and the prostate-specific antigen [PSA], expressed by prostate carcinoma cells); (2) oncofetal antigens that, like the tumor-associated antigens, represent self-proteins normally expressed during embryonic development but that are found on tumor cells (e.g., the carcinoembryonic antigen [CEA], expressed by multiple carcinomas, and α-fetoprotein [AFP], expressed by hepatocellular carcinoma and germ cell tumors); and (3) altered or overexpressed glycolipid and glycoprotein antigens. These include the gangliosides GM_2 and GD_2 found on melanomas and neuroblastomas; and the mucin antigens CA125, CA19-9, and MUC-1, which are predominantly expressed by ovarian, pancreatic, and breast carcinomas, respectively.

Effector Mechanisms in the Anticancer Immune Response

The immune response against cancer includes both the cellular response and the humoral response.

CELLULAR IMMUNE RESPONSE

The cellular effector response involves activity by five major cellular constituents. (1) $CD8^+$ cytotoxic T cells recognize tumor-associated antigens that are presented in association with major histocompatibility (MHC) class I molecules [*see Figure 2*]. (2) $CD4^+$ helper T cells recognize tumor-associated antigens that are presented in association with MHC class II molecules leading to cytokine release (help signals) for the generation and activation of cytotoxic T cells. (3) NK cells may kill tumor cells in a non–MHC-dependent fashion. Rather than binding directly to tumor-associated antigens, NK cells may be targeted to antibody-coated tumor cells via recognition and attachment to the Fc portion of the antibody. (4) Mononuclear phagocytes (macrophages), like NK cells, may be targeted to antibody-coated tumor cells, where their cytotoxic activity may depend upon the release of destructive proteases, cytokines (e.g., tumor necrosis factor [TNF]), and reactive oxidative intermediates (O_2^-). (5) Dendritic cells (DCs) are important APCs that can present antigen to both $CD4^+$ and $CD8^+$ T cells and are able to stimulate a naive T cell response (i.e., stimulation of a T cell response to an antigen to which the T cell has not been previously exposed).

The recognition of tumor target cells or tumor APCs depends on a direct binding interaction mediated by several receptor species [*see Figure 2*].[4] The specificity of binding is conferred by the T cell receptor (TCR), in association with CD8 or CD4 surface glycoproteins, which recognizes antigen as pre-

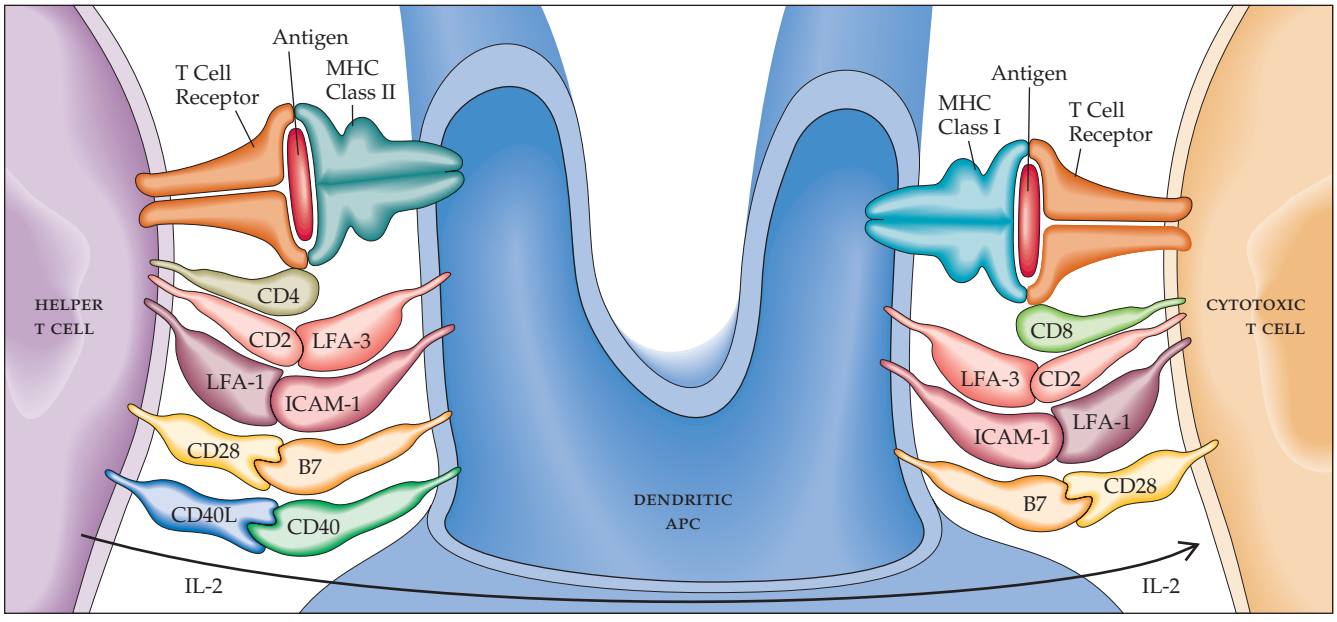

Figure 2 **T cell interaction with a dendritic antigen-presenting cell (APC). Helper T cells recognize MHC class II–associated antigens. Cytotoxic T cells recognize MHC class I–associated antigens. Release of interleukin-2 (IL-2) by the helper T cell provides a so-called help signal to the cytotoxic T cells. (ICAM—intercellular adhesion molecule; LFA—leukocyte function–associated antigen)**

sented by either class I (recognized by $CD8^+$ T cells) or class II (recognized by $CD4^+$ T cells) MHC antigens. Antigen recognition and concomitant T cell activation also depend on the binding of pairs of receptor and costimulatory molecules, including leukocyte function–associated antigen–1/intercellular adhesion molecule–1, CD28/B7, and CD2/leukocyte function–associated antigen–3. Helper T cell activation results in secretion of interleukin-2 (IL-2), which provides a necessary help signal to cytotoxic T cells. T cell binding to antigen on a target cell that does not express the requisite accessory molecules can lead to T cell apoptosis or anergy, thus preventing an immune response.

After effective membrane binding between cytotoxic T cells and tumor target cells, actual tumor cell cytolysis is accomplished by one of two general mechanisms[5]: (1) a perforin-dependent mechanism, in which killer cell enzymes (granzymes) are released from cytotoxic T cells and gain access to target cells via perforin pores, endocytosis, or granzyme receptor–mediated uptake, leading to target cell membrane damage with subsequent necrosis and apoptosis; or (2) a newly recognized mechanism of target cell cytolysis that depends on the recognition of the membrane protein Fas (expressed by certain tumor cells) by the Fas ligand expressed by killer T cells. The binding of Fas and its ligand leads to the generation of proapoptotic death signals to the target cell nucleus, resulting in DNA fragmentation and apoptosis.

HUMORAL IMMUNE RESPONSE

The recognition of tumor-associated antigens by $CD4^+$ helper T cells may also elicit a B cell humoral response leading to the development of antibodies that recognize tumor-associated antigens. Unfortunately, despite this mechanism of antitumor immunity, the results of animal experiments suggest that naturally occurring antibodies play little role in effective antitumor response. However, the administration of manufactured antibodies targeted to tumor-associated antigens may be quite useful in eliciting an effective antitumor response. Specifically, these antibodies may facilitate antibody-dependent cellular cytotoxicity (ADCC) by NK cells and macrophages, or they may be employed to kill tumor cells by direct mechanisms (e.g., induction of apoptosis or fixation of complement) or indirect mechanisms. In the latter case, antibodies may be conjugated (chemically linked) with cellular toxins (e.g., ricin or diphtheria toxin) or gamma radiation–emitting radionuclides; binding of the antibodies to tumor cells results in the death of those cells from internalization of the toxin or exposure to ionizing radiation.

Evading Antitumor Immune Responses

Despite the fact that the immune system has the potential to recognize tumor-associated antigens and to marshall an effective cytotoxic response, this response often fails to prevent the local growth and distant spread of cancers. A better understanding of the mechanisms by which tumor cells can evade a host response is emerging. Tumor cells may evade detection by multiple mechanisms, all of which are probably operational to some extent.[6] Tumor cells may express only low levels of tumor-associated antigens in cryptic sites that are covered by glycocalyx molecules, or they may undergo antigenic modulation by shedding tumor antigens. Tumor cells have been shown to express low levels or nondetectable amounts of MHC molecules or appropriate costimulatory molecules (e.g., B7) that are required for an effective immune response. In other circumstances, tumor cells that can stimulate an effective immune response may have already been eliminated, leaving only those cells that can evade an immune response. Finally, tumor cells have been found to secrete various soluble factors (e.g., transforming growth factor–β [TGF-β], IL-10, and Fas ligand) that have been found to be immunosuppressive.

Enhancement of Active Host Immune Responses

Two major approaches have been undertaken to counter the mechanisms by which tumor cells evade immune recognition: (1) more effective stimulation of a host immune response in tumor-bearing patients (active immunity) and (2) the adoptive transfer of cellular or humoral immunity to the tumor-bearing host (passive immunity).

STIMULATION OF A HOST IMMUNE RESPONSE

Nonspecific Immune Stimulation

Previous attempts at nonspecific stimulation of the immune response, such as direct intratumor injections of bacillus Calmette-Guérin (BCG) or other immune adjuvant compounds, often provoked local immune responses (with occasional regressions of injected tumors) but without consistent systemic effects on noninjected sites of disease. The local administration of BCG has been successful in treating and preventing the recurrence of noninvasive bladder cancer [*see 12:XIV Bladder, Renal, and Testicular Cancer*].[7]

Vaccine Therapy

A major strategy for generating a systemic immune response against cancer is the development of tumor vaccine therapy.[8] The goal of such therapy is to present tumor-associated antigens in association with appropriate costimulatory molecules in a way that circumvents the tumor-evasive mechanisms that would ordinarily lead to tolerance (a state of immune paralysis). Approaches to immunizing a tumor-bearing host with tumor-associated antigens have ranged from vaccination with intact tumor cells to administration of selected immunogenic peptide vaccines.

Vaccination with intact unmodified tumor cells Even with adjuvant compounds, vaccination with intact unmodified tumor cells has generally been ineffective in triggering a clinically relevant immune response. If tumor cells escape immune recognition in situ, immunization with cells from the tumor carries the same limitations.

Vaccination with genetically modified tumor cells In this strategy, host-derived tumor cells are transfected with genes encoding for allogeneic MHC genes, costimulatory molecules (e.g., B7), or immunomodulatory cytokines. These genetically modified tumor cells bearing MHC or costimulatory molecules compensate for the lack of these molecules in vivo. Tumor cells transfected with genes encoding for immunomodulatory cytokines may result in the release of these soluble factors (e.g., granulocyte-macrophage colony-stimulating factor [GM-CSF], IL-4, and IL-2), which recruit dendritic cell precursors or helper T cells into vaccination sites to facilitate the immune recognition of tumor antigen and the subsequent generation of an effector cytotoxic T lymphocyte (CTL) response. Rather than relying on the cumbersome technique of transfecting autologous tumor cells in vitro, a more practical approach is to admix autologous tumor cells with

generic transduced bystander cells or biopolymer microspheres containing cytokines or to use in situ intratumoral injection of genetic material. An alternative approach is to employ standardized (allogeneic) gene-transduced tumor cell lines that display broadly expressed antigens as a source of tumor vaccine.

Vaccination with tumor antigens or peptides The goal of this strategy is to immunize patients with tumor antigens or immunodominant peptides derived from those antigens. An example is the direct immunization with a peptide derived from the MART-1 antigen as a means of provoking an immune response from patients with melanoma. Several class I (HLA-A2)–restricted, highly immunogenic peptides of MART-1 and GP-100 have been created.[9,10] In one clinical trial, 42 patients with metastatic melanoma were vaccinated with a synthetic peptide derived from GP-100.[11] Eleven patients receiving the GP-100–derived peptide without IL-2 demonstrated no objective responses, but 13 of 31 patients (42%) receiving the peptide plus systemic IL-2 achieved a clinically relevant tumor shrinkage. The results of this early investigation are consistent with the concept that vaccines for treatment of cancer will need to be used along with adjuvants to enhance immunologic response (i.e., IL-2 or other signaling molecules).

A similar vaccination strategy was evaluated in 10 patients with multiple myeloma.[12] The vaccine consisted of autologous immunoglobulin idiotype (Id) protein purified from serum or urine, coupled to keyhole limpet hemocyanin (KLH), a protein commonly utilized as an adjuvant to augment an immune response. The patients received subcutaneous injections of Id-KLH conjugates along with low doses of GM-CSF or IL-2. Although the clinical impact of this immunization remains to be determined, 8 of 10 patients developed an Id-specific delayed-type hypersensitivity (DTH) reaction, indicating the immunocompetence of multiple myeloma patients for specific immunization.

Vaccination with recombinant viral or bacterial vaccines Another strategy for stimulating an immune response to a specific tumor antigen is through the use of recombinant viral or bacterial vaccines. In this approach, the viral or bacterial genome is modified to include a gene encoding the relevant tumor antigen with or without genes encoding for costimulatory molecules (e.g., B7). The recombinant viral or bacterial agents then act as vectors with the capacity of infecting APCs or tumor cells. This strategy also takes advantage of the natural adjuvant effect and intrinsic immunogenicity of viruses and bacteria.

Naked DNA vaccines Yet another strategy involves vaccination with so-called naked DNA encoding for a tumor-associated antigen. These nucleic acid vaccines may be less potent than vaccines comprising recombinant virus or bacteria, because unlike the latter, they have no mechanism for amplification in the host individual.

Dendritic cell vaccines The use of DCs as a major constituent of a tumor vaccine helps ensure effective presentation of antigen to $CD4^+$ and $CD8^+$ T cells.[13] Various approaches have been devised to load DCs with tumor-associated antigen, including (1) ex vivo incubation of autologous DCs with tumor antigen or tumor cell lysates before vaccination, (2) fusion of DCs with whole autologous tumor cells, and (3) ex vivo transduction with RNA or replication-defective recombinant viral vectors carrying tumor-associated antigens within their genome. An example of DC-based vaccination strategy has been evaluated in B cell non-Hodgkin lymphoma.[14] Autologous DCs were cocultured with idiotypic protein from the patient's malignant B cells and then utilized as a vaccine. Of the 35 patients vaccinated, the majority developed T cell or humoral anti-Id responses. Among the 28 patients with measurable disease at the time of vaccination (or subsequent booster injections), 11 experienced clinically significant tumor regressions, including four with complete responses (i.e., no clinically detectable tumor).

Systemic Administration of Immunostimulatory Cytokines

Another approach to stimulating an immune response in a patient with cancer is to administer recombinant cytokines that may enhance an otherwise ineffective immune response. An example of this strategy is the use of high-dose IL-2, which enhances the immune response by stimulating T cell and NK cell activity and increases the serum concentration of other immunostimulatory cytokines, such as TNF, IL-1, and interferon gamma. Systemic high-dose IL-2 has been extensively evaluated in the treatment of metastatic melanoma and renal cell carcinoma and is approved by the Food and Drug Administration for the treatment of these two diseases. The approval of high-dose IL-2 as therapy for metastatic melanoma is based in part on the collective experience of 270 patients who were entered into eight clinical trials in the United States. Doses of 600,000 to 720,000 IU/kg I.V. were administered every 8 hours over two 5-day periods, with a 6- to 9-day rest in between the 5-day cycles. Partial tumor shrinkage occurred in 10% of the treated patients, with another 6% demonstrating complete tumor shrinkage.[15] For the patients who experienced complete response, the median response duration was not reached, and 59% of these patients remained progression free. Similar response rates and durations of response were seen in patients with metastatic renal cell carcinoma.[16] The major drawback to this form of therapy is its associated toxicity, which includes the development of a capillary leak/shock syndrome.

Interferon alfa, which has direct antiproliferative effects and causes increased MHC class I expression, has been effective in inducing tumor regressions in a minority of patients with renal cell carcinoma, melanoma, hairy-cell leukemia, and lymphoma; it has also been effective in the treatment of chronic myelogenous leukemia. Other immunomodulatory cytokines that have been evaluated in clinical trials include TNF-α and interferon gamma, both of which have shown antitumor activity in vitro but are poorly tolerated or minimally active in vivo.

PASSIVE IMMUNITY AGAINST CANCER BY ADOPTIVE TRANSFER OF CELLS OR ANTIBODY

The strategy of adoptive transfer of preimmune cells or antibody to a tumor-bearing patient circumvents the potential limitation of stimulating an effective immune response in favor of boosting the host with previously activated elements of an immune effector response.

Adoptive Cellular Immunotherapy

Adoptive cellular immunotherapy is the transfer of ex vivo activated immune cells with antitumor activity into a tumor-bearing host. Examples of this strategy include the adoptive transfer of lymphokine-activated killer (LAK) cells. In this approach, peripheral blood lymphoid cells (primarily NK cells) are taken from patients with cancer and are subsequently acti-

vated and expanded in vitro with IL-2; they are then administered back to the patient (usually along with systemic IL-2). Initial results of the use of LAK cells with high-dose IL-2 in patients with renal cell carcinoma and melanoma were encouraging, but subsequent randomized trials failed to show any benefit of LAK cell administration over the modest response rate seen with high-dose IL-2 alone.[17] As an alternative to peripheral blood lymphocytes, investigators have evaluated the adoptive transfer of tumor-infiltrating lymphoid (TIL) cells isolated from inflammatory infiltrates of excised tumor nodules. Once expanded in IL-2, these cells may be enriched for tumor-specific cytotoxic T cells and NK cells. Of 86 patients with stage IV melanoma receiving TIL treatment at the National Cancer Institute, 34% had objective tumor responses (i.e., partial or complete tumor regressions).[18] Unfortunately, it was not possible to isolate sufficient numbers of TIL cells from all tumor specimens to accomplish adoptive transfer. Other patients experienced disease progression while their TIL cells were being cultured and therefore never received treatment. Despite the modest success of TIL therapy for melanoma, comparable results have not been observed in the treatment of patients with renal cell carcinoma. One of the side benefits of TIL technology has been its use in isolating and defining the tumor antigens recognized by T cells from TIL cell cultures, such as MART-1, GP-100, tyrosinase, p15, TRP-1, and β-catenin, which are all expressed by melanoma cells.[19]

Other sources for adoptively transferred immune effector cells include the ex vivo activation and expansion of lymphoid cells derived from draining lymph nodes at tumor vaccination sites or in situ genetic modification of tumor nodules (direct injection of genetic material that encodes for proteins into tumors, triggering an immune response).

Genetic-modification strategies have been used to enhance the cytolytic activity of adoptively transferred immune effector cells. This technique involves the transduction of autologous CTLs (or their bone marrow precursors) with genes encoding a TCR specific for a tumor antigen (e.g., a TCR that recognizes MART-1 antigen in melanoma) or involves a chimeric receptor (i.e., an antigen-binding domain linked to a signal-transducing domain that initiates cellular activation after cross-linking by antigen) recognizing a tumor-associated antigen such as the mucin antigen TAG-72 expressed by most adenocarcinomas.[20,21]

Mononuclear phagocytes have also been evaluated as a source of immune effector cells for adoptive cellular immunotherapy. This strategy has involved the ex vivo activation of peripheral blood monocyte–derived macrophages by interferon gamma or lipopolysaccharide, with the subsequent administration of these activated cells back into the tumor-bearing host. However, as with other adoptive cellular therapy strategies, there has been minimal therapeutic response to date.[22]

Another form of adoptive cellular therapy that has received considerable attention is the use of allogeneic donor lymphocyte infusions. The rationale for this strategy is the fact that in allogeneic bone marrow/stem cell transplantation, donor lymphocytes appear to exert a graft-versus-leukemia effect. This approach is supported by data showing a higher risk of leukemic relapse in patients receiving syngeneic bone marrow transplantation than in patients receiving allogeneic bone marrow transplantation, as well as a higher risk of relapse in patients receiving T cell–depleted bone marrow than in those receiving unmanipulated allogeneic bone marrow.[23] The greatest benefit of allogeneic lymphocyte infusions was seen in patients with chronic myeloid leukemia (CML) who had relapses after allogeneic bone marrow transplantation; of these patients, 70% had complete responses to donor lymphocyte infusions.[24] This donor-lymphocyte graft-versus-leukemia effect may reflect immune reactivity toward minor histocompatibility antigens shared between recipient tissues (resulting in graft-versus-host disease) and leukemic cells, as well as reactivity toward leukemia-associated antigens. The efficacy of donor-lymphocyte infusions seen in patients with CML has led to the use of such infusions in other diseases, and investigators are currently assessing the value of the graft-versus-tumor effect as a primary form of antineoplastic therapy. In this strategy, a nonmyeloablative (i.e., not causing sustained neutropenia) immunosuppressive preparative regimen is used to achieve engraftment of allogeneic peripheral blood or bone marrow–derived stem cells, with the express purpose of developing a graft-versus-tumor effect. After allogeneic stem cell transplant engraftment, additional infusions of donor lymphocytes are often used to enhance the graft-versus-tumor effect. When this approach was expanded to include patients with chronic lymphocytic leukemia (CLL) or indolent non-Hodgkin lymphoma (NHL), promising results were observed.[25] In one study involving 15 patients with CLL or indolent NHL, 11 patients were engrafted, and all 11 had objective responses; eight patients had complete responses. The encouraging results seen in patients with hematologic malignancies have precipitated clinical trials to determine the feasibility and efficacy of this approach in patients with solid tumors. Preliminary results indicate that this approach has some efficacy in renal cell carcinoma.[26]

Antitumor Antibody Therapy

The administration of antitumor antibodies to patients with cancer may result in tumor regression by a variety of mechanisms, including ADCC caused by NK cells and macrophages; cytotoxicity resulting from complement fixation; induction of apoptosis; and the delivery of toxins, cytotoxic pharmaceutical agents, or ionizing radiation to the tumor. In the treatment of lymphoma, promising results have been observed with the use of monoclonal antibodies that are specific for surface idiotype and for the CD20 differentiation antigen. An FDA-approved therapy for NHL employs a monoclonal antibody targeting an 85 kd B cell differentiation antigen (B1, CD20), which is expressed by most normal and malignant B cells but not by stem cells or plasma cells. The advantage of CD20 as a target of immunotherapy is that it is not shed, internalized, or otherwise modulated as a result of antibody binding. Its mechanisms of B cell cytotoxicity may include complement fixation, ADCC, and the transmission of apoptotic signals. Intravenous administration of the chimeric human/mouse CD20 antibody rituximab, alone or in combination with chemotherapy, has produced significant disease regression in patients with low-grade or follicular NHL. In a phase 3 trial of 166 patients who received four doses of rituximab alone after having relapses of indolent lymphoma,[27] 48% of the treated patients achieved a clinically relevant response, including 6% who experienced complete tumor shrinkage. The median time to progression was 13 months. In another study, in which rituximab was used to treat 28 evaluable patients with bulky relapsed NHL (the patients had a large tumor burden),[28] the response rate was 43%, and the median time to progression was 8.1 months. Rituximab may show its greatest clinical utility when used in conjunction with chemotherapy. Of 35 evaluable patients with NHL who were not previously treated, 100% of the patients experienced a re-

sponse to combination therapy; 63% experienced complete response.[29] Seven of eight evaluable patients had a so-called molecular complete response, as evidenced by the loss of the *bcl-2* oncogene on polymerase chain reaction analysis.

An alternative approach for the use of anti-CD20 antibody in the treatment of patients with low-grade or follicular NHL employs murine antibodies radioconjugated to either yttrium-90 ibritumomab (^{90}Y-ibritumomab) or iodine-131 tositumomab (^{131}I-tositumomab). In two therapeutic trials,[30,31] a single intravenous dose of ^{90}Y-ibritumomab given to patients with relapsed or refractory low-grade or follicular NHL produced overall response rates of 74% to 80% (15% to 30% had complete responses); the median time to progression was 6.8 to 11.2 months. Similarly, a single intravenous dose of ^{131}I-tositumomab given to a comparable group of NHL patients caused significant clinical responses in 57% to 65%; 17% to 32% of these patients achieved complete shrinkage of their visible tumor. The median duration of response was 20 months.[32,33] In previously untreated patients with follicular lymphoma, treatment with ^{131}I-tositumomab produced an overall response rate of 97%; 63% of these patients achieved a complete response. The rate of progression-free survival was 68% at 3 years.[34] These promising findings recently led to FDA approval of ^{90}Y-ibritumomab for the treatment of patients with relapsed or refractory low-grade or follicular NHL; FDA approval of ^{131}I-tositumomab is pending.

Antitumor antibody therapy has also proved effective against breast cancer. The antigenic target of an FDA-approved breast cancer treatment is HER-2/neu, the 185 kd transmembrane growth factor receptor that is overexpressed in 25% of human breast cancers (and in a variety of other malignancies). Preclinical studies demonstrated that anti–HER-2/neu monoclonal antibody exposure of cells overexpressing HER-2/neu had antiproliferative activity and may facilitate apoptotic cell death. On the basis of these promising preclinical findings, trastuzumab (Herceptin), a form of anti–HER-2/neu monoclonal antibody, was evaluated alone and in combination with chemotherapy in patients with metastatic breast carcinoma.[35,36] In 222 patients receiving weekly intravenous trastuzumab alone, the overall response rate was 14%, with 2% having complete response; the median duration of response was 9.1 months. In a separate clinical trial, 469 patients were randomized to receive either trastuzumab plus chemotherapy (with doxorubicin-cyclophosphamide or paclitaxel) or chemotherapy alone. The combination of trastuzumab and chemotherapy was superior to chemotherapy alone with regard to time to progression, overall response rate, and 1-year survival. These promising findings led the FDA to approve trastuzumab as an adjunct to chemotherapy in patients with HER-2/neu-positive breast cancers.

Antitumor antibody therapy has been applied to the treatment of patients with colorectal cancer. The antigenic target in this disease is a nonsecreted 40 kd glycoprotein recognized by the investigational 17-1A monoclonal antibody. The 17-1A antigen is overexpressed by most epithelioid tumors, including the majority of colorectal carcinomas. Although the 17-1A antibody displayed only minor to modest clinical activity when administered intravenously to patients with advanced stage IV disease, it may be more active as adjuvant therapy for patients who are at high risk for recurrence after surgical resection. In a study of 189 patients with stage III colorectal carcinoma (i.e., patients found to have local lymph node metastases) who were randomly assigned either to observation alone or to four postoperative infusions of 17-1A monoclonal antibody,[37] mortality in the treatment arm was reduced by 32%, and recurrence was decreased by 23%.

Other strategies of antitumor-antibody therapy include the use of toxin or drug-conjugated monoclonal antibodies targeted to tumor-associated antigens (in addition to radionuclide-conjugated antibody treatment). Another approach involves the administration of bispecific (heteroconjugate) antibodies consisting of two covalently linked antibodies, with one antigen recognition site targeted to the target tumor–associated antigen and the other recognition site targeted to a trigger molecule (expressed on the effector cell).[38] Antitumor antibodies may also be useful as a means of depleting tumor cells contaminating preparations of autologous bone marrow cells before transplantation.[39]

Immunotherapeutic approaches to the treatment of cancer is an area of active investigation. Most of these approaches are investigational and continue to be evaluated in clinical trials. However, several of the therapeutic agents (IL-2, trastuzumab, BCG, and rituximab) have been shown to be effective and are approved by the FDA.

Diagnostic Role of Monoclonal Antibodies

DIAGNOSIS OF LEUKEMIAS AND LYMPHOMAS

In addition to their potential role as therapeutic agents, monoclonal antibodies that recognize tumor-associated antigens are being used to facilitate the diagnosis of hematologic malignancies.[40,41] The rationale for their use as diagnostic tools stems from the fact that leukemias and lymphomas are thought to be neoplastic counterparts of subpopulations of normal lymphoid and myeloid cells. The identification of cell surface antigens common to both normal and neoplastic lymphoid and myeloid cells has made it possible to assign the normal cell lineage to the malignant counterparts. This lineage information provides an additional means of discriminating among the various forms of leukemia and lymphoma that may influence treatment decisions. An example of this concept is T cell differentiation [*see Figure 3*]. Research over the past 20 years has led to the identification of multiple cell surface antigens expressed by cells of the T cell lineage that are differentially expressed along the path of differentiation. Monoclonal antibodies have been developed for these so-called differentiation antigens and have been utilized in the diagnosis of leukemia and lymphoma. CD34 and MHC class II gene products, for example, are expressed by the prethymocyte but are lost by thymic T cell precursors. Conversely, in the thymus, CD4 and CD8 accessory molecules are coexpressed by a biphenotypic T cell precursor that gives rise to separate CD4 and CD8 lineages in the thymic medulla, with subsequent maturation of these lineages in peripheral lymphoid tissues. T cell acute lymphoblastic leukemia/lymphoma shares the surface marker phenotypic characteristics of the bone marrow prethymocyte and is therefore believed to be a malignant transformation of this normal stem cell. The T cell lymphomas and chronic leukemias, on the other hand, share the cell surface phenotype characteristic of mature CD4 or CD8 lymphoid cells found in the peripheral lymphoid tissues. They, in turn, are thought to represent malignant transformation of these more mature T cells.

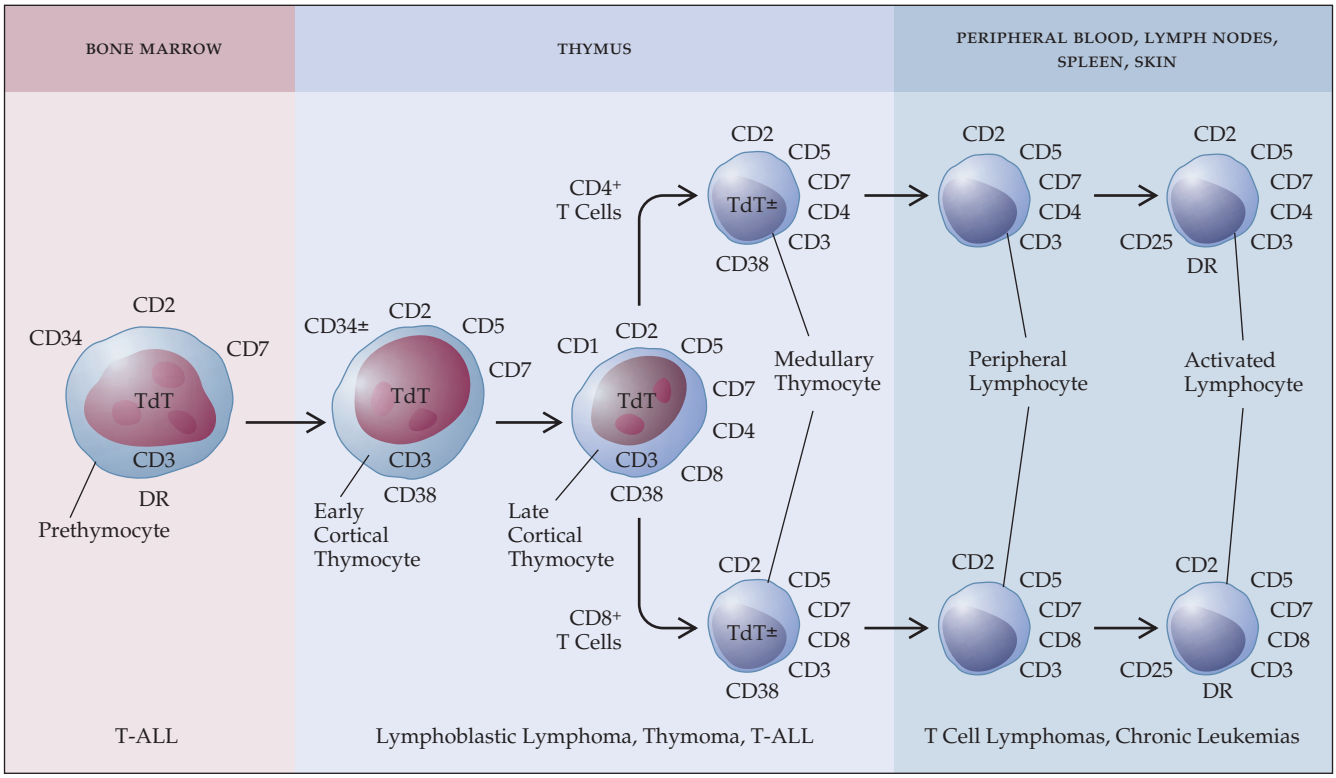

Figure 3 **Sequential expression of selected antigens during T cell development. Depicted is the pathway of T cell differentiation from the bone marrow stem cell to thymocyte maturation in the thymus, leading to the diversion of the $CD4^+$ helper and $CD8^+$ cytotoxic suppressor cell sublineages, each of which undergoes further differentiation in peripheral lymphoid tissues. Certain disorders are shown under the associated phenotypes. (DR—HLA class II; T-ALL —T cell acute lymphoblastic leukemia; TdT— terminal deoxynucleotidyl transferase)**

The expression of cell surface markers of leukemias and lymphomas can have diagnostic and prognostic significance:

1. Patients with T cell acute lymphoblastic leukemia whose cells express markers characteristic of the earlier stage of thymocyte development have a higher rate of treatment failure during induction than patients whose cells express a more mature phenotype.[42]
2. One third of patients with acute lymphoblastic leukemia (ALL) have leukemic cells expressing myeloid markers (biphenotypic ALL). Adult patients with biphenotypic ALL have a poor response to therapy and a shorter survival.[43]
3. Acute leukemias that are not classified by morphology or cytochemical characteristics (approximately 1%) can often be classified as belonging to a lymphoid lineage, as opposed to a nonlymphoid lineage, through the use of cell surface markers. In classifying myeloid leukemias into subgroups, analysis of cell surface markers can supplement morphology and cytochemical staining.
4. Of patients with CML in blast crisis, approximately one third express lymphocyte markers (e.g., CD10) and preferentially respond to the therapy for ALL.[40]

DIAGNOSIS AND STAGING OF CANCER IN VIVO

In addition to their potential utility in the pathologic diagnosis of leukemias and lymphomas, monoclonal antibodies have been employed in the diagnosis and staging of solid tumors.[44] Monoclonal antibodies specific for tumor-associated antigens have been useful in the diagnosis of carcinomas of unknown origin. Using a so-called cocktail of antibodies, pathologists are better able to determine the organ of origin of a metastatic carcinoma; such determinations may affect treatment decisions. In the setting of colon cancer, the CYT-103 (OncoScint) antibody has been approved by the FDA for use as a supplemental tool for the staging of colon cancer. The CYT-103 scan incorporates Indium-111–labeled CYT-103 antibody that is specific for a tumor-associated glycoprotein found on many mucin-containing adenocarcinomas, including many colon cancers. When used as a diagnostic tool, the CYT-103 antibody has a reported sensitivity of 92% and a specificity of 67%; its use results in a change in patient management in 33% of patients evaluated.[45] Its use may be superior to CT scanning in the detection of pelvic tumors and extrahepatic abdominal metastases. In addition, the CYT-103 antibody and other antibodies specific for the oncofetal protein CEA have been employed to identify the occult sites of metastatic disease in patients in whom the CEA level is rising, in the absence of radiographic evidence of disease recurrence. The CYT-103 antibody has also been used to detect recurrent ovarian carcinoma in the peritoneal cavity. A similarly tagged monoclonal antibody specific for prostate-specific membrane antigen is being utilized in the staging of prostate cancer.[46] Radiolabeled monoclonal antibodies specific for other cancers are being developed and evaluated for their utility in the management of cancer.

IV PRINCIPLES OF CANCER TREATMENT

Eric H. Rubin, m.d.
William N. Hait, m.d., ph.d.

Management of Cancer Cases

DIAGNOSIS

Proper care of cancer patients begins with an accurate diagnosis. Unlike other specialties, in which a diagnosis can often be deduced from symptoms, signs, and laboratory tests, the practice of oncology depends on obtaining tissue for accurate histology. For example, although a cigarette smoker presenting with cough, hemoptysis, and weight loss is likely to have lung cancer, the selection of treatment for such a patient requires obtaining tissue to confirm the diagnosis and to specify the histologic subtype (e.g., small cell versus non–small cell carcinoma).

Both immunohistochemical and molecular analyses enhance the precision of the diagnosis. For example, the subtyping of breast cancer requires assay of hormone receptors (estrogen and progesterone) and an analysis of chromosome number and proliferative index of the tumor with a DNA histogram, which evaluates the percentage of cells in the various stages of the cell cycle. Furthermore, the expression of cancer-causing agents such as the *HER-2/neu* oncogene is becoming a standard part of breast cancer evaluation.[1] Similarly, the modern diagnosis of hematologic malignancies requires a panel of cell surface markers, as well as an evaluation of chromosomal rearrangements. An understanding of the molecular pathology of individual cancers has led to more precise prescriptions for systemic therapy.

STAGING

Knowledge of the extent of the disease at the time of diagnosis (stage) is required to properly manage patients with cancer. Staging is based on three components: the size or depth of penetration of the tumor (T), the involvement of lymph nodes (N), and the presence or absence of metastases (M). The TNM staging system is now standard, and its use is required not only for the management of cancer patients but also for the reporting of cancer cases to cooperative groups and many tumor registries.

Within each TNM category, the extent of involvement correlates with prognosis. In breast cancer, for example, small (< 1 cm) node-negative tumors are associated with a less than 10% chance of recurrence, whereas 3 cm node-negative tumors have a 50% chance of recurrence.[1] In most types of cancer, it is worse to have extensive lymph node involvement than involvement of a single lymph node. Lymph node involvement is particularly relevant in breast cancer: prognosis worsens with the increase in the number of axillary lymph nodes involved. The site of lymph node involvement may also be significant: in lung cancer, involvement of ipsilateral mediastinal lymph nodes (N2) indicates a better prognosis than involvement of lymph nodes in the contralateral mediastinum (N3).[2] Finally, the presence of metastases at the time of diagnosis predicts a poor outcome in most malignancies. For even the most treatable tumors, including testicular cancer and lymphomas, the extent or bulk of metastatic disease measured by imaging or serum markers determines the ultimate chances of survival.

The staging of Hodgkin disease and non-Hodgkin lymphoma follows similar principles as the TNM system. Although the staging systems for these cancers do not include a true T classification, the number of involved lymph node regions may be considered analogous to T and N, and visceral involvement may be considered analogous to M1 disease. In the widely used Ann Arbor classification of Hodgkin disease, stage is proportional to extent or bulk of disease, as well as involvement of viscera. As with solid tumors, overall prognosis is highly dependent on precise histologic classification, which has been one of the most challenging aspects for the hematopathologist. Thus, a large cell lymphoma may be cured in 50% of the cases regardless of the stage at diagnosis, whereas a small cell or indolent lymphoma is most often incurable regardless of stage.[3] Furthermore, certain histologic subsets have particularly aggressive behaviors and may be most amenable to early use of experimental therapies or bone marrow transplantation.

PERFORMANCE STATUS

Performance status is a measure of the functional capacity of a patient and adds significantly to the staging evaluation; for any given stage, performance status appears to be an independent predictor of outcome. Although the Karnofsky score is the most rigorous method of determining performance status, it is cumbersome and does not add appreciably to the simple scoring schema adopted by the Eastern Cooperative Oncology Group (ECOG) and World Health Organization [*see Table 1*]. Suffice it to say, knowing whether a patient is confined to bed or living a normal life is the mainstay of these classifications, which have proved to be a valuable means of prognostication.

TREATMENT

The treatment of patients with cancer requires coordination between medical, surgical, and radiation oncologists who work closely with primary care physicians to plan and implement treatment. In addition, social workers, research nurses, and pharmacists are often needed to formulate a treatment plan and make adjustments once treatment has begun.

This team must decide, in consultation with the patient, whether to treat with curative or palliative intent. In a patient

Table 1 World Health Organization Performance Scale

0	Able to carry out all normal activity without restrictions
1	Restricted in physically strenuous activity but ambulatory and able to carry out light work
2	Ambulatory and capable of all self-care but unable to carry out work; up and about more than 50% of waking hours
3	Capable only of limited self-care; confined to bed more than 50% of waking hours
4	Completely disabled; cannot carry out any self-care; totally confined to bed or chair

with advanced-stage, non–small cell lung cancer, for instance, aggressive treatment with chemotherapy, surgery, or radiation may lead to a more rapid demise than may no treatment at all. The classic example is that of a heavy smoker with potentially resectable lung cancer and chronic obstructive pulmonary disease who has limited pulmonary reserve (e.g., an FEV_1 [forced expiratory volume in 1 second] of < 800 ml). Even if this patient's tumor could be removed surgically (e.g., stage I or II disease), the surgery could leave the patient with insufficient pulmonary function to sustain life.

Curative treatment is undertaken in a patient with a good performance status who, on the basis of stage (e.g., M0) or histology (e.g., large cell lymphoma), has a reasonable probability of entering a meaningful remission and has a reasonable chance of cure.

Palliative treatment refers to the care provided to cancer patients for whom there is no possibility of cure. This care may sometimes include the same modalities as those used in curative treatment. For example, a patient with metastatic colon cancer may require surgery or radiation to control gastrointestinal bleeding despite an overall poor prognosis. Similarly, radiation and chemotherapy offer effective palliation for most patients.

The management of cancer cases also requires the use of analgesics to relieve pain, antiemetics to combat nausea and vomiting, and antidepressants to control depression. Highly emetogenic chemotherapy can be given safely and comfortably with the proper use of effective medications such as the serotonin antagonists (e.g., ondansetron), dopamine receptor antagonists (e.g., metoclopramide), phenothiazines (e.g., prochlorperazine), cannabinoids (e.g., nabilone, dronabinol), and glucocorticoids (e.g., dexamethasone). Cancer pain, which is often chronic and debilitating, usually requires the use of both long-acting and short-acting narcotic preparations such as morphine and oxycodone, supplemented with nonsteroidal anti-inflammatory drugs (NSAIDS) and antidepressants. Finally, depression, which is underdiagnosed in cancer patients, may be treated with tricyclic antidepressants or selective serotonin reuptake inhibitors (e.g., fluoxetine or paroxetine), in addition to psychosocial counseling.

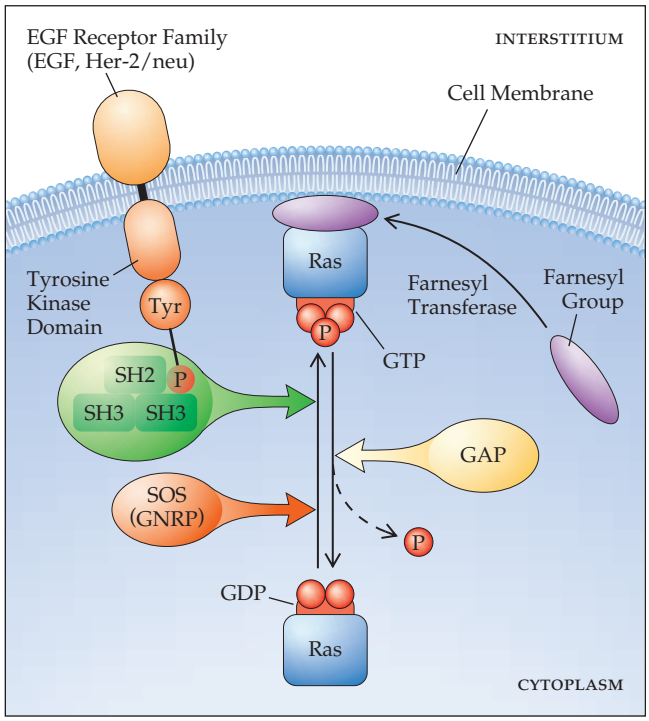

Figure 1 **Shown are growth factors, receptors, and signal transduction pathways that are targets for new cancer therapeutics. Receptor tyrosine kinases, such as the epidermal growth factor (EGF) receptor family, transmit cell proliferation signals through activation of the Ras oncoprotein through the src homology domain (SH) of the cytoplasmic portion of the receptor. Activation of Ras is enhanced by the son-of-sevenless (SOS) transducer. SOS functions as a guanine nucleotide–releasing protein (GNRP) in converting inactive Ras–guanosine diphosphate (GDP) to the active guanosine triphosphate (GTP)–bound form by a nucleotide exchange. Ras requires bound GTP for activity and is inactivated by a GTPase activating protein (GAP). Modification of Ras by farnesyl transferase allows Ras to embed in the plasma membrane, which is required for Ras activity.**

Scientific Basis of Cancer Treatment

CANCER BIOLOGY

Transformation and Proliferation

The origin of cancer in a person involves complex interactions between genes and environment, complicated further by the person's behavior and by aging. It is believed that the fundamental lesion is genetic—that is, changes in DNA lead to functional alterations in proteins that result in cellular transformation. Several of the genes and oncogenes involved in malignant transformation have been identified, including *p53*, *ras*, and *DCC* (deleted in colon cancer gene) [*see 12:II Molecular Genetics of Cancer*].[4] The expression of altered messenger RNAs (mRNAs) and proteins forms the basis of molecular diagnostic tests that will allow early detection of cells on their way to malignant transformation; such tests are under development.

Gene products involved in the development of cancer include growth factors, growth factor receptors, signal transduction pathways, and DNA transcription factors. In addition, telomerase, an enzyme that maintains the integrity of ends of chromosomes, must be active for tumors to continuously proliferate.[5] The identification of these gene products and the elucidation of their function have led to new therapeutic opportunities. For example, the *HER-2/neu* oncogene is a member of the epidermal growth factor receptor family[6] and is overexpressed in 20% to 30% of invasive breast cancers.[7] Trastuzumab, an antibody against the HER-2/neu protein, has therapeutic activity against breast cancer when used alone or in combination with chemotherapy.

The *ras* oncogene (*p21*) is mutated in 30% of human cancers, including colon cancer, pancreatic cancer, and breast cancer.[8] Ras activation leads to cell division by stimulating signal transduction pathways and transcription factors [*see Figure 1*]. Drugs that inhibit farnesyl transferase, a protein necessary for Ras to function properly, have shown promise in preclinical models and have now reached clinical trials.[9] Although inhibition of farnesylation is likely to affect other proteins besides Ras and therefore may not be as selective as originally hoped, this approach to anticancer treatment holds promise.

New therapeutic agents are being developed that inhibit the activity of both tyrosine and serine-threonine kinases.[10,11] Although members of this family of protein kinases share structural similarities, it appears possible to identify highly specific inhibitors that may have therapeutic value. The Bcr-Abl tyrosine kinase is an excellent example of a compelling target for drug

discovery. Bcr-Abl is a cytoplasmic fusion protein formed as a consequence of the t(9;22) translocation of the Philadelphia chromosome. Therefore, it does not exist in normal cells, making the potential for drug selectivity extremely high. Imatinib mesylate (Gleevec) inhibits the tyrosine kinase activity of Abl with high specificity and has been shown to have substantial activity with few side effects in the treatment of chronic myelogenous leukemia.[12] The removal of phosphates by protein phosphatases is also critical to growth control, and phosphatases are now also receiving attention as potential drug targets.

Currently available chemotherapeutic drugs are characterized as being cell-cycle or phase specific, referring to the observation that certain drugs are more active against cells traversing a specific phase of the cell cycle. A good example of the role of oncogenes in cell-cycle regulation comes from the elegant work done to confirm the Knudson hypothesis [*see 12:II Molecular Genetics of Cancer*], which predicts complete loss (both alleles) of tumor suppressor gene (*Rb* gene) function in the genesis of retinoblastoma—the so-called two-hit hypothesis.[13]

The Rb protein prevents cells from moving out of G_1 into the S phase of the cell cycle. Phosphorylation of Rb at the G_1/S interface releases bound E_2F and DRTF, two factors known to activate transcription of genes involved in DNA synthesis and cell division. These genes include the dihydrofolate reductase (*DHFR*) gene and the thymidylate synthase (*TS*) gene and may provide a molecular explanation for the cell-cycle specificity (S phase) of methotrexate and 5-fluorouracil (5-FU), drugs that target DHFR and TS proteins, respectively.

p53 is the gene most commonly mutated in human cancers.[14,15] p53 protein can activate or repress gene transcription. Cells with *p53* mutations acquire sensitivity to taxanes yet retain resistance to vinca alkaloids, both of which are chemotherapeutic drugs that target microtubules.[16] An explanation for this effect comes from the observation that wild-type p53 protein represses the transcriptional activation of a microtubule-associated protein, MAP4, which in turn regulates the stability of microtubules. Cells with mutant *p53* have increased MAP4 and stabilized microtubules, the target for taxanes such as paclitaxel and docetaxel. Conversely, cells with wild-type p53 are sensitive to vinca alkaloids and have decreased MAP4 and destabilized microtubules, the target for vinca alkaloids.

Cell Viability and Cell Death

Loss of telomeric chromosomal ends is believed to be the cause of the finite replicative potential (senescence) of nonmalignant cells. In malignant cells, this telomeric problem is solved by the reactivation of telomerase, a reverse transcriptase that systematically adds length to the shortened ends of chromosomes that occurs with each cell division.[17] Telomerase, therefore, is an attractive target for anticancer therapy and may be an early marker of cell transformation useful in early detection and chemoprevention.[18]

The accumulation of tumor cells represents a disequilibrium between cell proliferation and cell death. Programmed cell death (or apoptosis, from the Greek *apoptosis*, a falling off) involves the activation of energy-dependent suicide pathways within the cell.[19] Whereas necrotic cell death is characterized by cell swelling and disruption of cellular organelles and the cell membrane, apoptotic cells show cell shrinkage, blebbing of the plasma membrane, condensation of nuclear chromatin, and degradation of the genome into fragments that correspond to the size of nucleosomes. These nucleosomal fragments produce distinctive ladder-shaped patterns on electrophoretic gels. Apoptotic cell death is critical in normal embryonic development, during which time organs are formed and remodeled. Similarly, normal adult tissue is characterized by a steady state in which cell proliferation is balanced by cell death. The loss of this balance may result in cellular transformation [*see 12:II Molecular Genetics of Cancer*].

Invasion and Metastasis

With malignant transformation, cells acquire the ability to invade and metastasize. This process includes detachment from the primary site, invasion through the basement membrane, access to the blood or lymphatic vessels, entry to distant organs through adherence to visceral capillaries, and escape from a variety of other mechanisms designed to protect the host.

Normal cells survive and proliferate by adhering to each other and to the extracellular matrix (anchorage dependence).[20] Loss of these attachments causes normal cells to die. Therefore, cancer cells must lose their anchorage dependence—that is, they must acquire the ability to detach from the extracellular matrix without dying. Molecules such as E-cadherins and integrins mediate these attachments. E-cadherins provide the cell-cell connections essential for maintaining an organized epithelium.[21] The loss of functional E-cadherins is characteristic of malignant cells, and restoration of E-cadherin function blocks the ability of transformed cells to form tumors.

A critical moment in the life of a malignancy comes when it must acquire a blood supply of its own—a process known as angiogenesis.[22] To accomplish angiogenesis, tumor cells produce or attract angiogenic substances. Tumors produce both proangiogenic and antiangiogenic substances. Once the balance favors proangiogenic substances, new capillaries proliferate and become surrounded by rapidly dividing cancer cells. These cells secrete factors that promote the growth of both the tumor and its new blood supply. For example, capillary endothelial cells recruited to breast cancer cells produce interleukin-6, which can increase the migration of breast cancer cells into the bloodstream.[23] Interference with angiogenesis forms the basis of an exciting new approach to anticancer therapy.

PRINCIPLES OF CANCER PHARMACOLOGY

Dose Response and Schedule

A relation between dose and response exists for all drugs. The dose-response curve not only establishes effective doses but also defines the dose at which further increases produce no greater effect. The therapeutic index of a drug helps define its ultimate utility in patients. The therapeutic index is defined as the ratio of the dose that produces the desired effect 50% of the time (ED_{50}) to the dose that produces a toxic effect 50% of the time (TD_{50}). Because cancer cells originate from normal cells, it has been difficult to identify and exploit differences in sensitivity to drugs between neoplastic and nonneoplastic tissues. Moreover, many of the antineoplastic drugs in current use target cellular processes (e.g., DNA replication) that are present in both malignant and nonmalignant cells. Thus, there is often a small therapeutic index for cancer therapeutics.

In models of dose-response relations for several antineoplastic drugs, the percentage of tumor cells killed by a drug decreases as the number of cells increases. This phenomenon is related to a reduction in the percentage of proliferating cells (growth fraction) in larger tumors, defined by the Gompertz equation.[24] The decrease in growth fraction in larger tumors occurs as a result of

relative hypoperfusion and hypoxia in regions of tumor that are distant from blood vessels. The Gompertzian model correctly predicts several clinical observations: (1) increasing the drug dose may not improve antitumor activity; (2) treatment of minimal disease may be more effective than treatment of large tumor masses; and (3) small, frequent drug dosing (to decrease cell number in a large tumor mass) may be more effective than large, infrequent dosing.

With rare exception, optimal antineoplastic therapy requires repetitive dosing because even if all cells in a given tumor are sensitive to a drug, a single dose of the drug is not sufficient to kill the typically hundreds of millions or billions of cells that are present in a patient with cancer. The choice of schedule for repetitive drug administration usually relates to recovery of normal tissues. Although proper scheduling is critical for effective therapy, the drug schedule is often chosen empirically in initial drug development. The use of animal and pharmacokinetic models to optimize scheduling offers a rational alternative to empirical scheduling.[25]

Drug Resistance

For an anticancer drug to kill a cancer cell, the drug must enter the bloodstream, be activated or escape inactivation by drug-metabolizing enzymes, and reach the target in its active form. The drug–drug-target interaction must then produce cell death. Resistance to anticancer therapies results from interference with one or more of these critical steps [*see Figure 2*].[26]

To reach the target in an active form and at a therapeutic concentration, drugs must be absorbed or delivered into the body. Oral absorption requires a drug or drug formulation that resists the hostile environment of the stomach, traverses the epithelial lining of the gut, and escapes drug-metabolizing enzymes in the liver. Changes in drug metabolism can be inherited or acquired. Inherited drug resistance occurs in certain persons who rapidly metabolize drugs, so that less than therapeutic concentrations reach the pharmacologic target; or in the case of prodrugs such as cyclophosphamide, there is inadequate conversion to the active molecule. Acquired drug resistance occurs through induction of drug-metabolizing enzymes in the liver, other organs, or the tumor cells.

Finally, the tenuous blood supply to many tumor masses prevents adequate concentrations of drugs from reaching the target, or the drugs may find cells that are resistant because of relative hypoxia. Hypoxia causes resistance to both radiation and most chemotherapeutic drugs.[27] The mitomycins are an exception to this rule because these drugs are more active in hypoxic environments.

Resistance to drugs that act on extracellular receptors can occur if the receptor is modified. Many examples exist of receptors that are mutated during the process of oncogenesis. Therefore, effective therapeutic agents must recognize the altered form of the receptor protein.

A drug not only must reach the tumor in therapeutic concentrations but also must interact with targets that are often intracellular. Cancer cells acquire mechanisms to block the intracellular accumulation of drugs by producing proteins that transport drugs to the extracellular space, where they are removed by the circulation. Alternatively, cancer cells can neutralize the effects of drugs within the intracellular milieu.

Multidrug resistance (MDR) refers to the clinical and laboratory circumstance in which a tumor is no longer susceptible to several chemotherapeutic drugs having different mechanisms or targets. In the early 1980s, the *mdr-1* gene product P-glycoprotein was discovered in cells that were selected for resistance to antimicrotubule drugs.[28,29] P-glycoprotein is a member of the adenosine triphosphate (ATP)–binding cassette family that includes both eukaryotic and prokaryotic energy-dependent transporters. P-glycoprotein spans the plasma membrane and recognizes a broad spectrum of anticancer drugs, many of which are naturally occurring substances. In the presence of ATP, P-glycoprotein pumps the drugs to the extracellular space, so that an effective concentration at the intracellular target is never achieved. Examples of drugs recognized and transported by P-glycoprotein include anthracyclines, vinca alkaloids, taxanes, epidophyllotoxins, and other hydrophobic compounds. In contrast, many alkylating agents, platinating agents, and antimetabolites are not affected.

P-glycoprotein is a tantalizing target for new drug discovery. The structural features of drugs that block drug transport mediated by P-glycoprotein were defined in the mid-1980s,[30] and verapamil, an early prototype, soon reached clinical trial. The observation that cyclosporins could also inhibit P-glycoprotein led to the realization that nonimmunosuppressive analogues of cyclosporine and other immunosuppressives could be developed as modulators of MDR. Several of these compounds have been tested, and some have shown early clinical promise. In particular, it appears that PSC-833 (valspodar), a nonimmunosuppressive cyclosporine, in combination with mitoxantrone, etoposide, and cytosine arabinoside, can provide a therapeutic advantage for patients with refractory acute myelocytic leukemia.[31] Ongoing studies in myeloma, non-Hodgkin lymphoma, breast cancer, and other malignancies will define the utility of this new class of anticancer agent.

The multidrug resistance protein (MRP) is a second member of the ATP-binding cassette family that confers MDR. MRP was discovered when investigators found that certain cells with long-term exposure to anthracyclines or anthracenes behaved like MDR cell lines but did not express P-glycoprotein.[32,33] MRP is located on both the plasma membrane and the endoplasmic reticulum and removes drugs from the cell after conjugation to or association with glutathione. The spectrum of drugs affected by MRP is similar to that affected by P-glycoprotein, with the exception of taxanes, which are poorly transported. MRP avidly transports conjugated leukotrienes, which are proinflammatory substances that mediate numerous biologic and pathologic responses. Several substances that interfere with leukotriene transport inhibit the transport by MRP and may represent new classes of drug-resistance modulators. In addition, several drugs that block the function of P-glycoprotein also block the function of MRP. These broad-spectrum MDR modulators are also undergoing clinical trials. Finally, disruption of glutathione conjugation through depletion of glutathione or inhibition of glutathione transferase inhibits MRP-mediated drug transport and may also sensitize drugs to alkylating agents.

The breast cancer resistance protein (BCRP, also known as ABCP [placenta ABC protein] and MXR [mitoxantrone-resistance protein) is a new member of the ATP-binding cassette family and is implicated in resistance to anthracyclines, mitoxantrone, and camptothecins.[34,35] Expression of BCRP is associated with a poor response to induction therapy in childhood acute leukemia.[36]

Once a drug reaches its therapeutic target, the target must be susceptible to the anticancer agent. For example, the topoisomerases are the target for many anticancer drugs, including the anthracyclines, anthracenes, and epidophyllotoxins (topoiso-

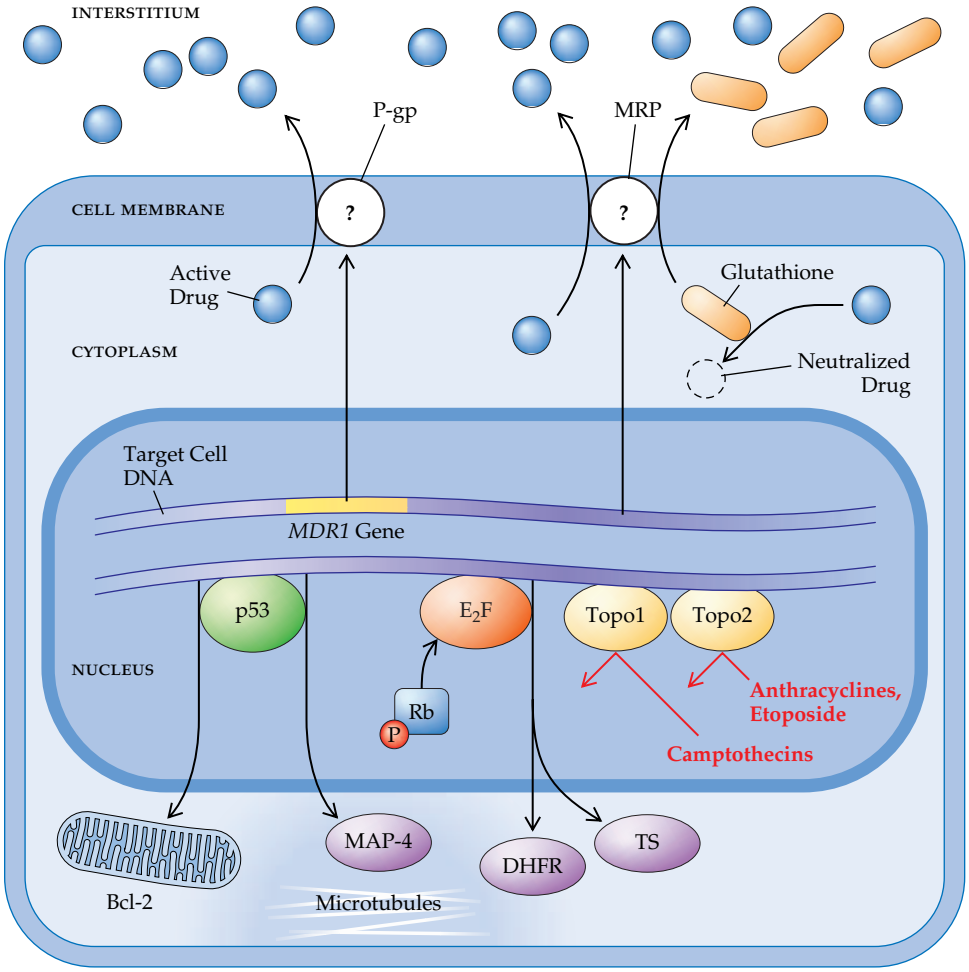

Figure 2 **Drug resistance can occur through failure of the drug to reach its target because of drug efflux mechanisms such as P-glycoprotein (P-gp), the *MDR1* gene product, or the multidrug resistance protein (MRP). MRP cotransports substances with glutathione, a molecule that can itself render cells resistant to a variety of alkylating agents through neutralization. p53 can regulate the sensitivity to drugs by changing the expression of proapoptotic and antiapoptotic molecules, such as Bcl-2, and by regulating the polymerization state of microtubules through microtubule-associated protein 4 (MAP4). Phosphorylation of the retinoblastoma protein (Rb) releases the transcription factor E_2F, which in turn regulates the sensitivity to methotrexate and fluorouracil through the production of dihydrofolate reductase (DHFR) and thymidylate synthetase (TS), respectively. Downregulation or mutations in topoisomerases (topo) produce resistance to camptothecins and topo II poisons, such as anthracyclines and etoposide.**

merase II), as well as the camptothecins (topoisomerase I).[37] Resistance to these drugs occurs through mutations in the drug-binding domain of the enzyme, the ATP-binding domain; through a decreased expression of the protein; or through failure of the enzyme to localize properly in the nucleus.[38,39] Binding of topoisomerase drugs to the enzyme activates a ubiquitin-mediated pathway of enzyme degradation.[40] Downregulation of one of the topoisomerases leaves the cell susceptible to poisoning by an inhibitor of the other. This discovery led to the sequential use of topoisomerase I and II inhibitors as a potentially more effective means of administering these chemotherapeutic agents.[41]

Resistance to methotrexate was one of the earliest understood phenomena in cancer pharmacology. Resistance can occur through mutations in the drug target, dihydrofolate reductase, which maintains cellular reduced folate pools that are required for DNA synthesis. Resistance to methotrexate can also occur by amplification or overexpression of the dihydrofolate reductase enzyme.[42] Similarly, resistance to 5-FU can occur by virtue of alteration or overexpression of the enyzme that generates thymidine for DNA synthesis, thymidylate synthase.

Resistance to antimicrotubule drugs occurs through MDR and through alterations in the drug targets. Vinca alkaloids bind depolymerized tubulin and prevent microtubule polymerization, whereas taxanes bind to and stabilize polymerized microtubules. Changes in the dynamic equilibrium of microtubules through alterations in microtubule-associated proteins or tubulin mutations can also alter the sensitivity to antimicrotubule drugs.[16]

Resistance to alkylating agents occurs through overexpression of both drug-neutralizing substances and metabolizing proteins such as glutathione and glutathione transferase. Depletion of glutathione with buthionine sulfoxamine sensitizes resistant cells to alkylating agents and is under clinical investigation.[43]

We now more fully understand the molecular mechanisms that account for changes in several drug targets. For example, inactivation of Rb through phosphorylation or mutation releases bound E_2F, which in turn leads to the transcriptional activation of several enzymes involved in cell proliferation, including dihydrofolate reductase and thymidylate synthase. Changes in expression of these drug targets affect the sensitivity to methotrexate and 5-FU, respectively. Finally, the presence of antiapoptotic proteins such as Bcl-2 may produce resistance to both chemotherapy and radiation by interfering with the cell death signal generated after an interaction between a drug and its therapeutic target.[44]

Combination Chemotherapy

Many cancers are incurable as a result of either intrinsic or acquired resistance to antineoplastic drugs. The Goldie-Coldman model relates the probability of drug resistance to cell number and the spontaneous mutation rate of cancer cells.[45] Assuming a spontaneous mutation rate of 1×10^{-6}, this model predicts that a 1 mm^3 tumor nodule (below the level of clinical detection) has a greater than 60% chance of harboring a cell with a resistance-conferring mutation. The Goldie-Coldman model also predicts that antitumor activity will be enhanced by combining drugs for which resistance mechanisms are independent. For example, in a 1 mm^3 tumor nodule, the likelihood of a cell possessing simultaneous resistance to two non–cross-resistant drugs is less than 0.000001. These predictions are consistent with the clinical observation that with few exceptions, cancers are cured only by combination chemotherapy.

The successful application of combination chemotherapy may thus depend on the availability of non–cross-resistant drugs with nonoverlapping toxicities. Although the existence of a wide variety of mechanistically distinct antineoplastic drugs suggests that finding non–cross-resistant drugs may be accomplished, cancer cells are known to possess a variety of mechanisms that confer multidrug resistance. These mechanisms of resistance contribute to the failure of combination chemotherapy to cure patients with common malignancies, such as metastatic colon or prostate cancer.

Common Toxicities

Most antineoplastic drugs target proteins or nucleic acids that are common to both malignant and nonmalignant cells and thus have a narrow therapeutic index. In addition, antineoplastic drugs are usually administered at the maximum tolerated doses identified in phase I trials. Coupled with interpatient variability in drug metabolism, this dosing strategy results in a relatively high incidence of toxicity. Although toxicities may be unique for a particular drug, several toxicities are shared by many antineoplastic drugs. These include nausea and vomiting, mucositis and diarrhea, myelosuppression, alopecia, infertility, and increased risk of secondary malignancy.

Nausea and vomiting result from local gastrointestinal effects, as well as activation of the chemoreceptor trigger zone in the central nervous system.[46] The identification of neurotransmitter pathways involved in chemotherapy-induced nausea and vomiting led to development of potent antiemetics such as the serotonin antagonists ondansetron and granisetron. The use of these drugs has significantly improved administration of highly emetogenic drugs such as cisplatin.

Mucositis and diarrhea are other common gastrointestinal toxicities that are attributable to the relatively high proliferative rate of normal gastrointestinal tissues, which makes these tissues more susceptible to the cytotoxic effects of many chemotherapeutics. Similar mechanisms result in chemotherapy-induced myelosuppression, alopecia, and infertility.

Many chemotherapeutics are found to be mutagenic when tested in vitro. Moreover, epidemiologic studies of patients cured of a pediatric cancer or lymphoma have demonstrated that certain therapies are associated with a higher risk of secondary malignancy than others.[47] Agents that damage DNA, such as alkylating agents and topoisomerase poisons, are believed to be responsible for these secondary malignancies. In vitro models suggest that even non–DNA-damaging agents, such as paclitaxel, may be carcinogenic.[48]

Pharmacokinetics and Pharmacogenetics

Given the narrow therapeutic index of most antineoplastic drugs, it is critical to administer an effective but tolerable dose to each patient. Individual dosage is based on a patient's body surface area (BSA); however, BSA is a poor predictor of clearance for most drugs.[49] In some cases, alternative strategies of individualized dosing are available. For example, because carboplatin is eliminated predominantly by the kidney, drug clearance correlates with renal function. Therefore, carboplatin dosing is based on a patient's creatinine clearance, which can be measured either directly or indirectly. The importance of individualized dosing is evident from a study of childhood leukemia, in which patients with B cell lineage leukemia randomized to receive individualized drug dosing (based on determination of patient clearances for each of the administered drugs) had significantly greater survival than patients who were treated with BSA-based dosing.[50]

Advances in understanding the molecular and genetic determinants of drug metabolism should lead to more precise, individualized dosing for other antineoplastic drugs. For example, certain polymorphisms in the dihydropyrimidine dehydrogenase gene, which degrades fluoropyrimidines, and the uridine diphosphate glucuronosyltransferase *1A1* gene, which when mutated results in Gilbert syndrome, may alter the metabolism of 5-FU and irinotecan, respectively.[51,52] These genetic polymorphisms result in increased toxicity in patients receiving these drugs. In the future, this problem may be addressed by customizing drug administration for each patient by use of genetic determinants of drug metabolism and toxicity.

In addition to allowing individualized dosing of drugs, genetic studies may soon allow physicians to predict response to a particular drug or drug combination. For example, certain polymorphisms in the thymidylate synthase gene are associated with reduced survival in patients treated with methotrexate for leukemia[53] or treated with 5-FU for colorectal cancer.[54] Conversely, a polymorphism in the glutathione S-transferase P1 gene is associated with improvement in patients with colorectal cancer treated with a combination of 5-FU and oxaliplatin.[55]

Specific Chemotherapeutic Agents

DRUGS THAT ALTER NUCLEIC ACID SYNTHESIS OR FUNCTION

DNA Alkylating and Cross-linking Agents

This category of drugs contains the oldest and some of the most widely used antineoplastic agents. They form covalent alkyl bonds with nucleic acid bases, resulting in intrastrand or interstrand DNA cross-links that are particularly toxic to cells

undergoing division. Examples include the nitrogen mustards (e.g., mechlorethamine, cyclophosphamide, and ifosfamide), the alkyl sulfonates (e.g., busulfan), the triazenes (e.g., dacarbazine), and the nitrosoureas (e.g., carmustine [BCNU]) [*see Table 2*]. By altering the structure of DNA, these drugs inhibit DNA replication and transcription. DNA damage produced by alkylators may be more likely to kill malignant cells than nonmalignant cells because of rates of proliferation and an altered balance of proapoptotic and antiapoptotic pathways. For example, testicular cancer, which is one of the few nonhematologic malignancies that are curable even when metastatic, is composed of cells that undergo apoptotic cell death more readily than normal cells after DNA damage.[56] Differences in the cellular mechanisms responsible for cell-cycle arrest and DNA repair (e.g., p53, the DNA mismatch repair pathway, and O^6-alkyltransferase) between malignant cells and normal cells may also contribute to the increased sensitivity of cancer cells to alkylating agents.

Alkylating agents such as cyclophosphamide are used in the treatment of most hematologic and nonhematologic malignancies. Because dose-response curves of alkylating agents in cell culture systems do not reach a plateau at high doses, cyclophosphamide is commonly used in high-dose chemotherapy regimens that involve bone marrow or stem cell transplantation. Certain alkylating agents are also useful in the treatment of brain tumors, including the nitrosourea BCNU and the triazene temozolomide.[57]

Myelosuppression is typically the most prominent toxicity observed with alkylating agents, such as busulfan, which is associated with prolonged bone marrow impairment. Treatment with alkylating agents is often associated with gonadal dysfunction, including oligospermia and amenorrhea. Bladder toxicity, such as hemorrhagic cystitis, can result from irritation by the acrolein metabolite of cyclophosphamide or ifosfamide, particularly when these drugs are administered at high doses. Not unexpectedly, alkylating agents can be carcinogenic, with secondary malignancies reported after therapy with several of these drugs.

Cisplatin, a simple compound containing a platinum atom, two amines, and two chlorides, produces effects similar to those of the alkylating agents by cross-linking adjacent or opposing guanine bases. Cisplatin or its analogue carboplatin is an important part of the treatment of many nonhematologic malignancies, including testicular, lung, bladder, and ovarian cancers. Oxaliplatin is a cisplatin analogue that is approved for the treatment of colorectal cancer. Toxicities associated with platinum agents include nausea and vomiting, alopecia, and myelosuppression. Cisplatin can produce severe renal toxicity and is therefore administered in conjunction with hydration and often an osmotic diuretic such as mannitol. Neurotoxicity may also be observed with cisplatin therapy, commonly consisting of peripheral neuropathies and auditory impairment.

Inhibitors of Nucleic Acid Synthesis

Many antineoplastic drugs, including folate analogues and nucleoside derivatives, inhibit the synthesis of nucleic acids and are often referred to as antimetabolites. These drugs are particularly effective in destroying cells during the S phase of the cell cycle, which is when DNA is synthesized. Thus, the selective toxicity these drugs exhibit toward cancer cells may relate to a greater rate of DNA replication in cancer cells than in normal cells. Nevertheless, these drugs share a common toxicity profile (e.g., myelosuppression and mucositis) that results from targeting of proliferating but nonmalignant tissues [*see Table 2*].

Methotrexate is a folate analogue that is used in the treatment of many different hematologic and nonhematologic malignancies. This drug inhibits dihydrofolate reductase, an enzyme that uses reduced folate as a methyl donor in the synthesis of pyrimidine and purine nucleosides. Similarly, the pyrimidine analogue 5-FU blocks production of thymine nucleotides by inhibiting thymidylate synthase. Other antineoplastic nucleosides, such as cytosine arabinoside and gemcitabine, are incorporated into DNA or RNA strands and either block further strand synthesis or cause structural perturbations that result in damage to DNA. 6-Mercaptopurine is a purine analogue that functions similarly. Hydroxyurea also belongs in this category, because it inhibits ribonucleotide reductase, an enzyme that converts ribonucleoside precursors into deoxyribonucleosides that are eventually used by DNA polymerases to replicate DNA.

Although both hydroxyurea and nucleoside derivatives destroy cancer cells by inhibiting nucleic acid synthesis, these agents exhibit different clinical antitumor activities. For example, 5-FU is effective in the treatment of gastrointestinal malignancies, whereas cytosine arabinoside is not. The converse is true for leukemia. Similarly, gemcitabine and cytosine arabinoside are very similar structurally [*see Table 2*], yet gemcitabine is active in several nonhematologic malignancies, whereas cytosine arabinoside is not. The reasons for these specificities are not understood, but they likely relate to additional unique effects of nucleoside derivatives on DNA and RNA metabolism, as well as differences in cellular and extracellular metabolism.

The success of folate and nucleoside analogues encouraged development of potentially more effective derivatives. For example, capecitabine is an orally administered drug that is metabolized to fluorouracil after ingestion and is approved for the treatment of breast cancer.[58] Capecitabine is converted to 5´-deoxy-5-fluorocytidine (5´-DFCR) by carboxylesterases in the liver and then to 5´-deoxy-5-fluorouridine (5´-DFUR) by cytidine deaminase in the liver and tumor tissue. DFUR is ultimately converted to fluorouracil by thymidine phosphorylase. Because there is more activity of thymidine phosphorylase in tumors than in certain normal tissues, capecitabine has the potential to be more selective than 5-FU.

Pemetrexed (Alimta) is a new folate antagonist that is active in the treatment of lung cancer and mesothelioma. This drug inhibits multiple enzymes involved in the folate pathway, including thymidylate synthase, glycinamide ribonucleotide formyltransferase, and dihydrofolate reductase.

DNA Topoisomerase Inhibitors

Topoisomerases correct alterations in DNA topology that occur during replication and transcription. These enzymes make transient single-strand (topoisomerase I) or double-strand (topoisomerase II) nicks in DNA. Several antineoplastic drugs inhibit either topoisomerase I or II. The effect of these drugs on topoisomerases is unique relative to other anticancer drugs that are enzyme inhibitors. They poison the enzymes and inhibit religation of the DNA nicks produced during topoisomerase catalysis.[59] Because cancer cells possess more topoisomerase activity than normal cells, there is more drug-induced DNA damage and resultant cell death. Toxicities observed with these drugs relate to targeting of topoisomerases in normal proliferating tissues and include myelosuppression and mucositis.

Topoisomerase II inhibitors such as doxorubicin, daunorubicin, etoposide, and teniposide are part of most combination chemotherapy regimens. Topoisomerase I inhibitors were iden-

Table 2 Chemotherapeutic Agents

	Class	*Structure*	*Route*	*Target*	*Uses*	*Toxicities*
Alkylating Agents	*Nitrogen Mustards* Mechlorethamine		I.V.	N-7 of guanine; carbamoylation of proteins	Hodgkin disease; non-Hodgkin lymphoma	Nausea and vomiting, lacrimation, myelosuppression, mucositis, alopecia, vesication
	Cyclophosphamide; ifosfamide		I.V., p.o.		Acute lymphocytic leukemia (ALL) and chronic lymphocytic leukemia (CLL); lymphomas; myeloma; neuroblastoma; breast, ovarian, lung, cervical, and testicular cancers; sarcoma; Wilms tumor	Myelosuppression, mucositis, alopecia, emesis, dizziness, hemorrhagic cystitis, skin pigmentation, cardiac, renal, central nervous system (particularly caused by ifosfamide, including seizures, altered mental status, coma, and paralysis at high doses), syndrome of inappropriate secretion of antidiuretic hormone
	Melphalan		p.o.		Myeloma and breast cancers	Myelosuppression
	Chlorambucil		p.o.		CLL, primary macroglobulinemia, Hodgkin disease, non-Hodgkin lymphoma	Myelosuppression, secondary leukemias and other tumors
	Ethylenimines and Methylmelamines Hexamethylmelamine		I.V.		Ovarian cancer	Nausea and vomiting, diarrhea, myelosuppression
	Thiotepa		I.V.		Bladder, breast, and ovarian cancers	Myelosuppression, mucositis, nausea, and vomiting
	Alkyl Sulfonates Busulfan		p.o.		Chronic myelogenous leukemia; acute myelogenous leukemia (in bone marrow transplantation cases)	Myelosuppression, prolonged thrombocytopenia
	Nitrosoureas Carmustine (BCNU)		I.V.	O-6 of guanine; carbamoylation of lysine ε-amino groups	Hodgkin disease, non-Hodgkin lymphoma, astrocytomas, myeloma, melanoma	Delayed myelosuppression (nadir at 4–6 wk); hepatic necrosis at high doses, nausea and vomiting, flushing; interstitial pulmonary fibrosis and renal failure at doses > 1,000 mg/m^2
	Lomustine (CCNU)		p.o.		Hodgkin disease, non-Hodgkin lymphoma, astrocytomas, small cell lung cancer	Myelosuppression
	Semustine (methyl-CCNU)		p.o.		Colon cancer	Myelosuppression
	Streptozotocin		I.V.		Insulinoma, carcinoid tumor	Nausea, renal (proximal tubule effects), hepatic, mild to moderate myelosuppression

Table 2 Chemotherapeutic Agents (*continued*)

	Class	Structure	Route	Target	Uses	Toxicities
Alkylating Agents	*Triazenes* Dacarbazine (DTIC)		I.V.	O-6 of guanine; N-7 of guanine	Melanoma, Hodgkin disease, sarcomas	Myelosuppression, nausea, vomiting, flulike syndrome
	Temozolomide		p.o.		Astrocytoma, melanoma	Lymphocytopenia, hepatic toxicity, nausea and vomiting, hyperglycemia, anemia, and thrombocytopenia
	Bioreductive Alkylating Agents Mitomycin-C		I.V.	N-6 of adenine; N-7 of guanine; and O-6 of guanine	Colon, rectal, breast, gastric, head and neck, lung, and cervical cancers	Myelosuppression with delayed recovery (6–8 wk), nausea, vomiting, diarrhea, mucositis, dermatitis, asthenia, interstitial fibrosis, hemolytic-uremic syndrome, congestive heart failure
Platinating Agents	*Platinum Compounds* Cisplatin		I.V.	Interstrand and intrastrand cross-linking of DNA	Testicular, ovarian, bladder, head and neck, lung, thyroid, cervical, and endometrial cancers; neuroblastoma, osteogenic sarcoma	Renal toxicity, nausea and vomiting, peripheral neuropathy, ototoxicity, myelosuppression, electrolyte abnormalities (hypomagnesemia, hypocalcemia, hypophosphatemia), anaphylactoid reactions
	Carboplatin		I.V.			Myelosuppression (thrombocytopenia)
	Oxaliplatin		p.o.		Colon cancer	Peripheral neuropathy, nausea and vomiting, myelosuppression
Nucleic Acid Synthesis Inhibitors	*Folate Analogues* Methotrexate		I.V., p.o.	Inhibition of dihydrofolate reductase; inhibition of folate-dependent synthesis of purines and thymidylate	ALL, choriocarcinoma, non-Hodgkin lymphoma; breast, head and neck, and lung cancers; osteogenic sarcoma	Myelosuppression, mucositis, renal failure, reversible pneumonitis, hepatic fibrosis (low-dose oral administration)
	Pyrimidine Analogues Fluorouracil (5-FU); floxuridine (fluorodeoxyuridine, FUDR), capecitabine		I.V., p.o.	Inhibition of thymidylate synthase; inhibition of RNA processing, incorporation into DNA	Breast, colon, stomach, pancreatic, ovarian, head and neck, bladder, cervical, and prostate cancers; hepatoma	Myelosuppression, mucositis, nausea, diarrhea, hair loss, nail changes, pigmentation, chest pain, hand-foot syndrome
	Cytarabine (cytosine arabinoside)		I.V.	Analogue of 2′-deoxycytidine; inhibition of DNA chain elongation	Acute myeloid leukemia (AML) and ALL, non-Hodgkin lymphoma	Myelosuppression, mucositis, conjunctivitis, reversible hepatic dysfunction

(*continued*)

Table 2 Chemotherapeutic Agents (*continued*)

	Class	*Structure*	*Route*	*Target*	*Uses*	*Toxicities*
Nucleic Acid Synthesis Inhibitors (continued)	Gemcitabine		I.V.	Analogue of 2′-deoxycytidine; inhibits DNA synthesis; incorporated into DNA; inhibits ribonucleotide reductase	Pancreatic, bladder, breast, and lung cancers	Myelosuppression, flulike syndrome, nausea
	Purine Analogues Mercaptopurine		p.o.	Inhibits de novo purine production; incorporates into DNA	ALL, AML, chronic myeloid leukemia (CML)	Myelosuppression, anorexia, nausea and vomiting, jaundice
	Thioguanine			Inhibits de novo purine production; incorporates into DNA	ALL, AML, CML	Myelosuppression, anorexia, nausea and vomiting
	Fludarabine		I.V.	Inhibits DNA polymerase, primase, ribonucleotide reductase DNA, and RNA	CLL, low-grade non-Hodgkin lymphoma	Myelosuppression, fever, chills, asthenia, anorexia; depletion of CD4 cells can lead to opportunistic infections; peripheral neuropathy, altered mental status, seizure, optic neuritis, and coma at higher doses
	Pentostatin (2-deoxycoformycin)		I.V.	Inhibits adenosine deaminase and blocks DNA synthesis	Hairy-cell leukemia, cutaneous T cell lymphoma, CLL	Myelosuppression, nausea, vomiting, skin rashes, abnormal liver function; depletion of T cells can lead to opportunistic infections
	Cladribine (2-chlorodeoxyadenosine)		I.V.	Incorporated into DNA and leads to strand breakage	Hairy-cell leukemia, CLL, cutaneous T cell lymphoma, low-grade lymphoma, Waldenstrom macroglobulinemia	Myelosuppression, nausea, infections, fever, headache, asthenia, skin rashes, tumor lysis syndrome
	Hydroxyurea		p.o.	Blocks conversion of ribonucleotides to deoxyribonucleotides; inhibits DNA synthesis	CML, polycythemia vera, essential thrombocytosis, melanoma	Myelosuppression, dermatologic changes
DNA Topoisomerase Inhibitors	*Anthracyclines* Doxorubicin		I.V.	DNA intercalation; free radical generation after metabolism by cytochrome P-450 reductase and reduced nicotinamide adenine dinucleotide phosphate, peroxidation of cell membrane lipids	Sarcomas; Hodgkin disease, non-Hodgkin lymphoma, ALL; bladder, thyroid, lung, breast, and gastric cancers; neuroblastoma	Cardiomyopathy, myelosuppression, mucositis, radiation recall, local flare reactions, vesication
	Daunomycin		I.V.		AML, ALL	

Table 2 Chemotherapeutic Agents (*continued*)

	Class	*Structure*	*Route*	*Target*	*Uses*	*Toxicities*
DNA Topoisomerase Inhibitors (continued)	Idarubicin		I.V.		AML, ALL	
	Epirubicin		I.V.		Sarcomas; Hodgkin disease, non-Hodgkin lymphoma, ALL; bladder, lung, gastric, and breast cancers	Less cardiac toxicity, alopecia, phlebitis; myelosuppression is dose-limiting
	Anthracenediones Mitoxantrone		I.V.	Less ability to form free radicals	AML, breast cancer	Myelosuppression, nausea and vomiting, mucositis
	Epipodophyllotoxins Etoposide		I.V., p.o.	Form ternary complexes with topoisomerase II and DNA	Testicular, lung, and breast cancers; Hodgkin disease, non-Hodgkin lymphoma, AML, Kaposi sarcoma	Myelosuppression, nausea and vomiting, mucositis, alopecia, hypotension, hepatic toxicity after high doses
	Teniposide		I.V., p.o.	Form ternary complexes with topoisomerase II and DNA	Pediatric ALL and AML	Myelosuppression, nausea and vomiting, hypotension
	Dactinomycin (actinomycin-D)		I.V.	DNA intercalation, forms ternary complexes with DNA and topoisomerase II	Wilms tumor, rhabdomyosarcoma, testicular cancer, choriocarcinoma, Kaposi and Ewing sarcoma	Nausea and vomiting, anorexia, myelosuppression, mucositis, cheilitis, glossitis, alopecia, erythema and desquamation of skin, radiation recall, vesication

(*continued*)

Table 2 Chemotherapeutic Agents (*continued*)

	Class	Structure	Route	Target	Uses	Toxicities
DNA Topoisomerase Inhibitors (continued)	*Camptothecins* Irinotecan		I.V.	Form ternary complexes with topoisomerase I and DNA	Colon and ovarian cancers	Myelosuppression, diarrhea, alopecia
	Topotecan		I.V.		Ovarian and lung cancers	Myelosuppression, diarrhea, alopecia
Other DNA-Damaging Agents	*Antibiotic* Bleomycin		I.V.	DNA cleavage caused by generation of reactive oxygen	Non-Hodgkin lymphoma, Hodgkin disease, testicular and head and neck cancers	Hypersensitivity reactions most prominent in patients with lymphomas, skin pigmentation and ulceration, interstitial pulmonary fibrosis
Antimicrotubule Agents	*Vinca Alkaloids* Vinblastine $R_1 = CH_3$		I.V.	Inhibit tubulin polymerization	Hodgkin disease, non-Hodgkin lymphoma; breast and testicular cancers	Myelosuppression, peripheral neuropathy, obstipation
	Vincristine $R_1 = CHO$				ALL, neuroblastoma, Wilms tumor, rhabdomyosarcoma, Hodgkin disease, non-Hodgkin lymphoma, small cell lung cancer	Peripheral neuropathy, myelosuppression
	Vinorelbine (structure not shown)				Breast and lung cancers	Myelosuppression, peripheral neuropathy, pain
	Taxanes Paclitaxel R = 		I.V.	Inhibit tubulin depolymerization	Ovarian, breast, lung, and bladder cancers	Myelosuppression, alopecia totalis, peripheral neuropathy, pain, hypersensitivity reactions
	Docetaxel $R = OC(CH_3)_3$				Ovarian, breast, lung, and bladder cancers	Myelosuppression, alopecia totalis, peripheral neuropathy, pain, capillary leakage, cardiac arrhythmias, hypersensitivity reactions
Signal Transduction Modulators	*Antiestrogens* Tamoxifen		p.o.	Block activation of estrogen receptor by estrogens; produce TGF-β; inhibit signal transduction enzymes	Breast cancer	Amenorrhea, hot flashes, nausea, weight gain, hypercalcemia, venous thrombosis, endometrial cancer
	Toremifene (structure not shown)				Breast cancer	Hot flashes, nausea, venous thrombosis
	Raloxifene (structure not shown)				Breast cancer	Hot flashes, nausea, venous thrombosis

Table 2 Chemotherapeutic Agents (*continued*)

	Class	*Structure*	*Route*	*Target*	*Uses*	*Toxicities*
Signal Transduction Modulators (continued)	*Antiandrogens* Flutamide		p.o.	Block activation of the androgen receptor by dihydrotestosterone	Prostate cancer	Nausea, diarrhea, constipation, mastodynia gynecomastia, galactorrhea, hot flashes, loss of facial hair
	Bicalutamide (structure not shown)					Similar to flutamide
	Nilutamide (structure not shown)					Similar to flutamide; also visual disturbances (delayed adaptation to dark)
	Monoclonal Antibodies Rituximab (structure not shown)		I.V.	Binds to CD20 and activates humoral and cellular immunity	B cell non-Hodgkin lymphoma, CLL	Infusion-related fever, chills, vomiting, urticaria, rash, rigors; non–infusion-related (uncommon) arrhythmias, pain, myalgias, angioedema, bronchospasm; myelosuppression; major toxicities associated with high numbers of circulating CD20-positive cells
	Trastuzumab (structure not shown)		I.V.	Binds to HER-2/neu receptor; blocks cell proliferation; elicits immune response	Breast cancer	Fever, chills, pain at tumor site, diarrhea
	Aromatase Inhibitors Aminoglutethimide		p.o.	Aromatase	Breast cancer	Glucocorticoid deficiency, skin rash, lethargy, orthostatic hypotension
	Anastrazole					Nausea, diarrhea, asthenia, headache, hot flashes, pain
	Letrozole					Headache, nausea, vomiting, constipation, heartburn
	Gonadotropin-Releasing Agents Leuprolide	pyro-Glu-His-Trp-Ser-Tyr-D-Leu-Leu-Arg-Pro-ethylamide	I.M.	Activate gonadotropin-releasing hormone receptor and block subsequent activation by receptor desensitization	Prostate and breast cancers	Loss of libido, impotence, hot flashes, diarrhea; increased pain at sites of bony metastases (tumor flare) resulting from initial gonadotropin stimulation
	Buserelin (structure not shown)					
	Progestin Megestrol acetate		p.o.		Breast and endometrial cancers	Weight gain

tified more recently and also exhibit a broad spectrum of antineoplastic activity. Currently approved topoisomerase I inhibitors include the camptothecin derivatives topotecan and irinotecan. These drugs are active in the treatment of leukemia, ovarian cancer, small cell lung cancer, and colon cancer.

Other Drugs That Impair Nucleic Acid Function

Bleomycin is a fungal product commonly used in the treatment of testicular cancer and has a relatively unique mechanism of damaging DNA. It possesses a tripeptide component that binds DNA and a metal-binding region. In the presence of oxygen and either iron or copper, bleomycin produces free radicals that create single-strand and double-strand DNA breaks.

ANTIMICROTUBULE DRUGS

Microtubules are subcellular structures that are essential for the normal function of cells. They form the mitotic spindle; maintain cell shape; organize the location of organelles; and mediate intracellular transport and secretion, neurotransmission, axonemal flow, and cell motility.[60] Microtubules are composed of α-tubulin and β-tubulin dimers arrayed in bundles of 13 protofilaments that form hollow cylinders. In living cells, microtubules grow in spurts or may disappear altogether. This process, termed dynamic equilibrium, is an essential feature of microtubule physiology. For microtubules to elongate, they require the addition of both α-tubulin and β-tubulin bound to guanosine triphosphate (GTP). Once bound to GTP, β-tubulin forms a GTP cap at the elongating end. Rapid growth requires that GTP be bound, which increases the affinity for other tubulin molecules. During depolymerization, GTP is hydrolyzed more rapidly than it can be added, resulting in weakening of the bonds that hold the tubulin molecules together.

Microtubule-associated proteins (MAPs) bind to microtubules, promote polymerization, and mediate interactions with other cellular components. The binding of MAPs to microtubules promotes polymerization by accelerating nucleation and inhibiting the dissociation of tubulin from microtubule ends, thereby stabilizing microtubules once they have formed.

Antimitotic drugs act by interfering with the normal dynamic equilibrium of microtubules, thereby disrupting the normal function of the mitotic apparatus. In addition, by affecting microtubules in interphase cells as well as in mitotic populations, they have the potential to inhibit cell motility and normal subcellular organization.

The two major classes of antimitotic drugs used to treat cancer are the vinca alkaloids and the taxanes. Vinca alkaloids bind to depolymerized microtubules and inhibit microtubule assembly. Taxanes bind to polymerized microtubules and inhibit disassembly. The result of these interactions is the failure of the cell to undergo a normal mitosis. This leads to a death signal mediated by yet-to-be-discovered pathways.

Vinca Alkaloids

Vinca alkaloids represent the active medicinal ingredients from the pink periwinkle plant (*Catharanthus roseus*, formerly *Vinca rosea*). The observation that plant extracts produced granulocytopenia in rats led to the isolation of four active alkaloids, of which two, vincristine and vinblastine, became active therapeutic agents.[61] Today, this class includes the original two alkaloids plus vinorelbine and vindesine.

Although the vinca alkaloids share structural similarities, their spectrum of activity and toxicities are somewhat different. For example, vincristine is highly effective against non-Hodgkin lymphoma, Hodgkin disease, and pediatric solid tumors, yet it has little activity against adult solid tumors. Vinorelbine, in contrast, is active against breast and lung cancer. Vinblastine is most frequently used in the treatment of testicular cancer and non-Hodgkin lymphoma and is a third-line agent in the treatment of breast cancer.

The mechanism of action of vinca alkaloids is related to concentration.[62] At substoichiometric concentrations, they bind to high-affinity sites at the ends of microtubules ($K_a = 5.3 \times 10^{-5}$ M) and prevent microtubule polymerization. At higher concentrations, vinca alkaloids bind to low-affinity, high-capacity sites ($K_a \sim 3 \times 10^{-3}$ M), which leads to the disintegration of formed microtubules.

The major toxicities of the vinca alkaloids are predictable on the basis of their mechanism of action and include dose-limiting myelosuppression and neurotoxicity. Vinblastine and vinorelbine produce far greater neutropenia than vincristine. Nadirs occur at 4 to 10 days, with recovery seen in most patients by 7 to 21 days. All three agents cause mild alopecia and are severe vesicants. Vinorelbine may cause chest pain and other deep-seated pain of unspecified origin. Respiratory reactions, including acute bronchospasm, subacute cough, dyspnea, and pulmonary infiltrates, have also been reported.

The most frequent neurotoxicities from the vinca alkaloids are numbness and tingling of the extremities, loss of deep tendon reflexes, and distal muscle weakness. Although sensory changes are bothersome, they usually reverse over time and do not require discontinuance of the drug. Loss of motor function is a later and more ominous side effect, requiring discontinuance of the medication or a search for other contributing factors.

Taxanes

The screening of plant extracts led to the isolation of an active moiety (paclitaxel) from the Pacific yew tree, *Taxus brevifolia*, in 1971.[63] However, the difficulty in formulation of this insoluble compound and its toxicities led to an initial lack of interest. When the unique mechanism of action was identified,[64] renewed interest in taxanes resulted in the development of one of the most active chemotherapeutic agents. Docetaxel is a semisynthetic derivative that is somewhat more water soluble and more potent in vitro.

Paclitaxel and docetaxel are the only taxanes approved for clinical use. They share a broad spectrum of similar antitumor activity in breast, lung, ovarian, and bladder cancers. Both drugs are also active against lymphoid malignancies.

The taxanes block the function of the mitotic apparatus by impeding the normal function of microtubules. Unlike vinca alkaloids, which affect the rates of tubulin polymerization, the taxanes inhibit microtubule depolymerization. The mechanism of action of the taxanes is dose dependent.[65] At nanomolar concentrations, taxanes induce a mitotic block without a demonstrable increase in microtubule polymer mass. These effects are associated with abnormalities in the metaphase plate and mitotic asters. At stoichiometric concentrations (1 M drug/1 M tubulin dimer), taxanes induce polymerization of stable microtubules in the absence of GTP or MAPs and are resistant to depolymerization by calcium or low temperature.

The main difference between paclitaxel and docetaxel is the spectrum of untoward side effects. Whereas both produce peripheral neuropathy, dose-limiting bone marrow suppression,

and alopecia, docetaxel appears to have unique vascular permeability properties that can lead to peripheral edema, pleural effusions, and ascites. Fluid retention is not usually evident at cumulative doses of less than 400 mg/m^2 and may be decreased by lower single doses (< 60 to 75 mg/m^2) or premedication with dexamethasone. Docetaxel also produces skin toxicities, including an erythematous maculopapular rash of the forearms and hands. Less common effects include superficial desquamation of the hands and feet and nail changes, including brown discoloration, ridging, onycholysis, and soreness and brittleness of the fingernails. In addition, the so-called hand-foot syndrome and asthenia have also been reported. Cardiac effects, including arrhythmias and ischemia, may be higher with paclitaxel, whereas stomatitis may be greater with docetaxel. Nausea, vomiting, and diarrhea occur with both drugs but are rarely severe. Both paclitaxel and docetaxel cause type I hypersensitivity reactions, characterized by flushing, bronchospasm, dyspnea, and hypotension.

Estramustine

Estramustine is a unique anticancer agent that has received increased attention. Although originally designed to target its alkylating moiety to cells with steroid hormone receptors, its activity is not dependent on the hormone-receptor interaction. It is now known that estramustine exerts at least part of its effects by binding to MAP4, leading to dissociation of MAP4 from microtubules, inhibition of microtubule assembly, and depolymerization.[66] Estramustine also binds to an estramustine-binding protein originally isolated from prostate tissue. Estramustine is part of an active combination against hormone-refractory prostate cancer.

DRUGS THAT AFFECT GROWTH FACTORS, RECEPTORS, AND SIGNAL TRANSDUCTION PATHWAYS

Normal cell division results from the interaction of growth factors with specific receptors. This interaction initiates a series of enzyme reactions (signal transduction), culminating in activation of nuclear transcription factors that produce cell proliferation molecules. It is not surprising that cancer cells usurp these normal pathways during their evolution. For example, mutations in the *HER-2/neu* oncogene result in an encoded receptor protein that does not require an extracellular ligand to activate intracellular signaling.[6] Similarly, mutations in the *ras* gene produce a form of the molecule that is locked in the on position by virtue of resistance to GTPases.[8] These activated signaling pathways may serve as critical viability factors for tumors and therefore may represent a so-called biologic Achilles heel. To date, both of these pathways have received considerable attention in the development of anticancer drugs. For example, trastuzumab is an antibody that binds to the HER-2/neu protein. Trastuzumab alone produces cell death in susceptible populations, and chemotherapeutic agents enhance its activity.

Similarly, imatinib mesylate is a 2-phenylaminopyrimidine tyrosine kinase inhibitor that specifically inhibits the Abl, platelet-derived growth factor receptor, and c-KIT tyrosine kinases. This drug is active in chronic myelogenous leukemia and in gastrointestinal stromal tumors, which are diseases dependent on the activity of the Bcr-Abl and c-KIT tyrosine kinases, respectively.

Other examples of disruption of growth factor–receptor interactions are found in the hormonal treatment of cancer. Antiestrogens, such as tamoxifen, are useful for the treatment of breast cancers that express hormone receptors (either estrogen or progesterone receptors).[67] The estrogen receptor resides in the cytosol and, upon occupation by estradiol, is transported to the nucleus, where it activates genes (including those encoding proliferation molecules) containing estrogen-response elements.

Tamoxifen binds to the estrogen receptor and disrupts this interaction in some but not all estrogen-responsive tissues. For example, tamoxifen is antiestrogenic in the breast and ovary but estrogenic in the uterus, liver, and bone. As a result, tamoxifen is an effective agent in the treatment of breast cancer but produces untoward estrogenic side effects, including blood clots (in < 1% of patients), endometrial cancer (in ~ 0.3% of patients), and early menopausal symptoms (e.g., hot flashes). In addition, tamoxifen lowers cholesterol levels and increases bone density.

The response to tamoxifen is directly proportional to the degree of expression of the hormone receptors with which it interacts. In cells that are strongly hormone receptor–positive, the response to tamoxifen is greater than 60%. In contrast, tamoxifen is of little benefit in women whose tumors do not express hormone receptors, despite the other potential therapeutic actions of this medication (e.g., stimulation of growth inhibitory factors, inhibition of growth stimulatory enzymes).

Tamoxifen is valuable in preventing and treating breast cancer. After surgical removal of the primary tumor, adjuvant treatment with tamoxifen in women whose tumors are hormone receptor–positive reduces the absolute odds of recurrence of this disease by more than 30%. For example, a woman with a node-negative cancer harbors a 10-year risk of recurrence of approximately 30%. Tamoxifen decreases the risk of recurrence by 30%. Thus, the absolute reduction is 9% (0.3 × 0.3 = 0.09), bringing the estimated risk of recurrence down to 21%. Tamoxifen may also reduce the appearance of breast cancer over a 3- to 5-year period by as much as 50% in women who do not have breast cancer but who are at high risk for the disease (on the basis of a model that defines high risk as the risk for an average 60-year-old woman in the United States). Additional antiestrogens that may have greater selectivity for the breast include raloxifene, toremifene, and fulvestrant, the last being a steroidal antiestrogen that binds to its receptor and induces receptor degradation.[68,69] Early studies of raloxifene for the treatment of osteoporosis found a decreased occurrence of breast cancer in those patients. Future studies will be required to define the long-term risks and therapeutic benefits of these newer drugs.

Antiandrogens such as cyproterone acetate and flutamide are competitive antagonists of the interaction between androstenedione and the androgen receptor. Flutamide is a nonsteroidal compound that has potent, pure antiandrogenic activity when metabolized to its hydroxylated derivative. When given in combination with drugs that decrease androgen production, flutamide is an effective treatment for hormone-dependent prostate cancer. Currently, there are three nonsteroidal antiandrogens approved by the Food and Drug Administration for the treatment of prostate cancer: bicalutamide, flutamide, and nilutamide. These drugs appear similar in regard to efficacy. The most common side effects resulting in discontinuance of nonsteroidal antiandrogens are nausea, diarrhea, and constipation. Androgenic blockade results in feminizing side effects in men, including mastodynia, gynecomastia, galactorrhea, hot flashes, and loss of facial hair. Nilutamide is associated with idiosyncratic reactions, including visual disturbances (delayed adaptation from light to dark in up to 50% of patients). Interstitial pneumonitis and alcohol intolerance have also been reported.

Indirect interference with the hormone–hormone receptor interaction can be accomplished by drugs that produce a medical

adrenalectomy or hypophysectomy or that inhibit the peripheral conversion of hormones to their active forms. For example, inhibition of aromatase is an effective treatment for postmenopausal women with breast cancer, in which the greatest source of estrogen comes from the conversion of androstenedione to estrone in liver, muscle, and fat.

Aromatase is an enzyme complex made up of two proteins, aromatase cytochrome P-450 (CYP19) and NADPH-cytochrome P-450 reductase. Inhibition of aromatase blocks the conversion of androgens to estrone in peripheral tissues, including fat, liver, muscle, and breast. Whereas treatment with aminoglutethimide was complicated by a loss of circulating glucocorticoids as well as skin rash, lethargy, and orthostatic hypotension, the high affinity of anastrozole and letrozole for CYP19 makes them far more selective and less toxic.[70] Exemestane is a steroidal aromatase inhibitor that binds to the enzyme complex and promotes enzyme degradation.

A medical hypophysectomy is produced by luteinizing hormone–releasing hormone agonists, such as leuprolide, buserelin, and goserelin, which inhibit secretion of follicle-stimulating hormone/luteinizing hormone (FSH/LH) by downregulating receptors for FSH/LH–releasing hormone in the pituitary. The end result is castrate levels of sex hormones and palliation of both breast and prostate cancers. An acute exacerbation of disease can occur when these drugs are started because of an initial surge of LH and FSH. This condition can be ameliorated by pretreatment with an androgen receptor antagonist such as flutamide.

DRUGS THAT INHIBIT METASTASES OR ANGIOGENESIS

By understanding the mechanisms of tumor growth and metastasis, it has been possible to design drugs to inhibit these processes. Tumor cells secrete a variety of proteins that facilitate angiogenesis and tissue invasion,[71] such as vascular endothelial growth factor, fibroblast growth factors, and matrix metalloproteinases (MMPs). Moreover, several intracellular tyrosine kinases are activated in endothelial cells after binding of angiogenic growth factors and are potential drug targets. Because antiangiogenesis drugs do not directly target malignant cells, drug-induced selection of resistant cells among a genetically diverse population is less likely to occur.[72]

Several drugs currently in various stages of clinical testing are designed to inhibit angiogenic growth factors. Although the mechanism of action of thalidomide is poorly understood, this drug possesses anti-angiogenic activity and is active in the treatment of multiple myeloma.[73]

GENE-BASED THERAPIES

Alterations in certain genes are known to be important in many cancers. Gene-targeting methods that are amenable to clinical application are now available, including gene-replacement or antisense therapies. The major difficulty with the clinical use of nucleic acid–based therapies is delivery of the gene vector or antisense oligonucleotide to its target.[74] Current approaches use modified viruses or liposomes. Earlier difficulties with the instability of injected antisense oligonucleotides have been lessened by modifying their structure without changing base specificity, such as replacement of oxygen with sulfur in the phosphodiester backbone, creating a more stable phosphorothioate.

Gene-based cytotoxic therapies are also under investigation, such as the use of viral vectors to deliver specific gene promoters to produce tissue-specific expression of a toxic protein or a prodrug-converting enzyme (such as herpes virus thymidine kinase, which converts ganciclovir to a cytotoxic agent). Although a gene-based therapy for cancer has not been approved, the recent approval of an antisense oligonucleotide drug (fomivirsen) for the treatment of cytomegalovirus retinitis suggests that similar approvals for cancer will be forthcoming.

There are several antisense strategies that are currently in clinical trials, including oligonucleotides that target *bcl-2* or the *bcr-abl* fusion gene. With regard to gene replacement, the frequent loss of *p53* function in malignancies has made this gene an attractive target for viral-based replacement therapies. For example, adenoviruses must inactivate *p53* to successfully invade and proliferate in host cells. In theory, tumor cells with mutant *p53* may be a better host than normal cells for adenoviruses lacking the *p53* inactivation molecule, E1A. These genetically modified viruses are currently being tested as potentially selective anticancer therapies. Alternatively, vectors can deliver wild-type *p53* to cells with mutant *p53*, with the hope that reestablishing the role of wild-type *p53* in tumor cells will initiate programmed cell death.

IMMUNOTHERAPIES

Cancer cells use several mechanisms to evade destruction by immunologic defenses. This knowledge led to methods of recruiting the immune system for the destruction of cancer cells and has resulted in agents that either activate immune effector systems (such as interferon alfa and interleukin-2) or activate a response that is specific for a particular tumor antigen.[75] The latter approach may involve either identifying or targeting a particular tumor antigen or using tumor specimens to generate vaccines.

Antibody-based therapies that have been approved for the treatment of malignancy include trastuzumab, a monoclonal antibody that targets the HER-2/neu protein; alemtuzumab, which targets CD52 on the surface of normal and malignant B and T cells; and rituxumab, which targets the CD20 antigen present on the surface of B cell lymphoma cells and chronic lymphocytic leukemia cells. Radiolabeled antibodies recognizing CD20 offer the potential of delivering a radioactive payload directly to the lymphoma. Examples include iodine-131 tositumomab and yttrium-90 ibritumomab tiuxetan, both of which are active in the treatment of patients with B cell non-Hodgkin lymphoma.[76]

Vaccine therapies are currently investigational but appear particularly promising in attempts either to prevent cancer in high-risk individuals or to treat microscopic diseases that may remain after a surgical resection. Vaccine therapy can incorporate genetic manipulation of tumors to make them more antigenic, such as transfecting tumor cells with a DNA construct that expresses cytokines to augment the immune response.

V COLORECTAL CANCER

Bernard Levin, m.d., f.a.c.p.

Epidemiology

Colorectal cancer is the second most common cancer and the second leading cause of cancer death in the United States.[1] An estimated 145,000 new cases and 56,000 deaths from colorectal cancer were expected to occur in 2005. Worldwide, the annual mortality from colorectal cancer is estimated to be about 500,000. The incidence and mortality of colorectal cancer increase with age, especially after 60 years of age. The lifetime probability (magnitude of absolute risk) for the development of colorectal cancer in the United States is about 6%. In the United States, the overall mortality declined by 1.8% a year from 1992 through 1998, although the mortality for African Americans remains higher than that for other ethnic and racial groups.[2]

Pathogenesis

adenomatous polyps (adenomas)

It is thought that most colorectal cancers arise from preexisting adenomas. Such potentially premalignant lesions should be distinguished from juvenile polyps, hamartomas, and inflammatory polyps, which are not thought to progress to colorectal cancer. Serrated adenomas, hyperplastic polyps, and admixed polyps may arise through a pathway different from that of conventional adenomatous polyps—that is, through abnormalities in mismatch repair.[3]

Adenomatous polyps are grossly visible, gland-forming mucosal protrusions that may be pedunculated (attached by a narrow base and a long stalk) or sessile (attached across a broad, flat base with no stalk)[4] [*see Figure 1*]. Histologically, adenomatous polyps may be tubular (composed of tubular glands extending downward from the outer surface of the polyp), villous (composed of fingerlike epithelial projections extending outward from the surface of the bowel mucosa), or both (tubulovillous).[4] The larger the adenoma, the greater the likelihood that a villous component will be present. Villous polyps are more likely to contain invasive carcinoma than are tubular polyps of the same size.[5,6] Regardless of histologic class, large polyps—especially those larger than 1.0 cm in diameter—are more likely to contain invasive carcinoma.[5,7]

Five lines of evidence suggest that colon cancers develop from premalignant adenomatous polyps:

1. Countries in which colon cancer is prevalent also have a high prevalence of colonic adenomatous polyps; conversely, a low prevalence of colon cancer correlates with a low prevalence of such adenomas.
2. Patients who have undergone resection of adenomatous polyps are at increased risk for the subsequent development of colorectal cancer.[8]
3. Adenomatous polyps occur in younger persons than do carcinomas,[9] a finding that is consistent with the suggestion that adenomas are precursor lesions.
4. Susceptibility to the development of adenomatous polyps and colorectal cancer is commonly inherited.
5. Colonoscopic polypectomy reduces the expected incidence of colorectal cancer.[10]

Adenomatous polyps are common: autopsy studies have demonstrated that such lesions are present in more than 30% of persons older than 50 years and that their prevalence increases with age.[11] However, fewer than 1% of adenomatous polyps ever become malignant.[9] After an adenomatous polyp is detected, the entire large bowel should be visualized endoscopically because synchronous lesions are found in approximately 33% of cases. Thereafter, colonoscopy should be repeated periodically, even in the absence of a documented cancer, because patients in whom one adenomatous polyp is detected have a 30% to 50% risk of developing another adenoma and are at higher than average risk for colorectal cancer.[12] The risk of subsequent colon cancer appears to depend on the histologic type, size, and number of adenomas found at the time of initial examination.[13,14] It is thought that most adenomatous polyps require more than 5 years of growth before they become clinically significant.

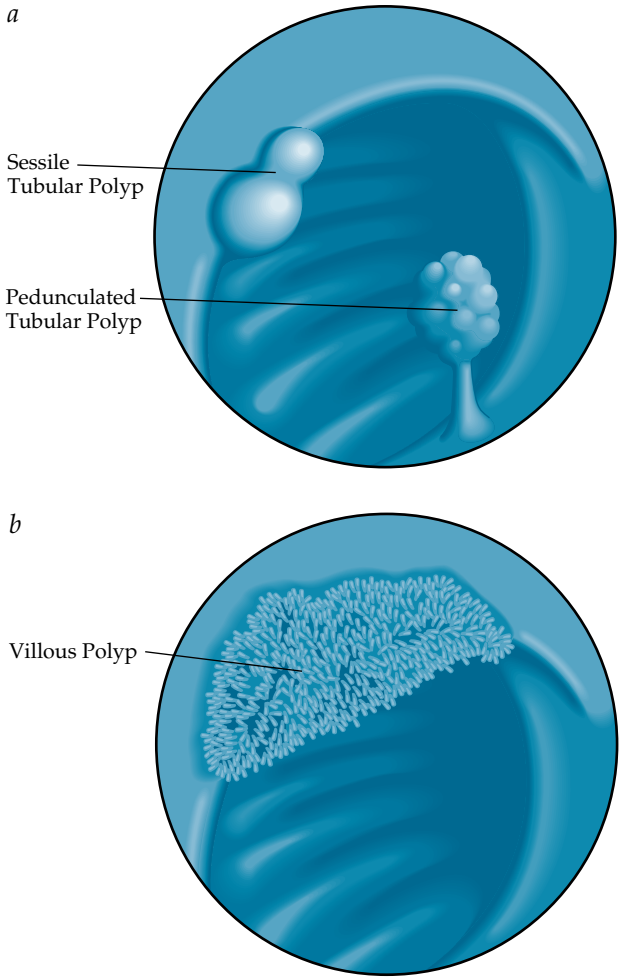

Figure 1 **It is thought that most colorectal cancers arise from adenomatous polyps, which may be tubular (pedunculated or sessile [*a*]), villous (*b*), or tubulovillous.**

GENETIC ALTERATIONS

Colorectal cancer is a heterogeneous disease arising from a complex series of molecular changes.[15] The successive evolution of normal colonic mucosa to a benign adenoma, then to an adenomatous polyp containing cancer, and then to a potentially life-threatening invasive cancer is associated with a series of genetic events occurring over a long period. The original model that was proposed over a decade ago involves key derangements in several genes, including *APC* (in patients with familial adenomatous polyposis [FAP]), K-*ras*, *DCC*, and *p53*. *APC* gene mutations alter cell adhesion by affecting the binding of β-catenin; they also affect the WnT signaling pathway. C-myc, a transcription factor, is activated by abnormal WnT signaling, skewing the balance between proliferation and apoptosis. Loss of APC influences tumor initiation, whereas inactivation of E-cadherin, which complexes with β-catenin, plays a role in tumor progression.

K-*ras* gene mutations induce proliferation via the EGFR-RAS-RAF-ERK-JUN/FOS pathway and inhibit apoptosis by phosphorylating procaspase. Other genes may be affected, including *SMAD4* and *SMAD2,* which in turn may interfere with transforming growth factor–β signaling. Additional genetic changes (e.g., DNA aneuploidy, *p53* overexpression), as well as other abnormalities, have been described in subsequent malignant transformation. Cancers arising through these mechanisms are termed microsatellite stable.

A different pathway involves deficiency of mismatch repair, as exemplified by hereditary nonpolyposis colorectal cancer. Dominant inheritance of a germline mutation involving *hMLH1, hMLH2, or hMSH6* coupled with somatic loss of the second allele results in a deficiency of mismatch repair. This mutator phenotype is characterized by the presence of multiple somatic mutations involving microsatellite repeats, termed microsatellite instability (MSI). MSI is also found in about 15% of sporadic colorectal cancers and is usually the result of acquired loss of *hMLH1* through hypermethylation of the gene promoter. Dense aggregates of the cytosine-guanine dinucleotide sequence (CpG dinucleotides) may occur in the promoter regions of several genes; these aggregates are termed CpG islands. Extensive methylation of cytosine bases is associated with promoter silencing. Cancers demonstrating methylation of multiple genes are described as CIMP (CpG island methylation phenotype) positive.

Etiology

As with many other cancers, the development of colorectal cancer typically results from a complex interaction between genetic and environmental influences.

HEREDITARY SYNDROMES AND PREDISPOSING CONDITIONS

As many as 25% of patients with colorectal cancer have a family history of the disease, which suggests the involvement of a genetic factor. Such inherited colon cancers can be divided into two main types: the well-studied but rare FAP syndrome, which accounts for approximately 1% of cases of colon cancer annually, and the increasingly well-characterized, more common hereditary nonpolyposis colorectal cancer (HNPCC), which accounts for 5% to 10% of cases.[16]

Familial Adenomatous Polyposis

FAP is an autosomal dominant disorder characterized by the appearance of thousands of adenomatous polyps, each typically smaller than 1 cm in diameter, throughout the entire large bowel. Such polyps may occasionally be accompanied by extracolonic findings, such as osteomas, desmoid tumors, epidermoid and sebaceous cysts, pigmented retinal lesions, upper gastrointestinal tract polyps, and periampullary cancers (Gardner syndrome) or brain tumors (Turcot syndrome).[16] Persons with FAP are born with normal-appearing colonic mucosa; polyps develop during the second and third decades of life. If surgical treatment is not performed, colorectal cancer is almost certain to develop by 40 years of age.

FAP is associated with a deletion of chromosome 5q21 (known as the *APC* gene)[17] in neoplastic cells (somatic mutation) and normal cells (germline mutation); this deletion apparently leads to abnormal proliferative patterns in the colonic mucosa.[18] Mutations at the 5′ end (first five exons), in exon 9, and in the distal 3′ end of the *APC* gene result in an attenuated form of FAP characterized by fewer adenomas, a proximal colonic distribution of polyps, a somewhat delayed development of adenomas and cancer, and a decreased colon cancer risk.[19]

Genetic testing is now the standard of care for FAP. Despite the detailed genetic knowledge of FAP that is now available, genetic testing is often poorly interpreted. Consequently, genetic counseling is an integral part of management and should precede genetic testing.[20] Testing for FAP in a family is most informative when it begins with the affected family member, to identify the mutation responsible for FAP within that family. Once a causal mutation has been identified in an affected person, predictive testing can be done to identify other family members at risk.[21] DNA testing for *APC* gene mutations has a sensitivity of 70% to 90% and a specificity of 100%. If the test result is positive or the test is not available, flexible sigmoidoscopy is performed at 10 to 12 years of age. During the procedure, mucosal biopsy specimens are taken to identify subtle adenomatous changes. Colonoscopy with mucosal biopsies is advisable at 18 to 20 years of age. If adenomas are detected, surgical prophylaxis should be considered. Routine gastroduodenoscopic surveillance is also recommended for patients with FAP, because these patients are at high risk for potentially precancerous gastric and duodenal adenomas.[22]

MYH is a base excision repair gene that is involved in repairing oxidative damage to DNA. Loss of *MYH* is associated with G:C to T:A transversions in APC, leading to polyp formation and carcinoma. The two most common *MYH* mutations, G382D and Y165C, account for approximately 85% of MYH-associated polyposis. Appropriate candidates for mutational analysis testing are patients with multiple adenomas or FAP who have a family history compatible with a recessive pattern of inheritance (i.e., colon cancers or multiple adenomas in only one generation or in skipped generations) and in whom testing has failed to show a germline *APC* mutation.

Surgical prophylaxis in FAP consists of resection of the entire large bowel to prevent malignant transformation. In the past, surgical alternatives included total colectomy with a permanent ileostomy and subtotal colectomy with an ileorectal anastomosis; the latter procedure is complicated by the frequent appearance of rectal polyps, which often necessitates a subsequent proctectomy. Currently, total proctocolectomy with J-pouch ileoanal anastomosis is advocated as surgical prophylaxis.

In a prospective, randomized trial of 83 FAP patients, a 6-month regimen of celecoxib was shown to reduce the number of colorectal adenomas by an average of 28%, compared with a 5% reduction with placebo ($P = 0.003$).[23] On the basis of this study, the Food and Drug Administration approved celecoxib as oral adjunctive

therapy for adults with FAP. Nevertheless, endoscopic surveillance and colectomy as indicated remain the standard of care.

Hereditary Nonpolyposis Colorectal Cancer

HNPCC, like FAP, is an autosomal dominant disorder. The median age at which adenocarcinomas appear in HNPCC is less than 50 years, which is 10 to 15 years younger than the median age at which they appear in the general population.[24,25] In contrast to FAP, HNPCC is associated with an unusually high frequency of cancers in the proximal large bowel. Also, families with HNPCC often include persons with multiple primary cancers; in women, an association between colorectal cancer and either endometrial or ovarian carcinoma is especially prominent.

Several sets of selection criteria have been developed for identifying patients with this syndrome. The Amsterdam-2 criteria comprise the following: histologically documented colorectal cancer (or other HNPCC-related tumor) in at least three relatives, one of whom is a first-degree relative of the other two; a family history of one or more cases of colorectal cancer diagnosed before 50 years of age; and cases of colorectal cancer in at least two successive generations of the family. Affected relatives should be on the same side of the family (maternal or paternal), FAP must be excluded in colorectal cancer cases, and tumors must be pathologically verified. Another selection set, the Bethesda criteria, is more sensitive than the Amsterdam criteria but is less specific. These selection criteria were developed to identify patients whose tumors should be tested for features consistent with HNPCC, such as MSI.[26,27] For tumors that display the MSI-H phenotype, *hMLH1* and *hMSH2* germline mutational analysis is indicated.

In addition to testing for MSI, genetic testing is available for three mismatch repair genes, *hMSH2, hMLH1,* and *hMLH6*, which account for about 90% of all HNPCC cases. Unfortunately, tests for mutations of these genes are not perfectly sensitive, and genetic sequencing is expensive. The discovery of a mutation in a family provides a rationale for predictive testing for at-risk family members, although such testing may cause the unaffected individuals unnecessary concern and lead to unnecessary screening procedures.[28]

If HNPCC is confirmed, affected family members should undergo colonoscopy between the ages of 20 and 25 or at the age that is 10 years less than the earliest age at diagnosis in the family, whichever is earlier. This procedure should be repeated every 1 to 2 years. Recommended screening for women includes an annual transvaginal ultrasound or endometrial aspiration, beginning at age 25 to 35 years.[29]

If an adenoma or adenocarcinoma of the colon is identified, total abdominal colectomy with an ileorectal anastomosis is recommended. In women, total abdominal hysterectomy and bilateral salpingo-oophorectomy are often considered, particularly if the patient has no intention of having children in the future because of the increased risk of ovarian and endometrial carcinoma.

Inflammatory Bowel Disease

Long-standing, extensive inflammatory bowel disease, including both ulcerative colitis and Crohn colitis, increases the risk of colon cancer. Surveillance colonoscopy with multiple biopsies of the entire colon should be considered every 1 to 2 years after 8 years of disease in patients with pancolitis or after 12 to 15 years of disease in those with left-sided colitis. Colectomy must be carefully considered in each case, depending on the biopsy results.[29]

ENVIRONMENTAL FACTORS

Specific factors that increase the risk of colorectal cancer have been identified, as have factors that reduce risk [*see Table 1*].

Diet

Diet plays a complex role in the etiology of colorectal cancer [*see Table 2*].[30] Both the total energy intake and individual components of the diet have been implicated.

The relationship between total energy intake and colorectal cancer risk is not simple; possible biologic mechanisms include increased levels of endogenous hormones (e.g., sex steroids, insulin, and insulin growth factor).[30] Nevertheless, a prospective study of a large United States cohort suggested that obesity (i.e., high body mass index [BMI]) is a significant risk factor for the development of colorectal cancer.[31] The relative risks of BMIs of 25 to 29.9, 30 to 34.9, and 35 to 35.9 were 1.20, 1.47, and 1.84, respectively. These data are consistent with previous case-control and cohort studies.

Dietary fat Many experimental studies have shown that intestinal tumorigenesis is enhanced as the fat content of the diet is increased. Dietary fat is thought to increase the concentration of bile acid in the bowel or to promote the formation of excess intraluminal diacylglycerol as the result of the interaction of fat, bile acids, and bacteria.[32] The effect of diacylglycerol may be to amplify cell-replication signals.[33] Early studies supported the relationship of dietary fat to colorectal cancer; these studies showed that colon cancer rates were high in populations with high total fat intake, with odds ratios of 1.3 to 2.2, and were lower in those consuming less fat.[34] However, many of these early studies failed to adjust for total energy intake. Cohort studies and a meta-analysis of 13 case-control studies of colorectal cancer failed to find clear evidence of the association of colorectal cancer with dietary fat intake.[32] In the aggregate, the epidemiologic and experimental evidence suggests that diets high in total fat may increase the risk of colorectal cancer.[30] A review of the data concerning

Table 1 Risk Factors for Colorectal Cancer

Average risk	Age 50 years and older
Decreased risk	High vegetable consumption Oral contraceptive use Estrogen replacement Multivitamins containing folic acid Long-term use of aspirin and other NSAIDs

Increased risk	Family history
	  Colorectal cancer
	  Colorectal adenomas
	Personal history
	  Colorectal adenomas
	  Ovarian, uterine cancer
	Familial adenomatous polyposis
	Hereditary nonpolyposis colorectal cancer
	Peutz-Jegher syndrome
	Juvenile polyposis
	Inflammatory bowel disease of long standing
	Physical inactivity (< 3 hr of exercise a week)
	Obesity
	Smoking
	Alcohol (> 1 drink/day)

NSAIDs—nonsteroidal anti-inflammatory drugs

Table 2 Food and Nutrition and the Risk of Colorectal Cancer

Strength of Evidence	*Decreases Risk*	*No Relationship*	*Increases Risk*
Convincing	Vegetables (not fruit)	—	—
Probable	—	—	Red meat Alcohol
Possible	Fiber Starch Carotenoids	Calcium Selenium Fish	High body mass* Greater adult height Frequent eating Sugar Total fat Saturated/animal fat Processed meat Eggs Heavily cooked meat
Insufficient	Resistant starch Vitamin C Vitamin D Vitamin E Folate Methionine Cereals Coffee	—	Iron

*Colon cancer only.

saturated fat concluded that diets high in fat possibly increased the risk of colorectal cancer but that the evidence relating risk to intake of monounsaturated fat and polyunsaturated fat was inconsistent.[30] High fat intake has also been found to increase the risk of adenoma recurrence after polypectomy.[35]

Meat An authoritative review concluded that red meat intake is associated with increased risk of colorectal cancer and that processed meat possibly increases the risk.[30] However, the data concerning red meat are not entirely consistent. The Nurses' Health Study reported that persons who consumed red meat frequently had an increased risk of colon cancer (relative risk, 2.5), compared with those who rarely consumed red meat.[36] No increase in risk with meat or fat consumption was seen, however, in two other large prospective studies: the American Cancer Society's Cancer Prevention Study II and the Iowa Women's Health Study.[37,38] It has been hypothesized that heterocyclic amines that are formed when fish or meat is cooked at high temperature may increase the risk, but not all of the mechanisms are well understood.

Dietary fiber The term fiber is used to describe a complex mixture of compounds that include insoluble fiber (typified by wheat bran) and soluble fiber (oat bran). Ingestion of fiber could modify carcinogenesis in the large bowel by a number of potential mechanisms.[39] A meta-analysis of 13 case-control studies from nine countries concluded that intake of fiber-rich foods is inversely related to cancers of both the colon and the rectum.[40] Despite the evidence of a protective effect from case-control studies, results from a large prospective trial in women (the Nurses' Health Study) found no difference in risk of colorectal cancer between the highest and the lowest quintile groups with respect to dietary fiber.[41] In a multicenter, randomized, controlled trial, a diet low in fat (20% of total calories) and high in fiber, fruits, and vegetables did not reduce the risk of recurrence of colorectal adenomas.[42] High-fiber cereal supplements also failed to influence the rate of recurrence of colorectal adenomas.[43]

Vegetables and fruit Many epidemiologic studies have examined the relationship between fruit and vegetable intake and the incidence of colon or rectal cancer, with considerable variation in the findings. A prospective study utilized food-frequency questionnaires to study dietary intake in 88,764 women and 47,325 men; no association was found in men or women between overall fruit and vegetable consumption and risk of colon or rectal cancer.[44]

Calcium Calcium may indirectly inhibit colorectal cancer by binding bile acids into insoluble soaps, thereby blocking contact with the luminal epithelium. It may also modulate protein kinase C and fatty acid–induced destabilization of cellular membranes. Experimental studies and epidemiologic studies[45] have reported an inverse relationship between calcium intake and cancer risk. A randomized, placebo-controlled trial tested the effect of calcium supplementation (3 g of calcium carbonate daily, which is equivalent to 1,200 mg of elemental calcium) on the risk of recurrent adenoma.[46] The effect was modest; supplemental calcium reduced the risk of recurrence by 19%. The effect may be dependent on dose. It is possible to safely administer up to 2,000 mg of calcium daily.

Antioxidants It has been postulated that antioxidants such as retinoids, carotenoids, ascorbic acid, α-tocopherol, and selenium prevent carcinogen formation by neutralizing free radicals. Epidemiologic evidence of their benefit is difficult to confirm, however, because antioxidants and other putative cancer-prevention agents are comingled in common foods such as fruits and vegetables. β-Carotene may reduce the risk of adenoma recurrence in nonsmokers but increases the risk in those who both smoke and drink.

Folate and methionine Fresh fruit and leafy green vegeta-

bles are rich in folate, whereas red meat, chicken, and fish have relatively high concentrations of methionine. Both folate and methionine supply the methyl groups necessary for essential cellular processes such as nucleotide synthesis and gene regulation. Retrospective and prospective studies support an inverse association between dietary folate or methionine intake and the risk of colorectal adenomas and carcinomas.[47] Both the level and duration of intake are important. For persons in the highest folate and methionine quintiles, the risk of distal colorectal adenomas was approximately 35% lower in participants in the Health Professionals Follow-Up Study and 25% lower in the Nurses' Health Study.[48] In women, the long-term (≥ 15 years) use of folate-containing multivitamins had a striking preventive benefit (75% risk reduction), whereas use of such multivitamins for 4 years had no preventive benefit.[49] Prospective studies of folate in patients who underwent resection of adenomas are in progress.

Medications

The ability of specific chemical compounds to reduce the incidence of colorectal cancer has been demonstrated in epidemiologic studies and is currently undergoing clinical testing [*see Table 3*]. Technological advances, including genomics and proteomics, will facilitate the identification of new molecular targets for chemoprevention.

Postmenopausal hormone therapy Many epidemiologic studies have examined the possible associations between exogenous estrogens and colorectal neoplasia risk. In a meta-analysis of 18 epidemiologic studies, postmenopausal hormone therapy (HT) was associated with a 33% reduction in the risk of colon cancer in recent users; the relative risk was 0.67, compared with a relative risk of 0.92 in women who had used HT more than 1 year ago.[50] Similarly, HT may protect against adenoma formation. In the Women's Health Initiative trial, which included over 16,000 postmenopausal women, the combination of estrogen and progesterone was associated with a reduction in the risk of colorectal cancer (hazard ratio, 0.56; 95% confidence interval, 0.38–0.81; $P = 0.003$).[51] Invasive colorectal cancers in the hormone-treated group were similar in histologic features and grade to those in the group receiving placebo. However, in patients who received HT, the number of positive lymph nodes was slightly greater, and the cancer was more advanced regionally or metastatically.

Table 3 Selected Agents under Study for Prevention of Colorectal Cancer in Humans[124]

Nonspecific NSAIDs	Miscellaneous
Aspirin	Folic acid
Piroxicam	Sulindac sulfone
Sulindac	Ursodeoxycholic acid
Cyclooxygenase-2–selective NSAID	DFMO
Celecoxib	Combinations
	Sulindac + DFMO
	Aspirin + folic acid
	Piroxicam + calcium
	Celecoxib + DFMO
	Celecoxib + selenium

DFMO—difluoromethylornithine NSAIDs—nonsteroidal anti-inflammatory drugs

Nonsteroidal anti-inflammatory drugs Most epidemiologic studies have reported reductions in the incidence of colorectal adenomas, colorectal cancer, and colon cancer mortality associated with the use of nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin. For example, a prospective study in over 660,000 adults found that mortality from cancers of the colon and rectum was about 40% lower in regular users of aspirin.[52] The Health Professionals Follow-Up Study of 47,000 men found that the regular use of aspirin (at least twice a week) was associated with a 30% overall reduction in colorectal cancer.[53] However, in the Physicians' Health Study, there was no reduction in invasive cancers or adenomas at a median follow-up of 4.5 years when aspirin was taken at a dosage of 325 mg every other day.[54] A study of patients with prior colorectal cancer who had undergone curative resection found that compared with placebo, 325 mg of aspirin a day over 13 months was associated with a 35% reduction in the risk of recurrent adenoma, as well as a prolongation in the time to detection of a first adenoma.[55] In a study of patients with a recent history of adenomas who had undergone resection by colonoscopic polypectomy, ingestion of 81 mg of aspirin a day for an average of nearly 3 years reduced the risk of recurrence of any adenoma by 19%.[56] For advanced neoplasms (i.e., adenomas measuring at least 1 cm in diameter or with tubulovillous or villous features, severe dysplasia, or invasive cancer), the reduction was about 41%. Interestingly, 325 mg of aspirin appeared to have minimal effect. The reason for this discrepancy in the dose-effect relationship is unknown. Side effects of treatment included upper gastrointestinal hemorrhage and hemorrhagic stroke. The potential value of other NSAIDs for primary prevention of colorectal neoplasia is being studied. Although rofecoxib was associated with a reduction in sporadic polyp recurrence in a randomized, placebo-controlled trial, this drug was removed from the market because of an increase in the risk of serious cardiovascular events with long-term use.[57] Similar trials with celecoxib have closed because of concern over increased cardiovascular risk.[58] Efficacy analyses are still being conducted to determine whether polyp recurrence is diminished.

Drugs in familial adenomatous polyposis Several medications may reduce colorectal cancer risk in FAP. Sulindac reduces the size and number of adenomas.[59] A randomized, double-blind, placebo-controlled study of 83 patients with FAP found that patients who received 400 mg of celecoxib twice a day had a 28% reduction in the mean number of colorectal adenomas and a 30.7% reduction in polyp burden (i.e., the sum of polyp diameters), as compared with a group receiving placebo; a lower dose (100 mg twice daily) was associated with a non–statistically significant reduction.[23]

Lifestyle Factors

Physical activity Most studies have shown an inverse relationship between physical activity and colon cancer incidence.[60] The average relative risk reduction provided by regular physical activity is 40%. In men, physical activity for 2 hours or more a week was more strongly associated with a reduction in risk of advanced adenomas than in a reduction in risk of nonadvanced

Table 4 Evidence Supporting the Effectiveness of Colorectal Cancer Screening Tests[125]

Test	*Quality of Evidence**	*Comments*
Fecal occult blood test (FOBT)	I	33% reduction in colorectal cancer mortality with annual rehydrated FOBT; 15%–18% reduction in colorectal cancer mortality with biennial, unrehydrated FOBT
Sigmoidoscopy	I	80% reduction in colorectal cancer incidence with flexible sigmoidoscopy
	II	60%–95% reduction in mortality for cases of distal colorectal cancer
Colonoscopy	III	Sensitivity 27%–47% greater than that of 60-cm flexible sigmoidoscopy for advanced adenomas
Double-contrast barium enema	III	Sensitivity for adenomatous polyps lower than that of colonoscopy but higher than that of FOBT

*I = randomized controlled trial; II = controlled observational study (case-control or cohort); III = descriptive study.

adenomas.[61] The mechanism by which physical activity provides protection is unknown but may be linked to effects on colonic mucosal prostaglandins.

Cigarette smoking Most case-control studies of cigarette exposure and adenomas have found an elevated risk for smokers.[62] In addition, a significantly increased risk of adenoma recurrence after polypectomy has been associated with smoking in both men and women.[63] In the Nurses' Health Study, the minimum induction period for cancer appears to be at least 35 years.[64] In the Cancer Prevention Study II, a large national cohort study, mortality was highest in current smokers, intermediate in former smokers, and lowest in persons who never smoked; an increased risk was observed in both men and women after 20 or more years of smoking.[63]

Screening

Screening and early detection (secondary prevention) are important in influencing the outcome in patients with colorectal neoplasia. Many deaths from colorectal cancers could probably be averted by appropriate use of screening.[65] Despite the acknowledged benefits of screening, most average-risk persons in the United States do not undergo screening for colorectal cancer. Data from the 1999 Behavioral Risk Factor Surveillance System Survey indicate that only 21% of respondents had undergone a fecal occult blood test (FOBT) within the previous year, and approximately 34% had undergone sigmoidoscopy or colonoscopy within the previous 5 years.[66] Improving screening rates for these persons remains a significant challenge.

A screening test is intended to distinguish those most likely to have a neoplastic lesion from those least likely. Those with abnormal results are advised to undergo diagnostic tests to confirm the presence or absence of cancer. The rationale for screening for colorectal neoplasia is twofold: first, detection of adenomas and their removal will prevent subsequent development of colorectal cancer; second, detection of localized tumors in asymptomatic individuals will increase the surgical cure rate.

Of the four screening tests currently in routine use, FOBT is supported by the strongest evidence. Intermediate-level evidence is available for flexible sigmoidoscopy. Only indirect evidence supports the use of colonoscopy and double-contrast barium enema (DCBE) [*see Table 4*].

FECAL OCCULT BLOOD TESTING

The rationale for screening for the presence of blood in the stool is that large adenomas and most cancers bleed intermittently. Small adenomas rarely bleed. Annual testing is recommended with FOBTs because randomized trials have demonstrated that testing every 2 years is less effective. Annual testing may allow detection of disease that, although undetected on previous occasions, has not yet reached an advanced and perhaps incurable stage. Meta-analysis of mortality results from randomized, controlled trials shows that in patients who underwent screening with FOBTs, colorectal cancer mortality decreased by 16% (relative risk, 0.84). When adjusted for screening attendance in the individual studies, the mortality reduction was 23% (relative risk, 0.77).[67]

Estimates of the sensitivity of FOBT have ranged from 25% to over 90%. In studies that show a higher sensitivity, the figure usually refers to so-called program sensitivity, which is the effectiveness of repeated FOBTs over several years. The major concern over low sensitivity is that patients who have a falsely negative test may be falsely reassured. A high false positive rate has also been a concern, because it results in persons who are free of colorectal neoplasia undergoing follow-up screening colonoscopy, with its associated risks and costs. It is estimated that if 10,000 people were included in a biennial FOBT screening program and two thirds underwent at least one test, there would be 8.5 deaths from colorectal cancer prevented over 10 years. Data from the Minnesota trial suggest that the screening process would also result in 2,800 participants having at least one colonoscopy, with 3.4 colonoscopy complications (perforation or hemorrhage).[67] Compared with endoscopic tests, FOBT detects relatively few adenomas; the principal benefit of an FOBT program is to increase detection of early-stage cancers.

Two types of FOBTs are used: chemical (guaiac-based) and immunochemical [*see Tables 5 and 6*]. Guaiac-based tests, which detect peroxidase activity, have been the most commonly used in population screening; typically, patients take test cards home and collect two samples from three consecutive specimens. These tests are subject to false positive results caused by dietary substances or drugs. Newer FOBTs have enhanced guaiac reagents, which improve sensitivity with little loss of specificity if recommended dietary measures are followed. The sensitivity of immunochemical FOBTs is better than that of guaiac-based tests, without an unacceptable decline in specificity.[68] Newer immunochemical FOBTs are more user friendly and can be read by automated techniques.[69] Immunochemical tests do not require any alteration in diet or medication intake.

ENDOSCOPIC SCREENING TESTS

Examination of the large bowel by flexible sigmoidoscopy or colonoscopy permits direct visualization of the mucosa and allows photodocumentation, biopsy of suspicious lesions, and endoscopic polypectomy.

Table 5 Main Features of Different Types of Fecal Occult Blood Tests (FOBTs)[65]

Type of FOBT	*Basis*	*Stool-Sampling Method*	*End Point*
Chemical	Guaiac; detects peroxidase	Wooden spatula and fecal smear for most	Blue color on paper card
Immunochemical	Antihemoglobin antibody	Wooden spatula, spoon, or brush	Latex or red cell agglutination Solid-phase immunochromatography Enzyme-linked immunosorbent assay

Flexible Sigmoidoscopy

A case-control study demonstrated a risk reduction of 70% for death from cancers within reach of the sigmoidoscope; the data suggested that the benefit may last as long as 10 years.[70] A prospective study showed that screening (primarily with flexible sigmoidoscopy) was associated with a 60% reduction in the incidence of distal colorectal cancer.[71] In a prospective, randomized trial in Norway, 400 patients underwent screening with flexible sigmoidoscopy; those patients in whom polyps were detected underwent colonoscopy. This protocol led to an 80% reduction in the incidence of colorectal cancer, compared with results in unscreened control subjects.[72] Two large-scale, prospective, randomized, controlled studies are examining the efficacy of flexible sigmoidoscopy. In the United States, the Prostate, Lung, Colorectal, Ovary (PLCO) trial has enrolled 154,000 patients 55 to 74 years of age. The final results will not be available for several years.[73] In the United Kingdom, the baseline findings of a multicenter trial showed that of approximately 40,000 patients screened, distal adenomas were detected in 12%, and distal cancers were detected in 0.3%.[74] Proximal adenomas were detected in 19% of those undergoing colonoscopy, and proximal cancer was detected in 0.4%; 62% of cancers were of early stage (Dukes stage A). There was one perforation after flexible sigmoidoscopy, and four perforations after colonoscopy.[75]

Sigmoidoscopy detects 70% to 85% of advanced lesions in the entire colon.[76] Patients with an advanced distal adenoma have a 6% to 10% chance of having an advanced proximal adenoma. When a nonadvanced adenoma is found during sigmoidoscopy, the chance of a proximal advanced lesion is lower—4.7%. Studies of screening colonoscopy have suggested that patients with an apparently normal sigmoidoscopy have a 1% to 2% risk of having an advanced proximal lesion.[77] In contrast, in patients with advanced distal polyps, the prevalence of advanced proximal neoplasia was 11.5%.

Obstacles to more widespread use of flexible sigmoidoscopy include lack of training and relatively low reimbursement rates. Training of nonphysicians to perform flexible sigmoidoscopy may facilitate more widespread use of this technique, especially in high-volume centers.

Combining FOBT with flexible sigmoidoscopy is a recognized approach to screening, but the data regarding the impact on mortality are limited. In a study of 2,885 veterans (97% men; mean age, 63 years), the prevalence of advanced adenoma at colonoscopy was 10.6%. Using examination of the rectum and sigmoid during colonoscopy as a surrogate for sigmoidoscopy, these researchers estimated that combined screening with one-time FOBT and sigmoidoscopy would detect 75.8% of advanced neoplasms. This represented a statistically insignificant increase in detection rate of advanced neoplasia when compared with flexible sigmoidoscopy alone (70.3%).[77] In assessing this study, it is important to note that in calculating the detection rate, the researchers assumed that all patients with an adenoma in the distal colon would undergo colonoscopy; it is also important to note that the use of one-time FOBT in this study differs significantly from the annual or biennial method used in large-scale trials.

Colonoscopy

The effectiveness of colonoscopy has been demonstrated by several studies. Observational, case-control, and prospective, randomized trials have shown that colonoscopic polypectomy lowers the incidence of colorectal cancers by 50% to 90%.[77-81]

Three nonrandomized studies have reported the baseline results of screening colonoscopy. In a study of 3,212 United States veterans (almost all men) with a mean age of 63 years, an adenoma incidence rate of 37% was reported.[76] The incidence of advanced adenoma (defined as adenomas with a diameter of at least 10 mm, villous features, and high-grade dysplasia or cancer) was 10.5%. A study in 1,322 women reported an adenoma incidence of 21% and an advanced adenoma incidence of 3%.[81] A randomized, controlled trial of screening colonoscopy to examine efficacy

Table 6 Usage Issues with Different Types of Fecal Occult Blood Tests[65]

Type of FOBT	*Diet Restrictions*	*Drug Interference*	*Site of Bleeding Detectable*	*End Point for Test Result*
Chemical	Must avoid red meats; possibly avoid certain raw plant foods*	Vitamin C; possibly NSAIDs†	Rectum > colon > stomach (in decreasing order of sensitivity)	Subjective and transient‡
Immunochemical	None required	None required	Colon and rectum	Agglutination tests‡—can be difficult to read Immunochromatography—easy to read ELISA—machine-read

*Delaying development for 72 hr minimizes interference from plant foods and avoids the need for their restriction.
†Low-dose aspirin is not a problem, but therapeutic doses for rheumatic disorders may be so.
‡The tests generally provide a qualitative result, but newer immunochromatographic tests may be quantifiable.
ELISA—enzyme-linked immunosorbent assay FOBT—fecal occult blood test NSAIDs—nonsteroidal anti-inflammatory drugs

Table 7 American Cancer Society Recommendations for the Early Detection of Colorectal Cancer in Average-Risk, Asymptomatic Men and Women[126]

Annual fecal occult blood test (FOBT), starting at age 50
or
Flexible sigmoidoscopy every 5 yr, starting at age 50
or
Annual FOBT* and flexible sigmoidoscopy every 5 yr, starting at age 50
or
Double-contrast barium enema every 5 yr, starting at age 50
and
Colonoscopy every 10 yr, starting at age 50

*FOBT, as it is sometimes done in physicians' offices, with the single stool sample collected on the fingertip during a digital rectal examination, is not an adequate substitute for the recommended at-home procedure of collecting two samples from three consecutive specimens. Toilet-bowl FOBT tests also are not recommended. In comparison with guaiac-based tests for detection of occult blood, immunochemical tests are more patient-friendly and are likely to have equal or better sensitivity or specificity. There is no justification for repeating FOBT in response to an initial positive finding. Flexible sigmoidoscopy together with FOBT is preferable to FOBT or flexible sigmoidoscopy alone.

has not been performed, although a pilot study is in progress.[82]

The American Cancer Society currently recommends colonoscopy every 10 years, starting at age 50, for asymptomatic adults at average risk for colorectal cancer. Repeat examinations at more frequent intervals are indicated for patients at increased or high risk [*see* Implementation of Screening, *below*].

DOUBLE-CONTRAST BARIUM ENEMA

There has not been a formal trial of DCBE as a screening test for colorectal neoplasia in a general population. A comparison study in patients who have undergone colonoscopic polypectomy found colonoscopy to be a more effective method of surveillance than DCBE.[83] The proportion of examinations in which adenomatous polyps were detected by DCBE, compared with colonoscopy, was significantly related to the size of the adenomas: the rate for DCBE was 53% for detection of lesions from 0.6 to 1.0 cm in size and 48% for lesions exceeding 1.0 cm. Although current screening recommendations for colorectal cancer include DCBE, the steady decrease in training of new radiologists in this technique and the development of other imaging techniques, such as virtual colonoscopy, is likely to limit its use in the future.

EMERGING TECHNOLOGIES FOR SCREENING

Molecular Detection Methods

Detection of gene mutations in the stool has been possible for over a decade.[84] It is technically feasible to detect *APC* and *p53* mutations, long DNA, and K-*ras* mutations.[85-87] In addition, right-sided lesions can be detected by the identification of *BAT-26* mutations. In a 2004 study of over 2,500 persons, a fecal DNA mutation panel detected 29 of 71 (41%) invasive cancers and adenomas with high-grade dysplasia. Specificity was 94%. This is a rapidly advancing field, and improvements in technology are likely to enhance sensitivity of detection.[88] The cost of such techniques is high, however, and it remains to be seen whether their use will be cost-effective relative to other techniques, including newer immunochemical tests for fecal occult blood.

Virtual Colonoscopy (Computed Tomography Colonography)

CT colonography relies on sophisticated graphic software to assemble, from a fast CT scan, an endoluminal image that includes surface and volume characteristics.[89] Data from specialized centers suggest a sensitivity of 90% for lesions larger than 1 cm. Advances in this technique are occurring rapidly and include the possibility that patients will not need extensive bowel preparation. The effectiveness of the technique in screening remains to be established; large-scale multicenter trials comparing conventional colonoscopy with virtual colonoscopy are currently under way. One cost analysis has suggested that CT colonography is unlikely to be cost-effective relative to colonoscopy or other screening modalities.[90]

IMPLEMENTATION OF SCREENING

The process of screening starts with targeting patients at risk for colorectal cancer. Adults 50 years of age and older who have no other risk factors are considered at average risk, and published screening recommendations endorse regular screening in this population [*see Table 7*].[28,91,92] Screening schedules and methods vary for patients at increased or higher risk [*see Table 8*]. Follow-up is an important part of the screening process [*see Table 9*].

COST-EFFECTIVENESS OF COLORECTAL CANCER SCREENING

Analyses of cost-effectiveness of colorectal cancer screening programs have been carried out to provide a basis for legislative decision making and to construct health plans. The cost-effectiveness of colorectal cancer screening is estimated to be approximately $20,000 to $40,000 per year of life gained. This compares favorably with the cost of other usually accepted preventive services, such as end-stage renal dialysis or mammography.[93]

Diagnosis

CLINICAL MANIFESTATIONS

The presenting symptoms that lead patients with colorectal cancer to seek medical attention vary with the anatomic location of the lesion. Because stool is relatively liquid as it passes into the right side of the colon through the ileocecal valve, tumors in the cecum and ascending colon can become large and can markedly narrow the bowel lumen without causing any obstructive symptoms or noticeably altering bowel habits. Lesions in the ascending colon frequently ulcerate, which leads to chronic blood loss in the stool; however, the stool retains a grossly normal color. Therefore, patients experience symptoms related to anemia, such as fatigue, palpitations, and even angina pectoris, and are found to have a hypochromic, microcytic anemia indicative of iron deficiency. Because the tumor may bleed only intermittently, a test for fecal occult blood (see above) may not always reveal the presence of occult blood in the stool. For that reason, colonoscopy should be performed in any adult who develops iron deficiency anemia, perhaps with the exception of a young menstruating woman.

Stool becomes more concentrated as it passes into the transverse colon. Cancers arising in this section of the large bowel cause abdominal cramping, occasional obstruction, and even

Table 8 American Cancer Society Guidelines on Screening and Surveillance for the Early Detection of Colorectal Adenomas and Cancer for Women and Men at Increased Risk or High Risk[126]

Risk Category	*Description*	*Age to Begin Screening*	*Recommended Screening Method*	*Comments*
Increased risk	Persons with a single, small (< 1 cm) adenoma	3–6 yr after the initial polypectomy	Colonoscopy*	If examination is normal, the patient can thereafter be screened as per average-risk guidelines
	Persons with a large (≥ 1 cm) adenoma, multiple adenomas, or adenomas with high-grade dysplasia or villous change	Within 3 yr after the initial polypectomy	Colonoscopy*	If normal, repeat examination in 3 yr; if normal then, the patient can thereafter be screened as per average-risk guidelines
	Personal history of curative-intent resection of colorectal cancer	Within 1 yr after cancer resection	Colonoscopy*	If normal, repeat examination in 3 yr; if normal then, repeat examination every 5 yr
	Colorectal cancer or polyps in any-degree relative before age 60 or in two or more first-degree relatives at any age (if not a hereditary syndrome)	Age 40, or 10 yr before the age of the youngest patient in the immediate family	Colonoscopy*	Every 5–10 yr; colorectal cancer in relatives more distant than first-degree does not increase risk substantially above the average-risk group
High risk	Family history of familial adenomatous polyposis (FAP)	Puberty	Early surveillance with endoscopy, and counseling to consider genetic testing	If the genetic test is positive, colectomy is indicated; these patients are best referred to a center with experience in the management of FAP
	Family history of hereditary nonpolyposis colon cancer (HNPCC)	Age 21	Colonoscopy and counseling to consider genetic testing	If the genetic test is positive or if the patient has not had genetic testing, every 1–2 yr until age 40, then annually; these patients are best referred to a center with experience in the management of HNPCC
	Inflammatory bowel disease (chronic ulcerative colitis, Crohn disease)	Cancer risk begins to be significant 8 yr after the onset of pancolitis, or 12–15 yr after the onset of left-sided colitis	Colonoscopy with biopsies for dysplasia Expert pathologic evaluation is essential	Every 1–2 yr; these patients are best referred to a center with experience in the surveillance and management of inflammatory bowel disease

*If colonoscopy is unavailable, not feasible, or not desired by the patient, double-contrast barium enema (DCBE) alone or the combination of flexible sigmoidoscopy and DCBE are acceptable alternatives. Adding flexible sigmoidoscopy to DCBE may provide a more comprehensive diagnostic evaluation than DCBE alone in finding significant lesions. A supplementary DCBE may be needed if a colonoscopic examination fails to reach the cecum, and a supplementary colonoscopy may be needed if a DCBE identifies a possible lesion or does not adequately visualize the entire colorectum.

perforation. Tumors that markedly narrow the bowel lumen (so-called napkin-ring lesions) in the transverse colon are often smaller than those in the more proximal bowel because the short duration and localized pattern of the symptoms lead to a somewhat earlier diagnosis.

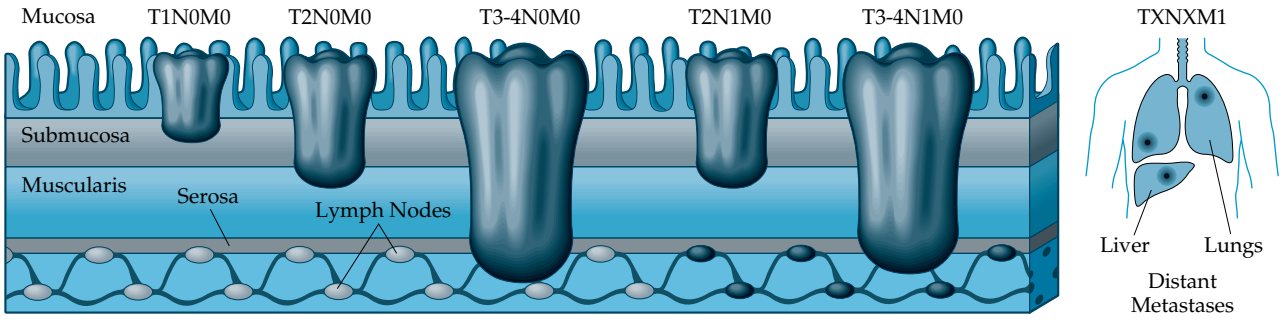
Cancers developing in the rectosigmoid are associated with tenesmus, narrowing of the stool, and hematochezia. Anemia is unusual, despite the passage of what appears to the patient to be copious quantities of bright-red blood from the rectum. Patients and physicians may attribute these symptoms to hemorrhoids. Development of altered bowel habits, rectal bleeding, or both mandates a digital rectal examination and colonoscopy.

STAGING AND PROGNOSIS

The prognosis for patients with adenocarcinoma of the colorectum is closely associated with the depth of tumor penetration into the bowel wall and the presence or absence of regional lymph node involvement and distant metastases. The most frequently used staging system, which incorporates these prognostic variables, was introduced by Dukes and later modified by Kirklin, Astler, and Coller, as well as others. More recently, the Dukes system has been applied to the TNM classification method, in which T represents the depth of tumor penetration; N, the presence or absence of lymph node involvement; and M, the presence or absence of distant metastases. In addition, the American Joint Committee on Cancer and the Union Interna-

Table 9 Screening Process for Colorectal Cancer[65]

- Target patients at risk for colorectal cancer
- Invite participation in screening program
- Identify special circumstances (e.g., symptoms, family history) early in the process so that appropriate measures can be advised
- Perform the screening test
- Use the result to identify patients who should undertake the diagnostic process (colonoscopy preferred)
- Ensure compliance with the appropriate diagnostic follow-up
- Provide adequate subsequent treatment
- Offer rescreening at appropriate intervals
- Monitor the outcomes of the program



TNM Stage	*Description*
T1N0M0	Infiltration no deeper than submucosa
T2N0M0	Infiltration of muscularis; no penetration through colonic wall; no lymph node involvement
T3-4N0M0	Extension through colonic wall; no lymph node involvement
T2N1M0	Infiltration of muscularis; no penetration through colonic wall; lymph node involvement
T3-4N1M0	Extension through colonic wall; lymph node involvement
TXNXM1	Distant metastases

Figure 2 **In the TNM (tumor, node, metastasis) staging system for colorectal cancer, a tumor is classified according to the extent of infiltration of the bowel wall and whether it has spread to lymph nodes or to distant organs such as the liver or lungs.**

tionale Contre le Cancer (AJCC/UICC) have developed a system that roughly parallels the modified Astler-Coller system but designates the stages as I through IV rather than as A through D [*see Figure 2 and Table 10*]. These staging systems divide colorectal cancer into the following categories[94]:

1. Stage A (T1N0M0). These are superficial lesions that do not penetrate the muscularis and do not involve regional lymph nodes.
2. Stage B. These are tumors that penetrate more deeply into the bowel wall without lymph node involvement; stage B is subdivided into stage B1 (T2N0M0), in which the tumor is restricted to the muscularis; stage B2 (T3NOMO); and stage B3 (T4NOMO), in which the tumor penetrates into or through the serosa.
3. Stage C. These are tumors that involve regional nodes; in the AJCC/UICC system, they are designated as stage III and are subdivided into stage IIIA (T1/2N1), stage IIIB (T3/4N1), and stage IIIC (any T, N2).
4. Stage D. These are tumors that have metastasized to liver, lung, bone, or other anatomically distant sites (TXNXM1).

In the absence of obvious evidence of metastatic disease, the stage of the disease can be accurately determined only after resection and histopathologic analysis of the specimen.

Because most recurrences after resection occur within 3 to 4 years, the cure rate is reasonably estimated by 5-year survival rates. Five-year survival is closely linked to the stage of the disease [*see Figure 3*]. For uncertain reasons, 5-year survival rates

Table 10 Staging of Colorectal Cancer

AJCC/UICC	*TNM*			*Modified Astler-Coller*	*Dukes*
Stage I	T1	N0	M0	Stage A	A
	T2	N0	M0	Stage B1	A

*N1 = involvement of one to three lymph nodes.
†N2 = involvement of four or more lymph nodes.
AJCC/UICC—American Joint Committee on Cancer/Union Internationale Contre le Cancer TNM—tumor penetration, lymph node involvement, distant metastasis [*see Figure 2*]

have improved for patients at almost every stage during the past several decades. This seeming improvement has been reported from single institutions[95] and multi-institutional groups[96] and represents the experience of community and university-affiliated hospitals.[96] It seems unlikely that changes in surgical technique or in the etiologic factors that lead to tumor development can explain this improvement. Rather, this change may best be understood as resulting from more thorough staging procedures, which involve careful intraoperative inspection of the liver and peritoneal cavity and more meticulous dissection of the resected specimen, including identification and examination of each of the lymph nodes surrounding the tumor. Improvements in adjuvant therapy also help account for the improvement in survival.

More exacting attention to pathologic detail has revealed that prognosis after resection not only is related to regional lymph node involvement but also may be more precisely defined by the number of involved nodes. The prognosis for patients with colorectal cancer is more favorable when tumor specimens reveal involvement of one to three lymph nodes than when they reveal four or more involved nodes. The impact of degree of local penetration and the number of lymph nodes is illustrated by the 5-year survival rates for three subcategories: 59.8% for stage IIIA, 42% for stage IIIB, and 27.3% for stage IIIC. Other indicators of poor prognosis in patients who have undergone a complete resection include poorly differentiated histologic type, tumor adherence to adjacent organs, bowel perforation, colonic obstruction at the time of diagnosis, and venous invasion by the tumor. Preoperative elevation of the carcinoembryonic antigen (CEA) level (see below) suggests that the tumor will recur, regardless of the clinicopathologic stage of the resected specimen.[97,98] The prognosis is also less favorable, particularly for patients who have undergone resection of stage B2 tumors, when the DNA content of the malignant cells (i.e., ploidy) and the percentage of proliferating cells are increased[99] or when there is allelic loss of chromosome 18q.[100] In contrast to the prognosis for patients with most other solid tumors, the prognosis for patients with colorectal cancer is not influenced by the size of the primary lesion when corrected for nodal involvement and histologic differentiation.[101]

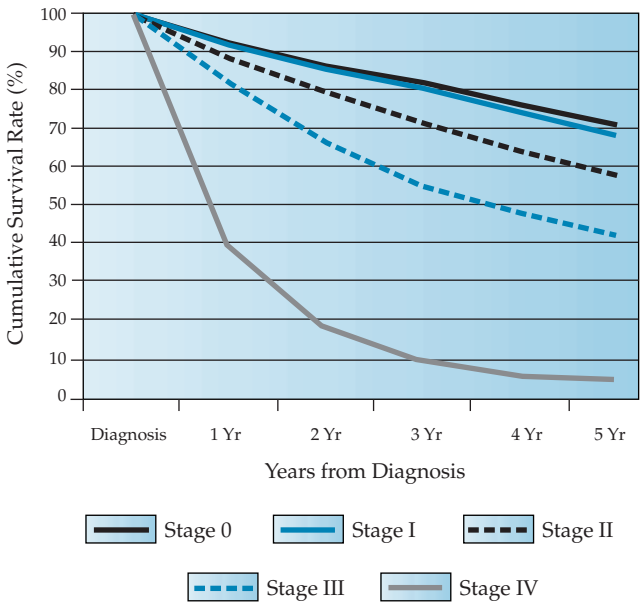

Figure 3 **Relationship between TNM stage and survival in colorectal carcinoma.[127]**

Table 11 Indicators of Poor Prognosis for Colorectal Cancer

Regional lymph node involvement
≥ 4 involved regional lymph nodes
Tumor penetration through the bowel wall
Poorly differentiated histologic findings
Tumor adherence to adjacent organs
Bowel perforation
Obstruction
Venous invasion
Preoperative elevation of carcinoembryonic antigen level to > 5.0 ng/ml
Increased DNA content (aneuploidy) of malignant cells
Allelic loss of chromosome 18q

Colorectal cancer initially spreads to regional lymph nodes and then through the portal venous circulation to the liver, which represents the most common visceral site of metastasis: the liver is the initial site of distant spread in one third of patients with recurrences, and liver involvement is seen in more than two thirds of patients by the time of death. As a rule, colorectal cancer rarely spreads to supradiaphragmatic sites, such as the lungs or supraclavicular nodes, or to less common areas, such as bone or the brain, without previous involvement of the liver. The main exception to this generalization occurs in patients whose primary tumor is in the distal rectum: tumor cells that are shed from these lesions may escape the portal venous system and spread through the paravertebral venous plexus to the lungs or supraclavicular nodes.[102] The median survival time for patients after the detection of distant metastases (stage D) is 6 to 12 months if untreated.

Carcinoembryonic Antigen

Although CEA is an imperfect tumor marker, it can provide useful information for the management of colorectal cancer patients if its limitations and attributes are understood[103] [*see Table 11*]. CEA is a glycoprotein that was initially found in association only with colorectal cancer and embryonic and fetal gut tissues. Plasma levels of CEA, which can be measured by radioimmunoassay, have subsequently been shown to be elevated in patients with many other malignant diseases (e.g., cancers of the stomach, pancreas, breast, and lung) and with various nonmalignant conditions (e.g., alcoholic liver disease, inflammatory bowel disease, heavy cigarette smoking, chronic bronchitis, and pancreatitis). Plasma CEA levels generally rise only when colorectal tumor cells have penetrated through the bowel wall (i.e., with cancer of at least stage B2). Therefore, the CEA assay is not useful as a screening test, even when applied to patients with gastrointestinal signs or symptoms. The CEA test is erratic as a quantitative measure of tumor bulk because the CEA level is highest when the liver is involved, even to only a minor degree, and may be barely elevated in patients with a bulky intra-abdominal recurrence [*see Table 12*].

Despite these shortcomings, there are several defined roles for the CEA assay:

1. Preoperatively, the CEA level is related to the stage of disease and may serve as a predictor of surgical incurability: preoperative CEA values greater than 5 ng/ml have been associated with a poor prognosis, independent of surgical stage.[97,98]
2. Postoperatively, the CEA level may serve as a measure of the completeness of tumor resection. If a preoperatively elevated CEA value does not fall to normal levels within 4 weeks (a period that is twice the plasma half-life of CEA) after surgery, the resection was probably incomplete or occult metastases are present.
3. The CEA level may serve as a useful monitor of tumor recurrence.
4. The CEA assay may serve as a monitor of response to treatment of metastatic disease. Serial CEA values parallel either tumor regression or tumor progression.[104] A rising CEA level is incompatible with tumor regression, whereas CEA values decrease in most patients who have responded to treatment.

Until better reagents become clinically available, the CEA assay will remain a source of information about tumor status that is unavailable through other means. Thus, this assay continues to merit a role in the management of selected colorectal cancer patients.

Table 12 Carcinoembryonic Antigen Level as a Marker for Colorectal Cancer

Uses	
	Preoperative prognostic indicator
	Postoperative measure of completeness of tumor resection
	Monitor of response of metastatic disease to treatment
	Most sensitive monitor of recurrence
Limitations	
	Nonspecific: elevated levels in many malignant and benign diseases
	Unsatisfactory screening test
	Erratic monitor of tumor bulk
	Not produced by poorly differentiated tumors

Treatment

SURGICAL MANAGEMENT

Curative resection offers the greatest potential for cure in patients with invasive colorectal cancer. Patients considered for such surgery are often elderly and should be evaluated preoperatively for metastatic disease by thorough physical examination, biochemical studies, and imaging of the chest and pelvis (when appropriate). These studies are particularly appropriate for patients with significant comorbid disease who might represent poor operative candidates and for patients who have symptoms suggestive of hepatic spread, such as weight loss, anorexia, and fever. The identification of metastases does not constitute an absolute contraindication to surgery in patients experiencing tumor-induced gastrointestinal bleeding or obstruction, but it frequently results in a more conservative operative procedure designed primarily to relieve symptoms. Before surgery, the CEA titer should be determined and, if possible, the entire bowel mucosa should be visualized by colonoscopy to detect synchronous polyps or neoplasms.

The most useful adjunct for the preoperative assessment of rectal lesions (in addition to a digital rectal examination) is endorectal ultrasonography. Endorectal ultrasound allows clear visualization of the layers of the rectal wall and thus enables the depth of invasion to be precisely determined. Endorectal ultrasound has an accuracy of 82% to 93% with respect to depth of invasion. Assessment of lymph node involvement is less reliable, with reported accuracy of 65% to 81%.

Surgery for colorectal cancer is based on the pattern of local disease spread and on the vascular anatomy of the bowel. Limited, or wedge, resections are inadequate; the regional lymph nodes draining a given segment of large bowel should be removed, along with associated blood vessels, and surgical margins of at least 5 cm should be obtained. During laparotomy, the surgeon should thoroughly examine the entire abdomen—including the liver, hemidiaphragms, and pelvis—and carefully palpate the full length of the large bowel.

The surgical management of cancers that arise in the distal rectum presents a particular problem because the traditional operative procedure for these lesions—abdominal-perineal resection—requires that patients receive a permanent sigmoid colostomy. Although such an operation remains unavoidable in most cases in which the cancer occurs within 5 to 6 cm of the anal verge, staple devices permit the construction of end-to-end anastomoses by experienced surgical oncologists for many patients with midrectal lesions. These anastomoses, which do not increase the risk of complications or tumor recurrence, allow the anal sphincter to be preserved. Preservation of the anal sphincter has also been achieved by the use of transanal or transcoccygeal resection in selected patients who have superficial, nonulcerated tumors that are too close to the anal verge for a stapled anastomosis.[105] The ideal margin for rectal cancer resection is 2 cm or more distally and 5 cm or more proximally. Lymphovascular resection of the rectum should include a wide anatomic resection of the mesorectum.[106]

Laparoscopic Colectomy

Laparoscopic techniques have become widely used in the management of colorectal cancer. These techniques can be safe and successful in the hands of an experienced surgeon. A slightly shortened hospital stay and more rapid postoperative recovery also are potential benefits. In a multicenter trial that excluded transverse colon and rectal cancers, rates of recurrence and of overall survival were equivalent, respectively, for patients undergoing open colectomy and for those undergoing laparoscopic colectomy.[107] Wound recurrence rates were lower than 1% in both groups. In a single-hospital study, laparoscopic resection was associated with lower cancer-related mortality, lower overall mortality, and a lower recurrence rate.[108]

Postoperative Surveillance

Colonoscopy Before a planned curative resection of a colorectal cancer, patients should undergo a preoperative colonoscopy to exclude the presence of synchronous neoplasia. If the colon is obstructed preoperatively, colonoscopy can be performed approximately 3 to 6 months after surgery. If this or a complete preoperative examination is normal, subsequent colonoscopy should be offered 1 year later; if the results of that colonoscopy are normal, colonoscopies should be performed every 3 to 5 years thereafter. The intent is to detect recurrent adenomatous polyps and new primary cancers.[28] Anastomotic recurrences, which occur in only about 2% of colon cancers, are common-

ly associated with intra-abdominal recurrence that cannot be surgically resected. Recurrent tumors may be missed, as demonstrated by a study in which the incidence of secondary colorectal cancers was increased despite intensive surveillance; the cumulative incidence of recurrence was 1.5% at 5 years in patients treated for localized colon cancer.[109]

History and physical examination There are no data that directly address the contribution of the history and physical examination to outcomes of colorectal cancer surveillance. However, a clinical history and pertinent physical examination should be performed every 3 to 6 months for the first 3 years and annually thereafter.[110]

Complete blood count Routine complete blood counts are not recommended.

Carcinoembryonic antigen If resection of liver metastases is clinically indicated and serious comorbid conditions are absent, it is recommended that postoperative serum CEA testing be performed every 3 months in patients with stage II or III disease for 2 years after diagnosis. An elevated CEA level, if confirmed by retesting, warrants further evaluation for metastatic disease but does not justify the institution of systemic therapy for presumed metastatic disease.

Liver enzymes Regular monitoring of liver enzyme levels after primary therapy for colon and rectal cancer is not recommended.

Fecal occult blood test Periodic FOBTs are not recommended.

Chest x-ray Routine yearly chest x-rays are not recommended. Chest x-rays may be ordered for patients with elevated CEA levels or symptoms suggestive of a pulmonary metastasis.

Computed tomography Routine CT scans are not recommended in the follow-up of patients with colorectal cancer.

Positron emission tomography Fluorine-18-deoxyglucose–labeled positron emission tomography (PET) is a complementary staging method that improves the management of patients with liver metastases, especially by detecting unsuspected extrahepatic disease.[111] The combination of PET and CT is now in use and can provide complementary information in the management of patients who are undergoing chemotherapy or radiation therapy.[112]

Flexible proctosigmoidoscopy Surveillance with flexible proctosigmoidoscopy is appropriate for selected patients with rectal cancer. A combination of chemotherapy and pelvic radiation therapy represents the standard treatment of rectal cancer of stage II or III (see below). For patients who have not received pelvic radiation, direct visualization of the rectum at periodic intervals is suggested. It is the custom of some surgeons to inspect the rectum in all patients who have undergone low anterior resection by performing proctosigmoidoscopy 6 and 12 months after resection.

RADIATION THERAPY

Radiation therapy plays an important role in the treatment of patients with stage B2 or stage C rectal tumors. Cancer recurs locally or regionally in 20% to 40% of these patients after complete resection.[113] This unusually high frequency of recurrence is presumably the result of two factors: the loss of integrity of the serosa of the large bowel as it enters the pelvis facilitates the infiltration of tumor, and the rich lymphatic supply of the pelvic side wall immediately adjacent to the rectum enhances the early spread of malignant cells into surgically inaccessible tissue. Therefore, adjuvant radiation therapy was introduced to remove tumor cells from perirectal tissue and to increase the chance of cure.

The rationale for using adjuvant radiation therapy to decrease pelvic recurrence appears sound, but it is uncertain whether such treatment should be administered before or after surgery. Patients with large, potentially unresectable rectal cancers may require preoperative irradiation to shrink the tumor sufficiently to allow its resection.

Prospective, randomized trials have demonstrated that neither preoperative[114] nor postoperative[115] irradiation alone significantly affects overall survival, although both forms significantly reduce the local recurrence rate. Survival is prolonged, however, when such adjuvant radiation therapy is combined with concomitant chemotherapy (see below).

Postoperative radiation therapy, when administered in doses of 4,500 to 5,000 cGy, causes transient diarrhea, cystitis, and perianal skin irritation; long-term damage to the small bowel or bladder is uncommon.[114] For patients whose tumor has spread through the bowel wall or who have lymph node metastases demonstrated by endorectal ultrasonography, preoperative chemoradiation has resulted in an increase in the percentage of sphincter-saving procedures that can be performed, with greater patient satisfaction. Postoperative lymph node status has been found to be an important predictor of recurrence and survival.[116]

CHEMOTHERAPY

After decades in which fluorouracil (5-FU) was the only chemotherapeutic agent available, the advent of new and more effective agents has completely changed the management of colorectal cancer. Although 5-FU remains the backbone of most regimens, new chemotherapeutic agents (i.e., irinotecan, oxaliplatin, and capecitabine) and new biologic agents (i.e., the monoclonal antibodies cetuximab and bevacizumab) offer additional benefit. Multiagent regimens that include oxaliplatin or irinotecan in combination with these monoclonal antibodies have entered widespread use.

Fluorouracil

Synthesized in 1952, 5-FU remains an important drug in the treatment of advanced colon cancer. 5-FU may be administered as a bolus injection either weekly or daily for 5 days every 4 weeks. Partial response rates with these regimens have been approximately 10% to 15%. The development of permanent venous access devices and portable infusion pumps now permits the continuous infusion of 5-FU on an outpatient basis. The use of continuous infusion enhances the likelihood that 5-FU will be present during the S phase of the tumor cell cycle, when this agent is most effective.

5-FU is modulated by leucovorin, which raises the level of 5,10-methylenetetrahydrofolate and results in the formation of a stable ternary complex of the folate coenzyme thymidylate synthase with 5-FU in the form of its principal metabolite, fluorodeoxyuridine. The use of 5-FU with leucovorin results in a higher response rate than with 5-FU alone.

Capecitabine

Capecitabine is a fluoropyrimidine—specifically, a prodrug of 5-FU—that mimics continuous-infusion 5-FU. It has the advantage of oral administration. In two studies that compared capecitabine with 5-FU in patients with advanced disease, capecitabine therapy was associated with an improved response rate (26% versus 17%) and with less toxicity, but there was no significant benefit in survival.[117] Diarrhea and microcutaneous toxicity (e.g., hand-foot syndrome) are common side effects.

Irinotecan

Irinotecan is a novel topoisomerase inhibitor that has significant therapeutic activity in metastatic colorectal cancer. It is used when the tumor has recurred or spread after standard chemotherapy. The primary toxicities are diarrhea and neutropenia, which can be life threatening if they are not treated promptly and aggressively.

Oxaliplatin

Oxaliplatin differs in its preclinical activity profile from cisplatin and also has a distinct toxicity profile. It causes no renal toxicity and minimal hematologic toxicity, but it is associated with both a reversible, acute, cold-related dysesthesia and a dose-limiting, cumulative, peripheral sensory neuropathy.

Cetuximab

Cetuximab is a chimeric monoclonal antibody that bonds to the external growth factor receptor, which is commonly expressed on colorectal carcinoma cells. Dysregulation of cell signaling through this receptor is thought to be an important factor in the growth of many epithelial malignancies. Patients treated with combinations of cetuximab and irinotecan have shown a higher response rate and a longer time to worsening of the metastatic disease than patients treated with either drug alone.[118] Side effects of cetuximab include an acneiform rash, malaise, and diarrhea.

Bevacizumab

Bevacizumab is a human chimeric antibody to vascular endothelial growth factor that stimulates angiogenesis. New blood vessel formation is important in tumor growth and invasion. The addition of bevacizumab to combination therapy with irinotecan, leucovorin, and 5-FU has been shown to increase therapeutic efficacy: patients receiving the four-drug combination survived for approximately 20 months—about 5 months longer than those receiving the three-drug combination.[119] Combinations of bevacizumab and cetuximab are also being assessed because of preclinical and early clinical data indicating synergistic activity.

Adjuvant Therapy

The use of 5-FU plus leucovorin is modestly effective in reducing tumor recurrence, with disease-free survival of about 60% and overall survival of about 65%. Capecitabine has been shown to be as effective as 5-FU plus leucovorin, with less associated toxicity and greater patient convenience. In patients with stage III colon cancer, the addition of oxaliplatin to 5-FU plus leucovorin has prolonged the 3-year disease-free survival from 73% to 77%.[120]

Management of Advanced Colorectal Cancer

Numerous combinations of chemotherapeutic drugs plus monoclonal antibodies are in clinical trials. The best choice for initial therapy remains to be determined. It is encouraging that median survival of patients with advanced disease has increased from about 13 months with 5-FU plus folinic acid, usually administered intravenously, to about 22 months with infusional 5-FU, leucovorin, and oxaliplatin. Outside of clinical trials, oncologists will need to consider not only the various toxicities caused by these new agents and the risk-to-benefit ratio but also the financial costs for each patient.

Other Molecular Targets

Molecular targets for therapy are becoming more widely known and include epidermal growth factors, tyrosine kinases, vascular endothelial growth factor, and intracellular signaling pathways. Many trials of compounds targeting these pathways in tumor cells and the surrounding stroma are in progress.

CHEMORADIOTHERAPY FOR RECTAL CANCER

Concomitant radiotherapy and chemotherapy decrease the probability of local or regional recurrences after complete resection of stage B2 or stage C rectal cancer and prolong survival.[121-123] In this setting, the chemotherapy is thought to make the radiation therapy more effective (a phenomenon known as radiosensitization). This approach produced its most successful outcome when a continuous intravenous infusion of 5-FU was administered through a portable pump for the entire 4- to 5-week period of radiation therapy.[123] Capecitabine is now being tested in combination with postoperative radiation therapy.

PALLIATION

Laser photoablation or stenting of obstructing rectosigmoid or rectal cancers should be considered if surgical decompression is not possible or advisable because of extensive metastatic disease or comorbidity.

The author has received grants for clinical research from Pfizer/Pharmacia.

VI PANCREATIC, GASTRIC, AND OTHER GASTROINTESTINAL CANCERS

Weijing Sun, m.d.
Daniel Haller, m.d.

On the basis of 2003 estimates from the American Cancer Society, cancers originating in the gastrointestinal tract rank second in both incidence and cancer-related deaths. One in four deaths in the United States is caused by cancer, and 25% of cancer-related deaths are caused by gastrointestinal malignancies; more than 40% of these deaths are caused by cancer of the pancreas, stomach, and esophagus [*see Table 1*].[1] In the past 10 years, advances in molecular biology, medical genetics, imaging and endoscopic techniques, and the development of antitumor agents have significantly altered approaches to the prevention, diagnosis, and treatment of GI cancers.

Esophageal Cancer

The esophagus extends from the cricopharyngeal sphincter to the gastroesophageal (GE) junction and is commonly divided into three portions: the cervical, upper to midthoracic, and thoracic. Histology and optimal treatment approaches may vary considerably because of the locations of the cancers.

EPIDEMIOLOGY

Esophageal cancer, which includes squamous cell carcinoma (SCC) and adenocarcinoma, is the ninth most common cancer worldwide. In the 1970s, approximately 90% of esophageal cancers were SCCs. The incidence of adenocarcinoma has increased dramatically and currently accounts for about 50% of new cases of esophageal cancer, a rate of acceleration greater than that of any other cancer in the United States.[2] The reason for the rapid increase in the incidence of esophageal adenocarcinoma is unknown. Esophageal cancer occurs about two to four times more frequently in men than in women. It is curable if the diagnosis is made in its early stages, but the disease usually presents in an advanced stage.

There is great geographical variation in the incidence of esophageal SCC. High-incidence regions, where rates may exceed 100 per 100,000 population, include northern China, India, parts of Iran, areas north and east of the Caspian Sea, and the Transkei area of South Africa.[3] Recent data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) indicate that the annual rate of SCC of the esophagus per 100,000 population declined from 3.4 during the period 1974 through 1976 to 2.2 during the period 1992 through 1994[4]; however, the disease is more common in black males (16.8 per 100,000 population) than white males (1.0 per 100,000 population).[2] The rate of SCC in black males continued to decline into the 1990s.

The incidence of esophageal adenocarcinoma is rapidly increasing in the United States and other countries.[5] It has been documented in population-based cohort studies that the incidence has increased 300% to 500% in the past 40 years.[6] Approximately 50% of new cases of esophageal cancer in the United States in 2002 were adenocarcinomas. Distal esophageal adenocarcinomas occur eight times more frequently in white males than in white females and are five times more common in white men than in black men, making white males the group at highest risk for the disease. The rate of esophageal adenocarcinoma in black women is too low to yield a reliable estimate of trends.[4]

ETIOLOGY AND RISK FACTORS

Tobacco Smoking and Alcohol Consumption

The major causes of SCC of the esophagus in the United States and other Western countries are cigarette smoking and alcohol consumption. Both have been found to be independent risk factors in men and women, and their combined use substantially increases risk.[7] It has been observed that the dose-response relationships for alcohol and tobacco are different. For tobacco smoking, the risk depends mainly on the duration of tobacco consumption (odds ratio is 6.4 for more than 35 years of smok-

Table 1 Estimated New Gastrointestinal Cancers and Deaths in the United States in 2003[1]

Site	New Cases			Deaths		
	Male	Female	All	Male	Female	All
Colon	49,000	56,500	105,500	28,300	28,800	57,100
Rectum	23,800	18,200	42,000			
Esophagus	10,600	3,300	13,900	9,900	3,100	13,000
Stomach	13,400	9,000	22,400	7,000	5,100	12,100
Pancreas	14,900	15,800	30,700	14,700	15,300	30,000
Hepatobiliary tract	14,800	9,300	24,100	10,500	7,400	17,900
Small intestine	2,700	2,600	5,300	600	500	1,100
Anus	1,700	2,300	4,000	200	300	500
Other sites	1,400	3,100	4,500	700	1,200	1,900
Total	132,300	120,100	252,400	71,900	61,700	133,600

ing); however, number of cigarettes a day also increases risk.[8] The risk associated with smoking black tobacco is two times higher than that with smoking blond or mixed tobacco. For alcohol consumption, the risk of esophageal SCC is based primarily on mean daily intake, not on duration of the drinking habit. The linear relationship between overall daily ethanol consumption and esophageal cancer is more marked for strong drinkers than for lighter drinkers. The risk of esophageal cancer also depends on the type of alcoholic beverage; spirits and beer carry the highest risk. A statistically significant synergistic interaction has been found between the type and amount of smoking and heavy alcohol drinking.[8] Those with simultaneous heavy black tobacco smoking and heavy alcohol intake represent the subgroup with the highest risk for SCC of the esophagus (odds ratio, > 100).

Cessation of smoking decreases the risk of esophageal SCC, and a 5-year cessation reduces the risk by 50%. In contrast, only after a 10-year abstention from alcohol consumption does the risk of esophageal cancer decline to the upper risk level of abstainers.[9] After 10 or more years' cessation of both habits, the risk of development of esophageal cancer is decreased to one tenth that of current smokers and drinkers.

It has been suggested that tobacco smoking has a strong role both in the initiation and ongoing development of esophageal SCC, whereas alcohol consumption appears more important as a carcinogenic factor in the later stages of development.[10]

Dietary Factors

Case-control studies indicate that dietary factors may play an important role in the development of esophageal SCC, and vitamin and trace mineral deficiencies are crucial as risk factors for esophageal SCC.[11] In particular, important vitamins and minerals include A, C, folic acid, E, B_{12}, and riboflavin.

Foods that lower risk Diets containing high amounts of green and yellow vegetables that are rich in β-carotene decrease the incidence of esophageal SCC. Citrus fruits that are high in vitamin C may also have a protective effect. Lower plasma levels of folic acid have been documented in patients with esophageal SCC. In the Linxian area of China, where esophageal cancer is endemic, riboflavin deficiency, manifested by cheilosis and glossitis, is common.[12] It appears that vitamins A, C, and E exert antioxidant effects; the last two vitamins are known to influence the formation of nitrosamines.

Foods that increase risk An inverse association has been shown between the levels of certain trace elements (e.g., selenium and zinc) and mortality associated with esophageal cancer in high-incidence areas in the world. Achalasia has also been proposed as a predisposing risk factor, with a prevalence of about 5% in individuals with chronic achalasia.[13]

Predisposing Medical Conditions

Risk factors for SCC Not surprisingly, patients with head and neck SCC are at increased risk for the development of esophageal cancer, and this risk is increased by alcohol and tobacco consumption.[14] Either coexisting or sequential esophageal cancers may occur at an annual rate of 3% to 7%. Approximately 10% of second primary cancers in patients with primary lung and oropharyngeal carcinomas arise in the esophagus.[15] As a result, endoscopic surveillance of the esophagus has been advocated in this setting. Factors that increase the risk of esophageal SCC include lye ingestion, ionizing radiation, celiac sprue, human papillomavirus infection, Plummer-Vinson syndrome, esophageal diverticula, and radiation treatment.

Risk factors for adenocarcinoma Gastroesophageal reflux disease (GERD) is a risk factor for esophageal adenocarcinoma. Barrett esophagus, a metaplastic change of the lining of the esophagus in which the normal squamous cell epithelium is replaced by columnar intestinal-type epithelium, is a complication of chronic reflux disease, and it is associated with an increased risk of adenocarcinoma of the esophagus. Whether Barrett esophagus is a necessary precursor to all cases of esophageal adenocarcinoma is unknown. There are no prospective cohort studies of patients with reflux to assess cancer risk; however, in population-based, case-control studies examining the relationship between reflux and adenocarcinoma of the esophagus, patients with esophageal adenocarcinoma were eight times more likely to have at least weekly symptoms of reflux or regurgitation than were control subjects.[16] An individual with long-term (> 20 years) and severe reflux symptoms has an increased risk for esophageal adenocarcinoma, with an odds ratio of 43.3. On the other hand, 40% of those who develop cancer do not have frequent symptoms. Although less than 1% of the general population has Barrett esophagus, 5% to 15% of those with long-term reflux symptoms will have Barrett esophagus.[17] High-grade dysplasia in Barrett mucosa is a marker indicating high probability of invasive adenocarcinoma[18]; therefore, Barrett esophagus is a likely precursor lesion that can evolve into esophageal adenocarcinoma. Individuals with Barrett esophagus have a risk of developing esophageal adenocarcinoma that is 40 to 125 times higher than the risk of the general population.[10] The annual risk of an individual with Barrett esophagus developing esophageal adenocarcinoma is approximately one in 200[19,20]; patients with high-grade dysplasia demonstrate a risk of subsequent adenocarcinoma exceeding 25%.[21] Evidence suggests that increasing body mass index is also associated with the risk of adenocarcinoma of the esophagus.[22]

SCREENING AND PREVENTION

Squamous Cell Carcinoma

High-incidence populations, such as those found in northern China, may merit endoscopic screening in the general population. The efficacy of a screening program has been documented in China, where 5-year survival is nearly 90% after operative resection of tumors detected through screening.[23]

Mass screening in the United States is not feasible for esophageal SCC, given the low incidence.[24] However, institution of screening and surveillance endoscopic programs may be applied to certain clinical scenarios, such as in patients with tylosis, achalasia, and a history of other upper aerodigestive tract cancers. The decreasing incidence of SCC of the esophagus in the United States appears secondary to improvement of socioeconomic status and behavioral and dietary changes, including cessation of smoking and a decrease in alcohol intake in high-risk populations.

Adenocarcinoma

Because GERD is a risk factor for esophageal adenocarcinoma and because Barrett esophagus is highly associated with the disease, there is increased clinical interest in pharmacologic, surgical, or endoscopic therapy to decrease the risk, as well as prevent the development, of adenocarcinoma of the esophagus. There is no evidence to suggest that proton pump inhibitors either stop

Table 2 American College of Gastroenterology Guideline for the Diagnosis and Surveillance of Barrett Esophagus[33]

Patient Characteristics	*Suggested Protocol*
Long-standing reflux symptoms, especially in individuals 50 years of age or older	A single upper endoscopy to rule out Barrett esophagus
Barrett esophagus, no dysplasia	After a second confirming endoscopy, surveillance every 2–3 yr
Barrett esophagus, low-grade dysplasia	Endoscopy every 6 mo for the first year, then annually
Barrett esophagus, high-grade dysplasia	Expert confirmation of the histology; if confirmed, consideration of esophageal resection or endoscopy every 3 mo

the progression of Barrett esophagus to adenocarcinoma or lead to regression in the presence of metaplastic tissue.[25] It is unclear whether surgical antireflux procedures would diminish the risk of developing esophageal adenocarcinoma for those with Barrett esophagus.[26] To reduce the risk of adenocarcinoma, several therapeutic endoscopic ablation modalities (e.g., lasers, argon plasma coagulation, multipolar electrocoagulation, and photodynamic therapy [PDT]) have been used to destroy areas of Barrett esophagus.[27-30] Each of these techniques may successfully destroy the metaplastic epithelium, but it is unclear whether treatment with these ablative therapies reduces risk of adenocarcinoma in the treated areas.[31,32] Studies show that reversion to squamous epithelium might be incomplete; Barrett mucosa may underlie what appears to be normal squamous cell epithelium, and adenocarcinoma may develop beneath the treated squamous cell epithelium. These therapeutic modalities are considered experimental at present, and their long-term utility remains uncertain.

Another issue is the periodicity of upper endoscopy screening appropriate for patients with GERD—especially those who show a change in symptoms—to rule out cancer or to assess for complications of reflux disease (e.g, stricture, erosive esophagitis, or Barrett esophagus). The American College of Gastroenterology has published surveillance guidelines for those patients with long-term reflux symptoms and Barrett esophagus [*see Table 2*].[33] However, there are no prospective trials demonstrating the prevention of esophageal adenocarcinoma or a survival benefit by use of screening endoscopy in patients with long-term GERD. A large population-based study that used data from SEER and Medicare health claims supports the role of screening endoscopy and surveillance for Barrett esophagus and highlights the underdiagnosis of the population at risk.[34] The study showed a shift toward earlier diagnosis of esophageal adenocarcinoma in patients who had a previous endoscopy or a diagnosis of Barrett esophagus and showed a reduced risk of death from esophageal cancer in those who underwent screening endoscopy.

MOLECULAR MUTATIONS AND PATHOGENESIS

With advances in molecular biology and genetics, it has been recognized that the accumulation of alterations in oncogenes, tumor suppressor genes, and DNA mismatch repair genes plays a significant role in the development of esophageal carcinomas. Perhaps the most critical oncogene in esophageal SCC pathogenesis is cyclin D1. Cyclin D1 is overexpressed in as many as 50% of esophageal squamous cell cancers and is associated with poor prognosis. Alteration of tumor suppressor genes *p53* and *p16* and loss of heterozygosity in other tumor suppressor gene loci, such as *pRb* and *APC*, have been described in the development of esophageal carcinomas.[35] The transition of Barrett metaplasia to adenocarcinoma involves progression through low-grade dysplasia, high-grade dysplasia, and carcinoma in situ. It has been demonstrated that abnormal DNA content, as reflected by aneuploidy measured through flow cytometry, is associated with dysplasia and adenocarcinoma. Increased expression of epidermal growth factor receptor and its ligands epidermal growth factor and transforming growth factor–α (TGF-α) are found in Barrett-associated adenocarcinoma when studied by flow cytometry.[36]

DIAGNOSIS

Clinical Manifestations

Few esophageal cancers are diagnosed at an early stage. In more than 90% of patients, dysphagia is the most common presenting complaint, which usually is not noticed until the esophageal lumen is narrowed to less than 40% of normal. The disease most commonly spreads to adjacent structures and lymph nodes. Patients may present with hoarseness, if the recurrent laryngeal nerve is involved, or cough, suggesting local extension into the trachea with resultant tracheoesophageal fistula. Supraclavicular or cervical lymph node metastases may also occur. The disease may also distantly metastasize to liver and lungs, which may present as malignant pleural effusion or ascites. Bone metastases can be identified by pain or by associated hypercalcemia. Other clinical presentations include hematemesis or melena, hemoptysis, and superior vena cava syndrome.

Diagnostic Evaluation

Upper gastrointestinal endoscopy (esophagoscopy), for both visualization and histopathologic diagnosis, should be performed in all patients suspected of having an esophageal abnormality. The combination of endoscopic biopsies and brush cytology has an accuracy of virtually 100% in obtaining tissue diagnosis of esophageal cancer. Bronchoscopy should also be performed to examine the larynx, trachea, and bronchi in patients with suspected esophageal cancer, especially if tumors involve the upper two thirds of the esophagus, to exclude invasion of the posterior membranous trachea or tracheoesophageal fistula and to diagnose associated lung cancers and cancers of the head and neck.

Barium contrast radiography may identify large esophageal lesions and can document contour and motility abnormalities, as well as unexpected airway fistulae [*see Figure 1*]. It does not facilitate biopsies and may not visualize small lesions; however, barium contrast radiography is useful for patients in whom upper gastrointestinal endoscopy is unsuitable (e.g., in patients at risk for sedation or injury from endoscopy) and in cases in which the entire esophagus has not been visualized endoscopically (e.g., in patients whose disease or complications have contraindicated use of endoscopy).

STAGING

Once a diagnosis has been established and careful physical examination and routine blood tests have been performed, a CT scan of the chest, abdomen, and pelvis should be obtained to assess tumor extent, nodal involvement, and metastatic disease.

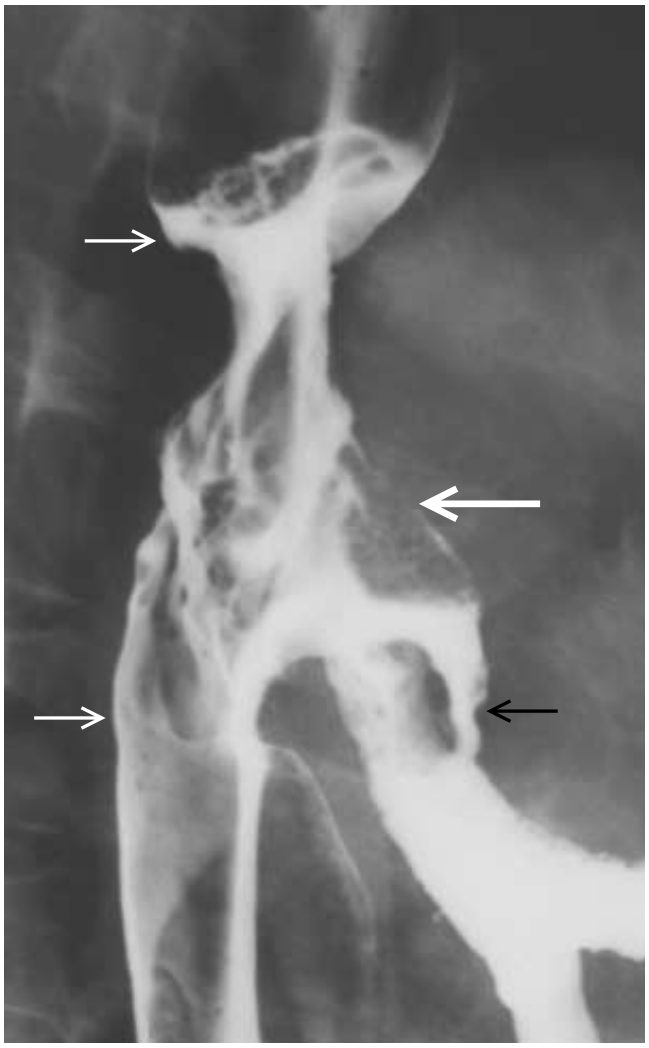

Figure 1 **Barium esophagogram of squamous cell carcinoma. The barium esophagogram shows a squamous cell carcinoma of the esophagus with esophagotracheal fistula. A 5 cm annular mass (between small, white arrows) is located in the midesophagus. The mucosa is nodular. The tumor has invaded the mediastinum, forming a cavity (large arrow). A fistula (black arrow) extends into the left mainstem bronchus.**

However, CT scanning may underestimate the depth of tumor invasion and periesophageal lymph node involvement in up to 50% of cases. Endoscopic ultrasonography (EUS) has the advantage of being able to image distinct wall layers, thereby providing a representation of the depth of tumor invasion with an accuracy of up to 90% and detecting regional lymph node involvement with an accuracy of 75% [*see Figure 2*]. EUS also can detect local tumor recurrence at an early stage. EUS should be considered as a mandatory procedure for staging workup, especially for patients who are being considered for preoperative treatments. Positron emission tomography (PET) scanning has become widely available and may be an important tool for staging, with both a sensitivity and a specificity of approximately 90%.[37] PET scanning is considered to be superior to CT scanning in the evaluation of distant metastases.

TREATMENT

Depending on the depth and degree of invasion of the primary tumor, on extension into surrounding lymph nodes and nearby vital structures, and on metastasis involving distant visceral organs, esophageal cancer can be classified as local and resectable, locally advanced and unresectable, or metastatic. Treatment options for esophageal cancer are based on the stage of the disease at presentation. Surgery remains the mainstay of treatment of esophageal cancer, and it can be curative in persons with resectable local and locoregional disease. Advances in surgical therapy, staging techniques, patient selection, and supportive care in the past several decades have led to a marked improvement in surgery-related mortality and morbidity. However, only about 40% to 60% of patients present with localized disease, and many are not candidates for curative resection. The overall 5-year survival in patients amenable to surgery ranges from 5% to 20%.

Local Disease

Surgery For patients with T1 and T2 lesions without any evidence of nodal involvement, surgery alone may be curative in more than 60% of patients. The two most common approaches for surgical resection of esophageal cancer are transhiatal esophagectomy (THE) and transthoracic esophagectomy (TTE); there are no obvious survival differences between the two procedures.[38] Factors that may affect the selection of one technique over the other include tumor location, depth of tumor invasion, status of lymphadenopathy, overall performance status and body habitus of the patient, previous treatment (i.e., radiation or chemoradiation), and the preference and biases of the surgeon. Comparisons between surgical data from Eastern and Western populations are confounded by the differences in the predominant type of cancer and in the extent of surgical resection.[39]

Surgery combined with other modalities Both local and distal recurrence rates of esophageal cancer are high, which may be based on the anatomic features of the esophagus, including the lack of a fibrous serosa and a rich lymphatic network in the sub-

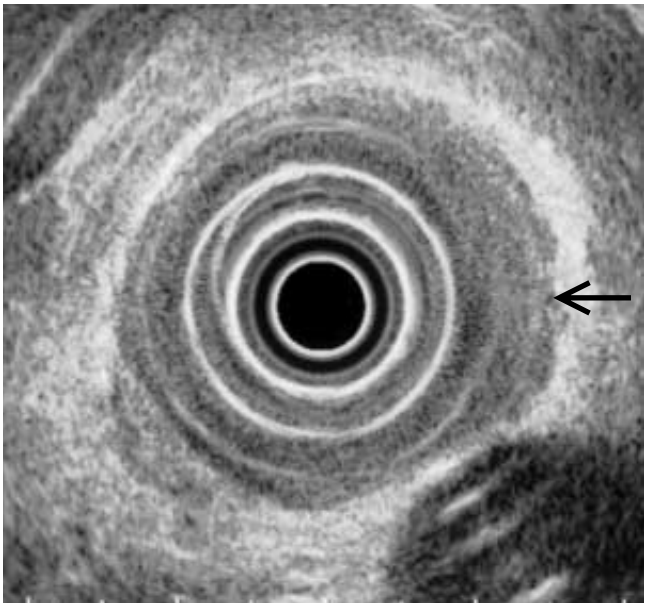

Figure 2 **Endoscopic ultrasonography (EUS) of esophageal cancer. An adenocarcinoma penetrates the full thickness of muscularis propria (arrow) of the esophageal wall.**

mucosa and muscularis. Multimodality treatment of esophageal cancer has been investigated extensively to improve treatment efficacy and survival.

A survival benefit for preoperative chemotherapy followed by surgery, compared with surgery alone, was shown in one study from the United Kingdom,[40] but this result was not confirmed in another large intergroup study from the United States.[41] Preoperative chemoradiation is the most intensely studied treatment strategy. Although the results from three published randomized phase III studies vary and controversies still exist, all favor preoperative chemoradiation.[42-44] Large randomized trials are needed to further address this approach. The benefit of postoperative chemoradiation in esophageal adenocarcinoma is suggested from a large intergroup gastric cancer trial, which included some patients with GE junction adenocarcinomas.[45]

Primary radiation therapy and primary chemoradiation Radiation as a single modality is limited to patients who are not candidates for surgical resection or who are medically unable to tolerate multimodality treatment.[46] Definitive primary chemoradiation therapy for esophageal carcinoma is considered an alternative to surgical resection, although there are no large prospective, randomized trials in which chemoradiation alone has been compared with surgery alone. The Radiation Therapy Oncology Group (RTOG) trial demonstrated the superiority of chemoradiation over radiation alone.[47] A total dose of radiation of 5,000 cGy (in fractions of 200 cGy) is given concurrently with intravenous 5-fluorouracil (5-FU) (1,000 mg/m^2/24 hr for 4 consecutive days) and cisplatin (75 mg/m^2 on day 1 in weeks 1, 5, 8, and 11). In the latest updated analysis, the 5-year survival rate was 26% in the chemoradiation group, compared with 0% in the group that received only radiation; 22% survived in the chemoradiation group at least 8 years after the treatment.[47] No deaths that occurred after 5 years were the result of esophageal cancer, suggesting that cure may be achieved with chemoradiation and indicating that chemoradiation may be considered a viable alternative for nonsurgical candidates.

Symptom management Intraluminal radiation (brachytherapy) or intraluminal stents can ameliorate symptoms resulting from obstructing cancers. Complications of brachytherapy include ulcers, strictures, and tracheoesophageal fistula in up to 25% of patients.[48]

Metastatic Disease

Chemotherapy For distant metastatic disease, systemic chemotherapy may provide palliation. 5-FU and cisplatin have been considered standard treatments, alone and in combination, but response rates (30% to 40%) and median survival (6 to 9 months) are modest.[49] Many new chemotherapy agents developed in the past several years (e.g., paclitaxel, docetaxel, gemcitabine, irinotecan, and oxaliplatin) have been associated with improved response rates and median survival rates in phase II trials but with uncertain advantages over standard therapy.[50-52] Other novel target-oriented agents are being tested in esophageal cancer, including antiangiogenesis agents, farnesyl tranferase inhibitors, vascular endothelial growth factor inhibitors, epidermal growth factor receptor tyrosine kinase (EGFR-TK) inhibitors, anti-EGFR antibodies, and antisense nucleotides.

Symptom management It should be emphasized that improvement in the quality of life, including management of primary symptoms and complications (e.g., dysphagia, malnutrition, pain, and tracheoesophageal fistulas), is extremely important for esophageal cancer patients, especially for those with unresectable and incurable tumors. Endoscopic dilatation can be employed to relieve strictures and is associated with a low complication rate; however, repeated dilations may be necessary.[53] Use of expandable metal stents is a good option to maintain patency; additionally, laser recannulization of the esophageal lumen and bipolar electrocoagulation therapy may be helpful in reducing dysphagia. Endoscopic stents can also control tracheoesophageal fistulas to prevent aspiration pneumonia.[54] Photodynamic therapy with porfimer sodium and an argon-pumped dye laser can provide effective palliation of dysphagia.[55] Surgical placement of a gastrostomy or jejunostomy feeding tube for nutritional support is necessary for many esophageal cancer patients, especially for those receiving perioperative chemoradiation treatments, and may relieve symptoms and improve quality of life in patients with unresectable disease.

Gastric Cancer

EPIDEMIOLOGY

Gastric cancer is an aggressive neoplasm that has a marked variation in both incidence and mortality between different populations. Although the incidence of gastric cancer has decreased in the past several decades in Western countries, gastric cancer is still one of the most common cancers worldwide. Overall prognosis has not changed: only 40% of patients are eligible to undergo potentially curative surgery. Gastric cancer represented the leading cause of cancer-related mortality in the United States until the 1930s and worldwide until the late 1980s, when it was surpassed by lung malignancies. In 2003, an estimated 22,400 persons in the United States will have developed gastric cancer and 12,100 will have died of the disease.[1] Global estimates for 1999 suggest that 789,000 persons were diagnosed with gastric cancer in that year and that 628,000 persons died from the disease.[56] A high incidence of gastric cancer is observed in Asia, South America (Chile and Costa Rica), Eastern Europe, and the Middle East. Although the etiology of gastric cancer has become clearer, there has been an inexplicable worldwide increase in cancers of the proximal stomach and GE junction. In the United States, the 4.3% annual increase in the rate of GE junction cancer is higher than the increase in the rate of lung cancer.

ETIOLOGY AND RISK FACTORS

Extensive research has identified factors and events that influence the initiation, promotion, and progression of stomach cancer. Gastric cancer is a disease of complex etiology involving multiple risk factors, including dietary, infectious, occupational, genetic, and preneoplastic factors. The pattern of decreasing incidence and mortality of gastric cancer in both high- and low-incidence regions [*see Table* 3] may reflect important changes in lifestyle linked to socioeconomic factors, such as refrigeration of stored foods, improved water supply, and a decline in infections and poor dietary habits.[57,58]

Dietary Factors

Salted, smoked, and dried foods contain high concentrations of nitrates, which convert into carcinogenic nitrosamines and nitrites by anaerobic bacteria, and diets rich in such foods may be associated with the development of gastric cancer.

Table 3 Decline in Age-Adjusted Incidence and Mortality of Gastric Cancer in Japan, Slovenia, and the United States, 1975–1995[57]

	Japan		*Slovenia*		*United States*	
	Men	*Women*	*Men*	*Women*	*Men*	*Women*
Decrease in incidence (per 100,000)	76.0 → 53.0	38.4 → 21.3	40.2 → 24.1	16.6 → 10.8	9.5 → 6.9	4.3 → 2.9
Decrease in mortality (per 100,000)	60.2 → 34.2	30.5 → 14.1	37.7 → 21.2	13.8 → 9.0	5.6 → 4.7	2.5 → 2.3

Infections

Infection from *Helicobacter pylori*, a gram-negative spiral bacterium, is a primary risk factor for gastric cancer. The first strong data came from three separate, nested case-control studies.[59-61] The statistically significant relative risk ranged from 2.8 in a British population to 6.0 in a cohort of Japanese males living in Hawaii.

H. pylori gastritis causes cell proliferation with increased risk of DNA damage, leading to inadequate repair and malignant transformation.[62] *H. pylori* infection is very common, with the prevalence ranging from 40% or less in developed countries to 70% or higher in developing countries. Several cofactors or modifiers have been examined to associate *H. pylori* with gastric cancer.[63] Infection at an earlier age (i.e., 29 years or younger) may increase the risk of gastric cancer. Those infected with *cagA*-positive strains (associated with cytotoxin expression) have a risk of developing gastric cancer that is two to three times higher than those with *cagA*-negative strains.[64]

Other gastric cancer risk factors, such as diet (including low intake of ascorbic acid, β-carotene, and vitamin E) and cigarette smoking, have been examined as possible modifiers of the association between *H. pylori* and gastric cancer.[65] Atrophic gastritis secondary to *H. pylori* infection consumption of excessively salty food, achlorhydria, pernicious anemia, or previous partial gastrectomy cause the loss of gastric acidity, which leads to the process of intestinal metaplasia, atypia, and neoplasia. Although reports suggest that patients who underwent gastric resection for benign disease have an increased risk for the development of gastric cancer, this association has not been definitely proved.[66] The relationship of pernicious anemia to the development of gastric carcinoma is also questionable.

Familial Syndromes

Although most cases of gastric cancer appear to be sporadic, approximately 10% of cases involve familial clustering.[67] Hereditary diffuse gastric cancer is a familial syndrome with autosomal dominant inheritance [*see Figure 3*], high penetration (60% to 80%), and high mortality; hereditary diffuse gastric cancer develops at a young age.[68,69] Inactivating mutations in the E-cadherin gene (*CDH1*) have been identified in hereditary diffuse gastric cancer kindreds, which account for approximately 25% of cases of hereditary diffuse gastric cancer worldwide.[70] For those with suspicious familial clustering, genetic tests can clearly identify persons at high risk and allow for targeted intervention, from aggressive surveillance to prophylactic gastrectomy.[69]

Other hereditary cancer syndromes in which gastric cancer may occur include hereditary nonpolyposis colorectal cancer, familial adenomatous polyposis, the Li-Fraumeni syndrome, and the Peutz-Jeghers syndrome. The unique patterns of cancer that define each syndrome must be taken into account in assessing the genetic risk of cancer.[71] For sporadic gastric cancer, molecular analyses also show critical, acquired alterations, including aneuploidy, loss of heterozygosity (LOH) of 17p and 18q, microsatellite instability (MSI), and mutations in *p53*, *p16*, and E-cadherin.[72]

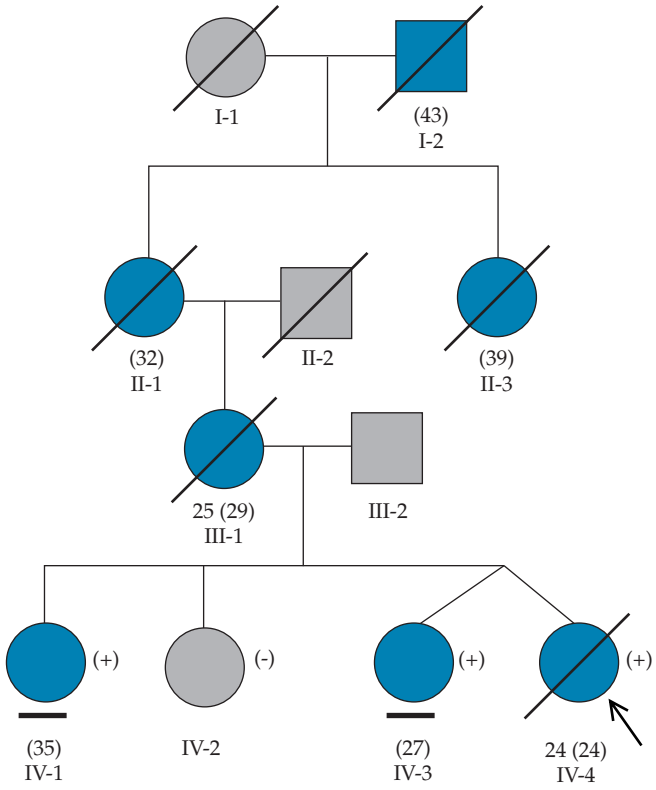

Figure 3 **Pedigree of a family with germline mutation inactivation of E-cadherin and associated cases of hereditary diffuse gastric cancer. Squares represent male family members, and circles represent female family members. Gray symbols indicate unaffected persons, and blue symbols indicate affected persons. A slash over the symbol represents death, and a line under the symbol signifies a family member who received prophylatic gastrectomy. A plus sign to the right of the symbol indicates E-cadherin mutation positive, whereas a minus sign indicates E-cadherin mutation negative. The arrow identifies the proband. The ages at diagnosis and at death (in parentheses) of each individual are marked below each symbol.**

Overexpression of EGF and EGFR, including c-*erbB*-2, TGF-α, and cyclooxygenase–2 (COX2) in gastric cancer are involved with tumor proliferation, invasion, and migration. Recent application of cyclic DNA (cDNA) array technology in gastric cancer has shown at least 40 genes with significantly altered expression in primary gastric cancer.

SCREENING AND PREVENTION

Screening general populations for gastric cancer is not practical in Western countries because of the disease's low incidence. However, mass screening is more appropriate in high-risk areas, such as Japan. Japanese screening guidelines include initial endoscopy at 50 years of age, with periodic follow-up. Routine screening should also be considered in individuals with known genetic predisposition [*see* Familial Syndromes, *above*].

Table 4 TNM Staging of Gastric Cancer[74]

Primary Tumor (T)		
TX		Primary tumor cannot be assessed
T0		No evidence of primary tumor
Tis		Carcinoma in situ: intraepithelial tumor without invasion of the lamina propria
T1		Tumor invades lamina propria or submucosa
T2		Tumor invades muscularis propria or subserosa*
	T2a	Tumor invades muscularis propria
	T2b	Tumor invades subserosa
T3		Tumor penetrates serosa (visceral peritoneum) without invasion of adjacent structures†‡
T4		Tumor invades adjacent structures†‡
Regional Lymph Nodes (N)		
NX		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N1		Metastasis in 1 to 6 regional lymph nodes
N2		Metastasis in 7 to 15 regional lymph nodes
N3		Metastasis in more than 15 regional lymph nodes
Distant Metastasis (M)		
MX		Distant metastasis cannot be assessed
M1		No distant metastasis
M2		Distant metastasis

*A tumor may penetrate the muscularis propria, with extension into the gastrocolic or gastrohepatic ligaments, or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified T2. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified T3.

†Including spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.

‡Intramural extension to the duodenum or esophagus is classified by the depth of the greatest invasion in any of these sites, including the stomach.

PATHOPHYSIOLOGY

Approximately 95% of gastric cancers are adenocarcinomas, with two distinct histologic types: intestinal and diffuse. Other malignancies are very rare, including SCC, carcinoid tumors, adenoacanthoma, leiomyosarcoma, and gastric lymphoma.

Cohesive neoplastic cells that form glandlike tubular structures characterize the intestinal form of gastric cancer, whereas the diffuse type lacks cell cohesion. The intestinal type is more differentiated and is associated with precancerous lesions, gastric atrophy, and intestinal metaplasia. The intestinal form accounts for the majority of distal cancers and is associated with *H. pylori* infection and environmental factors.

The diffuse type of gastric cancer exhibits undifferentiated signet-ring histology and is more common in younger patients. In the diffuse type, there is a predilection for submucosal spread (because of the disease's characteristic lack of cell adhesion), which results in linitis plastica appearance and contiguous spread to the peritoneum. Patients with genetic predisposition are more likely to develop the diffuse type of gastric cancer. The association between *H. pylori* infection and diffuse-type gastric cancer is less clear than the *H. pylori* association with the intestinal type. The prognosis of diffuse gastric cancer is worse than that of the intestinal type, stage for stage.[73]

STAGING AND PROGNOSIS

The overall prognosis of gastric cancer is based primarily on the depth of penetration of the primary tumor, the extent of involvement of local regional lymph nodes, and distant metastasis. To eliminate the likelihood of stage migration (i.e., inappropriate staging) , the American Joint Committee on Cancer (AJCC) sixth-edition staging system changed the nodal staging from anatomic location to the number of nodes involved [*see Table 4*].[74] Stage migration mainly results from variable surgical techniques and extent of lymphadenectomy in different countries and whether node analysis is optimal, as noted from different prognoses in patients with similarly staged gastric cancer in Japan and the United States.[75,76] The AJCC and the International Union Against Cancer (UICC) both have recommended analysis of at least 15 lymph nodes for accurate staging of gastric cancer.

Another important and unique prognostic factor in gastric cancer is the location of the primary tumor. Stage for stage, proximal gastric cancers have worse prognoses, which suggests that the biologies of proximal and distal gastric cancers are different. Proximal gastric cancer in Japan accounts for fewer than 10% of gastric cancer cases, in contrast to much higher percentages in Europe and the United States.[77,78] Other factors, including age and overall performance status, also influence the prognosis of patients with gastric cancer. The prognostic implications of tumor suppressor genes, oncogenes, and factors altering proliferation and apoptosis are areas of active investigation.

DIAGNOSIS

Clinical Manifestations

Because initial clinical symptoms are nonspecific, gastric cancer frequently is diagnosed at an advanced stage. The most com-

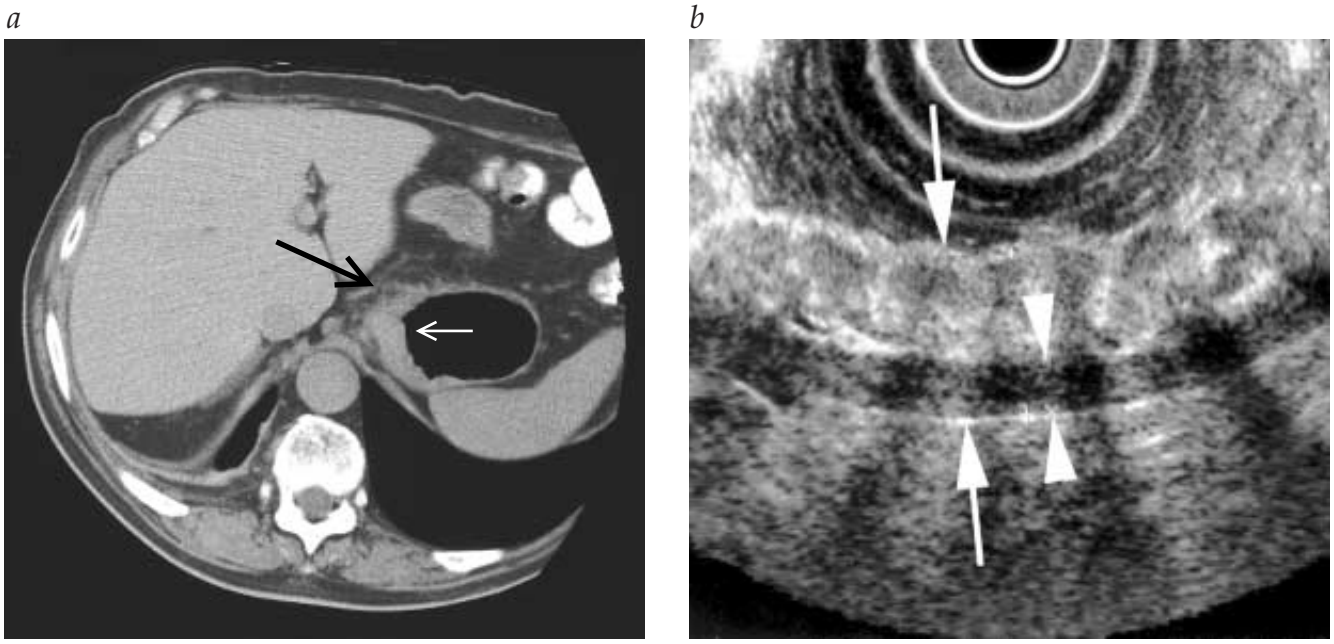

Figure 4 **(*a*) CT scan of gastric cancer. A gastric adenocarcinoma is located at the posterior wall of the gastric fundus (white arrow), and invasion of the gastrohepatic ligament (black arrow) is evident. (*b*) EUS of gastric cancer. The arrows show a linitis gastric cancer with diffused invasion of all levels of the stomach wall and a linitis plastica appearance.**

mon presenting symptoms are abdominal or epigastric pain and weight loss. Early satiety may be the first symptom, especially in those with the linitis plastica form of diffuse gastric cancer. Other symptoms are dysphagia, nausea and vomiting, gastrointestinal bleeding, reflux, fatigue, abdominal wall masses or subcutaneous nodules, and lymphadenopathy. Classic but common physical examination findings are those secondary to metastatic involvement of lymph nodes and peritoneal membrane–namely, periumbilical lymph nodes (Sister Mary Joseph node), supraclavicular lymph node (Virchow node), anterior axillary lymph node (Irish node), and the peritoneal cul-de-sac (Blumer shelf). Two important but infrequent signs of gastric cancer are thrombophlebitis and microangiopathic hemolytic anemia. Other paraneoplastic syndromes that may be associated with gastric cancer include acanthosis nigricans, dermatomyositis, circinate erythemas, pemphigoid, and seborrheic keratoses. Clinical findings include anemia, weight loss, and abnormalities of electrolytes and liver enzymes. About 40% to 50% of gastric cancer cases have increased carcinoembryonic antigen (CEA), and 30% have elevated α-fetoprotein (AFP) or serum carbohydrate antigen 19-9 (CA19-9).

Diagnostic Evaluation

Upper gastrointestinal endoscopy is routinely performed as an initial procedure to identify suggestive lesions and has a diagnostic accuracy of 95%. Double-contrast barium swallow is only 75% accurate and should be used only when upper GI endoscopy is unavailable or patients are unable to tolerate the procedure. Although CT scanning is useful for assessing local extension, lymph node involvement, and the presence of metastasis, understaging is a major issue. EUS, a relatively new staging technique, can assess the depth of tumor invasion and perigastric regional nodes more accurately than CT and should be mandatory for those considered for surgical resection or neoadjuvant treatment [*see Figures 4a and b*].[79]

TREATMENT

Local Disease

Surgery Surgical resection with extended lymphadenectomy and negative surgical margins remains the only therapeutic modality capable of cure.[80] With the application of screening and the awareness of the high risk of gastric cancer in Japan's general population, many early-stage, noninvasive cancers are detected,[81] allowing for more complete surgical resection than is generally accomplished in Western countries.

The location and extent of the primary cancer dictate the type of surgical procedure. With distal lesions, subtotal gastrectomy is preferred over total gastrectomy if the fundus or GE junction is not involved, because the former provides comparable survival and lower morbidity. Proximal gastrectomy may be performed for tumors in the GE junction or the proximal third of the stomach, but this procedure is associated with increased postoperative morbidity and mortality. Total gastrectomy is more appropriate if tumor involvement is diffuse or if it arises in the body of the stomach and has extension to within 6 cm of the cardia. Transection of the distal esophagus and proximal duodenum with an omentectomy is required when a total gastrectomy is performed.

Complete (R0) resections along with depth of invasion and adequate nodal staging remain the most important prognostic factors, shown by the results of the National Cancer Data Base report that provides stage-stratified survival rates [*see Figure 5*]. Considerable controversy has surrounded the notion of what is defined as an adequate lymphadenectomy for the potentially curative treatment of gastric cancer. In a D1 dissection, only the perigastric lymph nodes of the stomach (N1 lymph node group: right and left cardia, lesser and greater curvature, and suprapyloric and infrapyloric lymph nodes) are removed. Extended D2 dissection involves more extensive N2 lymph node group resection (left gastric, common hepatic, splenic, and celiac axis artery lymph nodes). For patients with N2 lymph node

disease, complete resection of diseased tissue can be achieved only by D2 dissection.[82,83] This operation has become standard practice in Japan and other high-incidence countries because of the apparent improvement in disease-free and overall survival in nonrandomized comparisons; however, it has been difficult to separate the effect of stage migration from the therapeutic effects of lymphadenectomy. Controversy still exists over the benefit of D2 dissection because of the lack of evidence for improved survival as demonstrated in randomized, controlled trials.[84,85] Because of the excess morbidity and mortality associated with the D2 dissection, many surgeons now advocate the D1+ procedure, which entails extended lymphadenectomy but no splenectomy.

There is no standard postsurgical follow-up, but options include periodic clinic visits for liver function tests and radiologic imaging. Unlike colon cancer, for which a small but clinically important group of patients with metastatic disease can be cured with surgery, there is no effective salvage therapy for recurrent gastric cancer, limiting the effectiveness of routine surveillance. If subtotal gastrectomy is performed, periodic upper endoscopy is recommended to detect second primary tumors. Nutritional support, including vitamin B_{12} supplementation, should be delivered postsurgically.

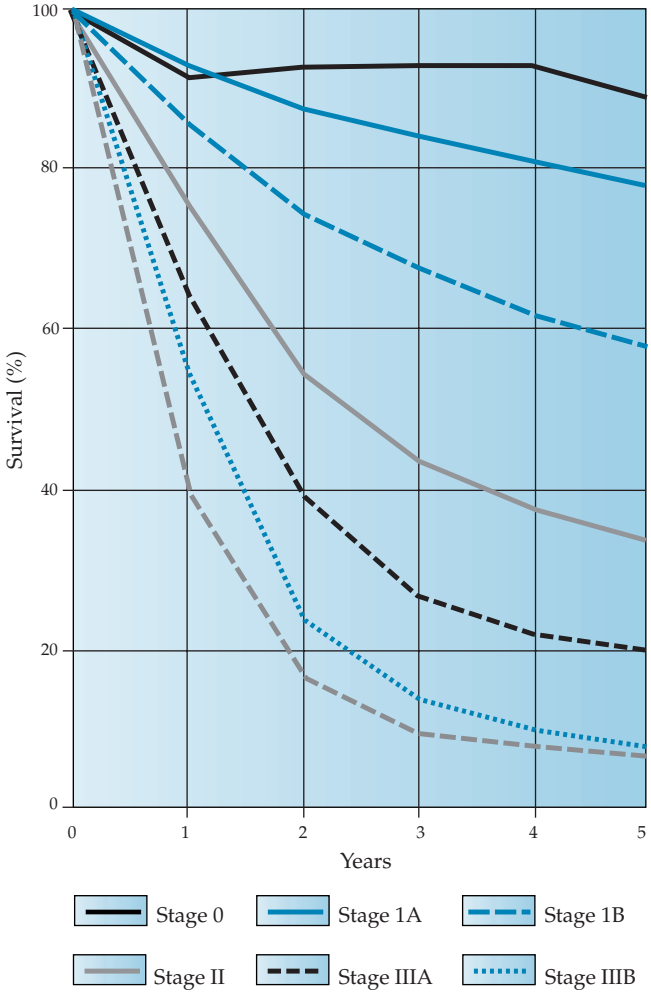

Figure 5 **Gastric cancer survival rate (years 1985 through 1996) after gastrectomy by stage.**

The 5-year survival rate after curative resection for gastric cancer is only about 40%. Treatment failure results from a combination of local or regional recurrence and distant metastases.

Surgery combined with other modalities Multidisciplinary approaches using postoperative (adjuvant) and preoperative (neoadjuvant) therapeutic principles have received increasing attention as strategies to increase the cure rate from surgery. Benefits of early studies involving chemotherapy or radiation alone as adjuvant treatment are not clear because of inadequate clinical trial design and the lack of effective regimens.[86-88] However, a survival benefit from adjuvant chemoradiation therapy in patients who had gastric cancer resection was demonstrated in a large, well-controlled prospective study in the United States.[45] Patients with complete resections were randomized to receive either surgery alone or surgery plus postoperative chemotherapy with 5-FU and leukovorin (LV) and concurrent radiotherapy.[45] Patients in the treatment group were treated over 6 to 7 months with regimens of chemotherapy (intravenous 5-FU and LV), followed by chemoradiation (4,500 cGy [fractions of 180 cGy/day] with 5-FU/LV), and more chemotherapy (5-FU/LV) after the chemoradiation treatment. Benefit in both disease-free survival and overall survival was evident in the treatment group (3-year disease-free survival of 49% versus 32%, and 3-year overall survival of 52% versus 41%, $P = 0.005$). The median duration of relapse-free survival was 30 months in the chemoradiation group and 19 months in the surgery-alone group ($P < 0.001$). This combination of adjuvant chemotherapy and chemoradiation is now considered the standard treatment in the United States. However, two important issues were identified in the study. One is the precision and accuracy of the radiation field, which is based on the result of locoregional patterns of recurrence of gastric cancer.[89] All radiation treatment plans were centrally prereviewed, and 35% were found to contain potential major or minor deviations (because of either potential critical-organ toxicity or failure to treat protocol-defined target volumes) requiring correction.

Another issue is the significance of nutrition for this population, in which chemoradiation might do harm without proper support. J-tube placement is encouraged for these patients before treatment. The results of this trial, therefore, can be generalized only if an experienced group of surgeons, radiation oncologists, and medical oncologists, together with nutritional support personnel, are involved in patient selection and treatment. This trial has also been criticized because few patients underwent D2 dissection, and the assumption has been made that the benefit from treatment was simply improvement in local-control outcome after inadequate surgery. Without a drastic change in surgical practice, postoperative treatment appears advisable; however, additional trials of chemoradiation are warranted in patients who have undergone D1+ or D2 dissections.

Preoperative chemoradiation therapy can reduce the size of the tumor, effectively downstaging gastric cancer (including pathologic complete response [pCR]) in some patients, to the extent that an initially unresectable cancer may be converted to resectable status.[90,91] Large phase III randomized trials are needed to further evaluate preoperative chemoradiation in terms of potential improvements in treatment tolerability, tumor resectability, and relapse or survival outcomes.

For patients with locally advanced unresectable gastric cancer, a combination of chemotherapy and radiotherapy is also the treatment of choice.

Metastatic Disease

When possible, all newly diagnosed patients with metastatic gastric cancer should be considered for clinical trials. Although many chemotherapy agents show activity in advanced gastric cancer, the overall benefit is still disappointing; on average, trials show a median survival of 8 to 9 months. Single agents include 5-FU, cisplatin, mitomycin, anthracyclines (doxorubicin and epirubicin), etoposide, and methotrexate. Combination treatments (e.g., cisplatin and 5-FU) may increase response rate but with only a modest impact on overall survival.[92,93] There are several new agents that have demonstrated activity in gastric cancer, including taxanes (paclitaxel and docetaxel), oxaliplatin, and irinotecan. The response rates for combinations of these new agents are 50% or higher in selected patients from phase II trials, but the confirmation that these regimens are superior to standard regimens (e.g., 5-FU and cisplatin) requires phase III evaluation.[94-96] Another treatment option available for highly selected patients with gastric cancer is intraoperative hyperthermic intraperitoneal chemotherapy.[97] Many novel target-oriented agents are currently under study for gastric cancer treatment.

Pancreatic Cancer

EPIDEMIOLOGY

Pancreatic cancer is the fourth leading cause of death from cancer in both males and females in the United States.[1] From 1930 to 1970, the incidence increased approximately twofold, to 10 cases per 100,000 men and 7.2 cases per 100,000 women, but the incidence has stabilized and even decreased modestly. The yearly incidence and mortality are roughly equivalent, indicating the lethal nature of this disease. In 2002, an estimated 30,300 persons in the United States and 200,000 persons worldwide were diagnosed with pancreatic cancer. Approximately 95% of pancreatic malignant tumors are exocrine pancreatic cancers, two thirds of which occur in the pancreatic head and one third in the pancreatic body and tail; the remaining 5% of malignant lesions are mostly islet cell tumors.

The mean age of patients at onset of pancreatic cancer is about 65 years; the disease is extremely unusual in patients younger than 30 years, and it rarely occurs before age of 50. The incidence of pancreatic cancer is higher in males than in females and is higher in blacks than in whites.[98] An association between diabetes and pancreatic cancer has been recognized; however, a causal relationship has not been fully elucidated.[99,100]

ETIOLOGY AND RISK FACTORS

Tobacco Smoking

Tobacco smoking has been the most consistently demonstrated risk factor, implicated as a cause in roughly 30% of cases of pancreatic cancer.[101-103] Most studies show a dose response, and the relative risk ranges from 1.5 in light smokers to 10 for two-pack-a-day smokers. Smoking remains the strongest risk factor amenable to preventive intervention.

Age

Age is also an extremely important determinant of risk. With increasing age, the risk of pancreatic cancer increases exponentially.[98]

Table 5 Familial Pancreatic Carcinoma[109]

Syndrome	*Affected Gene*	*Frequency (%)*
Familial pancreatic cancer	Unknown	< 1
Familial breast/ovarian cancer	*BRCA2*	5–7
Hereditary nonpolyposis colorectal cancer	MMR genes	< 3
