I ON BEING A PHYSICIAN

David C. Dale, m.d., f.a.c.p.
Daniel D. Federman, m.d., m.a.c.p.

Medical practice is constantly changing. Almost daily there is important new information regarding basic disease mechanisms and new therapies. There is a constant need to reconsider how we diagnose and treat both common and rare diseases. The way that hospitals and clinics are organized, how we pay for health care, and how our services are evaluated are also changing. The future promises more changes, some of which will undoubtedly increase the burden of illness and the work for physicians. Population growth, poverty, and emerging infectious diseases, as well as inactivity, dietary changes, and obesity, are worldwide problems that have immense medical implications. Other changes are coming rapidly that should improve health care and be helpful to physicians—new information technologies to aid in obtaining current medical information and record keeping, applications of discoveries from basic sciences and the human genome project to make diagnosis more precise and treatments more specific, and the development of new drugs and vaccines on the basis of increasing understanding of normal physiology and disease processes.

Although change is a watchword for medicine, many aspects of medicine are not changing rapidly; some of these are the most important and most satisfying aspects of being a physician. In the community and in the patient-doctor relationship, physicians are still seen as persons skilled in the art of healing and in teaching others about health and disease. Physicians are still the ones who receive the extensive training, the licensure by the state, and the approval of society to provide all levels of care: to give advice for a healthy life, to examine and diagnose illness, to prescribe drugs to relieve suffering, and to care for those who are seriously ill and dying. Although physicians now share the many responsibilities involved in patient care and work closely with nurses, physician assistants, pharmacists, technicians, therapists, and family members of patients, it is still the physician who bears most of the responsibility for the care of the patient.

Being a patient's physician carries many responsibilities and requires at least three attributes. First, knowledge of the applicable biomedical science and clinical medicine is necessary to understand a patient's problem. There is no limit to the knowledge that may be needed, but it is important to be able to answer correctly the patient's questions, such as "How did this happen to me?" and "Will I be better soon?" The physician needs to understand disease processes well enough to identify and categorize a patient's problem quickly. It is important, and sometimes critical, to know whether the problem will resolve spontaneously or whether detailed investigations, consultations, or hospitalization is needed. A thorough and up-to-date understanding of diagnosis and treatment is essential for the day-to-day exchange of information that occurs between physicians as they solve the problems of individual patients and work together to organize systems to improve patient care.

Second, some specific skills are necessary to diagnose and treat a patient. The ability to communicate—both to speak and to listen—is essential, especially for physicians providing primary care. Effective and sensitive communication can be challenging in communities characterized by diverse cultures and languages. At times, the physician must be, in part, an anthropologist to grasp the patient's understanding of illness and of the roles of patient and doctor. Knowing how to communicate empathically is also invaluable: It is important to welcome each patient at every visit, to reach out and hold the hand of a troubled person, and to express understanding and concern. The ability to balance the time spent with the patient and the time required for organizing services for the patient in a busy practice is an increasingly important skill.

The physical examination remains a fundamental skill; the ability to recognize the difference between normal and abnormal findings, adjusting for age, sex, ethnicity, and other factors, is crucial. Good record keeping is essential—with regard to both a written record and a mental record—so that the circumstances of visits are remembered and changes in a patient's appearance or other characteristics that may not have been recorded can be recognized. With practice and attention, these skills—history taking, physical examination, and record keeping—can grow throughout a professional lifetime. Other aspects of care, such as selecting and performing diagnostic tests, procedures, and treatments, require evolving expertise. For all physicians, it is necessary both to practice medicine and to study regularly to maintain all of these essential skills.

The third, but by no means least important, attribute is the physician's responsibility to the patient and the medical community to conform to appropriate professional and ethical conduct. The first principle of the doctor-patient relationship is that the patient's welfare is paramount. Putting the patient first necessitates understanding the patient and the patient's values. It often means spending precious personal time explaining illness, determining the best method of treatment, or dealing with emergencies. It places the physician in service to the patient. Ethical conduct includes seeing clearly and acknowledging situations in which the physician's interest may conflict with the interest of the patient. Ethical conduct also requires recognizing and acknowledging conflicts of interest in profiting from the prescribing of services and treatments, ownerships of equities and properties, and personal and business relationships. Finally, personal exploitation of the intimacy and privacy of the doctor-patient relationship is never allowed.

Thus, the work of the physician—recognizing illness, providing advice and comfort, relieving pain and suffering, and dealing with illness and death—has not changed much even since ancient times. On another level, however, the work has changed greatly. Better medical record keeping, quantitative observation, meticulous experimentation, and carefully conducted clinical trials have contributed to the rapid evolution of medical practice in this century. Simultaneously, medical education at the undergraduate, graduate, and postgraduate levels has been dedicated to the organization of a truly scientific knowledge base and its translation into intellectually cohesive approaches to understanding disease. Extraordinary advances in the biologic sciences, the development of medical and surgical specialties, and the explosion of medical information have brought with them great benefits. They have also added to the costs and the potential costs of almost every aspect of health care.

Efficiency and cost containment are now watchwords of the payers for health service. Practice guidelines, hospital care pathways, and other efforts to codify the practice of medicine are receiving much attention. When based on good evidence, these efforts are beneficial; they save precious resources—time and money—for both patients and physicians. The development of managed care in the United States has created a new challenge for physicians: to serve as advocates for their patients. In this role, physicians are responsible for overcoming organizational, geographic, and financial barriers to the provision of services that are important for their patients. In organizations in which guidelines for care have been established, it may be necessary for a physician to explain to administrators the specific needs and problems of individual patients—sometimes over and over again, because laypersons may be less apt to recognize that guidelines for clinical practice must remain just guidelines. Because more and more physicians are salaried and thus bound to the needs of populations of patients, physicians face the problem of balancing the needs of individual patients with the expectations of the employer. This is a delicate and, in some places, even fragile balance. To serve both patients and the employer well, a physician must develop good judgment in managing patient care under conditions in which the allocation of resources is conservative.

The increasing organization of health care on a for-profit basis has raised new issues. The physician's obligation to put the patient first, the thoroughness inculcated in physicians throughout their training, and the increasing costs of diagnostic tests and therapies can collide head-on with health care management's attempts to protect earnings for investors. Professional responsibility to patients and the public good is clear and at times poses difficult challenges for the physician.

A profession is defined by a specialized body of knowledge requiring advanced training and by the dedication of its practitioners to the public good over their own enrichment. In exchange, professionals are granted considerable autonomy in setting standards and in the conduct of their work. Circumstances within the medical profession have changed. The public in general and patients in particular have much more knowledge of medicine than at any time in the past, and the modern organization of medicine has severely restricted the autonomy of physicians. But delivery of expert medical care and the welfare of the patient remain central to the physician's professional responsibility. Maintaining professionalism as the ground moves under us is more important than ever.

The weight of all these responsibilities may suggest that it is impossible, or nearly impossible, to be a good physician. Quite the contrary, persons with vastly different personalities, interests, and intellects have become and are becoming good physicians and are deeply satisfied in this role. The information necessary for practicing medicine is now more accessible than ever before. The skills the physician needs can be learned through experience, sharpened through practice, and focused through specialization. The ethical requirements of physicians are not onerous. They are, in fact, expectations of all good citizens, regardless of their careers. Being a physician is both exciting and satisfying; it provides a unique opportunity to combine modern scientific knowledge with the traditions of an ancient and honored profession in serving and helping one's fellow man.

ACP Medicine is written and edited by physicians to help other physicians meet the ideals enunciated in this introduction. A principal goal of *ACP Medicine* is to be the most up-to-date textbook of medicine available. The section Clinical Essentials presents the contemporary skills and knowledge needed by all physicians to encourage and maintain good health, to analyze medical information, to deal compassionately with the end of life, and to understand issues of medical ethics. The other sections organize and summarize the most important information on pathophysiology, diagnosis, and treatment for most problems encountered in practicing medicine for adults from general and specialty journals, as interpreted by experienced clinicians. The material is evidence-based, with extensive bibliographic citations that are updated regularly. Authors are selected who understand both the constraints of managed care and the quality of care that is possible with scientific advances. In short, *ACP Medicine* is committed to conveying the information necessary for physicians to provide excellent care to their patients.

II CONTEMPORARY ETHICAL AND SOCIAL ISSUES IN MEDICINE

Christine K. Cassel, m.d., m.a.c.p.
Ruth B. Purtilo, ph.d.

In the past, medical ethics was thought to refer solely to proscriptions against physicians advertising their services and fees or engaging in questionable economic arrangements such as fee-splitting. Within the past 20 years, however, medical ethics has evolved into a discipline in which clinicians (physicians, nurses, and other health professionals), philosophers, theologians, and social scientists speak knowledgeably about value conflicts that arise in the practice of medicine.[1,2] Physicians have come to recognize the need to be knowledgeable about complex and wide-ranging moral issues as the result of advances in biomedical science and technology; changes in the delivery of health care; changing worldwide demographic trends; epidemics (e.g., the AIDS and severe acute respiratory syndrome epidemics) and new or reemerging infectious illnesses (e.g., avian influenza and Marburg viruses); and a growing understanding of the interconnectedness of individual and public health concerns. The AIDS pandemic has brought awareness that global health threats and cross-cultural contacts can present clinical, epidemiologic, and ethical challenges. For example, what responsibility does the international community have to provide assistance to severely underprivileged, impoverished countries experiencing an AIDS epidemic when treatment of the disease is readily available but out of reach of millions of people who suffer from its ravages?

Ethical issues in the clinical setting persist, and physicians need to be aware of legal decisions and new technologies that affect clinical practice. The rapid, continuing advances of medical technology have raised a host of moral issues around such fundamental questions as when does life begin, when and how does life end, which services can patients require of physicians, and which requests can physicians legitimately refuse. These questions become even more complex in a society as diverse and multicultural as our own, where moral norms may conflict. Respect for the personal values of our patients requires physicians to examine ethical dilemmas carefully and analytically. Consider the following ethical dilemmas and the questions that each one raises for physicians today:

- A 90-year-old woman, totally disabled from several strokes, lives at home, where she receives 24-hour care. Her strokes have left her cognitively impaired and unable to communicate. She signed a living will 15 years ago, and her husband is her designated health care proxy. She was hospitalized because she had stopped eating, and while in the hospital, she developed aspiration pneumonia. Four days into her hospitalization, she developed a bleeding ulcer and hemorrhaged several units of blood. She had a cardiac arrest, was resuscitated after 45 minutes of asystole, and is now unresponsive and ventilator dependent. Her husband insists that she be kept alive by whatever means possible. The hospital team is strongly divided about the morally appropriate course of action. Some agree with the patient's husband and argue that the patient should receive life-sustaining treatment, even though she has virtually no chance of recovery. Others argue that it would be more respectful to discontinue intrusive medical care—an action consistent with her advance directive—and allow her to die. What clinical and moral value considerations should govern their final decision?
- A 58-year-old man living in Oregon is suffering from end-stage AIDS with lymphopenia, multiple refractory fungal infections, and Kaposi sarcoma. He has significant pain from mucosal lesions and skin breakdown and has sustained fractures, including one from a spinal metastasis that has led to paraplegia and urinary and fecal incontinence. He is cognitively intact and has given oral and written directives indicating that he does not want to be kept alive any longer. He has repeatedly asked his physician to give him an overdose of sedative so that he will die and be released from his intractable suffering. The physician is convinced that this patient is competent, that he is well-informed about his condition, and that his wish to die is made in good faith. The patient's companion of 15 years agrees with the patient's decision. Both have known the physician for a long time and trust her judgment. Physician-assisted suicide is currently legal in Oregon. Should the physician comply with this patient's wishes? If she cannot do so in good conscience, must she refer her patient to a physician who can? Why or why not?
- Science allows physicians to transplant hearts, livers, kidneys, and other living organs, tissues, and cells. Overall, there are drastic shortages of donors. Hundreds, sometimes thousands, of people die each year before an organ match becomes available. Currently in the United States, people who wish to donate organs are encouraged to indicate that wish on their driver's licenses. In the absence of such clear evidence of consent, physicians and other hospital staff are often reluctant to ask bereaved family members for donations because many people, understandably, cannot deal with such a request in a time of crisis. Should the United States adopt a policy—already practiced in other countries—of allowing hospitals to harvest organs upon the death of a patient unless that person has specified otherwise? Could one policy ever work to everyone's benefit in a diverse society in which there may be differing attitudes about treatment of the dead, the moral use of animals, and other culturally derived considerations? Would therapeutic cloning or xenotransplantation provide ethically preferable alternatives?
- A woman whose family has a strong history of breast and ovarian cancer wants to be tested to determine whether she is a carrier of the *BRCA* family of genes, which confer high risk for these malignancies. She is between jobs and is about to apply for a position with a small, innovative firm that has a self-insured health care plan. She knows that the disclosure of this information would dramatically skew the insurance risk and insurance costs for this company, which is largely composed of young people who have relatively low health care costs. She might be denied the job for these reasons. The patient wants to undergo *BRCA* screening but asks you not to note the results in her medical record. You know that her fears are well founded. What should you do?

These examples highlight the complexity of ethical dilemmas and the need for a common language by which clinicians and society can openly deliberate about ethical issues. Often, there is not a single right answer to an ethical dilemma; in almost all cases, there are competing values that need to be weighed against each other before a decision is made that most fully upholds the moral values by which physicians must guide their practice. As in many other areas of medicine, there may be a high degree of uncertainty. For that reason alone, it is useful to have a framework for ethical decision making.

A Context and Process for Ethical Decision Making

A conflict of values lies at the center of each ethical dilemma. Most medical ethicists agree that several fundamental ethical norms can be drawn from the overarching principle that patients should be treated with respect. These ethical norms include the responsibility to act in a way that benefits the patient (beneficence); the responsibility, whenever possible, to do no harm (nonmaleficence); the responsibility to acknowledge the autonomy of the patient and his or her right to self-determination; and the responsibility to treat people fairly and equitably. Although it would be hard to argue against any of these values taken individually, they come into conflict with one another every day in medical practice. Three steps are useful for making decisions when ethical conflicts arise.

First, the clinician needs to gather all available relevant information regarding the patient. Inadequate information can result in decisions that do not reflect the interests and desires of the patient. However, the clinician must be aware that cultural differences and language barriers may limit a patient's understanding of the choices that need to be addressed.[3] Key information includes not only information about the medical condition of the patient but also information about the patient's values and preferences, the family and social situation, and the realities of the options open to the patient.

Second, ethical dilemmas must be clarified and presented clearly to all those involved in the decision-making process. For example, a spouse of an incompetent patient who argues for aggressive, clinically futile treatment in the face of an imminently terminal and untreatable illness can present the physician with a conflict between respecting the considered wishes of family members and doing what the physician judges is best for the patient.[4] Sometimes, enhanced communication between physician, patient, and family helps bring the matter to resolution.[5,6] For example, having a discussion with the family that is focused on the likelihood that aggressive measures would only prolong the suffering of the patient may convince them to end life-prolonging interventions. In other circumstances, however, the patient's and family's beliefs may necessitate that the physician take aggressive measures to preserve life at all costs.[7,8] It may be important to discuss the spiritual and moral dimensions of the impending decision explicitly. It is often helpful to involve other physicians or nonphysician mediators, such as the hospital ethicists, patient advocates, social workers, and clergy members, in the decision-making process.[9] Once values are explicitly discussed and differences clarified, a plan may be agreed upon by which all parties can abide.

Third, once a decision has been made, it is essential that the decision be carried out effectively, compassionately, and with continuing respect for the patient's needs and wishes. For example, if genetic testing is indicated and there are potential consequences regarding the patient's future eligibility for health insurance, the physician must ensure the confidentiality of information about the tests.[10,11] If complete confidentiality is not possible, the physician should be sure that the patient understands and accepts the risks.[12,13] Whatever the topic at hand, the physician must employ the clinical and interpersonal skills necessary to carry out the patient's wishes respectfully and compassionately.

Areas of Current Ethical Debate

Three broad societal concerns that have important implications for clinical practice lie at the center of many current ethical dilemmas.

DIFFERENCES OF OPINION ABOUT THE MORAL LIMITS OF MEDICAL INTERVENTION IN AN ERA OF TECHNOLOGICAL IMPERATIVES

Modern medicine has been criticized for generating an ethos in which clinicians assume that if an intervention is available, it should always be used. A physician might offer a new intervention as a way of either sustaining hope for the patient and family or avoiding the reality of a poor prognostic situation. In these circumstances, the chances of success can sometimes be overestimated. There are times when the better course is to help patients and families deal realistically with their losses. Physicians' ethics should allow them to consider each medical intervention in the light of their patient's values and wishes and with due regard for the appropriateness of the treatment in that particular setting.[14,15] Several questions frame the current debate about the appropriate use of medical technology—among them, questions as to when life begins and ends, what constitutes quality of life, and is it appropriate to withhold interventions in the face of medical futility.

THE ENIGMA OF WHAT CONSTITUTES A PERSON AND WHEN LIFE BEGINS AND ENDS

Physicians sometimes face extreme and unfamiliar situations in discharging their duty to respect a patient's autonomy. Current research in genetics, for example, challenges traditional assumptions of the uniqueness of individual identity and the acceptability of genetic interventions.[16] Germline interventions were considered completely ethically unacceptable just a few years ago because of the reluctance on the part of geneticists to create changes that would persist through subsequent generations. However, research has now progressed to the point of growing human stem cells under laboratory conditions, and stem cell research is thought to be one of the most promising new areas for clinical interventions.[17] Although the debate has become intensely political and national funding of stem cell research by the National Institutes of Health is strictly proscribed, many in the scientific community are actively supporting stem cell research and are taking steps to address some of the ethical concerns raised by the use of these cells. This shift has occurred in part because stem cell techniques do not create permanent germline changes. Scientific research is ongoing, especially in other countries[18]; in the United States, interest in the clinical promise of stem cell technology continues to grow. Legislators in California and Massachusetts have created and funded state-level research centers, and other states are considering whether to undertake similar initiatives.

Attempts to promulgate practice guidelines for governing the conduct of stem cell research engender extensive debate; such debate generates rich ethical discourse that addresses the very essence of personhood. Reproductive technologies, including the potential for cloning, have an impact on this issue and have spurred new questions about the ethics of medical intervention in human reproduction. The debate about abortion in the United States continues to encompass many points of controversy that directly affect the practice of medicine, sometimes violently.

At the other end of the continuum of care is the question of when life ends. This question is brought into sharp focus by dramatic life-extending technologies. For example, although rational criteria for brain death have served to guide organ transplantation, the extreme shortage of donor organs and evolving technological capabilities have prompted new ethical considerations regarding organ recovery. As utilization of organ donations from non–brain-dead but irreversibly comatose persons has become an increasingly common practice, commitment to clarifying and addressing the ethical dilemmas associated with the use of such donors remains warranted.[19,20] Finally, the debate about assisted suicide raises profound questions of quality of life and the limits of personal choice [*see 11:VII Anoxic, Metabolic, and Toxic Encephalopathies and 13:IV Care and Management of the Patient at the End of Life*].[21-24]

APPROPRIATE APPROACHES TO ASSESSING QUALITY OF LIFE

Discussions of quality of life gain broader clinical relevance as technical advances make it easier to extend life beyond a point where many people would consider it meaningful. When a patient or family member raises the issue, it is important for the physician to learn more about what that person means by "quality of life." Physicians, family members, and patients may disagree about what constitutes an acceptable quality of life. Often, the phrase is used in the context of how long clinicians should continue attempts to extend life. The ideal setting for gathering this key information is in an ongoing caregiving relationship that allows the patient time to think about the issues, discuss them with those close to him or her, and come back to the physician for a fuller discussion.[25] Unfortunately, this ideal relationship is becoming increasingly rare. Crucial decisions must often be made among relative strangers in times of great stress (for example, in an intensive care unit or when the patient is on the brink of having a cardiac arrest precipitated by critical illness).[26]

For that reason, physicians should try to open the door to these discussions with patients ahead of time whenever appropriate.[27] Increasingly frequent discussions of death and dying in the popular media have set the stage for patients and families to be receptive to such discussions and to be better informed about the facts and issues involved.

In general, questions related to acceptable quality of life should be answered by the patient.[28] Often, however, the patient is unable to speak for himself or herself when the answer is needed.[29,30] For example, patients with advanced dementia from Alzheimer disease or with irreversible coma cannot make these decisions, and few such patients have written detailed and specific advance directives. A proxy decision maker, usually a family member or a friend, should be asked about the patient's likely wishes in such a situation. It is crucial to emphasize to a proxy that it is the patient's values, not the proxy's, that should be conveyed in these situations. In addition to providing clear information about prognosis and likely outcomes, it is important for the clinician to recognize that a proxy is in a very difficult position—often in the midst of acute grief or anxiety—and should be provided a comforting context in which to make a decision. A proxy should not be made to feel that he or she is alone in making this decision, especially in the common situation in which the patient is likely to die in any case. Written advance directives—so-called living wills—can be helpful in this regard, mostly as adjuncts to discussions between patient and physician. Assigning a trusted proxy is still recommended, however, because situations are often more complex than can be adequately addressed in a written document.

Traditional Medical Ethics and the Changing World of Medicine

One of the reasons the medical profession has been able to maintain a strong ethical standard for more than 2,000 years is that the standard has been so simple. From the Hippocratic oath to the prayer of Moses Maimonides, statements of medical ethics have required the physician to do what is best for the patient, putting the patient's interest before the physician's own. Admittedly, there have been breaches of the standard. Many physicians became rich selling unproven patent medicines before the advent of scientific medicine. More recently, some have overcharged patients or have ordered unnecessary tests, medications, and procedures to further their own financial interests. Overtreatment can be as unethical as undertreatment, for two reasons: (1) all treatments carry some degree of risk to the patient and (2) rising health care costs contribute to the difficulty our nation faces in extending health care access to the uninsured and underinsured. Generating costs to enhance one's own income, with no benefit to the patient, adds to the barriers facing populations who are underserved by the health care system. Physicians have a responsibility for societal health, as well as the health of their individual patients.[31]

In the past, the accountability structure for health care was clearly delineated between physician and patient. Today, changes in the economics and delivery systems of managed care have so affected this classic ethical construct of undivided loyalty to the patient that even previously inviolable ethical relationships are being challenged.[32,33]

Managed care has been criticized for withholding care from patients, and physicians have been seen as the agents of rich insurance companies rather than as advocates for the best health care for their patients. Good managed care, however, allows physicians to limit risk to patients and reduce waste and cost. Physicians are challenged to examine whether their role in such managed care programs is truly in the patients' best interest; to do so could ameliorate the loss of public trust in the profession.[34] Studies by the Institute of Medicine and the RAND Corporation have spurred new approaches in the provision of quality care.[35,36] Physicians are being asked to measure the quality of their care and make this information available to payers, consumers, certifying/accrediting organizations, and others [*see CE:XIII Performance Measurement in Clinical Practice*]. Such measures are imperfect but will reveal to patients and others standards for ideal care. How should physicians respond to these new demands for transparency? Understanding the fundamental responsibility of the profession to the welfare of the patient is an important starting point for dealing with any ethical problems arising from social change, technological innova-

tion, and changes in the delivery and financing of health care. The Physician Charter on Medical Professionalism identifies a modern framework that may be used to clarify professional standards in this more complex world.[37,38]

POPULATION-BASED MEDICINE AND THE RIGHTS OF THE INDIVIDUAL

Although simple in the abstract, the physician's responsibility to the patient is not always clear in actual practice. For example, the traditional standard requires a physician to do everything possible for patients directly in his or her care. Arguing that a more utilitarian standard is needed, some theorists have suggested changes to meet the requirements of population-based medicine, in which some treatments that are potentially beneficial to the individual patient are forgone to benefit larger numbers of patients with the available resources.

Utilitarian considerations are sometimes discussed in the context of a communitarian philosophy, which holds that all members of the society are better off if standards are based on the benefit to communities rather than to individuals exclusively.[39] Many European governments base policies on communitarian premises, whereas in the United States, policy makers have traditionally focused more sharply on the rights of the individual. However, it may be that the rights of a far greater number of individuals would be better served with a health care structure that emphasizes more collective responsibility and resolution.

One area where this tension can be seen is in end-of-life care. In recent decades, there has been a presumption and a legal standard in the United States that patients may make their own decisions about the care they receive at the end of life and, in particular, that every person has the right to refuse life-sustaining treatment. This freedom of choice is the thrust of the Patient Self-Determination Act of 1990, which requires hospitals and nursing homes to inform patients of local laws regarding advance directives and to help them prepare advance directives if they choose to do so. In several well-publicized cases (e.g., the Quinlan, Cruzan, and Schiavo cases),[40,41] courts supported families or patients who wished to end life-sustaining treatment. However, attention is now being drawn to instances in which patients or their proxies ask for life-sustaining treatment over objections from health care payers and, sometimes, providers. In the relatively few cases in which such conflicts have been brought to litigation, courts, again, have been generally supportive of patients' and families' desires. Interestingly, these cases conflict with the recent judgments that financial incentives to restrict care are acceptable in the context of insurance law.

In recent years, some ethicists have worked to define a standard of medical futility that would give physicians the right to withhold treatment in specific cases.[42,43] There is profound disagreement, however, about the definition of futility and its statistical basis. For example, the chances of success with cardiopulmonary resuscitation (CPR) are remarkably small in patients of very advanced age who have debilitating illness and poor functional status, particularly in cases of an unwitnessed cardiac arrest; however, many physicians would be uncomfortable making the decision to withhold CPR without consulting the patient's family.[44] From one perspective, this inclination to involve and communicate with patient and family is a sound one, motivated by respect and caring.[45] In other cases, however, an insistence on family permission in the context of medical futility is a misguided gesture, perhaps driven by liability con-

cerns. Ethicists have asserted the physician's duty to regain the responsibility of prognostication and decision making inherent in the older paternalistic model of medical practice.[46,47] This belief can be supported by two arguments: (1) there is a responsibility to avoid wasteful use of scarce resources and (2) the attitude of caring means to avoid inflicting unrealistic choices on grieving families and to offer reassurances of aggressive palliative care and relief from suffering for patients who are dying.

Outside of the context of life and death, the allocation of medical resources is an area in which the tensions between wasteful expenditure and appropriate care are regularly played out. For example, the high cost of brand-name medications would lead a physician to prescribe equally effective generic agents whenever possible; however, direct-to-consumer advertising and drug detailing to physicians have created a demand for brand-name medications, even when there is no evidence that they are better than older formulations. On the basis of biomedical and clinical evidence, government agencies (e.g., the Centers for Medicare and Medicaid Services, the Veterans Administration, and certain state agencies) and health care plans have created formularies that determine the most cost-effective medications. These formularies are regularly used in the filling of prescriptions covered by health care payers. When these formularies are used, patients may not be given the brand of medication they request; however, they receive a formulation that is equally effective. The savings resulting from the adjustment in prescription allows health care plans to cover the health care costs of larger numbers of people. Patients who prefer the more expensive brand-name medication may have it if they pay for it. In these instances, does the physician's responsibility to avoid waste override the responsibility to respect the patient's values? The Physician Charter calls on physicians to reduce waste and improve quality. The achievement of this dual goal may require concerted effort to educate patients—and possibly policy makers—about the best uses of their health care resources.[31,37,38]

A BROADER CONTEXT FOR CLINICAL DECISION MAKING

The role of the physician and the nature of the doctor-patient relationship may be challenged, not only by changes in the practice of medicine but also by the increasing interconnectedness of communities and societies and the emergence of public health as a global concern. Regional and national health care systems are commonplace; epidemics can occur worldwide because of widespread international travel, immigration, and dislocation caused by war and civil strife.

The global, multicultural aspect of modern medicine will have increasingly significant implications for ethical decision making in clinical practice in coming years. For example, in seeking to honor a patient's right to autonomy, a physician may have to balance the traditional standard of care with a patient's desire to choose an alternative or complementary therapy; or following the traditional Hippocratic model, a physician may feel justified in using the most powerful antibiotic available to treat a patient's infection, despite the fact that the widespread use of powerful antibiotics leads to the emergence of new and more resistant organisms throughout the world.

Caring for patients in this new environment raises challenges for modern physicians that their predecessors never faced. Physicians must now analyze ethical issues systematically, understand the conflicts modern medicine poses for some traditional Hippocratic precepts, and come to terms with the conflict between their responsibility to their patients and the consequences of individual clinical decisions for the broader population. Even as electronic communication systems evolve to keep physicians abreast of new global realities, the moral and ethical framework of clinical decision making must begin to encompass those realities [*see Sidebar* Biomedical Ethics Information on the Internet]. It is critical that physicians learn the language of medical ethics and follow its literature closely so that their voices will help shape basic medical values in the future, even as they cope with complex ethical challenges in their daily practice.

III REDUCING RISK OF INJURY AND DISEASE

HAROLD C. SOX, JR., M.D.

Prevention: A Brief Overview

During the past 2 decades, disease and injury prevention has occupied an expanding share of medical practice. Public interest in prevention is very high, driven by a steady accumulation of high-quality evidence that preventive interventions do reduce cause-specific death rates. The purpose of these interventions is to eliminate the root causes of diseases that precede death (e.g., heart disease, cancer, and stroke), which in the United States in 1990 were tobacco use (400,000 deaths), poor diet and inadequate physical activity (300,000 deaths), alcohol consumption (100,000 deaths), microbial agents (90,000 deaths), toxic agents (60,000 deaths), firearms (35,000 deaths), unprotected sexual intercourse (30,000 deaths), motor vehicle accidents (25,000 deaths), and use of illicit drugs (20,000 deaths).[1] These causes of death are the targets of disease and injury prevention. They contribute to 50% of the deaths in the United States. Most are simply bad habits, and changing those habits reduces the risk of dying.

Physicians have two principal roles in prevention: they identify risk factors for disease and injury, and they act as teachers and counselors. Physicians must expand their routine questioning beyond diet, exercise, and substance abuse to include recreational activities that increase the risk of death (e.g., boating, bicycling, and riding motorcycles), gun ownership, use of swimming pools, smoke detectors in the home, and domestic violence. In counseling patients about a healthy diet (including vitamin supplements), exercise, and other elements of a healthy lifestyle, physicians must often help patients adopt healthy living habits. Some patients simply require reinforcement of a chosen lifestyle. Others need help in changing harmful habitual behaviors to healthy behaviors.

The report of the second United States Preventive Services Task Force (USPSTF)[2] contains evidence-based guidelines on 70 prevention topics [*see Table 1*]. As they become available, the third USPSTF reports will appear on its Web site (http://www.ahcpr.gov/clinic/cps3dix.htm). Other literature is also helpful [*see CE:IV Diet and Exercise, CE:V Adult Preventive Health Care, 7:XXXIII HIV and AIDS, 13:III Alcohol Abuse and Dependency, and 13:VI Drug Abuse and Addiction*].

CAVEATS IN DISEASE AND INJURY PREVENTION

Although disease and injury prevention can have a significant effect on the health of the public, physicians should observe several caveats. First, the baseline risk of most diseases is very low in the average person. Each year, colon cancer occurs in 165 per 100,000 men 60 to 64 years of age. The low baseline risk means that the number needed to screen or treat to prevent one death is often very high. Annual fecal occult blood testing must be performed on more than 300 people for 12 years to prevent one death from colon cancer. Whether this inefficiency is important depends partly on the cost of the intervention. Fecal occult blood testing can be costly because it must be performed annually and because abnormal results trigger costly diagnostic tests. Seat belts and smoke alarms are very cost-effective because they incur a onetime cost.

Second, disease prevention does not prevent death. At best, it postpones death by shifting the cause of death from the targeted disease to another disease that strikes later in life. In the Minnesota Colon Cancer Control Study, a randomized trial of fecal occult blood testing, annual testing reduced deaths from colon cancer during 18 years of surveillance. However, the total mortality was the same in the control group and the intervention groups. Our preventive efforts may reduce the likelihood of death from the target disease, whose identity and natural his-

Table 1 Recommendations of the United States Preventive Services Task Force[2]

Tobacco Use

Provide tobacco cessation counseling to patients who use tobacco products. Counsel pregnant women and parents about the potentially harmful effects of smoking on fetal and child health. Prescribe nicotine patches or gum to selected patients as an adjunct to counseling. Give antitobacco messages to young people as part of health promotion counseling.

Alcohol Abuse

Screen all adults and adolescents for problem drinking, using a careful history or a standardized screening questionnaire. Advise pregnant women to limit or abstain from drinking. Counsel all persons who use alcohol about the dangers of operating a motor vehicle or engaging in other potentially dangerous activities while drinking.

*Drug Abuse**

Although the evidence is insufficient for a strong recommendation to be made, it is reasonable to ask adolescents and adults about drug use and drug-related problems. All pregnant women should be advised of the potential adverse effects of drug use on fetal development. Refer drug-abusing patients to specialized treatment facilities where available.

Preventing Motor Vehicle Injuries†

Counsel all patients and the parents of young people to use occupant restraints (lab/shoulder safety belts and child safety seats), to wear helmets when riding motorcycles, and to refrain from driving while under the influence of alcohol or other drugs.

Preventing Falls‡

Counsel elderly patients on specific measures to reduce the risk of falls. Effective measures include exercise, balance training, environmental hazard reduction, and monitoring and adjusting medications. Provide multifactorial individualized interventions to elderly patients at especially high risk for falls.

Fires

Advise homeowners to install smoke detection devices and test them periodically. Infants and children should wear flame-resistant nightclothes. Smokers should cease or reduce smoking.

Drowning

Families with swimming pools should install four-sided 4-ft isolation fences with self-latching gates.

Firearm Injuries

Remove firearms from the home or store them unloaded in a locked compartment.

*There is insufficient evidence to recommend routine screening for drug abuse with standardized questionnaires or biologic assays.
†There is insufficient evidence to recommend for or against counseling patients to avoid pedestrian injuries.
‡There is insufficient evidence of effectiveness of external hip protectors.

tory we know. Inevitably, we raise the lifetime probability of dying from another disease.

Third, we know little about the age at which we should stop our efforts to prevent disease. Our studies provide good information on effectiveness in the study population, which is usually in middle age, but we do not know how the results apply to older people, whose care will occupy an increasing amount of the primary care physician's time.[3] Interventions that take years to show their impact may be ill suited to people whose life expectancy is measured in years rather than decades.

The decision to do a screening test on an older person should depend on the person's general health, which may be quantified as the person's physiologic age. The physician can determine a patient's physiologic age by asking the patient to rate his or her health as excellent, good, fair, or poor.[3] The most likely age at death is the sum of the patient's actual age and the life expectancy that corresponds to the patient's physiologic age. For example, a 75-year-old man in excellent health has a physiologic age of 67 years, which corresponds to a 14.7-year life expectancy [*see Figure 1*]. The most likely age at death is 75 years plus 14.7 years, or 90 years. This information can be very helpful in deciding how hard to press preventive efforts. With a life expectancy of almost 15 years, a 75-year-old man has plenty of time in which to experience gains from preventive efforts.

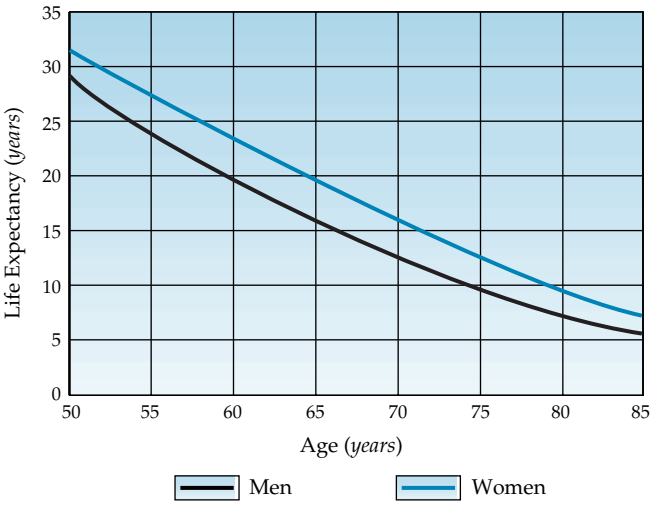

Figure 1 **Life expectancy of men and women in the United States.**

CHANGING BEHAVIOR

Many interventions of proven efficacy are not completely effective because patients are reluctant to change long-established risky behaviors. The USPSTF recommends the following steps for helping patients use their ability to change (self-efficacy)[4]:

1. Match teaching to the patient. Identify a patient's beliefs about a behavior, and adjust advice to the patient's lifestyle. Building the patient's confidence in his or her ability to change requires recognizable successes; define success in terms of goals the patient can achieve.
2. Tell why, what, and when. Patients need to know the reason for a recommendation and the results of following the recommendation. They must also know the time scale for the results so that they do not become discouraged when results do not occur immediately.
3. Small changes succeed. As the patient achieves small successes, propose larger but achievable goals.
4. Be specific. Couch suggestions in terms of current behavior, and give precise instructions in writing.
5. Add new behaviors. Adopting good habits is often easier than discarding bad ones.
6. Link positive behaviors with the daily routine. For example, patients can be encouraged to exercise before lunch or to take medication immediately after brushing teeth.
7. Do not mince words. Tell the patient directly, simply, and specifically what you want and why.
8. Extract promises. Get explicit commitments from the patient. Have the patient tell you exactly how he or she will achieve a goal. Assess the patient's self-confidence and address concerns about succeeding.
9. Use combination strategies. An approach that combines several strategies is more likely to succeed than a single strategy.
10. Involve others. Members of the physician's office staff can become educators. Anyone can offer encouragement to patients.
11. Refer. Subspecialists in many chronic diseases have trained teams that can educate patients far more effectively than individual physicians can. Another form of referral is sending novice patients to talk with successful patients.
12. Stay interested. According to research findings, a call from a health professional to inquire about progress is very effective in changing a behavior. A well-organized office will have a protocol for making these calls a matter of routine.

Health Risks from Substance Abuse

Substance abuse exacts a large toll on the health of the American people, accounting for at least 520,000 deaths in 1990, or 24% of all deaths.[1] Unfortunately, many physicians do not place diseases resulting from self-abuse in the same category as diseases that strike seemingly by chance. Two factors make helping patients shed their habitual use of tobacco, alcohol, and illicit drugs a very efficient way for physicians to add healthy years to patients' lives. First, there is a high baseline risk that substance abuse will lead to serious disease. Therefore, the absolute reduction in risk from a successful intervention is high. This principle is especially true of substance abuse during pregnancy. Second, substance abuse is primarily a problem of youth and middle age, so a successful intervention can add many years of healthy life.

TOBACCO USE

Tobacco contains an addictive drug, nicotine, as well as other substances that contribute to death from cardiovascular disease, cancer, and chronic lung disease. Smoking also contributes to 10% of infant deaths and 20% to 30% of low-birth-weight infants.[5] Tobacco use contributed to one in every five deaths in the United States in 1990 (420,000 deaths a year). In one 40-year cohort study of male physicians in the United Kingdom, half of the deaths after age 35 were smoking related, and smoking caused 25% of the residential fires that resulted in death.[5] Tobacco use is less common than it was several decades ago, but 25% of adults smoke, and an increasing number of smokers are women. Women are starting to smoke earlier—many as high-school students—and they are heavier smokers; nearly twice as many women smoked at least 25 cigarettes a day in 1985 as in 1965.[6]

Cigarettes are highly addictive. Fewer than 10% of people who quit smoking for a day are still abstinent 1 year later. Nicotine, like other highly addictive substances, acts on the dopaminergic mesolimbic pathway, the brain reward pathway that controls motivated behaviors [*see 13:VI Drug Abuse and Addiction*]. The use of nicotine is self-reinforcing, leading to compulsive use. Nicotine produces a withdrawal syndrome that begins within a few hours of abstinence, peaks within the first week, and continues for several weeks. The withdrawal syndrome includes dysphoria, insomnia, irritability, anxiety, difficulty in concentrating, restlessness, slowed heart rate, and increased appetite.[7]

Detection of cigarette smoking is easy; most smokers are truthful when asked about their habit and its extent, and the odor of tobacco is an additional diagnostic clue.

Smoking cessation reduces mortality dramatically. The risk of some diseases (e.g., myocardial infarction and stroke) declines rapidly within a few years after quitting [*see Table 2*].[8] This information is important when one is trying to convince long-term smokers to quit.

Research has shown that a strong message from a personal physician is the most important factor in successful quitting. The elements of successful quitting are consistent, repeated, and strong advice to stop smoking; setting a specific quit date; and follow-up visits to reinforce behavior [*see Table 3*]. However, not all physicians counsel smokers to quit. In one study, only 78% of cigarette smokers reported that their physician had advised them to quit.[9]

A current theory in behavioral psychology suggests that changes in behavior reflect predictable stages in the readiness to change, ranging from no intention to change, to definite plans to change in the near future, to active attempts at change. A stage of readiness to change is predictive of quitting,[10] and this behavioral model may help clinicians shape smoking-cessation efforts to the patient's state of mind.

School-based prevention has received extensive study, and it is effective for at least 2 to 4 years. Clinicians, especially those caring for adolescents, must reinforce the messages of school-based programs.

Nicotine products are an important adjunct to counseling.[11] Drugs are most reinforcing when the level in the brain rises very rapidly, as with inhaled nicotine. Nicotine in medication form, especially transdermal products, appears in the blood much more slowly than inhaled nicotine and produces much less of the reinforcing effect that leads to craving for cigarettes. Plasma nicotine concentrations after transdermal administration reach stable levels in 2 to 3 days. Nicotine medications reduce the symptoms of withdrawal, so that symptoms in the first week are reduced to the level of symptoms at 5 to 10 weeks. Nicotine medications may also provide some nicotine-like effects, such as helping patients to sustain concentration and deal with stress.

Nicotine medications improve abstinence rates, but abstinence at 1 year is still the exception. A meta-analysis summarized the results of 46 trials of nicotine gum and 20 trials of nicotine patches.[12] At 12 months, 19% of patients who received nicotine gum were abstinent, as compared with 11% of patients who did not receive gum. The number needed to treat to achieve one success at 1 year (NNT) was 17 ($P < 0.001$). Transdermal nicotine led to similar rates. At 12 months, 16% of patients who received a transdermal nicotine patch had quit smoking, as compared with 9% who did not receive the patch (NNT, 16). Clonidine also increases the rate of abstinence at 12 months. Weight gain is a common occurrence in patients who have stopped smoking. The average weight gain in a national sample of adults who had stopped smoking was 4.4 kg for men and 5.0 kg for women.[13]

Table 2 Years of Smoking Abstinence Needed to Reduce Risk of Disease[2,8]

Disease	*Years until Risk Is Half of a Current Smoker's Risk*	*Years until Risk Is Equal to a Never-smoker's Risk*
Recurrent myocardial infarction or death from coronary artery disease	1	15
Stroke	2–4	5–15
Oral and esophageal cancer	5	—
Lung cancer	10	20

The dose of nicotine medications should depend on the degree of nicotine dependence.[11] The score on the Fagerstrom questionnaire[14] and the number of cigarettes a day are measures of dependence. Follow-up calls at prearranged times will help the patient to maintain abstinence. It is best to designate a specific member of the physician's office staff to be the smoking-cessation coordinator.

The starting dose of nicotine gum (nicotine polacrilex) is 2 mg per two cigarettes; in patients who smoke more than 20 cigarettes a day, the dose should be 4 mg per three or four cigarettes. Patients may take additional unit doses if their withdrawal symptoms are unpleasant. The medication should be taken at regular intervals throughout the waking hours. The patient should compress the gum a few times with the teeth and then hold it in the mouth, repeating the cycle every minute or so for 15 to 30 minutes for each dose. After 1 to 2 months, weaning can begin with a reduction of 1 unit dose a week.

With transdermal nicotine, patients who smoke more than 10 cigarettes a day should use the largest patch (21 mg). After 1 to 2 months, weaning can begin with each of the lower doses (usually 14 mg and 7 mg, respectively), prescribed for 2 to 4 weeks. Patients who smoke fewer than 10 cigarettes a day can start with the 14 mg dose. A hairless site allows the best absorption. The patient should rotate sites to avoid skin irritation.

Nicotine medications are quite safe[11]—certainly safer than cigarette smoking—even for patients with cardiovascular disease. The only contraindication is hypersensitivity to nicotine or to a component of the delivery system. Twenty-four-hour application of transdermal medication can result in sleep distur-

Table 3 Elements of a Successful Smoking Cessation Strategy

- Direct, face-to-face advice and suggestions
- Reinforcement, especially in first 2 weeks
- Office reminders: a sticker on chart of smokers may stimulate physician to deliver antitobacco message at each visit
- Self-help materials
- Community programs for additional help
- Drug therapy

bance, which subsides if the medication is removed before sleep. Nicotine medication during pregnancy is of concern but probably of less concern than heavy smoking during pregnancy. Medication during pregnancy should be reserved for women who have failed to quit without medication and who smoke more than 10 to 15 cigarettes a day. Dependence on nicotine medications is most likely with delivery systems such as a nasal spray, which causes a rapid rise in the plasma nicotine concentration, and a small number of patients will still be using nicotine medication 1 year after starting treatment.

Nicotine therapy is not the only pharmacologic approach to smoking cessation. Another approach focuses on dopamine. Nicotine releases norepinephrine in the brain and increases dopamine in areas of the brain associated with reinforcing the effects of addictive substances, such as opioids. Bupropion potentiates the effect of norepinephrine and dopamine by acting as a weak inhibitor of their neuronal uptake. Thus, bupropion can mimic some of the central nervous system effects of nicotine and act as a substitute for nicotine in people who are trying to quit cigarettes. Randomized clinical trials have shown that abstinence rates are approximately twice as high with bupropion as with placebo.[15] In one trial, for example, the rates of abstinence from tobacco at 1 year were 12% for those taking placebo and 23% for those taking 150 or 300 mg of bupropion.[16] Side effects of bupropion include agitation and insomnia. Seizures are very uncommon when the daily dose of bupropion is 300 mg or less.

The recommended dose of bupropion is 150 mg/day for the first 3 days and then 150 mg twice daily. The patient should wait to stop smoking until he or she has been on bupropion for 1 week. There are no peer-reviewed reports comparing nicotine-replacement products with bupropion or detailing possible synergy between the two drugs.

ALCOHOL ABUSE

Habitual excessive alcohol consumption causes 100,000 deaths annually in the United States.[1] Although more than one million adults are under treatment for alcoholism, a far greater number engage in drinking that injures their health or has social consequences. The Institute of Medicine estimates that 20% of the population of the United States are problem drinkers, but only 5% are alcohol dependent.[17] Therefore, it is important to distinguish alcohol dependence from problem drinking. Alcohol dependence is associated with major withdrawal symptoms, tolerance, complete loss of self-control, and preoccupation with drinking. Problem drinking, on the other hand, is a less severe condition. Problem drinkers are younger, have a shorter drinking history, have fewer alcohol-related job problems, and have better social resources. In community surveys, the prevalence of problem drinking has been shown to be highest in young men (17% to 24% in 18- to 29-year-olds) and lowest in men and women older than 65 years (1% to 3% and less than 1%, respectively). Women are more frequently problem drinkers than alcohol dependent.

Problem drinking has consequences that affect others, such as motor vehicle accidents, fetal-alcohol syndrome, unsafe sex, domestic violence, and psychological damage to children of problem drinkers. Binge drinking, which is especially prevalent in young adults, leads to violence, unsafe sex, and drunk driving.

Screening for problem drinking and alcohol dependence can be time consuming, and most methods are inaccurate. The gold-standard test for alcoholism is the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria, which require a detailed interview and do not constitute a suitable screening instrument. Results of physical examination and laboratory tests are often normal in problem drinkers. Screening questionnaires such as the modified Michigan Alcoholism Screening Test (MAST), the Alcohol Use Disorders Identification Test (AUDIT), and the CAGE test are the most accurate instruments for detecting problem drinking[2] [*see Tables 4 and 5 and 13:III Alcohol Abuse and Dependency*]. The questions in the MAST and CAGE instruments focus on alcohol dependence and are much less sensitive or specific for binge drinking. The AUDIT screening instrument[2] may be more generally useful because it also asks about quantity of alcohol imbibed, frequency of drinking, and binge behavior. The CAGE and MAST questionnaires may also fail to detect a level of alcohol use that is dangerous during pregnancy.

The treatment of problem drinking depends on the severity of the problem. Problem drinkers often respond to brief office interventions (as short as 10 or 15 minutes), which use motivational techniques such as goal setting, contracts, and enhancing self-efficacy. In most instances, the goal is usually controlled moderate drinking rather than abstinence. The first step toward successful counseling is to get the patient to recognize that there is a problem. It is important to help the patient see a relationship between drinking and current medical or psychosocial problems. Strong advice to reduce consumption is also important. Regular follow-up visits to monitor progress are just as important for problem drinkers as they are for patients with high blood pressure.[18] One meta-analysis of brief intervention trials for nondependent problem drinkers showed a reduction of 24% in average alcohol consumption.[19] Another meta-analysis of nine studies showed somewhat smaller effects. In five of nine studies in men, the number of drinks a week decreased (range of decrease, five to 20 a week). The effects in women were smaller.[20] A third meta-analysis of nine randomized trials found that brief interventions

G: Have you ever felt bad or **G**uilty about your drinking?

E: Have you ever had a drink in the morning to steady your nerves or get rid of a hangover (**E**ye-opener)?

were associated with alcohol moderation 6 to 12 months later (pooled odds ratio, 1.91; 95% confidence interval = 1.61 to 2.27).[21] An excellent guide to managing problem drinking is available from the National Institute on Alcohol Abuse and Alcoholism (http://www.niaaa.nih.gov/publications/brochures.htm).

In contrast to the success of brief office-based interventions for problem drinking, successful treatment of alcohol dependence requires intensive therapy from specialists in substance abuse. A randomized trial of employees with alcohol dependence showed the importance of intervening intensively. Participants were randomly allocated to compulsory 3-week hospitalization followed by 1 year of attendance at Alcoholics Anonymous (AA) meetings, mandatory attendance at AA meetings at least three times a week, or a choice of treatment. Rates of being fired from work were similar in all groups, but rates for hospitalization for additional alcohol treatment were much lower in the mandatory-hospitalization group.[22]

The personal physician does have an important role to play in the management of patients with alcohol dependence. In addition to managing medical complications of alcoholism, physicians should be able to use adjunctive therapy for alcohol dependence, such as naltrexone. Another key role for the personal physician is encouragement. Patients need to know that the abstinence rate can be as high as 60% at 10 years after intensive treatment. Finally, the personal physician can lead efforts to help patients solve life problems that are contributing to alcohol dependence.

DRUG ABUSE

The abuse of illicit and legal drugs is a large problem in the United States. A 2001 household survey showed that use of illicit drugs within the previous month peaked among 18 to 20 year olds, at 22.4%, and declined steadily with increasing age. Casual use of marijuana accounts for most of these reports, but as many as 1.7 million Americans use cocaine weekly and 130,000 use heroin. The drug abuser is at risk for many medical complications, but the social cost of drug abuse far outweighs the personal costs. Illicit drug use plays a major role in spreading HIV infection and in homicide, suicide, and motor vehicle accidents. The health care costs of drug abuse are estimated to be $3.2 billion annually, and the cost of federal and state government efforts to stem the flow of illicit drugs is several times higher [*see 13:VI Drug Abuse and Addiction*].

Many professional organizations recommend that physicians ask about drug abuse as part of a periodic health examination of a well person. However, learning about drug abuse may be difficult in the office setting. Patients may be unwilling to acknowledge drug abuse until presented with incontrovertible evidence or after persistent questioning by an alerted physician. There is little information about the accuracy of the history or questionnaires in detecting drug abuse.

Toxicologic testing is the best way to detect illicit drug use. Compared with reference tests, current tests can detect drugs in the urine with 99% sensitivity. However, detection depends on when the patient supplies the specimen relative to the last drug exposure. Marijuana is detectable up to 14 days after use, whereas cocaine, opiates, amphetamines, and barbiturates are present for only 2 to 4 days after use.

Although physicians sometimes test for illicit drugs without obtaining the patient's consent, they do so in the context of trying to determine the cause of a clinical problem that could be caused by an illicit drug. Whether it is ethical to test for illicit drugs in an apparently healthy person who is at high risk for drug abuse is an open question. Regardless of the circumstances leading to testing, abnormal results deserve the physician's best efforts to maintain confidentiality, because they may affect the patient's employability, insurability, and personal relationships. At present, no professional organization recommends drug testing in apparently healthy people.

Physicians must learn to think of drug abuse as a chronic disease. Recidivism after intensive treatment programs is very common, no doubt in part because psychiatric disorders, unemployment, and homelessness often coexist with drug abuse. On the other hand, treating heroin abuse with maintenance methadone, an opioid agonist, can dramatically reduce the social effects of abusing the drug. Heroin addicts in methadone maintenance programs report less use of heroin and reduced rates of HIV infection, criminal behavior, and unemployment. There is no similarly effective treatment for cocaine addiction. Changes in the law now encourage methadone maintenance in office practice. Physicians who wish to treat their regular patients will need to learn about the new regulations.[23]

Health Risks from Accidents and Violence

A person's environment contains many threats to health: motor vehicle accidents, accidents in the home, recreation-related accidents, and domestic violence. Passive strategies, which change the environment in which accidents can occur, are generally more successful at accident prevention than active strategies, which require people to change their behavior. Improving roads saves more lives than exhorting people to drive carefully. For a fuller account, refer to the report of the USPSTF[2] and to a comprehensive review published in 1997.[24]

MOTOR VEHICLE INJURIES

Motor vehicle accidents are the leading cause of loss of potential years of life before age 65. Alcohol-related accidents account for 44% of all motor vehicle deaths. One can experience a motor vehicle accident as an occupant, as a pedestrian, or as a bicycle or motorcycle rider.

Injuries to Motor Vehicle Occupants

In 2000, 37,409 people died of injuries sustained in motor vehicle accidents in the United States.[25] The two greatest risk factors for death while one is driving a motor vehicle are driving while intoxicated and failing to use a seat belt. The physician's role is to identify patients with alcoholism [*see* Alcohol Abuse, *above*], to inquire about seat-belt use, and to counsel people to use seat belts and child car seats routinely. In one study, 53.5% of patients in a university internal medicine practice did not use seat belts. Problem drinking, physical inactivity, obesity, and low income were indicators of nonuse. The prevalence of nonuse was 91% in people with all four indicators and only

25% in those with no indicators.[25] Seat belts confer considerable protection, yet in one survey, only 3.9% of university clinic patients reported that a physician had counseled them about using seat belts.[25]

Three-point restraints reduce the risk of death or serious injury by 45%.[26] Air bags reduce the risk of death by an additional 6% in drivers using seat belts.[27] Because air bags reduce the risk of death by only 14% in unbelted drivers,[27] physicians must tell their patients not to rely on air bags.

Injuries to Motorcyclists

Motorcycle deaths in the United States have been rising since 1997, reaching 3,181 in 2001.[28] The chance of death per mile when one is riding a motorcycle is 35 times higher than when one is riding in an automobile. Most deaths are caused by head injuries. Helmets reduce the risk of a fatal head injury by 27%, but only 50% of riders use helmets. Laws mandating helmet use are quite effective; the rate of helmet use rose to 95% in California after passage of a law, and the rate of head injuries dropped by 34%. Substance abuse is very common among injured motorcyclists.

Physicians should inquire about motorcycle use. They should redouble their efforts to screen for substance abuse in motorcyclists and should recommend using helmets.

Injuries to Pedestrians

Pedestrian injuries caused by motor vehicles accounted for 4,739 deaths in 2000, a 27% decrease from 1990. Children are at greatest risk for injury. Among adults, the elderly are at greatest risk, principally because of sensory deficits, locomotor disability, and inability to process simultaneous stimuli.

Injuries to Cyclists

Each year, there are approximately 900 deaths from bicycle injuries in the United States.[29] Children are at greatest risk. Head injuries account for two thirds of hospitalizations and three quarters of deaths related to bicycling. A meta-analysis of case-control studies showed that use of safety helmets reduced the risk of head injuries by 63% to 88%.[29] Helmets are effective for all ages and provide protection even in collisions with motor vehicles. Community-based education efforts have raised the rate of helmet use to 50%. Physicians should ask about bicycle use and counsel riders to use safety helmets.

INJURIES FROM FALLING

Falling is a serious health risk for older persons [*see Table 6*]. The lifetime risk of hip fracture, perhaps the most important consequence of a fall, is 40% for a 50-year-old woman. One approach to reducing the risk of hip fracture is to prevent osteoporosis. Strategies for prevention of osteoporosis include vitamin D and supplementation of dietary calcium intake,[30] drugs that increase bone mass, such as etidronate and alendronate, and estrogen replacement after menopause. In a cohort study, weight-bearing exercise, such as walking, was associated with a 40% lower risk of hip fracture in women and a 50% lower risk in men.[31] Exercise works in part by increasing bone mass and in part by reducing the likelihood of a fall. Combined interventions that included home visits, modifying home hazards, and exercise and gait programs reduced the risk of falls by 31% in a randomized clinical trial.[32] Physicians should identify patients who are at greatest risk for falling [*see Table 6*], treat osteoporosis, and link the patient to community-based programs for improving mobility and reducing hazards in the home. Hip pads are also effective; in a randomized trial, a pad worn over each hip reduced the risk of hip fracture from 46 per 1,000 patient-years to 21.3 per 1,000 patient-years ($P = 0.008$).[33]

Table 6 Risk Factors for Falls among the Elderly[32]

Prior falls	Low body mass index
Cognitive impairment	Female sex
Chronic illness	General frailty
Balance and gait impairment	Hazards in the home

INJURIES FROM FIRE

Prevention of death from fires is an example of a successful passive strategy. Smoke detectors prevent fire injury. A study in Oklahoma City measured the effects of door-to-door distribution of smoke detectors to residents of an area that had much higher rates of burn injuries than the rest of the city. The fire-injury rate declined 80%, to the same level as that in the rest of the city. The injury rate per fire also declined dramatically.[34] Physicians should inquire about smoke detectors in the home and recommend them to people who don't have them. Persons who are alcohol dependent or who smoke in bed are at high risk and need special effort.

DROWNING

In most instances of witnessed drowning, bystanders report that the victim becomes motionless while swimming or simply fails to surface after a dive. Struggle is unusual. This observation raises the possibility that many cases of drowning occur when something such as a seizure, an arrhythmia, or an injury occurs.[35]

All victims of immersion have hypoxemia. Aspirated freshwater is hypotonic and therefore rapidly absorbed by the pulmonary circulation and distributed throughout the body water compartment. Freshwater alters pulmonary surfactant and causes alveolar collapse and atelectasis. Saltwater is hypertonic and draws water into the alveoli, causing perfused but poorly ventilated alveoli and hypovolemia with concentration of electrolytes. The end result with both types of water is venous admixture and hypoxemia, often resulting in metabolic acidosis. Saltwater drowning often leads to hypovolemia as well.

The main goal of treatment is to prevent brain injury.[35] The first step is to initiate cardiopulmonary resuscitation if the victim is apneic and pulseless. The American Heart Association recommends abdominal thrusts only to clear the airway in case of suspected foreign-body aspiration or failure to respond to artificial ventilation. Supplemental oxygen is indicated as long as the patient is hypoxemic. The most effective single treatment of hypoxemia is continuous positive airway pressure (CPAP), using mechanical ventilation to expand collapsed alveoli caused by freshwater immersion.[35] Hypothermia, which often accompanies near-drowning, can protect the brain from injury by reducing its metabolic requirements when the patient is hypoxemic.

Most efforts to prevent drowning focus on children, for whom the passive strategy of requiring fencing around swimming pools is associated with reduced drowning rates. In adults, alcohol ingestion is a risk factor for drowning. The efficacy of personal flotation devices is not known. Relatively few boaters (14%) wear personal flotation devices, but this rate is

similar to that of drowning victims. Physicians should ask patients whether they use boats recreationally and advise avoiding alcohol and using a personal flotation device while boating.

DOMESTIC VIOLENCE

For women especially, the home is the most dangerous place. In one large study of women in a primary care clinic, one in 20 had experienced domestic violence in the previous year, one in four had experienced it as adults, and one in three had experienced it in their lifetime.[36,37] A condition so prevalent in primary care practice demands the attention of the physician.

Among those abused in the previous year, approximately equal numbers had been abused once, two or three times, or four or more times. In this study, the definition of domestic violence was an affirmative answer to the question "Have you been hit, slapped, kicked, or otherwise physically hurt by someone?" or "Has anyone forced you to have sexual activities?" Generally, a husband, ex-husband, boyfriend, or relative is the abuser in domestic violence.

Most of the rapidly developing literature on domestic violence focuses on screening, diagnosis, and management, and there is little on preventing the first episode. Screening for domestic violence typically occurs in the office setting. Many authorities recommend that physicians routinely ask about domestic violence as part of the screening history.[37,38] Domestic violence occurs in homosexual relationships as well, so it is best to ask both men and women. Some physicians introduce the question by saying that they are now asking all their patients about domestic abuse, in view of the growing awareness of the problem. Then they ask, "At any time [or since I last saw you] has your husband [lover, partner, boyfriend] hit, kicked, threatened, or otherwise frightened you?" If the patient replies in the affirmative, the physician should gather more information, including the name of the abuser, and record it. Because many people are ashamed of their situation and their inability to break out of it, the physician should avoid any judgmental statements other than to confirm that what is being done to the patient is wrong.

In many cases, patients will not disclose an abusive relationship but their medical and social history contains clues to the true situation. Somatic symptoms that are particularly indicative (prevalence ratio > 2.5) of an abusive relationship include multiple symptoms (especially with no apparent physical cause), poor appetite, nightmares, eating binges, pain in the pelvic region, vaginal discharge, musculoskeletal injuries, and diarrhea.[36] Even more indicative are emotional symptoms such as high anxiety, severe depression, a high level of somatization, and low self-esteem; current or past use of street drugs; positive items on the CAGE questionnaire for alcohol abuse; a current or past drinking problem; a husband or partner who abuses alcohol or uses street drugs; a history of suicide attempt; and abuse as a child (prevalence ratio > 10.0 for all of these).[36,39] Pregnancy is often associated with an escalation of violence.

Some abused patients will disclose a history of abuse, but many will not. Therefore, during the physical examination, the physician should be alert to signs of injury. One expert states that a woman who presents with any injury should be considered a victim of domestic abuse until proved otherwise.[38] Trauma to the face, abdomen, breasts, or genitals is especially likely to be from domestic abuse, as are bilateral or multiple injuries, injuries in different stages of healing, and injuries that occurred well before the patient sought help. Injuries to the ulnar aspect of the elbows may occur as a woman raises her hands to protect herself during an assault.

Older persons are subject to several forms of abuse: self-neglect or caregiver neglect, emotional and psychological abuse, fiduciary exploitation, and physical abuse. Signs of elder abuse include bruising and other signs of trauma, malnutrition, volume depletion, and poor hygiene.

The physician should communicate concern and validate the patient's belief that domestic abuse is wrong. The physician should not only provide medical treatment of injuries but also talk with the patient about how to avoid serious injury during an assault, review the patient's options, and facilitate referral to community and other resources for abused partners [*see Sidebar* Domestic Violence Information on the Internet].

INJURIES FROM FIREARMS

The rate of death by firearms in the United States peaked at 39,595 in 1993, and it has since declined, reaching 28,663 in 2000.[40,41] Firearms accounted for 992 accidental deaths, 13,677 homicides, and 17,767 suicides in 1997. In two large communities, 58% of suicide victims used a firearm. Seventy percent of the suicides occurred at home. Firearms kill more teenagers than all natural causes of death combined. The Bureau of Alcohol, Tobacco and Firearms estimates that there are 192 million firearms in private hands. Firearms, often bought for protection in the home, are far more dangerous to the occupants than to an intruder. After controlling for other suicide risk factors, the odds of suicide are 1.9 times greater in homes in which there is at least one gun.[42,43] The odds of homicide are 2.2 times higher in homes in which there is a firearm.[44]

Physicians strongly support regulation of firearms and community efforts to restrict ownership.[45] Physicians also have a role to play in preventing injury from firearms.[46] They should inquire about firearms in the home and counsel owners about storing their firearms in a safe place. With the increased number of teenagers who own guns and commit homicide with guns, the need to educate parents is urgent. The American Academy of Pediatrics has developed an information kit for physicians to use in counseling parents and children. The kits, called Steps To Prevent Firearm Injury In The Home, are available without charge from the Brady Center to Prevent Gun Violence, 1225 Eye Street NW, Suite 1100, Washington, DC 20005, or they can be obtained on the Internet, at http://www.bradycenter.com/stop2/.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

IV DIET AND EXERCISE

Harvey B. Simon, m.d.

Many chronic diseases result from unhealthful eating and a sedentary lifestyle. Poor nutrition and inadequate exercise substantially increase the risk of such maladies as coronary artery disease, hypertension, stroke, diabetes, obesity, osteoporosis, and certain cancers and account for about 300,000 deaths in the United States each year.[1] Dietary factors also contribute to cholelithiasis, hemorrhoids, hernias, constipation, irritable bowel syndrome, and diverticulosis. A rigorous program that combines a low-fat, high-fiber diet with daily exercise can produce dramatic improvement in cardiovascular risk factors in as little as 3 weeks' time.[2]

Diet

In the 20th century, the average American diet shifted from one based on fresh, minimally processed vegetable foods to one based on animal products and highly refined, processed foods. As a result, Americans now consume far more calories, fat, cholesterol, refined sugar, animal protein, sodium, and alcohol and far less fiber and starch than is healthful.

In the United States, two out of every three adults are overweight (body mass index [BMI] of 25 to 30) or obese (BMI > 30), compared with fewer than one in four in the early 1960s.[3] The consequences include a substantial decrease in life expectancy and an increase in morbidity similar in magnitude to the burden imposed by smoking.[4]

Obesity is a complex, multifactorial disorder, but an element common to all cases is a positive energy balance in which more calories are consumed than expended. Excess calories are stored in body fat; each pound of adipose tissue contains 3,500 calories. Weight loss is accomplished only by achieving a negative energy balance.

ENERGY

Genetic, metabolic, and behavioral variables make it difficult to predict an individual's caloric requirements with precision. However, physicians can provide estimates: sedentary adults require about 30 cal/kg/day to maintain body weight; moderately active adults require 35 cal/kg/day; and very active adults require 40 cal/kg/day. On average, therefore, a 70 kg (154 lb) person can expect to maintain body weight by consuming 2,100 to 2,800 calories daily.

Although any source of dietary energy, including carbohydrate, protein, and alcohol, can be converted in the body to fatty acids and cholesterol, the caloric value of foods varies considerably; for example, fat provides 9 cal/g and alcohol provides 7 cal/g, but protein and carbohydrates each provide only 4 cal/g. Patients with excess body fat should be encouraged to shift from high-fat, calorie-dense foods to low-fat, less-caloric foods. Even in a well-balanced diet, it is important to control food-portion size, which has increased dramatically[5] in concert with the obesity epidemic in the United States. As an example, to lose 1 lb a week, patients must consume 500 fewer calories than they expend each day; in almost all cases, sustained weight loss requires both an energy-restricted diet and regular vigorous exercise.

FAT AND CHOLESTEROL

Structure

Most dietary lipids are triglycerides, in which three fatty acids are joined to one glycerol molecule. At the core of every fatty acid is a chain of carbon atoms with a methyl group at one end and a carboxyl group at the other [*see Figure 1*]. The biologic properties of fatty acids are determined by the presence or absence of double bonds between carbon atoms, the number and location of the double bonds, and the configuration of the molecules.

Most of the fatty acids in foods are composed of an even number of carbon atoms, generally in chains of 12 to 22 atoms. The number of double bonds between carbon atoms determines the saturation of fats. Fatty acids with no double bonds are fully saturated; they have no room for additional hydrogen atoms. Fatty acids with one double bond are monounsaturated, and those with two or more double bonds are polyunsaturated.

Fatty acids contain zero to six double bonds, where additional hydrogen atoms can be attached. The location of the double bonds is of great physiologic importance; an unsaturated fatty acid's group (i.e., omega-3, omega-6, or omega-9) is determined by the position of the double bond closest to the methyl group. In omega-3 fatty acids, for example, three carbon atoms lie between the methyl end of the chain and the first double bond.

Most of the fatty acids in natural foods are in the curved, or *cis*, configuration. When hydrogen is added back to unsaturated fats during food manufacturing, however, the molecules assume a straightened, or *trans*, configuration [*see Figure 1*].

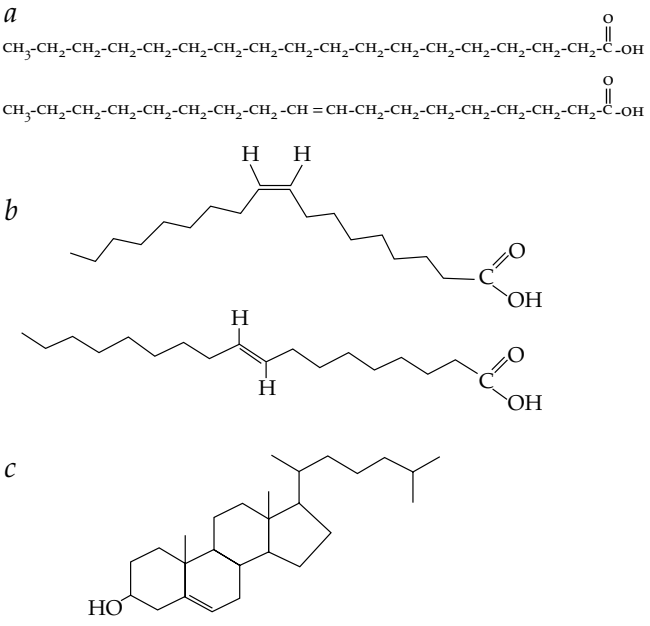

Figure 1 **The structure of fat and cholesterol is shown. (*a*) Stearic acid (top) is a saturated fatty acid. Oleic acid (bottom) is a monounsaturated omega-9 fatty acid. (*b*) Oleic acid (top) displays a *cis* double bond. Elaidic acid (bottom) displays a *trans* double bond. (*c*) Cholesterol has a structure similar to that of fatty acids.**

Cholesterol is a waxy, fatlike molecule that is present in the membranes of all animal cells but is absent from plant cells. Although cholesterol is a sterol rather than a true fat, its metabolism is intimately linked to the dietary intake of fatty acids.

Effects on Blood Lipids and Cardiovascular Risk

Although all fats have the same caloric value (9 cal/g), their effects on human health vary greatly, largely because of their disparate effects on blood cholesterol levels. Saturated fats stimulate hepatic cholesterol production, thus increasing blood cholesterol levels. Of the four saturated fatty acids that predominate in the American diet, myristic acid (14 carbons) has the most potent hypercholesterolemic effect, followed by palmitic acid (16 carbons) and lauric acid (12 carbons). Stearic acid (18 carbons) has little effect on blood cholesterol levels. Evidence strongly suggests that the degree to which saturated fat and cholesterol intake increase the risk of coronary artery disease depends on their effects on blood cholesterol concentration.[6]

Unsaturated fatty acids are generally derived from vegetable and marine sources; they are often called oils rather than fats because they are liquid at room temperature. When monounsaturated or polyunsaturated fatty acids are substituted for saturated fats, blood cholesterol levels fall. Neither type of unsaturated fat, however, has a direct ability to lower low-density lipoprotein (LDL) cholesterol or raise high-density lipoprotein (HDL) cholesterol levels. Although monounsaturated and polyunsaturated fats have a similar, generally neutral, effect on blood cholesterol levels, monounsaturated fats are less susceptible to oxidation and may therefore be less atherogenic. Omega-3 polyunsaturated fatty acids in particular have been shown to have a cardioprotective effect.

Consumption of omega-3 fatty acids is inversely related to the incidence of atherosclerosis and the risk of sudden death[7,8] and stroke.[9] In high doses, omega-3 fatty acids may reduce blood triglyceride levels, but in dietary amounts, they have little effect on blood lipids. Even in modest amounts, however, omega-3 fatty acids reduce platelet aggregation, impairing thrombogenesis. They may also have antiarrhythmic[10] and plaque-stabilizing properties.[11] Diets high in α-linolenic acid appear to reduce the risk of coronary artery diseases[12-14] and stroke.

Like saturated fats, *trans*-fatty acids increase blood LDL cholesterol levels; unlike saturated fats, *trans*-fatty acids reduce HDL cholesterol levels, making *trans*-fatty acids even more detrimental.[15] Diets high in *trans*-fatty acids have been associated with an increased risk of atherosclerosis and coronary events.

Dietary cholesterol increases blood LDL cholesterol levels but has a less potent hypercholesterolemic effect than saturated fat. Diets high in cholesterol are associated with an increased risk of coronary artery disease independent of their effects on blood cholesterol levels,[12] reinforcing the importance of reducing cholesterol intake.

Fat and Health

A high intake of saturated fat from animal sources appears to increase the risk of colon cancer[16] and prostate cancer[17] but not breast cancer.[18] However, some dietary fat is essential. For example, omega-3 and omega-6 fatty acids cannot be synthesized endogenously and therefore must be obtained from food. Dietary fat is required for the absorption of fat-soluble vitamins. Lipids are essential components of cell membranes and steroid hormones; adipose tissue is the body's major energy depot, and it provides insulation against heat loss. As little as 15 to 25 g of dietary fat a day can provide essential physiologic functions.

Table 1 Recommended Daily Intake of Fat and Other Nutrients*

Nutrient	*Recommended Intake*
Total fat	20%–35% of total calories
Saturated fat†	< 7% of total calories
Polyunsaturated fat	≤ 10% of total calories
Monounsaturated fat	≤ 20% of total calories
Cholesterol	< 300 mg/day 50%–60% of total calories
Carbohydrate††	≥ 25 g/day
Fiber	15% of total calories
Protein	—
Total calories§	Balance energy intake and expenditure to maintain desirable body weight and prevent weight gain

*See reference 24
†*Trans*-fatty acids, which raise low-density lipoprotein (LDL) and lower high-density lipoprotein (HDL) cholesterol, should also be kept at low levels.
††Carbohydrates should be derived predominantly from foods rich in complex carbohydrates, including grains, especially whole grains, fruits, and vegetables. Simple sugars should contribute no more than 25% of total calories.
§Daily energy expenditure should include at least moderate physical activity (consuming 200 kcal/day).

Dietary Recommendations

The American Heart Association (AHA) dietary guidelines[19] for healthy adults suggest that no more than 30% of calories should come from fat, with less than 10% coming from saturated fat and the remainder coming from unsaturated fat in vegetables, fish, legumes, and nuts. The AHA guidelines also specify consumption of less than 300 mg of cholesterol a day. Patients with atherosclerosis or diabetes and persons who are hyperlipidemic or obese should follow more stringent limits, such as a saturated-fat intake of no more than 7% of daily calories, with a corresponding decrease in cholesterol consumption to less than 200 mg a day. In some persons, very low fat diets providing 15% to 22% of calories from fat can reduce blood HDL levels and produce other adverse effects,[20,21] but in carefully monitored high-risk persons, diets with about 10% fat and virtually no cholesterol have been beneficial.[22] Although reductions in total fat intake can help reduce body fat and serum cholesterol levels, the risk of coronary artery disease may depend more on the type of fat in the diet; saturated fats and *trans*-fatty acids are the most atherogenic, whereas monounsaturated and omega-3 fatty acids are the most desirable [*see Table 1*].[7,12-15,23,24]

Food labels list the fat, saturated fat, and cholesterol contents of packaged foods. They will soon be required to list *trans*-fatty acids; until then, patients should be advised to check the ingredients list at the bottom of the label for the presence of partially hydrogenated vegetable oils.

CARBOHYDRATES

Carbohydrates are a vital source of energy for metabolic processes. They are also vital constituents of nucleic acids, glycoproteins, and cell membranes.

Plants are the principal dietary sources of carbohydrates. The only important carbohydrates that originate from animal sourc-

Table 2 Types of Dietary Fiber and Representative Food Sources

Fiber Type	*Food Sources*
Gums*	Oats, beans, legumes, guar
Pectin*	Apples, citrus fruits, soybeans, cauliflower, squash, cabbage, carrots, green beans, potatoes
Mucilage*	Psyllium
Hemicellulose*†	Barley, wheat bran and whole grains, brussels sprouts, beet roots
Lignin†	Green beans, strawberries, peaches, pears, radishes
Cellulose†	Root vegetables, cabbage, wheat and corn, peas, beans, broccoli, peppers, apples

*Soluble fiber †Insoluble fiber

es are the lactose in milk and the glycogen in muscle and liver. Carbohydrate-rich foods contain varying amounts of simple and complex carbohydrates. Simple carbohydrates include monosaccharides such as glucose, fructose, and galactose and disaccharides such as sucrose (table sugar), maltose, and lactose. Complex carbohydrates include polysaccharides (e.g., starch and glycogen that can be digested into sugars by intestinal enzymes) and fiber (i.e., high-molecular-weight carbohydrates that cannot be split into sugars by human intestinal enzymes). Sugars, starches, and glycogen provide 4 cal/g; because fiber is indigestible, it has no caloric value.

Carbohydrates contribute about 50% of the calories in the average American diet—half from sugar and half from complex carbohydrates. Because sugars are more rapidly absorbed, they have a higher glycemic index than starches. In addition to provoking higher insulin levels, carbohydrates with a high glycemic index appear to reduce HDL cholesterol levels and may increase the risk of coronary artery disease.[25] Processed foods containing simple sugars are often calorie dense, whereas foods that are rich in complex carbohydrates provide vitamins, trace minerals, and other valuable nutrients. A healthful diet should provide 55% to 65% of calories from complex carbohydrates found in fresh fruits and vegetables, legumes, and whole grains.[19,23]

DIETARY FIBER

Dietary fiber is a heterogeneous mix of very long chain branched carbohydrates that resist digestion by human intestinal enzymes because of the ways their monosaccharide components are linked to one another. Fiber is found only in plants, particularly in the bran of whole grains, in the stems and leaves of vegetables, and in fruits, seeds, and nuts. The two general categories of dietary fiber are soluble and insoluble.

Soluble fiber delays gastric emptying, which produces a sensation of satiety, and slows the absorption of digestible carbohydrates, which reduces insulin levels. Soluble fiber also lowers blood cholesterol levels, probably by inhibiting bile acid and nutrient absorption in the small intestine and by promoting bile acid sequestration by colonic bacteria.[26] Because soluble fiber is metabolized by these bacteria, it has little effect on fecal bulk. In contrast, insoluble fiber increases the water content and bulk of feces and shortens intestinal transit time [*see Table 2*].

Diets that are high in fiber also tend to be low in fat. Such diets have been associated with a reduced risk of intestinal disorders, including constipation, irritable bowel syndrome, cholelithiasis, hemorrhoids, and diverticulosis. Although earlier data are mixed, new studies suggest that a high intake of fiber can substantially reduce the risk of colorectal cancer.[27,28] In addition, a dietary pattern that includes a high intake of fruits, vegetables, legumes, fish, poultry, and whole grains but little red meat, processed meats, sweets, and refined grains appears protective.[29,30] A high intake of fiber is associated with a reduced risk of diabetes and, in patients with diabetes,[31] improved glycemic control and decreased blood lipids[32]; it is also associated with a reduced risk of obesity[33] and coronary artery disease[34,35] and a lower all-cause mortality. A healthful diet should contain at least 25 to 30 g of fiber a day, including substantial amounts of soluble fiber.

PROTEINS

Unlike reserves of fat (which is stored in large amounts as triglyceride in adipose tissue) and reserves of carbohydrate (which is stored in small amounts as glycogen in liver and muscle), there are no endogenous reserves of amino acids or protein; all the proteins in the body are serving a structural or metabolic function. As a result, bodily function can be impaired if proteins are catabolized because of energy deficiency, wasting diseases, or dietary protein intake that is not sufficient to replace protein losses.

All proteins in human cells are continuously catabolized and resynthesized. In a healthy 70 kg adult, about 280 g of protein is degraded and replaced daily. In addition, about 30 g of protein is lost externally through the urine (urea), feces, and skin.

In healthy adults, daily protein losses can be fully replaced by as little as 0.4 g/kg. Because not all dietary proteins are fully digestible, the recommended dietary allowance (RDA) of protein for healthy adults is 0.8 g/kg. People who exercise strenuously on a regular basis may benefit from extra protein to maintain muscle mass; a daily intake of about 1 g/kg has been recommended for athletes. Women who are pregnant or lactating require up to 30 g/day in addition to their basal requirements. To support growth, children should consume 2 g/kg/day.

A healthful diet should provide 10% to 15% of its calories from protein.[19] For healthy, nonpregnant women, an intake of 44 to 50 g/day of protein is required, and for men, an intake of 45 to 63 g/day of protein is needed. Although excessive protein intake has not been proved to be harmful, there are several potential disadvantages to a very high protein intake. The protein in foods derived from animals is often accompanied by large amounts of fat. In the body, excessive protein can be transaminated to carbohydrate, adding to the energy surplus responsible for obesity. When excess protein is eliminated from the body as urinary nitrogen, it is often accompanied by increased urinary calcium, perhaps increasing the risk of nephrolithiasis and osteoporosis. Because nitrogen is excreted in the urine, an increased protein intake is associated with an increase in renal plasma flow and glomerular filtration rates and, eventually, with increased renal size. In some animal models, increased dietary protein is associated with accelerated renal aging; and in humans with kidney disease, high dietary protein intake is associated with more rapid disease progression.[36] On the other hand, high dietary protein intake appears linked to somewhat reduced blood pressure readings,[37] possibly because of increased urinary sodium losses, and protein supplements may be beneficial for patients with acute or chronic illnesses.[38]

The thousands of proteins in the human body are synthesized from just 21 amino acids. Most amino acids can be synthe-

Table 3 The Vitamins

Vitamin	*Functions*	*Deficiency Effects*	*Toxic Effects*	*Sources*	*RDA for Adults*
A (retinol, retinoic acid)	Vision, epithelial integrity; possible protection against epithelial cancers and atherosclerosis	Night blindness; increased susceptibility to infection	Teratogenicity, hepatotoxicity, cerebral edema, desquamation; yellowish skin discoloration by carotenoids	Liver, dairy products, eggs; dark-green and yellow-orange vegetables (carotenoids)	Men, 5,000 IU or 1,000 RE; women, 4,000 IU or 800 RE
B_1 (thiamine)	Metabolism of carbohydrates, alcohol, and branched-chain amino acids	Beriberi, Wernicke-Korsakoff syndrome	None	Grains, legumes, nuts, poultry, meat	Men 19–50 yr: 1.5 mg; men > 50 yr: 1.2 mg; women 19–50 yr: 1.1 mg; women > 50 yr: 1.0 mg
B_2 (riboflavin)	Cellular oxidation-reduction reactions	Stomatitis, dermatitis, anemia	None	Grains, dairy products, meat, eggs, dark-green vegetables	Men 19–50 yr: 1.7 mg; men > 50 yr: 1.4 mg; women 19–50 yr: 1.3 mg; women > 50 yr: 1.2 mg
B_3 (niacin, nicotinic acid)	Oxidative metabolism; reduces LDL cholesterol; increases HDL cholesterol	Pellagra	Flushing, headaches, pruritus, hyperglycemia, hyperuricemia, hepatotoxicity	Meat, poultry, fish, grains, peanuts; synthesized from tryptophan in foods	Men 19–50 yr: 19 mg; men > 50 yr: 15 mg; women 19–50 yr: 15 mg; women > 50 yr: 13 mg
B_6 (pyridoxine)	Amino acid metabolism and heme synthesis; neuronal excitability; reduces blood homocysteine levels	Anemia, cheilosis, dermatitis	Neurotoxicity	Meat, poultry, fish, grains, soybeans, bananas, nuts	2 mg
B_{12} (cobalamin)	DNA synthesis (with folate); myelin synthesis (without folate); reduces blood homocysteine levels	Megaloblastic anemia, neuropathies	None	Meat (especially liver), poultry, fish, dairy products	2–4 μg
Folic acid	DNA synthesis (with B_{12}); reduces blood homocysteine levels	Megaloblastic anemia, birth defects	None	Vegetables, legumes, grains, fruit, poultry, meat	400 μg
Biotin	Metabolic processes	Rare	None	Many foods	30–100 μg
Pantothenic acid	Metabolic processes	Rare	None	Many foods	4–7 mg
C (ascorbic acid)	Collagen synthesis; possible protection against certain neoplasms	Scurvy	Nephrolithiasis, diarrhea	Fruits, green vegetables, potatoes, cereals	Men, 90 mg; women, 75 mg
D (calciferol)	Intestinal calcium absorption	Osteomalacia and rickets	Hypercalcemia	Fortified dairy products, fatty fish, egg yolks, liver	< 50 yr, 200 IU; 50–70 yr, 400 IU; > 70 yr, 600 IU
E (α-tocopherol)	Reduces peroxidation of fatty acids: possible protection against atherosclerosis	Rare	Antagonism of vitamin K, possible headaches	Vegetable oils, wheat germ, nuts, broccoli	15 mg
K	Synthesis of clotting factors VII, IX, X, and possibly V	Hemorrhagic diathesis	None	Leafy green vegetables (K_1), intestinal bacteria (K_2)	Men, 120 μg; women, 90 μg

HDL—high-density lipoprotein IU—international units LDL—low-density lipoprotein RDA—recommended dietary allowance RE—retinol equivalents

sized endogenously, but nine cannot. Not all dietary proteins contain all nine essential amino acids; in particular, vegetable proteins may be incomplete. However, by eating a varied diet with foods that contain a mix of proteins, even strict vegetarians can obtain all the amino acids they need.

VITAMIN AND MINERAL CONSUMPTION

Vitamins

Vitamins are either fat soluble or water soluble. Vitamins A, D, E, and K are fat soluble. They are found in fatty foods and are absorbed, transported, and stored with fat. Because excretion is minimal and storage in fat is abundant, deficiencies of fat-soluble vitamins are rare, but toxic amounts can accumulate if intake is excessive. Vitamin C and the B-complex group are water soluble; they are absorbed in the intestine, bound to transport proteins, and excreted in the urine. Because storage is minimal, water-soluble vitamins should be ingested regularly, and except for large doses of B_3 and B_6, toxicity is rare [*see Table 3*].

Although there is great disparity between popular beliefs about vitamins and their known physiologic effects, new medical information may narrow the gap. First, it is becoming clear that many persons in the United States, particularly the elderly and the poor, do not consume adequate amounts of vitamin-rich foods. Second, laboratory and animal experiments demonstrate that antioxidant vitamins can retard atherogenesis and suggest that antioxidants may lower the risk of carcinogenesis. Indeed, many epidemiologic and observational studies have demonstrated an association between a low dietary intake or low plasma levels of antioxidants and an increased risk of ath-

erosclerosis and certain cancers. Similarly, studies have linked low levels of folic acid, vitamin B_6, and vitamin B_{12} with elevated blood homocysteine levels and increased cardiovascular risks.[39] People who consume multivitamins appear to have a reduced risk of coronary artery disease[40] and colon cancer[41]; protection may be attributed principally to folic acid. However, with the exception of the Cambridge Heart Antioxidant Study, which demonstrated the efficacy of vitamin E in reducing the risk of myocardial infarction in patients with coronary artery disease, randomized trials have not demonstrated benefit from vitamin supplements.[42] Moreover, β-carotene supplements actually appear to increase the risk of lung cancer in smokers,[43] and hypervitaminosis A is linked to an increased risk of fractures.[44] It is clear that additional studies are required to clarify the impact of vitamins on health.

Women of childbearing age, the elderly, and people with suboptimal nutrition should take a single multivitamin tablet daily; others may benefit as well.[45] Strict vegetarians should take vitamin B_{12} in the recommended daily amount (2–4 μg); because many people older than 60 years have atrophic gastritis and cannot absorb B_{12} bound to food protein, they may also benefit from supplementary B_{12}. Multivitamin supplements may also be necessary to avert vitamin D deficiencies, particularly in the elderly.[46] A supplement that combines antioxidants with zinc can slow the progression of age-related macular degeneration.[47] Use of so-called megadose vitamins should be discouraged. Expensive brand-name and so-called all-natural preparations are no more effective than reputable generic preparations. In any case, vitamin supplements should never be used as a substitute for a balanced healthful diet that provides abundant amounts of vitamin-rich foods.

Minerals

Although minerals are chemically the simplest of nutrients, their roles in metabolism and health are complex. At least 16 minerals are essential for health [*see Table 4*]; 10 are classified as trace elements because only small amounts are required. Other minerals, such as boron, nickel, vanadium, and silicon, have been shown to be essential in various animal studies but have not been found to be necessary for humans. Many persons in the United States consume too little of some minerals (e.g., calcium and iron) or too much of others (e.g., sodium).

Table 4 Essential Minerals and Trace Elements

Minerals and Elements	*RDA/ESADDI for Healthy Individuals*
Macrominerals	
Calcium	1,000 mg before age 50; 1,200 mg after age 50
Phosphorus	800 mg
Magnesium	Men, 350 mg; women, 280 mg
Sodium	1,100–3,300 mg
Potassium	1,875–5,625 mg
Chloride	1,700–5,100 mg
Trace elements	
Iron	Men and postmenopausal women, 8 mg; premenopausal women, 18 mg; pregnant women, 27 mg
Zinc	Men, 15 mg; women, 12 mg
Iodine	150 μg
Copper	1.5–3.0 mg
Manganese	2–5 mg
Fluoride	1.5–4.0 mg
Chromium	Men, 35 μg; women, 25 μg
Molybdenum	75–250 μg
Selenium	55 μg
Cobalt	Required in small amount as a component of vitamin B_{12}

ESADDI—estimated safe and adequate daily dietary intake RDA—recommended dietary allowance

Sodium The body can conserve sodium so effectively that only small amounts are required in the diet. The Food and Nutrition Board of the National Academy of Science estimates that an intake of no more than 500 mg of sodium a day is needed for health; the average American diet contains more than 4,000 mg a day.

Population studies have demonstrated conclusively that a high sodium intake increases blood pressure, especially in older people.[48] The Dietary Approaches to Stop Hypertension (DASH) trial demonstrated that reduction of sodium intake from high amounts to moderate amounts will result in lower blood pressures and that further reductions in sodium intake will produce additional benefits.[49] When combined with other elements of the DASH diet (increased consumption of fruits, vegetables, whole grains, and low-fat dairy products, along with decreased consumption of saturated fat and sugar), sodium restriction can lower systolic blood pressure by an average of 7.1 mm Hg in normotensive persons and 11.5 mm Hg in patients with hypertension. Hence, reductions in dietary sodium could substantially reduce the risk of stroke and coronary artery disease. A high sodium intake also increases urinary calcium excretion, which increases the risk of osteoporosis.

There is no RDA for sodium, and additional controlled clinical trials will be needed to provide conclusive evidence that sodium restriction is beneficial to normotensive persons. Pending such information, the AHA recommends that daily consumption of sodium not exceed 2,400 mg,[19] and the National Academy of Science proposes a 2,000 mg maximum. Patients with illnesses such as hypertension, congestive heart failure, cirrhosis, and nephrotic syndrome may benefit from substantially lower sodium intakes.

About 80% of dietary sodium comes from processed foods. Physicians should review these hidden sources of salt with patients who would benefit from sodium restriction.

Calcium A high intake of calcium, either from dairy products or supplements,[50] improves bone density. Dietary calcium intake is inversely related to blood pressure[51] and to the risk of stroke[51,52]; however, calcium supplements produce only small reductions in systolic blood pressure.[53] Calcium supplements appear to reduce the risk of colorectal adenomas[54] but may increase the risk of prostate cancer.[55,56]

At present, fewer than 50% of persons in the United States consume the RDA of calcium [*see Table 4*]. Persons who do not consume enough calcium from foods should consider a supplement such as calcium carbonate or calcium citrate. High-calcium diets do not increase the risk of nephrolithiasis,[57] but prolonged overdoses of supplements may produce hypercalcemia (milk-alkali syndrome) or nephrolithiasis.

Iron Iron deficiency is the most common cause of anemia. In the United States, 9% to 11% of women of childbearing age are iron deficient and 2% to 5% have iron deficiency anemia, but only 1% of men are iron deficient. Routine administration of iron

supplements is recommended only for infants and pregnant women[58]; dietary sources should provide adequate amounts of iron for other healthy people.

A high intake of iron is harmful for patients with hemochromatosis and for others at risk for iron overload. A Finnish study linked high iron levels to cardiac risk.[59] However, studies in the United States have not confirmed these observations, and one study indicated a possible inverse association between iron stores and mortality from cardiovascular disease and other causes.[59]

Potassium Dietary potassium is inversely related to blood pressure and to stroke mortality in hypertensive men.[60] Although potassium supplements may assist in the treatment of hypertension,[61] current data do not justify the routine use of potassium supplements. Physicians should encourage a high dietary potassium intake in most individuals,[19,49] but low-potassium diets may be necessary for patients with renal disease or other conditions that cause hyperkalemia.

Selenium Selenium is a cofactor of the free radical scavenger enzyme glutathione peroxidase. A randomized clinical trial reported that selenium supplements of 200 μg/day appear to reduce mortality from various cancers.[62] Selenium levels have been inversely associated with mortality from prostate cancer[63] and gastroesophageal malignancies.[64] These data, however, do not yet support the routine use of selenium supplements, which can be toxic in high doses. Selenium is present in many foods, including tomatoes, poultry, shellfish, garlic, meat, egg yolks, and grains grown in selenium-rich soil.

Chromium Although chromium plays a role in glucose metabolism, there is no scientific basis for the claims that chromium supplements contribute to weight loss or increased energy. Chromium supplements may be beneficial for persons with low HDL cholesterol levels, but more study is needed. Dietary sources of chromium include brewer's yeast, whole grains, legumes, peanuts, and meats.

Magnesium Magnesium deficiency is common in diabetics, alcoholics, patients who take diuretics, and hospitalized patients. Persons with hypomagnesemia may require magnesium supplements, but others can rely on foods such as green vegetables, whole grains, bananas, apricots, legumes, nuts, soybeans, and seafood to provide magnesium.

WATER AND FOOD CONSUMPTION

Water

On average, adults consume about 2 L/day of water, with two thirds coming from beverages and the remainder coming from food. Healthy people have no need to track their water intake. Patients with conditions such as nephrolithiasis and urinary tract infections may benefit from consciously increasing their fluid intake; patients who are at risk for hyponatremia should restrict their water consumption.

Foods

Fruits and vegetables Fruits and vegetables provide many desirable nutrients, including complex carbohydrates, fiber, vitamins, and minerals. Deep-green and yellow-orange vegetables may be particularly beneficial because of their carotenoids, and citrus fruits may be valuable because of their vitamin C, soluble fiber, and potassium. Cruciferous vegetables, such as cabbage, may reduce the risk of certain cancers. Vegetables and fruits are low in sodium and calories; none contain cholesterol, and only coconut, palm oil, and cocoa butter contain saturated fat.

The findings of case-control and cohort studies strongly suggest that the consumption of fruits and vegetables is inversely related to the risk of coronary artery disease,[65] stroke,[66] malignancies of the respiratory and digestive tracts,[29] chronic obstructive lung disease,[67] and all-cause mortality.[68] A dietary-intervention trial demonstrated that a diet rich in vegetables, fruits, and low-fat dairy products can substantially reduce blood pressure.[49] The United States Department of Agriculture's Dietary Guidelines for Americans recommends eating two to four servings of fruit and three to five servings of vegetables a day; at present, only 35% of women and 19% of men meet these standards.[69]

Legumes Often neglected in the Western diet, legumes (beans, peas, and lentils) are rich in complex carbohydrates with low glycemic indices, iron, and B vitamins. Legumes are an excellent source of dietary fiber, including soluble fiber that can reduce blood cholesterol levels. Because of their high protein content, legumes are an excellent meat substitute. Soy protein can reduce blood cholesterol levels, and soy intake is inversely related to the risk of prostate and breast cancers.

Legumes can increase intestinal gas, causing bloating, flatulence, and cramps. Distress can be minimized by use of the nonprescription α-galactosidase preparation Beano.

Grains The seed-bearing fruits of grains, called kernels, consist of three layers: the inner germ, which contains vitamins and polyunsaturated fats; the middle endosperm, which contains complex carbohydrates; and the outer bran, which contains dietary fiber. Because milling removes the bran and endosperm, whole grains are nutritionally superior to refined grain; whole-grain consumption is inversely related to the risk of coronary artery disease[70] and stroke.[71] Whole-grain flour can be used to make cereals, baked goods, and even pasta. Whole grains such as brown rice, couscous, and yellow cornmeal (polenta) are easily prepared and healthful side dishes. Oats and barley contain soluble fiber that can lower blood cholesterol levels.

Meat and poultry Although meat is a source of protein, vitamins, and iron and other minerals, its high content of saturated fat, cholesterol, and calories makes it a potentially unhealthy food. Patients who eat meat should be encouraged to select lean cuts, trim away visible fat, and use cooking methods that remove, rather than add, fat. It is even more beneficial to reduce the amount of meat consumed by reducing portion size and frequency; a reasonable goal is to eat about 4 oz one to three times a week.

Poultry is a more healthful source of protein and other nutrients. Chicken and turkey are best, but the skin should be removed before cooking to reduce the fat content.

Dairy products and eggs To reduce intake of saturated fat and cholesterol, nonfat or low-fat dairy products can be substituted for whole-milk products. The use of nondairy creamers, imitation cheese, margarine, and other products that contain *trans*-fatty acids in partially hydrogenated vegetable oils should be limited. The consumption of up to one egg a day does not appear to increase the risk of cardiovascular disease in healthy, nondiabetic

Table 5 Dietary Guidelines for Healthy People

Eat more vegetable products than animal products
Eat more fresh and homemade foods than processed foods
Less than 30% of calories should come from fat
Limit cholesterol to less than 300 mg a day
Eat at least 25 g of fiber a day
55%–65% of calories should come from complex carbohydrates
10%–15% of calories should come from protein
Limit sodium to less than 2,400 mg a day
Obtain 1,200–1,500 mg of calcium a day from food or supplement
Eat 6 or more servings of grain products a day
Eat 3–5 servings of vegetables and legumes a day
Eat 2–4 servings of fruit a day
Eat two 4 oz servings of fish a week
Eat no more than two 4 oz servings of red meat a week
Chicken and turkey should be eaten in moderation with skin removed
Eat no more than one egg yolk a day, including those used in cooking and baking
Use vegetable oils, preferably olive and canola oils, in moderation
Have no more than two alcoholic drinks a day
Adjust caloric intake and exercise level to maintain a desirable body weight
Avoid fad diets and extreme or unconventional nutrition schemes
Avoid untested nutritional supplements, including megavitamins, herbs, food extracts, and amino acids

people,[72] but additional egg-yolk consumption should be limited. One egg yolk contains about two thirds of the total amount of cholesterol that is recommended for an entire day. Egg whites and egg substitutes are good alternatives to egg yolks.

Fish A 1997 study reported that participants who consumed 245 g or more of fish a week enjoyed a 38% reduction in fatal myocardial infarctions over a 30-year period.[73] Although at least three other observational studies did not find that fish consumption was protective, a 1989 intervention trial that randomized 2,033 myocardial infarction survivors to usual care or usual care plus fish consumption found that eating two or three fish meals a week reduced 7-year mortality by 29%.[74] Fish consumption has also been associated with a reduced risk of primary cardiac arrest,[75] hypertension, stroke,[9] and prostate cancer.[76,77] As little as 4 oz of fish twice a week may provide protection.[19] Fish should be baked, broiled, grilled, steamed, or poached rather than fried, and high-fat sauces should be avoided. Because of their higher content of omega-3 fatty acids, oily, deep-water fish may be best. People who are reluctant to eat fish may benefit from fish oil supplements in the modest dose of about 1 g/day.[78] More study is required to confirm the value of fish and fish oil and to define the optimal types and amounts of fish.

Cooking oils Canola oil contains an omega-3 fatty acid, α-linolenic acid. High serum levels of α-linolenic acid have been associated with a decreased risk of stroke, and consumption of canola oil is inversely related to the risk of myocardial infarction.[12] Canola oil and olive oil have a high content of oxidation-resistant monounsaturated fatty acids. Olive oil may be a cardioprotective element in the Mediterranean diet and may also reduce the risk of breast cancer. Although more study is needed, canola and olive oils appear to be the most beneficial oils for food preparation.

Nuts Nuts are high in monounsaturated and polyunsaturated fatty acids and fiber. Nut consumption appears to be inversely related to the risk of coronary artery disease[79] and diabetes.[80]

Garlic Medical studies of garlic have shown mixed results. Some meta-analyses suggest that garlic extracts can improve blood cholesterol levels, but others do not.[81] The putative benefits of garlic on blood pressure and coagulation are even less clear.

Flavonoid-rich foods Flavonoids are polyphenolic antioxidants that are found in a variety of vegetable foods, including apples, onions, tea, and red wine. Although not all studies agree, consumption of these foods has been inversely related to the risk of coronary artery disease and stroke.[82]

Alcohol Rarely regarded as a nutrient, alcohol should be considered when dietary recommendations are formulated. Containing 7 cal/g, alcohol is a calorie-dense food. Numerous studies demonstrate that low to moderate alcohol consumption substantially reduces the risk of coronary artery disease, peripheral vascular disease, and all-cause mortality.[83] The major mechanism of protection is alcohol's ability to increase HDL cholesterol levels; favorable effects on blood coagulation mechanisms may also contribute. Protective doses of alcohol can be obtained from one to two drinks a day; 5 oz of wine, 12 oz of beer, or 1.5 oz of spirits is counted as one drink. Despite its antioxidant content, red wine is no more protective than other alcoholic beverages.[84]

Caffeine Studies have failed to confirm putative links between caffeine and peptic ulcers, hypertension, coronary artery disease, breast disease, or cancer. Caffeine can trigger migraines in sensitive individuals, and caffeine withdrawal can precipitate headaches or depression in habitual consumers. Caffeine can cause anxiety, insomnia, and gastroesophageal reflux. Brewed coffee can increase blood cholesterol levels, but filtered coffee does not. The effects of caffeine on pregnancy are not fully understood, but it is reasonable to discourage consumption of large amounts.[85] Caffeine restriction does not reduce palpitations in patients with idiopathic premature ventricular contractions.[86]

DIET AND HEALTH

Much remains to be learned about the complex relation between nutrition, health, and disease. Dietary preferences are no less complex and individual. Despite these uncertainties, a dietary pattern characterized by a high intake of vegetables, fruits, legumes, whole grains, fish, and poultry is associated with major health benefits for men[87] and women.[30,88] Physicians have an important role in educating patients about healthful nutrition and providing dietary guidelines [*see Table 5*].

Exercise

Numerous observational studies have demonstrated a dose-related inverse relation between habitual physical activity and the risk for many of the chronic illnesses that afflict people in industrialized societies.[89] The protective effect of exercise is strongest against coronary artery disease but is also significant against hypertension, stroke, type 2 (non–insulin-dependent) diabetes mellitus, obesity, anxiety, depression, osteoporosis, and cancers of the colon, breast, and female reproductive tract. Despite these

proven benefits, only 25% of adults in the United States exercise at recommended levels.[90] Of all deaths in the United States, as many as 12%, or about 250,000 annually, can be attributed to a sedentary lifestyle.[91]

EXERCISE PHYSIOLOGY

The physiologic effects of exercise depend on the type of exercise, its intensity, its duration, and its frequency.[92] Exercise is either isometric or isotonic. Isometric contraction of muscle is characterized by an increase in muscle tension without a significant change in fiber length. No external work is accomplished, but substantial energy is expended. Examples of isometric work include handgrip exercises, pushing or pulling against a fixed resistance, and holding a heavy weight. In contrast, isotonic work involves a shortening of muscle fibers with little increase in tension; examples include swimming, bicycling, and running. Most exercise includes both isometric elements and isotonic elements.

Isometric and isotonic exercises differ substantially in their physiologic effects. Isometric work increases total peripheral resistance; both systolic blood pressure and diastolic blood pressure rise substantially, with relatively little increase in stroke volume or cardiac output. Isotonic work lowers total peripheral resistance, but heart rate and cardiac output rise. Systolic blood pressure rises substantially, but diastolic pressure changes little, resulting in a small increase in mean arterial pressure. Isometric work places a pressure load on the heart, whereas isotonic work imposes a volume load.

Isometric exercise increases muscle strength and bulk, which is desirable for competitive athletes, for patients recovering from musculoskeletal injuries, and for individuals who wish to attenuate the loss of muscle mass and bone strength that accompanies sedentary aging and certain chronic illnesses.[93] However, static exercises produce minimal cardiovascular conditioning, and the circulatory demands of intense isometric work can be hazardous to patients with heart disease. In contrast, dynamic exercises enhance endurance and can produce adaptive cardiovascular changes in healthy individuals and cardiac patients.

Cardiovascular Response to Dynamic Exercise

The acute circulatory response to maximal dynamic exercise is a dramatic rise in cardiac output, from about 5 L/min to 20 L/min in healthy young men. The increased cardiac output results from a 300% increase in heart rate. This increased transport of oxygen is matched by a threefold increase in peripheral oxygen extraction. Total peripheral resistance falls, and blood is shunted away from nonworking muscles and the viscera toward exercising muscles and the coronary circulation, where blood flow increases fourfold.

The physiologic adaptations produced by repetitive dynamic exercise are known collectively as the training effect. The magnitude of the training effect depends on the intensity, duration, and frequency of exercise. Training requires rhythmic, repetitive use of large muscle groups for prolonged periods. Fitness can be developed and maintained in healthy adults with three to five exercise sessions a week. Each day's exercise should involve isotonic work at 60% to 90% of maximal heart rate for 20 to 60 minutes, either continuously or in increments of 10 minutes or longer.[94] Obviously, sedentary persons and patients with cardiopulmonary disease must initiate training at lower intensities and shorter durations and build up gradually.

Perhaps the most obvious training effect is resting bradycardia; heart rates of 40 to 50 beats/min are common in highly trained endurance athletes. The mechanisms responsible are not fully understood but probably involve increased vagal tone, decreased sympathetic activity, and increased stroke volume. The best overall measurement of the training effect and of physical fitness is the maximal oxygen uptake ($\dot{V}O_{2MAX}$).

Oxygen consumption relates directly to the amount of muscular work; maximal oxygen uptake therefore reflects maximal work capacity. Many factors determine an individual's $\dot{V}O_{2MAX}$, including age, gender, lean body mass, genetics, and, most important, the level of habitual exercise. Just 3 weeks of bed rest will cause a 20% to 25% decline in $\dot{V}O_{2MAX}$. It is no wonder that patients are debilitated after being confined to bed by illness or treatment regimens. In contrast, regular training lasting weeks or months will increase $\dot{V}O_{2MAX}$, typically by 30% to 40%.

Both central (cardiac) and peripheral (muscular) adaptations are involved in the training effect. In healthy individuals, training produces dramatic changes in cardiac structure. The dimensions of all cardiac chambers increase by up to 20%, and myocardial mass may increase as much as 70%.[95] Although increased coronary blood flow and collateralization have not been demonstrated directly in humans, echocardiographic studies show that elite athletes have increased proximal coronary artery size, which is proportional to their increased left ventricular mass. Cardiac function is also enhanced by training; left ventricular contractility and stroke volume increase, and angiographic studies have demonstrated increased dilating capacity in the coronary arteries of endurance athletes. Exercise training also improves endothelial function in patients with coronary artery disease and in elderly persons.[96,97]

In addition to these cardiac changes that allow enhanced oxygen delivery, there is improvement in peripheral oxygen extraction caused by enhanced O_2 extraction by the skeletal muscles themselves. This effect on skeletal muscle is specific for the muscles that have been trained; if only leg muscles are trained, the circulatory response to strenuous leg exercise will improve, but the response to vigorous arm exercise will not change.

Exercise training decreases the risk of hypertension. A meta-analysis of 54 controlled intervention studies concluded that isotonic exercise training lowers both systolic blood pressure by about 4 mm Hg and diastolic blood pressure by about 3 mm Hg.[98] Regular exercise can even reduce left ventricular hypertrophy and blood pressure in patients with severe hypertension.[99] Regular exercise also lowers catecholamine levels, protecting against arrhythmias, and it reduces myocardial oxygen demands.[89]

Although isotonic exercise reduces resting blood pressure, isometric exercise increases total peripheral resistance and acutely elevates blood pressure. However, sustained hypertension is not a complication of resistance training, which may even reduce resting blood pressure.[100] Unsupervised isometric exercising should be avoided by patients with cardiovascular disease; with appropriate precautions, however, it can be safe for selected cardiac patients and can produce favorable effects on muscular function.[101]

Pulmonary Response

Except in people with intrinsic lung disease, the pulmonary diffusion capacity does not limit exercise. At heavy work loads, however, skeletal muscle oxygen demands exceed oxygen delivery. As a result, muscle metabolism becomes anaerobic; the lactic acid that accumulates is buffered by bicarbonate, so that

the pH remains nearly normal. The CO_2 that is liberated by the buffering reaction produces an increased ventilatory drive and tachypnea. Athletes know when they have crossed the anaerobic threshold by a markedly increased respiratory rate and a sensation of dyspnea. Habitual exercise does not improve pulmonary function in healthy people, but exercise training may be helpful in patients with chronic lung disease as a result of adaptations in muscles rather than in the lungs.

Musculoskeletal Response

Isotonic exercises increase muscle endurance. Training increases capillary density, and it can increase muscle mitochondria and oxidative capacity more than twofold. These changes account for the greater oxygen extraction that is an important element of the training effect. Isometric training builds muscle mass, which improves performance and may decrease injuries. Isometric exercises involving slow repetitions of work against high resistance produce fiber hypertrophy and strength but do not alter muscle enzyme content.

Exercise training affects tissues in addition to muscles. Of great importance, weight-bearing exercises increase bone mineral density, reducing the risk of osteoporosis. Repetitive performance of athletic tasks improves coordination and efficiency; changes in neuromuscular recruitment may be partially responsible. Tendon strength and bone density increase as a result of repetitive use. Joint wear and tear remains a concern, but as long as there is no trauma, habitual exercise probably does not produce degenerative joint disease.[102] In fact, aerobic and resistance exercise may help reduce disability in patients with osteoarthritis and fibromyalgia.[103,104]

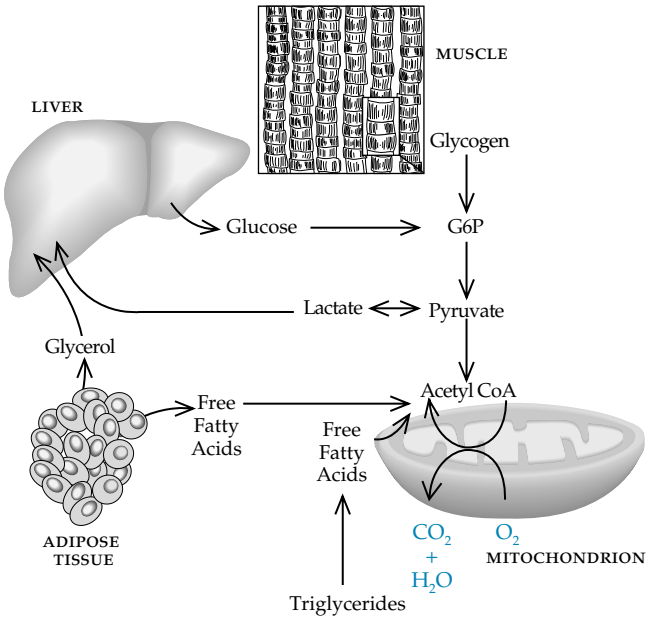

Figure 2 **During exercise, catecholamine stimulation of adipose tissue rapidly mobilizes free fatty acids to achieve blood levels that are six times the normal level, which are far higher than the muscle can use. Glucose derived from the liver and muscle glycogen are initially phosphorylated to yield glucose-6-phosphate (G6P). The G6P, the free fatty acids from adipose tissue, and the muscle's own triglycerides are metabolized to acetyl coenzyme A (acetyl CoA). This compound then undergoes oxidative metabolism in the mitochondrial Krebs cycle (blue), thus providing energy for exercising muscle.**

Metabolic Effects

Skeletal muscle contains only very limited energy stores; preformed adenosine triphosphate (ATP) and creatine phosphate (CP) can supply less energy than that which is consumed in a 100-yard dash. Clearly, ATP and CP must be generated during exercise. Only three sources of fuel are available to skeletal muscle for this purpose: endogenous muscle glycogen, blood glucose, and free fatty acids (FFAs) derived either from muscle triglyceride or from adipose tissue. Normally, the body's skeletal muscle contains only 120 g of glycogen and the liver only 70 g. The 600 kcal of energy available from these two sources could sustain running for only 6 miles. The blood glucose provides only 40 kcal more. In contrast, the average person's 15,000 g of adipose tissue provides 100,000 kcal of energy, theoretically enough to fuel a run from Boston to Atlanta.

At rest and during low-intensity exercise, both FFAs and muscle glycogen provide energy. As exercise begins, catecholamines stimulate adipose lipase, which cleaves triglyceride into glycerol and three FFA molecules [*see Figure 2*]. In muscle cells, FFAs are metabolized to acetyl coenzyme A (acetyl CoA); in the presence of oxygen, acetyl CoA undergoes oxidative metabolism by enzymes of the citric acid (Krebs) cycle in mitochondria.

As the intensity of exercise increases, the relative contribution of FFAs decreases and glycogen becomes more important, and at maximum work, muscle depends entirely on glycogen. When oxygen is available, glycogen is metabolized in the cytoplasm to pyruvate, which then undergoes oxidation in the mitochondria via the citric acid cycle to water and CO_2. However, when the demands of muscle outstrip the availability of oxygen, energy can be generated only anaerobically via glycolysis. Anaerobic metabolism is much less efficient: from a gram of glycogen, anaerobic metabolism generates only 5% of the energy that aerobic metabolism generates. In addition, pyruvate cannot be converted to acetyl CoA. Instead, pyruvate is reduced to lactate. Acidosis limits muscular performance, and buffering by the bicarbonate system generates CO_2, causing tachypnea.

Although the blood glucose itself constitutes only a modest caloric reserve, glucose turnover is greatly accelerated by exercise. During exercise, the liver releases glucose by both glycogenolysis and gluconeogenesis. Simultaneously, peripheral glucose uptake is enhanced. As a result of these metabolic events, blood glucose can account for 10% to 30% of exercising muscle's metabolic needs. The blood glucose level remains normal and may even rise during modest exertion. However, hypoglycemia can occur if hepatic glycogen stores are depleted and high-intensity exercise continues to consume blood glucose and muscle glycogen.

These changes in glucose metabolism are moderated by a number of hormonal alterations. Circulating catecholamines, growth hormone, cortisol, and glucagon levels rise. Insulin levels fall. All of these factors tend to elevate blood glucose levels. Glucose that is ingested during exercise will also tend to maintain blood glucose levels, but ingestion of glucose before exercise may actually raise insulin levels, thus impeding energy mobilization. Contrary to popular so-called instant-energy theories, preexercise meals should not contain concentrated sweets. Indeed, preexercise meals should be sparse, and people should probably ingest little other than water during the 2 hours before exercise.

Exercise increases the insulin sensitivity of muscle, thereby increasing glucose transport and muscle glycogen synthesis.

Even moderate physical activity such as walking can help prevent the development of type 2 diabetes mellitus[105] and the metabolic syndrome.[106] Because exercise improves glucose tolerance in diabetic patients, patients taking insulin may require special precautions to exercise safely [*see* Medical Complications of Exercise, *below*].

During exercise, the rate of protein synthesis is depressed. As a result, amino acids are available for anabolic processes, including hepatic gluconeogenesis. Amino acids also may directly provide a small fraction of the energy needed for muscle contraction. It is not clear whether athletes have higher nutritional protein requirements than sedentary persons; the ingestion of protein and amino acid supplements does not enhance athletic performance.

Regular aerobic exercise also alters body weight and body composition. If dietary caloric intake remains constant, exercise will produce slow weight loss.[107] It takes 35 miles of walking or jogging to consume the calories present in 1 lb of adipose tissue. Intense exercise also stimulates both energy expenditure and lipid oxidation for up to 17 hours after exercise itself, thus further contributing to a reduction in body fat. Even as body fat declines, muscle mass increases; because muscle is denser than fat, net weight loss may be slight. Swimming appears to be less effective than land exercise for reducing body fat and increasing bone mineral content.

Effects on Blood Lipids

Exercise increases serum levels of HDL-associated cholesterol (HDL-C), probably by delaying hepatic HDL-C catabolism. The amount of exercise appears to be the major determinant of the magnitude of the increase in HDL-C. As little as 5 to 10 miles of jogging a week will elevate HDL-C levels, which rise with increasing exercise in a dose-response fashion; beyond about 35 miles a week, however, additional training does not produce a further increase in HDL-C levels.[108] Similar changes in HDL-C levels have also been demonstrated in walkers, cross-country skiers, tennis players, bicyclists, and other endurance athletes. The effects of exercise are independent of other factors known to alter HDL-C levels, such as diet, body weight, smoking, and alcohol consumption. Exercise must be sustained to maintain high HDL-C levels.

The effects of exercise on HDL-C levels are observed consistently, but changes in the other blood lipid levels have varied. In general, exercise produces a fall in triglyceride and chylomicron levels. Total cholesterol and LDL cholesterol levels also tend to decline. Heritable factors, in part, determine lipid profile responses to exercise.[109]

Hematologic Effects

A mild decrease in hematocrit is commonly observed in endurance athletes. This so-called sports anemia is usually a pseudoanemia, because red blood cell mass is normal but plasma volume is increased; decreased viscosity has also been observed. Exercise-related hemolysis or gastrointestinal blood loss may be an additional factor in some cases of anemia in athletes. No consistent long-term changes in polymorphonuclear leukocytes, lymphocytes, or immunoglobulins have been noted.

Hemostatic mechanisms are influenced by exercise. Endurance exercise acutely increases fibrinolytic activity, and repetitive exercise is associated with reduced fibrinogen levels. In contrast, intense exercise can activate platelets,[110] perhaps contributing to a prothrombotic state that may contribute to exertion-induced cardiac events[111] [*see* Medical Complications of Exercise, *below*]. The effects of exercise on platelet function require further study.

Effects on Body Fluids

During exercise, skeletal muscle generates a tremendous amount of heat. Sweating is necessary to dissipate this heat. During strenuous exercise in a warm environment, up to 2 L can be lost each hour. Because sweat is hypotonic, the serum sodium concentration rises. Even in the absence of systemic acidosis, serum potassium levels may rise because of an efflux of potassium from muscle cells, but potassium levels normalize within minutes after exertion ceases.

The decline in blood volume, together with a shift in blood flow from the kidneys to skeletal muscle, produces a sharp decline in urine volume during exercise. The rise in plasma osmolarity increases thirst. However, thirst lags behind volume requirements, and fluid intake is often inadequate during athletic events. Volume depletion impairs athletic performance and can contribute to renal dysfunction or heatstroke. Unfortunately, coaching lore often limits fluid intake for fear of cramps, when, in fact, athletes can tolerate large volumes of fluids during brief pauses in exercise. Although water is an excellent fluid replacement, excessive amounts during prolonged exercise can produce severe, even fatal, hyponatremia.[112] Athletes do not require supplemental potassium or salt, so popular glucose-sodium-potassium solutions make little sense physiologically.

Psychological Effects

Endurance exercise produces improvements in mood, self-esteem, and work behavior both in healthy people and in patients undertaking cardiac rehabilitation; exercise training can help treat depression.[113] Several mechanisms have been suggested to explain the psychological effects of exercise. Purely psychological factors, such as distraction, may be involved. The serum levels of β-endorphin, monoamines, and other neuropeptides are affected by exercise in direct relation to the intensity and duration of exercise. Changes in endogenous opioid peptides may mediate the subjective effects of exercise (so-called runner's high).

EXERCISE AND THE ELDERLY

Many physiologic changes attributed to aging closely resemble those that result from inactivity.[114] In both circumstances, bone calcium wastage occurs, and there are decreases in $\dot{V}O_{2MAX}$, cardiac output, red blood cell mass, glucose tolerance, and muscle mass; total peripheral resistance and systolic blood pressure are increased, as are body fat and serum cholesterol levels. Regular exercise appears to retard these age-related maladies. Exercise training improves left ventricular systolic function and increases stroke volume to maintain exercise cardiac output in healthy, older people.[115] The age-related decline in $\dot{V}O_{2MAX}$ has been found to be twice as great for sedentary men as for active men, and even low-intensity training can improve $\dot{V}O_{2MAX}$ in the elderly. Exercise training also helps blunt the age-related decline in peripheral vascular function experienced by sedentary people. Endurance training improves glucose tolerance and serum lipid levels in older men and women, and regular exercise appears to blunt the age-related decline in resting metabolic rate. Physical activity in the elderly is associated with increased functional status and decreased mortality. Exercise is safe in the elderly if simple precautions are observed [*see* Prescribing Exer-

cise, *below*]. Walking programs increase aerobic capacity in persons 70 to 79 years of age, with few injuries; healthy elderly persons who are randomly assigned to aerobic exercise acquire fewer new cardiovascular disorders than control subjects. Appropriate resistance weight programs are not hemodynamically stressful in the elderly and produce increases in muscle strength, functional mobility, and walking endurance. Even frail nursing home residents (mean age, 87 years) responded to resistance training with an increase in muscle mass and strength, as well as improved gait velocity, stair-climbing power, and spontaneous activity. Although more studies are needed to clarify correlations between aging, inactivity, and exercise, enough information is available to warrant a recommendation of carefully planned exercise programs for the elderly.

EXERCISE AND LONGEVITY

Primary Prevention of Atherosclerosis

Exercise training can favorably modify many of the conditions associated with an increased risk of coronary artery disease, including hypercholesterolemia, elevated blood pressure, glucose intolerance, obesity, and the less firmly incriminated traits of hypertriglyceridemia, hyperinsulinemia, hyperfibrinogenemia, and psychological stress. Studies conducted in men, women, and children demonstrated a consistent inverse relation between physical fitness and body weight, percent body fat, systolic blood pressure, and serum levels of cholesterol, triglycerides, and glucose.[116] In addition, exercise appears to reduce levels of C-reactive protein and other inflammatory markers of cardiovascular risk.[117]

Is a sedentary way of life itself a risk factor independent of these other traits? Investigators at the Centers for Disease Control and Prevention (CDC) reviewed 43 methodologically sound studies of exercise and coronary artery disease.[118] Collectively, these studies showed that sedentary living increases coronary risk by 1.9 times. An independent meta-analysis derived the same relative risk.[119] The magnitude of this excess risk is similar to that conferred by other risk factors: hypertension, 2.1 times; hypercholesterolemia, 2.4 times; and cigarette smoking, 2.5 times.[118] Because sedentary living is at least two to three times more prevalent than any of these other risk factors, it can be argued that physical inactivity makes the most significant contribution to the epidemic of coronary artery disease in the United States. Maintaining a physically active way of life can be expected to reduce the risk of myocardial infarction by 35% to 70%.

Although reductions in coronary artery disease account for the great majority of the improvements in survival conferred by exercise, other factors may play a role. Physical activity protects against stroke[120] and reduces the risk of colon cancer.[121] Exercise also reduces the risk of breast cancer[122] and cancer of the reproductive organs in women, and very intensive exercise may reduce the risk of prostate cancer. Physical activity is associated with a reduced risk of age-related cognitive dysfunction[123] and hip fractures.[124] Current studies continue to confirm observations that have occurred over the past 50 years, demonstrating that there is a graded, inverse association between activity and mortality.[125,126]

Secondary Prevention of Ischemic Heart Disease

Since the 1970s, interest in the potential role of exercise in the rehabilitation of patients after myocardial infarction and in the prevention of recurrent cardiac events has grown.[127] Certain benefits of supervised exercise programs have been clearly established, including physiologic and symptomatic improvements and the reduction of risk factors. Patients completing exercise programs demonstrate the training effect, including a lower heart rate at rest and both a lower heart rate and a lower systolic blood pressure at submaximal work loads. These changes reduce myocardial oxygen demands, thereby increasing the angina threshold. Significant improvements in maximal oxygen uptake and work capacity can also be demonstrated. Exercise training can improve walking distances in patients with claudication.[128] Exercise can be useful even for patients with severe ischemic left ventricular dysfunction and chronic congestive heart failure, although extra precautions should be taken in these patients. In addition, cardiac exercise programs are safe.[129] Most centers note a substantial improvement in mental attitudes, a decrease in the use of medications, and widespread patient satisfaction. Most important, randomized trials demonstrate that cardiac exercise programs reduce mortality by 20% to 25%.[129,130] Unsupervised moderate exercise, such as walking or gardening, also appears to reduce mortality in older patients with coronary artery disease.[131]

PRESCRIBING EXERCISE

Physicians can provide important incentives for their patients by educating them about the benefits, as well as the risks, of habitual exercise. Healthy, sedentary individuals are the largest group in need of such advice. In addition, physicians may be responsible for the medical screening of competitive athletes or for prescribing exercise for patients with chronic illnesses.

A careful history and physical examination are central to the medical evaluation of all potential exercisers. Particular attention should be given to a family history of coronary disease, hypertension, stroke, or sudden death and to symptoms suggestive of cardiovascular disease. Cigarette smoking, sedentary living, hypertension, diabetes, and obesity all increase the risks of exercise and may indicate the need for further testing. Physical findings suggestive of pulmonary, cardiac, or peripheral vascular disease are obvious causes for concern. A musculoskeletal evaluation is also important.

The choice of screening tests for apparently healthy individuals is controversial. A complete blood count and urinalysis are reasonable in all cases. Determination of blood glucose, serum cholesterol, and creatinine levels may also be useful in screening for risk factors or occult disease. The Valsalva maneuver and the isometric handgrip may be useful additions to the workup.

Young adults who are free of risk factors, symptoms, and abnormal physical findings do not require further evaluation. It is not at all clear that more aggressive medical screening can prevent sudden cardiac death. Although echocardiography and electrocardiography might reveal asymptomatic hypertrophic cardiomyopathy in some patients, the infrequency of this problem makes routine screening impractical.

The role of exercise electrocardiography as a screening test before an individual begins an exercise program is controversial. The AHA no longer recommends routine exercise testing for asymptomatic individuals.[89] In fact, a study of 3,617 asymptomatic men 35 to 59 years of age casts doubt on the value of exercise electrocardiography for routine preexercise screening.[132] None of the men had known coronary artery disease on entry into the study, but all were at increased risk because of hypercholesterolemia. Each individual had an exercise test on entry;

Table 6 Exercise Time Required to Consume 2,000 kcal

Activity	*Time (hr)*
Strolling	10
Bowling	8.5
Golf	8
Raking leaves	7
Doubles tennis	6
Brisk walking	5.5
Biking (leisurely)	5.5
Ballet	4.5
Singles tennis	4.5
Racquetball, squash	4
Biking (hard)	4
Jogging	4
Downhill skiing	4
Calisthenics, brisk aerobics	3.3
Running	3
Cross-country skiing	3

the tests were repeated annually over a mean follow-up period of 7.4 years. Exercise proved safe in this group, with approximately 2% experiencing exercise-related cardiac events. Only 11 of the 62 men who experienced such events had abnormal exercise tests on entry, a sensitivity of only 18%. The cumulative sensitivity of annual tests was also low (24%). Even in elderly people, routine exercise testing before starting a moderate exercise program may not be necessary.[133]

Despite its limitations as a screening test for silent coronary artery disease, exercise testing can be useful for detecting exercise-induced arrhythmias, establishing a maximal heart rate for the exercise prescription, and determining work capacity. Serial testing may help motivate a patient by demonstrating increased work capacity. Specialized tests such as pulmonary function tests and exercise ergometry, Holter or telemetric monitoring during exercise, and echocardiography may be very useful in the evaluation of patients who have known or suspected cardiovascular abnormalities.

Screened patients will fall into one of three groups:

1. Healthy persons who can exercise without supervision. (Medical guidelines [see below] may still be helpful.)
2. Patients with ischemic heart disease or other significant cardiovascular abnormalities who should have medically supervised, graded exercise programs. (If structured programs are not available, such patients should engage in milder forms of exercise, such as walking or bicycling, with appropriate precautions.)
3. Patients for whom physical exertion is contraindicated because of decompensated congestive heart failure, complex ventricular irritability, unstable angina, significant aortic valve disease, aortic aneurysm, uncontrolled diabetes, or uncontrolled seizure disorders.

People can exercise in the course of daily life or in formal exercise programs. Although most physicians have recommended structured exercise, recent studies demonstrate that even modest levels of physical activity are beneficial.[131,134] Walking and gardening are good examples[131,134,135]; such activities are protective even if they are not started until midlife or late in life.[136] In one study, for example, elderly men who walked less than 1 mile a day had nearly twice the mortality of men who walked more than 2 miles a day.[137] Compliance with walking is good,[138] and lifestyle interventions appear to be as effective as formal exercise programs of similar intensity in improving cardiopulmonary fitness, blood pressure, and body composition.[139,140]

People should be encouraged to exercise nearly every day. Formal, intense exercise is not necessary; even moderate exercise that consumes about 150 kcal/day or 1,000 kcal/wk is very beneficial to health. Warm-ups, stretches, and a graded increase in exercise intensity can help prevent musculoskeletal problems.

Whereas all people can benefit from moderate daily activity, additional benefit can be obtained from more intense exercise; people who consume about 2,000 kcal in exercise a week obtain the greatest reduction of cardiovascular risk and mortality[125,141] [*see Table 6*]. On average, people can obtain optimal health benefits from about 30 minutes of intense exercise or 45 to 60 minutes of mild to moderate exercise a day.

Physicians who provide specific practical advice are most likely to motivate their patients to adopt better health habits, including diet and exercise [*see Table 7*].

The success of a structured fitness program depends on the frequency, duration, and intensity of exercise. At least three sessions a week are needed. An alternate-day schedule will help prevent muscle soreness, but as fitness improves, individuals should be encouraged to increase exercise sessions to five or even seven times a week. Each session consists of 15 to 60 minutes of continuous aerobic activity. Untrained individuals may not be able to sustain even 15 minutes at first, but they should be encouraged to progress slowly as they improve. Each exercise session should be preceded by a 5- to 10-minute warm-up period and followed by a 5- to 10-minute cool-down period; stretching, gentle calisthenics, and walking are ideally suited for this purpose. These same exercises are excellent for a 5- to 10-minute cool-down period.

The intensity of exercise can best be judged by the target heart rate. A heart rate of 60% to 85% of maximum is considered optimal for training. If an exercise test has not been performed, a maximal heart rate can be calculated by subtracting

Table 7 Exercise Advice for Patients

- Get a medical checkup before beginning a formal exercise program
- Warm up before each exercise session, and cool down afterward with 10 minutes of stretching and light calisthenics
- Start slowly and build up to 30 minutes of moderate to intense exercise or 45–60 minutes of mild to moderate exercise
- Begin with aerobic-type exercise, and later add stretching exercises for flexibility and low-resistance weight training for strength
- Exercise daily if possible, and alternate harder workouts with easier ones
- Dress comfortably
- Use good equipment, especially good shoes
- Do not eat during the 2 hr before you exercise, but drink plenty of water before, during, and after exercise, particularly in warmer weather
- Do not ignore aches and pains that may signify injury
- Do not exercise if you are feverish or ill
- Learn warning signals of heart disease, including chest pain or pressure, disproportionate shortness of breath, fatigue, sweating, erratic pulse, light-headedness, or even indigestion
- Consider getting instruction or joining a health club

the patient's age from 220. Unfit people should start at the lower end of the target heart rate range. Healthy people need not monitor pulse rate. Instead, they can adjust the intensity of effort to a talking pace: they are working hard but still able to talk to a companion without a sensation of dyspnea.

Many kinds of exercise can be used to attain fitness. Dynamic (i.e., isotonic or aerobic) exercises in which large muscle groups are used continuously in a rhythmic, repetitive fashion for prolonged periods are ideal. The energy requirements of various activities have been measured. An energy expenditure of 5 to 6 METs (metabolic equivalents) or more is desirable for exercise training (1 MET is equal to the energy expenditure at rest or equivalent to approximately 3.5 ml O_2/kg body weight/min). Brisk walking, jogging, swimming, cross-country skiing, skating, bicycling, and vigorous singles racket sports all provide good conditioning. Sports that allow prolonged periods of inactivity, such as doubles tennis, golf, bowling, and baseball, are much less desirable for fitness.[125] Activities requiring sudden bursts of intense isometric activity, such as weight lifting, provide little cardiovascular conditioning and are contraindicated for patients with hypertension or heart disease. Contact sports cannot be recommended for health.

Although physicians should encourage patients to choose the sports that appeal most to them, medical considerations may also be important. For example, swimming is particularly desirable for individuals who have various musculoskeletal problems, and it is also ideal for people who experience exercise-induced asthma (EIA). Walking and bicycling are ideal for older individuals or for anyone who is starting from a low level of fitness. Jogging can be recommended because it is convenient and because the participants can easily adjust intensity and duration upward as fitness develops. Most desirable of all is a balanced program containing a variety of activities that exercise different muscle groups. People who have several activities at their command find it easier to remain active despite constraints of climate, schedules, and minor injuries. Although aerobic exercise is most important for metabolic improvement and cardiovascular health, exercises for flexibility and strength should be part of a balanced fitness program.[94] Stretching exercises promote flexibility and help prevent injuries. A stretching routine should be performed at least two to three times a week, but it is best when incorporated in the warm-up and cool-down periods that should surround aerobic exercise. Low-resistance strength training is important to preserve muscle mass and power in the face of the aging process; two to three sessions a week are ideal.

COMPLICATIONS OF EXERCISE

Reducing Risk of Injury and Complications

Physicians can minimize injuries and medical complications associated with exercise by educating patients about potential problems. Physicians should stress the need for such safety devices as helmets for biking, eye guards for squash and racquetball, and elbow and knee pads for roller-skating. Diet, weight control, stress management, smoking cessation, and other preventive health measures should be discussed [*see CE:III Reducing Risk of Injury and Disease*], as should the warning signs of cardiac disease and the precautions for exercising in cold or hot climates.

Medical Complications of Exercise

Exercise promotes health, but it can also have adverse consequences. In some cases, the physiologic adaptations to exercise produce changes that may be misinterpreted as pathologic; athlete's heart is one example. In other cases, however, exercise can precipitate clinically important problems.

The cardiac complications of exercise include ischemia, infarction, and sudden death, often caused by rupture of an atherosclerotic plaque.[142] These dire events are infrequent and can be minimized by proper patient screening and instruction [*see* Prescribing Exercise, *above*]. Exercise-induced cardiac events are less common in people who exercise regularly than in sedentary individuals.[143] On balance, exercise is clearly beneficial for the heart.

The most common pulmonary complication of exercise is EIA, which usually responds well to treatment.[144] A much less common problem that can mimic hypersensitivity disorders is exercise-induced anaphylaxis.

The gastrointestinal response to exercise may produce reflux, diarrhea, or bleeding, which is usually occult and transient. Women who exercise very strenuously may experience oligomenorrhea or amenorrhea; the menstrual dysfunction is reversible but may be accompanied by osteoporosis. With appropriate precautions, exercise is safe during pregnancy. Precautions are also in order for prevention of hypoglycemia in diabetics who exercise.

People who exercise regularly can experience increased plasma volume that produces hemodilution or pseudoanemia. True anemia is less common but may result from shortened red cell life span caused by vascular trauma or iron deficiency. Exercise can produce proteinuria or hematuria; both are benign but are indications for studies to rule out renal disease. In warm, humid weather, exercise can produce heat cramps, hyperthermia, or heatstroke, all of which are preventable.

Exercise does not appear to cause or accelerate osteoarthritis.[102] Acute muscle injury, manifested by transient elevation of creatine phosphokinase levels, is common, but exertional rhabdomyolysis is rare. Musculoskeletal problems, however, are the most frequent side effects of exercise.[145] Overstress, overuse, or trauma is usually responsible. Poor technique, faulty equipment, or fatigue often contributes to injury. Soft tissue injuries such as sprains, strains, and tendinitis usually respond well to simple treatment regimens. The same is true of stress fractures. Primary care physicians can manage many of these problems, but more serious injuries may merit referral to a sports medicine facility.

V ADULT PREVENTIVE HEALTH CARE

MARK HELFAND, M.D.

Over the past 20 years, prevention has become a major activity in primary care. During a typical day, primary care clinicians spend much of their time managing asymptomatic conditions in which the main goal is to prevent death or complications (e.g., hypertension, hyperlipidemia, osteoporosis). Many chapters in *ACP Medicine* include information on screening or prevention of specific disorders in asymptomatic patients or those at increased risk [*see Table 1*]. This chapter focuses primarily on preventive screening recommendations from the United States Preventive Services Task Force (USPSTF).

Rationale and Evolution of Preventive Care Guidelines

The rationale for delivering preventive care during an office visit is strong. In 2002, life expectancy in the United States was 77.4 years, an all-time high.[1] Behavioral risk factors, including tobacco use, diet, and alcohol use, as well as factors such as hyperlipidemia and hypertension, contributed to the most frequent causes of death [*see Table 2*]. From the viewpoint of clinical preventive services, modifiable risk factors such as these, rather than the diseases they affect, are the true causes of death.[2]

Primary care visits provide an opportunity to assess risk, discuss options, and recommend behaviors and treatments that have been proved to reduce the risks of diseases and death. During 2002, an estimated 558 million visits were made to primary care physicians in the United States, an overall rate of about two visits per person per year.[3] On average, these physicians spent 20 minutes with the patient at each visit.

In 1975, Frame and Carlson published a series of articles that examined the quality of evidence for periodic screening conducted in the routine physical examination.[4] These authors argued that any preventive strategy should meet certain criteria of accuracy and usefulness [*see Table 3*]. The criteria are helpful in understanding the controversy about screening proposals. Several scholars have pointed out that clinical intuition about screening is often wrong, leading to errors in inference about the effects of screening. Some of these logical fallacies and hidden assumptions are now well recognized and even find their way into board examinations [*see Table 4*].

The work of Frame and Carlson gave rise to evidence-based decision making in prevention. The Canadian Task Force on the Periodic Health Exam used independent reviews of the scientific literature and a set of rules to grade the strength of evidence supporting a clinical service.

The USPSTF, founded in 1984, was modeled on the Canadian Task Force. It published its first set of guidelines for clinical preventive services in 1989.[5] The current USPSTF has experts from the specialties of family medicine, pediatrics, internal medicine, obstetrics and gynecology, geriatrics, preventive medicine, public health, behavioral medicine, and nursing.

Other expert panels also make recommendations about prevention [*see Table 5*]. Despite general agreement that recommendations should be evidence based, opinions about the effectiveness of specific preventive services differ. These differences arise because interpretation of the evidence is ultimately a subjective process, especially regarding the balancing of benefits and risks—an equation that includes such disparate factors as mortality reduction, costs or burden of illness, and patient discomfort.

To avoid errors in judging the evidence and weighing benefits and harms, expert panels, as well as individual clinicians, should do the following: (1) use an independent systematic review to distinguish assertions based on evidence from those based on other grounds, (2) make the rationale for a recommendation explicit, and (3) be free from financial and political conflicts of interest. Although the use of these measures does not guarantee a correct decision, they represent the best safeguards against bias.

USPSTF Evidence Ratings

The USPSTF assigns an overall grade of A, B, C, D, or I to each prevention service. The grades reflect the overall strength of evidence and the magnitude of benefit, defined as benefits minus harms [*see Table 6*].[6]

A grade of A indicates services that have solid supporting evidence and at least a moderate net benefit. A grade of B suggests that there are information gaps (so-called fair evidence) or that the benefits are only moderately greater than the harms for all patients. A grade of C denotes a toss-up, whereas a D grade indicates a service that is either proven ineffective or unlikely to provide benefits that outweigh the harms.

When there is too little evidence to determine whether or not a service works, the USPSTF assigns a grade of I for insufficient evidence. Some of the services with an I grade make good clinical sense and some are very promising, but without better research, it is not possible to say with confidence that they improve outcomes. Other grade I services have uncertain benefits but definite harms.

Noncancer Prevention Imperatives

Several preventive measures have earned an A grade on the strength of their good supportive evidence, substantially greater benefits than harms, and broadest applicability to primary care practice [*see Table 7*]. Implementation of these measures is described in detail in other *ACP Medicine* chapters [*see Table 1*].

IMMUNIZATION

The USPSTF has not issued recommendations about immunization since 1996, and those recommendations are now out of date. The Advisory Committee on Immunization Practices (ACIP), which consists of 15 experts in fields associated with immunization, is currently the only entity in the United States federal government that makes recommendations about immunizations. In contrast to the USPSTF, the ACIP does not use systematic reviews and does not usually describe the quality of evidence supporting a recommendation.

The ACIP publishes schedules for vaccination against certain infectious diseases in adults, depending on age and risk factors; these recommendations are discussed in individual *ACP Medicine* chapters and are available on the Internet (http://www.cdc.gov/nip/recs/adult-schedule.pdf). For example, general recommendations include a tetanus-diphtheria booster every 10

7:IV Infections Due to Gram-Positive Bacilli	Prevention of diphtheria, listeria, anthrax
7:V Anaerobic Infections	Tetanus prevention
7:VII Lyme Disease and Other Spirochetal Zoonoses	Prevention of Lyme disease
7:X Infections Due to Haemophilus, Moraxella, Legionella, Bordetella, and Pseudomonas	*H. influenzae* immunization and secondary prevention; pertussis immunization
7:XVII Infections Due to Rickettsia, Ehrlichia, and Coxiella	Prevention of Rocky Mountain spotted fever, typhus
7:XVIII Infective Endocarditis	Prevention for high-risk patients/procedures
7:XXII Vaginitis and Sexually Transmitted Diseases	Screening recommendations for sexually transmitted diseases
7:XXV Respiratory Viral Infections	Prevention of influenza and other respiratory viral infections
7:XXVI Herpesvirus Infections	Prevention of herpes simplex, varicella-zoster, and cytomegalovirus infections
7:XXVIII Enteric Viral Infections	Polio prevention
7:XXIX Measles, Mumps, Rubella, Parvovirus, and Poxvirus	MMR, smallpox vaccination

years in all adults, influenza vaccination every year in adults 50 years of age and older, and pneumococcal vaccination once in adults 65 years and older. The ACIP has made specific recommendations for vaccination of health care workers [*see Table 8*].[7]

Cancer Prevention

Only two cancer screening tests meet the USPSTF criteria for a strong recommendation: (1) Papanicolaou (Pap) smears for cervical cancer and (2) fecal occult blood testing or endoscopic procedures for colorectal cancer [*see Table 9*]. With both of these conditions, the aim of screening is to remove precancerous lesions, which prevents invasive cancer, saves the involved organ, and reduces disease-specific mortality. By contrast, the more controversial cancer screening tests, such as prostate-specific antigen (PSA) and mammography, detect invasive cancers and lead to aggressive treatments (prostatectomy and mastectomy) that often destroy the involved organ and that have more substantial morbidity than cone biopsy for cervical cancer and polypectomy for colorectal cancer.

CERVICAL CANCER

Although no data from randomized, controlled trials support the value of the Pap smear in reducing mortality from cervical cancer, indirect evidence suggests that it is among the most effective cancer screening techniques.[8] By current standards, the sensitivity of traditional Pap testing is low (51%).[9,10] Cervical dysplasia is slow to progress to invasive carcinoma, however, so periodic screening can make up for the low sensitivity of a single exam.

The USPSTF recommends screening with Pap smears at least

every 3 years, beginning within 3 years after the start of sexual activity or age 21 (whichever comes first). The Task Force recommends against annual screening. In women who have had consistently negative Pap smear results, continuing screening past age 65 is unnecessary because of the declining incidence of high-grade cervical lesions and an increased risk for potential harms, including false positive results and invasive procedures. The USPSTF also recommends against routine Pap smear screening in women who have had a total hysterectomy for benign disease.

The specificity of Pap smears for detection of dysplasia and cancer is 98%. False positive results occur infrequently, but Pap smears may correctly detect a large number of low-grade lesions that, without treatment, would remain stable or regress.[11] As a consequence, many women who would never develop invasive cervical cancer are subjected to anxiety and to colposcopy and biopsy.

In a systematic review, the effectiveness of liquid-based cytology, computerized rescreening, and algorithm-based screening have been compared with that of conventional Pap smear screening in reducing the incidence and mortality of invasive cervical cancer. The review concluded that the liquid-based monolayer preparation (ThinPrep) appears to offer higher sensitivity but lower specificity than conventional Pap smears.[10] However, the USPSTF could not determine whether the potential benefits of the three new screening approaches relative to conventional Pap smears are sufficient to justify a possible increase in potential harm or cost. They also found insufficient evidence to recommend for or against the routine use of human papillomavirus testing as a primary screening test for cervical cancer.

COLORECTAL CANCER

Screening modalities for colorectal cancer include fecal occult blood testing (FOBT), sigmoidoscopy, double-contrast barium enema, colonoscopy, and computed tomographic colonogra-

Table 2 Major Causes of Death in the United States[1]*

Cause of Death	*Number of Deaths*	*Age-Adjusted Death Rate (per 100,000 population)*
Diseases of the heart	695,754	204.4
Malignant neoplasms	558,847	194

Chronic lower respiratory diseases	125,500	43.7
Accidents (unintentional injuries)	102,303	35.3
Diabetes mellitus	73,119	25.4
Influenza and pneumonia	65,984	22.7
Alzheimer disease	58,785	20.2

*Preliminary data for 2002; these causes account for three quarters of all deaths.

phy [*see 12:V Colorectal Cancer*]. FOBT is the only screening modality that has been shown in randomized controlled trials to reduce colorectal cancer mortality. In the Minnesota Colon Cancer Control Study, 33 volunteers 50 to 80 years of age were randomized to annual FOBT, biennial FOBT, or a control group. After 18 years of follow-up, colorectal cancer mortality was 33% lower in the annual FOBT group and 21% lower in the biennial group than in the control group.[12] In this study, the slides were rehydrated, a technique that increases sensitivity but reduces specificity; during the trial, 38% of patients in the annual FOBT group underwent colonoscopy because of a positive test result. Two randomized, controlled trials from Europe have demonstrated 16% and 18% reductions in colorectal cancer mortality using FOBT.[13,14] In the European trials, unlike in the Minnesota study, patients were drawn from the general population, the slides were not rehydrated, and all testing was biennial.

In the screening trials, FOBT reduced mortality from colon cancer but did not reduce all-cause mortality. For example, the Minnesota trial findings indicate that 10 years of screening would result in 12 (95% confidence interval, 1 to 24) fewer colon cancer deaths per 10,000 persons screened. In that trial, however, the 95% confidence interval for all-cause mortality was 334 to 350 with annual screening, 333 to 348 with biennial screening, and 336 to 351 in control subjects.[12]

Evidence for the efficacy of sigmoidoscopy comes from case-control studies, which suggest that the protective effect of a single sigmoidoscopy lasts at least 6 years. The results of a large United Kingdom trial of screening with flexible sigmoidoscopy are not yet complete. Preliminary results suggest that flexible sigmoidoscopy is safe and that about 5% of persons 55 to 64 years of age have high-risk polyps (three or more adenomas; size 1 cm or greater; villous, severely dysplastic, or malignant).[15]

Because of the imperfect sensitivity of FOBT and sigmoidoscopy and because many patients who undergo these procedures end up requiring colonoscopy anyway, many clinicians are advising their average-risk patients to undergo colonoscopy as a screening test, either as a one-time procedure or periodically (e.g., every 10 years) beginning at age 50. Colonoscopy is the most sensitive test for detecting polyps; however, as for other slow-growing lesions, such as cervical dysplasia, it is not clear whether improved sensitivity for polyps at a single point in time will translate into fewer invasive cancers in the long run.

In 2002, for the first time, the USPSTF included screening colonoscopy as an option, but with the qualification that the potential added benefits of colonoscopy may not always be great enough to justify the increased risks and inconvenience.[16] All colon cancer screening tests have a low yield—over 500 patients must be screened to prevent one invasive cancer[17]—so even a slightly increased rate of serious complications with colonoscopy might negate the benefit. Several gaps in the evidence base for colonoscopy can also be mentioned. First, the frequency of one procedure every 10 years was arrived at by means of mathematical models; in fact, no one knows how many patients will develop invasive cancer less than 10 years after a negative colonoscopy. Second, surveys suggest that gastroenterologists overuse colonoscopy for surveillance in patients who have clinically insignificant hyperplastic polyps or low-risk lesions, such as small adenomas. As a result, colonoscopic screening may lead to the use of a scarce, expensive resource, primarily in patients who have little chance of benefit. Third, the accuracy of colonoscopy when performed by the so-called average colonoscopist is not known. The primary advantage of colonoscopy, visualization of the entire colon, is negated if the operator cannot reach the cecum consistently or does not view the entire circumference of the lumen during the procedure.

No direct evidence supports the use of double-contrast barium enema for screening, and patients find it more uncomfortable than other alternatives. CT colonography may prove to be more sensitive and better tolerated than double-contrast barium enema and safer than colonoscopy; as of yet, however, there are insufficient data to determine whether it would result in better outcomes.[18]

BREAST CANCER

It was predicted that in the United States in 2004, invasive breast cancer would be diagnosed in an estimated 215,990 women; in situ disease would be diagnosed in 55,700 women; and 40,110 women would die of the disease.[19] A 40-year-old woman has a 13.2% (approximately one in eight) chance of developing invasive breast cancer during her life, but her risk of developing breast cancer within 10 years is only 1.47% (approximately one in 68). Modalities for breast cancer screening include mammography, clinical breast examination, and breast self-examination.

Table 3 Criteria for Evaluating a Screening Program

1. Does the program target a disease that causes serious morbidity and mortality that might be prevented by the service?
2. Can the screening test accurately identify healthy people who are at high risk for developing advanced disease?
3. Is the screening test feasible to use in primary care?
4. Does treatment given before symptoms occur result in better outcomes than treatment given later?
5. Do the overall benefits outweigh the harms of screening and treatment?

Table 4 Sample Board Examination Questions About Screening

Question	*Answer and Explanation*
A screening test correctly identifies 95% of patients who have prexerostosis and 95% of patients who are well. If 1 of every 500 patients has prexerostosis, what is the likelihood that a patient who has a positive test has the disease?	The correct answer is 3%; the positive predictive value is commonly overestimated because of neglecting Bayes theorem.
The 5-year survival of stage 0 lung cancer is 95%, versus 10% for more advanced stages. In usual care, 70% of patients present in advanced stages. When screening with a CT scan, 90% of patients have stage 0 disease. By how much will screening reduce mortality?	The correct answer is that the effect of screening on survival cannot be determined; increasing detection of disease in a "curable stage" may improve 5-yr survival but does not necessarily reduce mortality because of overdiagnosis bias, length bias, and lead-time bias—for example, screening may detect slower-growing cancers that would never have become lethal.
With improvements in treatment, mortality from advanced HIV infection has dropped by 63%. Because effective treatment is now available, screening and early treatment should result in even greater mortality reductions. True or false?	The conclusion may be, but is not necessarily, true. If treatment of advanced disease is very effective, screening may not confer any additional advantage. Screening is most likely to improve outcomes when advanced disease is untreatable but treatment of earlier, asymptomatic disease can result in cure.

Mammography

In 2000, a Danish meta-analysis of the major randomized trials of mammography concluded that there was no evidence that mammography reduced mortality from breast cancer.[20] However, another analysis of the same trials conducted for the USPSTF concluded that mammography reduced breast cancer mortality in women 40 to 70 years of age.[21] The controversy centered on disagreement about the quality of the randomized trials of mammography: the Danish investigators excluded five of the eight trials that showed mammography to be beneficial, whereas the United States investigators excluded only two of those eight trials on grounds of quality.

The USPSTF demoted mammography from grade A to grade B to reflect their view that the quality of the evidence was fair and that the net benefit (benefits minus harms) was moderate. Coming after the widely publicized Danish study, the USPSTF recommendation of grade B for mammography received a mixed reception. One independent review, published in 2003, confirmed the USPSTF view that although the trials were flawed, the balance of the evidence still favored screening mammography in women 40 years of age and older at least every 2 years.[22] Conversely, the National Cancer Institute's Physician Data Query program largely endorsed the idea that most of the mammography trials were seriously flawed.

The USPSTF's most controversial decision regarding mammography was to promote screening in women 40 to 50 years of age from a grade C to a grade B. This was done because with several additional years of follow-up since the previous recommendations, in 1996, the pooled risk reduction for women who began screening at this age had become statistically significant. Nevertheless, the number needed to screen is higher, and the balance of benefits and harms narrower, in women 40 to 50 years of age than in older women.

For clinicians, the most difficult question is how to present information about the risks and benefits clearly and fairly to patients. At the time of an earlier controversy over the effectiveness of mammography in women 40 to 49 years of age, a survey of 509 women in the United States found that most believed the

C—No recommendation for or against D—Service not recommended
I—Insufficient evidence

controversy was really about cost.[23] Women may interpret the lifetime risk of one in eight to be their immediate risk of developing breast cancer if they defer or miss their next mammogram.[24] In deciding how to inform patients, clinicians should carefully consider the major criticisms of the USPSTF recommendation. These criticisms represent differences in values rather than disagreements over the facts. There are four principal issues:

1. Is reducing breast cancer mortality important? In the trials, which involved nearly half a million women, mammography clearly had no effect on all-cause mortality. The USPSTF, although fully aware of this fact, chose to base their assessment of the benefits on the narrower grounds of breast cancer mortality. They chose to let women decide for themselves whether reducing the risk of dying of breast cancer was important to them.
2. How large is the reduction in breast cancer mortality? Judging from the trials, about 1,200 women 40 to 70 years of age must be invited to be screened four to five times over 10 years to prevent one death from breast cancer. Of women 40 to 49 years of age, 1,792 (95% CI, 764 to 10,540) must be invited to be screened to prevent one death from breast cancer, a death that would not have occurred until about 20 years after screening began. The specification "invited to" is important: it is likely that the trials underestimated the true benefit because they are diluted by a large number of subjects who were assigned to have mammography but did not.[25] Nevertheless, to benefit even one woman, a large number of women must have a large number of mammograms over many years.
3. Are these estimates from the randomized trials still valid? Evidence from the trials may be out of date**.** The first trial began in 1963, and the others began between 1976 and 1982. Improvements in mammography since then might translate into better outcomes than were seen in the trials. On the other hand, improved systemic treatment for clinically detected breast cancer may have eliminated the advantage that earlier detection conferred in the era of the trials.
4. How large are the harms? The USPSTF was criticized for ignoring or underestimating harms. In fact, the USPSTF considered the harms, but it was also influenced by evidence that many healthy women stated that they would be willing to take on these risks, as well as the morbidity associated with treatments, to avoid a breast cancer death.[26]

What are the harms? Women who get 10 annual mammograms have about a 50% chance that at least one of them is a false positive result; many of these false positive results necessitate a biopsy. Of women who are found to have invasive cancer, about 30 must undergo major surgery, or surgery plus radiation or tamoxifen, to prevent one death from breast cancer. In addition, screening identifies many women with ductal carcinoma in situ, and many of these women also undergo surgery, with uncertain benefit. In sum, many women experience immediate morbidity from treatment; without screening, most of them would not have had consequences of their breast cancer (and no morbidity from mastectomy) for many years, if ever.

Table 7 Strongly Recommended Noncancer Preventive Services in Adults*

Service	*Candidates*	*Established Benefits*
Aspirin for primary prevention of cardiovascular events	Adults at high cardiovascular risk	Reduces the risk of stroke
Blood pressure screening	All adults	Reduces the risk of stroke
Screening for lipid disorders	Men 35 yr of age and older; women 45 yr of age and older; and younger adults at increased risk for coronary artery disease	Reduces overall mortality, as well as mortality from cardiovascular disease
Chlamydial infection screening	Sexually active women 25 yr of age and younger; other asymptomatic women at increased risk for infection	Reduced the risk of pelvic inflammatory disease in one randomized trial[36]
Hepatitis B virus (HBV) infection screening	Pregnant women	Reduces prenatal transmission of HBV
Syphilis screening	Persons at increased risk for infection; all pregnant women	Penicillin treatment during pregnancy reduces the risk to the fetus of acquiring congenital syphilis
HIV screening†	Pregnant women High-risk men and women	Reduces prenatal transmission of HIV Delays mortality from HIV disease and permits counseling to reduce transmission
Screening for asymptomatic bacteriuria	Pregnant women (urine culture at 12–16 weeks' gestation)	Prevents symptomatic urinary tract infections, low birth weight, and preterm delivery

*As per the United States Preventive Services Task Force. †As per the CDC.[37,38]

Table 8 Recommended Vaccination Schedule for Health Care Workers[7]*

Vaccine	*Schedule*
Tetanus-diphtheria	Every 10 yr after complete primary series or for persons lacking documentation of vaccination
Influenza	Annual
Pneumococcal (polysaccharide)	For persons with medical indications† or at risk for exposure
Hepatitis B	For persons lacking documentation of vaccination or evidence of disease
Hepatitis A	No data to support a recommendation
Measles, mumps, rubella (MMR)	For persons lacking documentation of vaccination or history of disease‡
Varicella	For persons lacking documentation of vaccination or history of disease

*As per the Advisory Committee on Immunization Practices.

†*Medical indications:* Chronic pulmonary disorders, excluding asthma; cardiovascular disease; diabetes mellitus; chronic liver disease, including liver disease as a result of alcohol abuse (i.e., cirrhosis); chronic renal failure; chronic renal failure or nephrotic syndrome; functional or anatomic asplenia (e.g., sickle cell disease or splenectomy); lymphoma, multiple myeloma, generalized malignancy, or organ or bone marrow transplantation; chemotherapy with alkylating agents, antimetabolites, or long-term systemic corticosteroids; or cochlear implants.

‡*Measles component:* Adults born before 1957 can be considered immune to measles. Health care workers born during or after 1957 should receive two doses of MMR vaccine unless they have a medical contraindication, documentation of one or more dose, or other acceptable evidence of immunity. *Mumps component:* One dose of MMR vaccine should be adequate for protection. *Rubella component:* Administer one dose of MMR vaccine to women whose rubella vaccination history is unreliable, and counsel women to avoid becoming pregnant for 4 wk after vaccination. For women of childbearing age, routinely determine rubella immunity and counsel regarding congenital rubella syndrome. Do not vaccinate pregnant women or those planning to become pregnant during the next 4 wk. For women who are pregnant and susceptible, vaccinate as early as possible in the postpartum period.

Clinical Breast Examination

The USPSTF could not determine the benefits of clinical breast examination (CBE) alone or the incremental benefit of adding CBE to mammography (grade I recommendation). No screening trial has examined the benefits of CBE alone (without accompanying mammography). Four of the eight trials of screening used mammography alone, and four used mammography plus CBE. In the trials that used both methods, CBE detected 40% to 69% of breast cancers. It is not clear from the trials whether CBE contributed to the reduction in breast cancer mortality observed in some of the trials.

Breast Self-examination

A randomized trial from China failed to show a reduction in breast cancer mortality or an improvement in tumor stage at presentation in women receiving instruction in breast self-examination.[27] Results from a Russian trial were similar.[28] In both trials, women who had been instructed in breast self-examination were more likely to seek medical advice for benign breast lesions.

Genetic Risk Assessment

In women whose family history suggests an increased risk of deleterious *BRCA1* or *BRCA2* mutations, the USPSTF recommends referral for genetic counseling and evaluation for *BRCA* testing (grade B recommendation). However, the USPSTF recommends against routine testing for breast cancer susceptibility genes (i.e., *BRCA1* or *BRCA2*) or routine referral for genetic counseling in women whose family history does not suggest an increased risk of deleterious mutations in these genes (grade D recommendation). Such screening and counseling have few or no benefits and could have important adverse ethical, legal, social, and medical consequences.

Cancer Screening Measures That Are Not Recommended

The USPSTF recommended against screening for bladder, ovarian, pancreatic, and testicular cancers. In each case, the deciding factor was that screening and treatment caused serious, immediate harms, whereas evidence of a benefit was inconclusive. As with mammography for breast cancer, screening for

Table 9 Recommended and Strongly Recommended Measures for Cancer Prevention*

Service	*Recommendation Grade*	*Candidates*	*Comment*
Cervical cancer screening	A	Women who have been sexually active and have a cervix; begin screening within 3 yr of onset of sexual activity or at age 21 (whichever comes first) and screen at least every 3 yr, stopping at age 65	Reduces the risk of invasive cervical cancer and mortality from cervical cancer
Colorectal cancer screening	A	Adults 50 yr and older (earlier in patients with a strong family history)	Reduces the risk of invasive colon cancer and mortality from colon cancer
Breast cancer screening	B	Women 40 yr and older	Reduces mortality from breast cancer
Breast cancer chemoprophylaxis	B	Women at high risk for developing breast cancer	Reduces the incidence of invasive breast cancer

*As per the United States Preventive Services Task Force [*see Table 6*].

Table 10 Recommended Preventive Noncancer Screening*

Condition	*Screening Measure*	*Comments*
Abdominal aortic aneurysm	Abdominal palpation, ultrasonography	Men 65 to 70 yr of age who have ever smoked should be screened one time by ultrasonography
Depression	Standardized questionnaire	In most trials, screening alone had nonsignificant effects on treatment rates and on clinical outcome; however, larger benefits were observed in studies in which the communication of screening results was coordinated with effective follow-up and treatment; in such settings, 110 patients would need to be screened to produce one additional remission after 6 mo of treatment
Obesity	Measurement of body mass index (BMI)	Screening can identify obesity (BMI ≥ 30 kg/m^2); programs that combined diet and physical activity produced modest weight loss (6.4 lb on average for 1 yr or more); most trials did not report the proportion of subjects who lost weight
Osteoporosis	Dual–energy x-ray absorptiometry	Women older than 65 yr and high-risk women 50 yr of age and older should be screened; alendronate reduces the risk of fracture over 3–5 yr, but the longer-term benefit of treatment is unclear

*"B" recommendations, United States Preventive Services Task Force.

these cancers is aimed at detection of early invasive disease, and treatment has substantial morbidity. This degree of morbidity is in contrast to that associated with screening for colonic polyps or cervical dysplasia, for which treatment is relatively safe and is aimed at preserving, rather than removing, the involved organ.

Prostate Cancer Screening

The USPSTF concluded that evidence was insufficient to recommend for or against prostate cancer screening. This conclusion was based on the following considerations: (1) there are no completed randomized, controlled trials of screening, although studies are ongoing in the United States[29] and in Europe[30]; (2) although prostate cancer is a major cause of cancer death in men, many cases are clinically indolent (in autopsy studies, the prevalence of histologic prostate cancer in men older than 50 years is about 30%, but only 3% of men die of prostate cancer)[31]; (3) the value of treatment for the localized cancers targeted by screening is unknown; the one randomized, controlled trial of radical prostatectomy, which found no improvement in the 15-year survival rates of patients undergoing surgery, has been criticized for methodological problems[32] (another randomized, controlled trial comparing expectant management with radical prostatectomy for the treatment of localized cancer is under way)[33]; (4) aggressive treatments for localized disease are associated with significant morbidity; and (5) mortality from prostate cancer has not declined in the United States despite 15 years of widespread use of PSA testing.

Lung Cancer Screening

The USPSTF concluded that evidence was insufficient to recommend for or against screening asymptomatic patients for lung cancer with low-dose CT, chest x-ray, sputum cytology, or a combination of these tests. Although there is fair evidence that screening with these measures can result in detection of lung cancer at an earlier stage, there is poor evidence that any screening strategy for lung cancer decreases mortality. Moreover, the invasive nature of diagnostic testing and the possibility of a high number of false positive tests in certain populations raises the potential for significant harms from screening.

Noncancer Screening

Selected screening tests for diseases other than cancer are recommended for all adults, or for groups defined by age and sex. These diseases include abdominal aortic aneurysm in older men, depression, obesity, and osteoporosis [*see Table 10*].

Behavioral-Counseling Interventions

Unhealthy behaviors have a huge impact on mortality and morbidity. Tobacco use remains the leading preventable cause of death in the United States, contributing to more than 440,000 deaths each year. Misuse of alcohol is responsible for 100,000 more deaths. Although tobacco use has decreased, alcohol abuse, obesity, and diabetes have increased in recent years, bringing new attention to the need to eat, drink, and exercise sensibly.

The evidence base supporting brief counseling by primary care physicians has grown substantially in the past 10 years. To date, however, efficacy has been proved only for counseling on tobacco cessation and alcohol use [*see Table 11*]. Evidence to support counseling on diet, exercise, and other behaviors (e.g., use of sunscreens, seat-belt use) is limited. In many instances, follow-up in the available studies was too short to confirm that behavior change is sustained long enough to reduce the risk of developing disease or injury.

Table 11 Selected Recommendations for Counseling and Patient Education

Counseling Topic	*USPSTF Grade**
Tobacco use	B
Alcohol use/driving after drinking	B
Healthy diet	I
Physical activity	I
Seat-belt use	I
Regular dental care	I
Avoidance of sun exposure/use of protective clothing	I
Adequate calcium intake (women)	I
Use of sunscreens	I

*See Table 6.
USPSTF—United States Preventive Services Task Force

SMOKING CESSATION

There is strong evidence that smoking bans, increasing the price of tobacco products, and public-information campaigns can discourage people from starting to smoke and encourage them to stop. Smoking cessation rapidly decreases the risk of stroke and heart disease and slowly decreases the risk of lung cancer [*see CE:III Reducing Risk of Injury and Disease*]. In patients with peripheral vascular disease, smoking cessation reduces the risk of limb amputation and recurrent stroke.

Brief counseling by clinicians can help smokers take action. Counseling by physicians becomes increasingly important as more patients become motivated to quit. Because many patients have tried and failed before, brief messages should emphasize that repeated efforts often bring success.

ALCOHOL USE

Screening and counseling of alcohol use in primary care is aimed at drinkers who are at risk for harm from alcohol consumption that exceeds daily, weekly, or per-occasion norms (i.e., risky or hazardous drinking) [*see 13:III Alcohol Abuse and Dependency*]. Unlike harmful drinking and alcohol abuse or dependence, risky drinking behavior has not yet resulted in physical, social, or psychological harm to the drinker, and such drinkers do not meet diagnostic criteria for alcohol dependence.[34] In contrast to persons who engage in risky drinking, alcohol-abusing and alcohol-dependent drinkers may require intense addiction treatment and are unlikely to respond to brief advice from a physician.

Self-administered questionnaires or brief interviews can be used to assess average quantity or frequency and binge use. In the United States, about 8% to 18% of patients screen positive for binge drinking. CAGE is a four-item screening questionnaire to detect alcohol abuse and dependence. Its name derives from the topics of the four questions: Have you ever felt you ought to **C**ut down on drinking? Have people **A**nnoyed you by criticizing your drinking? Have you ever felt bad or **G**uilty about your drinking? Have you ever had a drink in the morning to steady your nerves or get rid of a hangover (**E**ye-opener)? In contrast, the Alcohol Use Disorders Identification Test (AUDIT), a 10-item instrument, is designed to identify risky and harmful use. In several controlled trials conducted in primary care settings, it was found that brief, multicontact behavioral-counseling interventions reduced risky and harmful alcohol use. About one in 10 risky drinkers reduced their alcohol use to sensible levels for up to 1 year.[35]

Reminder Systems

The USPSTF has created patient pocket guides that are based on its guidelines and that clinicians can use as reminder systems to promote patients' involvement in their own preventive care. These pocket guides are available on the Internet. There is one for all adults (http://www.ahrq.gov/ppip/adguide), one for adults older than 50 years (http://www.ahrq.gov/ppip/50plus/index.html), and one for women (http://www.ahrq.gov/ppip/healthywom.htm).

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

VI OCCUPATIONAL MEDICINE

Linda Rosenstock, m.d., m.p.h., f.a.c.p.
Mark R. Cullen, m.d.

Awareness of the impact of the work environment on health has increased dramatically in the past few decades. Common clinical problems, such as carpal tunnel syndrome and respiratory irritation and allergy, are increasingly being related to physical, chemical, and biologic hazards at work.[1] In this chapter, we cover some of the most common occupational disorders diagnosed in industrialized countries, and we present examples of known or suspected causes [*see Table 1*]. More extensive descriptions of specific disorders are presented in other chapters of *ACP Medicine* and in textbooks of occupational medicine.[2-4] An increasing amount of information about occupational medicine is available on the Internet from the National Institute for Occupational Safety and Health (http://www.cdc.gov) and the Occupational Safety and Health Administration (http://www.osha.gov).

Data on the frequency of occurrence of most occupational disorders are limited; however, data demonstrating the extent of the problem are available. Recent estimates are that each year, approximately 55,000 deaths result from occupational illness, and 3.8 million disabling occupation-related injuries occur.[5] Costs of occupational deaths and related injuries have been estimated to be $125 billion to $155 billion a year.[5,6] Occupational illness is common and has substantial clinical ramifications.

Basic Principles of Occupational Disease

It is important to debunk the widespread and erroneous perception that most occupational disorders are pathologically unique. Although some disorders, such as silicosis, do have distinguishing pathologic characteristics, the majority do not. Most occupational diseases—such as lung cancer induced by ionizing radiation, bladder cancer caused by fumes from coke ovens, asthma triggered by the inhalation of platinum salts, and fatty liver resulting from the absorption of the solvent dimethylformamide through the skin—are pathologically indistinguishable from disorders with more familiar causes. However, it is virtually always possible to differentiate occupational diseases from their nonoccupational counterparts. Laboratory testing and data gathering provide the best clues for the diagnosis of occupational disease, but to recognize these disorders, it is critical to ask appropriate questions when taking the medical history [*see* Clinical Evaluation, *below*].

Workplace toxins and hazards, when adequately studied, have predictable and discrete pathologic consequences. Although other diseases share common final pathways, the initial mechanisms of injury are generally highly specific for each agent. Aside from the possibility of idiosyncratic responses, as occur with pharmacologic agents, the actual potential effects of most toxins are few. For example, beryllium may cause an acute inflammatory pneumonia (acute beryllium disease) within hours after intense exposure, or it may cause a delayed hypersensitivity response with granulomatous lung disease (chronic beryllium disease [CBD]) in persons with recurrent or long-term exposures; no other form of nonmalignant lung disease is known to be caused by this metal or its salts.

Both the likelihood that workplace hazards will produce effects and the severity of those effects are determined by the amount of toxin to which the patient is exposed (hereafter referred to as dose). The nature of the relation between dose and response depends on the mechanism of action of the agent. For direct-acting toxins, which cause effects by directly disrupting cellular function or cell death at the target-organ level, there is usually a dose beneath which no biologic effects are observed—a so-called threshold level. Above this level, there is typically a sigma-shaped dose-response correlation as dose rises, until a lethal dose is reached. Similarly, an increasing percentage of the exposed population is affected as dose rises; eventually, everyone is affected. This is characteristic of heavy metals, organic solvents, and pesticides. For agents that cause allergic-type or idiosyncratic responses, such as latex and epoxy resins, which affect only susceptible people, dose contributes to the likelihood of sensitization, though not necessarily to the severity of the reaction. Further, once a worker has become sensitized, a very low dose may be sufficient to induce a full-blown clinical response. For mutagens and carcinogens, current knowledge presumes a linear dose-response model, with each increment in cumulative dose resulting in a proportional increase in the risk of cancer. The severity of the resultant cancer bears no predictable relation to the induction dose, though the time from exposure to onset generally is shorter when doses are higher.

The temporal relation between exposure and effect is highly predictable for each agent and each effect. For many direct toxins, effects occur within minutes or hours after exposure to an appropriate dose, such as the syndrome of cholinergic storm after organophosphate pesticide poisoning. Similarly, immunologically mediated responses, such as asthma and dermatitis, will occur within minutes or hours after exposure. Conversely, other effects are predictably delayed. Asbestos and silica rarely cause pneumoconiosis in less than 10 years after first exposure, except after very high exposure levels. Solid tumors, such as lung cancer associated with these same dusts, emerge, on average, 20 to 30 years after first exposure. Other effects occur in an intermediate time frame: some organophosphates cause a paralysis whose onset is delayed by weeks to months after an intense overexposure. The presentations of acute lead, mercury, or arsenic poisoning are insidious, coming after the poison accumulates to a dangerous level, usually after weeks or months of exposure.

When the clinician is approaching patients with new medical problems, consideration should be given to occupational causes. If the problem is acute, such as the relatively sudden onset of a rash or of liver function abnormalities or hemolysis, the search for a possible occupational cause should focus on recent events: Has there been a new or increased exposure to an agent that can cause such toxicity in the hours, days, or, at most, weeks before onset? On the other hand, for chronic disorders, such as pulmonary fibrosis and cancer, the search for causes should begin with a work history that goes back years.

With regard to work histories, it is important to note that host factors may modify temporal and dose-response correlations; all workers do not react alike to comparable exposures.

Table 1 Common Occupational Disorders

	Disorders	*Examples of Causal Factors*
Respiratory tract	Pneumoconiosis	Coal, silica, asbestos
	Asthma	Latex, polyurethane
	Allergic alveolitis	Vegetable matter, machining fluids
	Metal fume fever	Metal fumes
Skin	Contact dermatitis	Oils, rubber, metals
	Acne	Herbicides, oils, friction
	Urticaria	Latex
Urinary tract	Glomerular disease	Organic solvents, mercury
	Tubulointerstitial disease	Cadmium, lead
Liver	Acute or subacute necrosis	Organic solvents, TNT, 2-nitropropane
	Cholestatic hepatitis	Methylene dianiline
	Acute and chronic hepatitis	Viruses (hepatitis B, C)
	Steatosis	Organic solvents
	Hepatoportal sclerosis	Vinyl chloride, arsenical compounds
	Hepatocellular injury	Lead, arsenic, phosphorus, dioxin
Musculoskeletal	Carpal tunnel syndrome	Repetitive trauma
	Raynaud phenomenon	Repetitive vibrations, vinyl chloride
	Scleroderma	Coal mining
Nervous system	Parkinsonism	Manganese
	Peripheral neuropathy	Solvents, lead, acrylamide, arsenic
	Acute encephalopathy	Organic solvents, asphyxiants
	Acute or subacute cholinergic crisis	Organophosphate and carbamate pesticides
	Subacute encephalopathy	Mercury, lead, arsenic, manganese, carbon disulfide
	Subacute peripheral neuropathy	Organophosphates
	Chronic basal gangliar disorder	Manganese, carbon monoxide (postasphyxiation)
	Chronic encephalopathy	Recurrent organic solvent exposures
Hematologic conditions	Hemolysis	Lead, organic nitrites
	Accelerated red cell destruction	
	Acute hemolysis	Nitro and amine compounds
	Subacute hemolysis	Lead
	Disorders of oxygen transport	
	Methemoglobinemia	Nitro and amine compounds
	Carboxyhemoglobinemia	Carbon monoxide
	Disorders of red cell production	
	Hyperplastic anemia	Lead
	Aplastic anemia, hypoplastic anemia	Ethylene glycol ethers, benzene, arsenic, ionizing radiation
	Myelodysplasia	Benzene, ionizing radiation
	Polycythemia	Cobalt
Infectious	Hepatitis B, C	Health care
	Influenza A (H5N1)	Poultry workers
	SARS	Health care
	Anthrax	Animal handling
Endocrine and reproductive	Hypogonadism	Lead
	Azoospermia, oligospermia	DBCP, ionizing radiation
	Teratogenesis	Organic mercury, PCBs

DBCP—1,2-dibromo-3-chloropropane (pesticide) PCBs—polychlorinated biphenyls SARS—severe acute respiratory syndrome

In every workplace, some people appear to be immune to the effects of even the most toxic agents, and others seem to react to low doses, often lower than the threshold deemed toxic by regulatory authorities. These differences may be caused by genetic, dietary, or constitutional factors or by the preexistence of other illnesses.

In addition, many workplace hazards and toxins interact with one another and with nonoccupational factors to cause disease. Dose-response correlations for industrial hazards may be markedly shifted in the presence of other hazards, habits, or medications. An important example is the likelihood of disease resulting from thermal stress (i.e., heat or cold) in the presence of hemodynamically active agents, such as calcium channel blockers, autonomic agents, and diuretics.[7] Likewise, the effects of vibration trauma on wrists and digits may be amplified by nicotine.[8] The effects of one hazard may be significantly altered in the presence of another; for example, the combined effect of noise and solvents on hearing loss[9] and of asbestos and smoking on lung cancer[10] are greater than the effect of exposure to each hazard alone.

Defining the Pathophysiologic Basis of the Patient's Complaints

When searching for the pathophysiologic basis of a patient's complaints, it is important to ascertain the following: Is the process an acute or relapsing process, with precipitous changes in physiologic status, reflecting a recent or ongoing exposure? Or is it a chronic process, more likely the result of noxious exposure in the distant past? Dysfunction of what organ or organs best explains symptoms? Is there evidence of physiologic disruption, or is the disorder predominantly one of subjective difficulties?

Taking the Occupational History

Every patient should be questioned regarding the essentials of occupation, including current and past workplaces, job type, and materials used. Open-ended questions are always appropriate (e.g., "Are there dangerous materials or hazards in your workplace?" and "Do you believe that your work is causing you any health problems?").[11] The exploration of work as the basis for a complaint or medical problem entails an incisive approach and depends on the nature of the clinical problem being investigated. Evidence suggests that physicians need to become more adept at assessing a patient's occupational history.[12]

Approach to the Patient with an Acute Disorder

The emphasis should be on new exposures, increased exposures, and accidental exposures. Has the patient recently begun a new job or task involving hazards? Were new materials recently introduced at work? Has there been a change in working conditions, such as a failure of the ventilation system? Has there been a leak, spill, or accident? If the answer to all of these questions is no, the likelihood is low that the acute illness is related to work processes or chemicals.

Other than acute effects that are immunologically mediated, most effects are not idiosyncratic and will follow a sigma-shaped dose-response correlation like that discussed for direct-acting toxins (see above). In such circumstances, it would be expected that a high proportion of exposed persons would be affected, although individual thresholds and dose responses may differ. Questions probing effects in other exposed persons are extremely helpful, as in the investigation of food poisoning or respiratory infections. Although a negative answer does not exclude a work-related effect, the suggestion of an outbreak or a cluster makes the probability of an association high and increases the urgency of a prompt, correct diagnosis.

Approach to the Patient with Recurrent Manifestations

A patient may have repeated or recurring manifestations, such as intermittent cough, rash, or nausea. Although the cause may be difficult to establish in some situations, especially when symptoms have been very persistent or chronic, the time course, particularly at the onset of recurring manifestations, is often extremely revealing. For example, a new asthma patient whose symptoms occur on vacations and weekends is unlikely to have an occupationally related disorder.

Approach to the Patient with Chronic Disease

When patients present with evidence of irreversible organ damage or malignancy, the approach is altogether different. Although the longer latency between initial exposure and disease onset is useful in determining whether occupational exposures have played an important role, questions directed at temporal associations between symptoms and exposures are not helpful. Rather, the first step is to establish a clear pathophysiologic picture of the disease process itself. Sometimes, knowledge of past exposures may assist in directing this evaluation. For example, a worker who has been exposed to asbestos and who presents with a malignant pleural effusion should be carefully evaluated for mesothelioma, which is otherwise an uncommon disorder.

Once the disease process is characterized, a role for occupational factors can be more seriously considered by obtaining a more detailed history of exposures. Because only a handful of agents are suspected of causing or have been proved to cause any single chronic disease, the goal of this history is to determine whether exposure to any of those agents has occurred and whether the exposure occurred at a time and dose that suggest a causal connection to the disease.

Approach to Subacute and Insidious Disease

The greatest diagnostic challenge in clinical occupational medicine is the clinical disorder of gradual onset over days to weeks for which none of the above approaches are effective. Examples include peripheral neuropathies, anemia, and a change in bowel habit in the absence of evidence of malignant or irreversible organ system damage. Often, in such cases, the search for the underlying pathophysiologic process and the search for its cause seem intricately related and must proceed simultaneously. Lessons from these paradigms may be helpful. If indeed the subacute process is toxic, it most likely reflects the effects of a recent exposure, typically of an agent that is accumulating slowly. Heavy metals, pesticides, and various toxic organic chemicals often accumulate in this fashion; under typical conditions of exposure, it may take weeks or months for these agents to accrue to levels of pathogenic significance. Although it is unnecessary to identify an accidental leak or spill to make a diagnosis in such cases, it is essential to note any enhanced opportunity for exposure or any novel exposure that may have occurred relatively recently. The distant exposure history is not likely to be helpful, because the subacute disorders almost always present at the point of maximal accumulation; once the worker is removed from the site of the exposure, latency or delay in onset is unusual.

CONFIRMING AND QUANTIFYING EXPOSURE

There are two basic approaches to obtaining additional exposure information. The first involves the collection of independent information about present or former work (depending on which is relevant). After the physician obtains consent from the patient (to ensure that the patient is protected from unwanted consequences), information about exposures is requested from the employer, a trade union, or a regulatory agency. Such information is usually reported through the use of a material safety data sheet (MSDS). The MSDS provides generic chemical names, compositions, and basic toxicity information of all materials used. In addition, employers may be able to provide evidence of objective sampling that may have been done to test air levels of hazardous substances. Job descriptions, results of medical tests performed at work, information about other workers with health problems, and the use of protective equipment or other methods to limit exposure may all be of value in assessing workplace exposures.

The second potential source of dose information is biologic testing. For a few hazards, testing of urine, blood, or hair may enable the physician to determine the body burden of the agent;

Table 2 Common Occupational Hazards for Which There Are Widely Available Biologic Tests of Exposure

Hazard	*Comments*
Metals	
Arsenic	Hair sampling can detect historic exposures
Cadmium	Detectable in urine for many years if there is renal injury
Fluorides	Transient in urine
Lead	Half-life 40 days in blood
Mercury	Detectable in urine for days to weeks
Asphyxiants	
Carbon monoxide	Half-life 4 hr in blood
Pesticides	
Organophosphates	Detectable indirectly, by measurement of cholinesterase, which may be depressed for days to months
Organochlorines (e.g., DDT, chlordane, dieldrin)	Persists in blood
Organic solvents	
Benzene and toluene	Metabolites transiently in urine
Antigens	IgE antibodies measurable by RAST
Miscellaneous	
PCBs	Persists in blood

PCBs—polychlorinated biphenyls RAST—radioallergosorbent test

the results of such testing correlate with current or recent levels and, less commonly, with remote exposures [*see Table 2*]. Most of these tests cannot detect chemicals that have been cleared from the body or deposited in bodily organs; this substantially limits their usefulness for diagnostic decision making. Of course, there are no simple tests for chemicals that cause topical injury to skin or respiratory mucosa but are not absorbed. For agents that act by immune sensitization, radioallergosorbent testing or skin-patch testing may be useful both for documenting exposure and for subsequent elicitation of an immune response.

Most important of all is to remember that a test for exposure can be interpreted only in the context of the history and the clinical problem. It should not be directly interpreted as a test for disease, regardless of how the laboratory reports the data. For example, a whole blood lead level of 25 mg/dl is clear evidence of excess lead exposure. If the history indicated that the patient had recently been exposed for the first time, this level would suggest a modest, generally subtoxic dose of lead. If, however, the patient had worked around lead for many years and quit a year before the test was performed, this same value would suggest a very high previous exposure and might well be associated with health effects caused by high long-term exposure. Similarly, a large proportion of bakers working around flour dust may have IgE antibodies to wheat, rye, or other grain antigens, even though the vast majority of those bakers are symptom free and will most likely remain so. Given all these limitations, biologic testing plays only a limited role in occupational medicine and can never be a substitute for the occupational history.

DIAGNOSTIC DECISION MAKING

The determination that a patient's symptoms are work related often entails extensive ramifications for the patient's employer, as well as potentially serious public health and medicolegal implications. These may present a significant challenge to the clinician, because for many occupational disorders, there is no gold standard for diagnosis.

The decision-making process should address the following questions:

1. Is the clinical illness—including the history, physical examination, and laboratory findings—consistent with other case descriptions?
2. Is the timing between exposure and clinical onset compatible with the known biologic facts about the hazard?
3 Is the exposure dose within the range of doses believed to cause such effects?
4. Are there special attributes of the particular patient that make it more or less likely that he or she would be so affected?
5. Are there alternative ways of constructing the case that better fit the available facts?
6. Where there remains significant uncertainty about the cause, how important is it to be certain?

Regarding the certainty of identifying the cause, the general legal standard for workers' compensation purposes is "more likely than not," which is a relatively low hurdle of certainty (i.e., at least 50% certain). However, there may be other situations that demand a higher level of confidence, irrespective of the standard for obtaining compensation benefits. In general, problems involving current working conditions demand a far greater level of certainty than historical ones. For example, a diagnosis of occupational asthma in a spray painter would likely dictate removing the patient completely from exposure to the offending paint or constituent; correct identification of that agent might be crucial to saving his or her career. Similarly, if a surgeon presented with recurrent anaphylactic reactions, it would be very important to determine whether the reactions were to latex, an anesthetic agent, or some extrinsic factor.

In situations where a high level of certainty is needed, it is often worth the effort to refine the diagnostic impression by serial observations, usually while the patient remains exposed, or by utilizing diagnostic challenges of removal followed by reexposure. Using serial functional measurements, such as peak expiratory flow records or serial blood tests, a more certain judgment can be made. This may also be an appropriate circumstance for referral to occupational physicians who specialize in evaluating challenging cases.

Major Occupational Disorders in Developed Countries

The spectrum of occupational disorders of clinical importance is rapidly shifting as a result of several factors: these include changes in the economy, which have brought about a decline in traditional manufacturing and a rise in service-sector activities; better control of many hazards, such as mineral dusts (e.g., asbestos, silica, coal), heavy metals (e.g., lead, arsenic, mercury), and the most toxic solvents (e.g., benzene); rapid introduction of many new technologies whose health risks remain inadequately characterized; and changing demographics in the workplace, in which the proportion of women, minority, and older workers is increasing. In the sections that follow, the disorders that are most important in clinical practice in developed countries are briefly discussed by organ system.

Only a small fraction of known chemical agents and a handful of physical and biologic hazards appear capable of inducing neoplastic change in mammalian tissues. In general, the risk of cancer being induced increases in direct proportion to total dose of toxin to which the person is exposed. Typically, the target organ is relatively specific and is determined by metabolism and transport of the agent. However, a few agents, including ionizing radiation and asbestos, appear to have potential to cause malignancy at more than one human site. There is invariably a long lag time between initial exposure and onset of clinical disease. Only a small number of hazards found in the workplace have been clearly established as carrying substantive cancer risk for workers. An additional group of hazards are suspected, but additional studies are needed. The list of potential carcinogens is expanding; for example, evidence suggests that exposure to cadmium may play a role in the development of prostate cancer.[13] Studies provide some indication that workers in print shops, service-station employees, farm-product vendors, horticulturists, farmers, and aircraft mechanics are at increased risk for renal cell carcinoma[14,15] [*see Table 3*].

Table 3 Established Occupational Carcinogens

Cancer Site	*Hazard*	*Setting*
Lung	Asbestos	Insulation, textiles
	Ionizing radiation	Uranium mining
	Arsenic	Refining
	Polyaromatic hydrocarbons	Coke ovens
	Nickel	Nickel refining
	Chromium	Tanning, pigments
	Alkylating agents	Chemical industry
	Silica	Mining, stonecutting
	Ceramic fibers	Insulation
	Formaldehyde	Chemicals, plastics
	Beryllium	Nuclear weapons, aerospace industry
	Cadmium	Batteries
	Acrylonitrile	Plastics
	1,3-Butadiene	Rubber, plastics
Pleura and peritoneum	Asbestos	Construction materials
Upper respiratory tract	Wood dust	Carpentry
	Nickel	Refining
	Chromium	Plating
	Asbestos	Friction products
	Formaldehyde	Chemicals, plastics
Urinary bladder	Benzidine and related amines	Dyes, chemicals
	Polyaromatic hydrocarbons	Aluminum reduction
Liver	Vinyl chloride monomer	Plastics
	Arsenic	Pesticides
Upper GI tract	Asbestos	Shipbuilding
	Coal dust	Mining
	Acrylonitrile	Plastics
Hematologic system	Benzene	Chemicals, rubber
	Ionizing radiation	Defense industry
	Ethylene oxide	Chemicals, sterilizers
Soft tissue	Dioxin	Chemical industry
Brain	Vinyl chloride	Chemical industry
	Formaldehyde	Chemical industry

The respiratory tract is a frequent target of toxic effects. Complaints referable to the lungs or upper respiratory tract often require a careful evaluation for occupational causes. The presence of other possible causal factors, such as common allergy and smoking, does not exclude the possibility of an occupational cause and may, in fact, increase the likelihood of one.

Acute Disorders and Recurrent Disorders

The most prevalent acute effects—inflammatory reactions of the mucosae of the upper or lower airway system—are caused by environmental irritants.[16] An extraordinary array of agents are irritating, including simple inorganic gases (e.g., ammonia and chlorine), organic solvents, acid and alkaline mists, metal fumes (i.e., tiny particles of metal and metal oxide that occur when vaporized metals hit cool air), mineral dusts (e.g., fibrous glass and coal), and almost all the pyrolytic products of combustion. The anatomic site of irritation for dusts, mists, and fumes depends on the deposition of particles; for gases, it depends on water solubility (i.e., the more water soluble the gas, the more it will dissolve in the upper respiratory tract). Expression of symptoms, from mild burning of the eyes, nose, and throat to small airway and alveolar injury associated with the acute respiratory distress syndrome, depends on dose, duration of exposure, and the potency and composition of the irritant; there is also substantial host variability. The period from the time of exposure to the onset of symptoms is very brief for the upper respiratory structures and can be from minutes to hours for lower structures.

Most of the consequences of acute irritation are self-limited; the upper respiratory tract is particularly resilient, although patients who work in areas of poor air quality will experience frequent recurrences, punctuated by commonplace complications such as sinusitis. Such cases require steps to modify exposure. More severe insults may result in fixed scarring of airways or lung parenchyma; late inflammatory sequelae such as bronchiolitis obliterans are occasionally reported. A newly recognized and probably common outcome of significant lower airway injury is the occurrence of persistent mucosal irritation and bronchospasm, a variant of asthma induced by a single exposure or repeated exposures to irritants. Initially dubbed reactive airways dysfunction syndrome,[17] this disorder is best classified as nonimmune occupational asthma or simply asthma without latency. Unfortunately, the condition tends to be highly resistant to therapy, and patients derive only modest benefit from inhaled steroids or other bronchodilators. Typically, cough with some phlegm, chest discomfort, and occasionally even dyspnea persist despite early and intensive therapy. Reassurance and reduction of further exposures to irritants are the mainstays of treatment.

Occupational asthma, including the nonimmune- and the immune-mediated varieties, is prevalent.[18] There are now over 200 established causes of presumed immune-mediated asthma[19]; these are usually categorized as proteins and other high-molecular-weight antigens (e.g., animal danders, latex antigens, and grains) and small molecules such as the isocyanates—the ubiquitous chemicals used in polyurethane products. Typically, the classic antigens differentially affect those with atopy and are associated with identifiable IgE antibody responses to the sensitizer.[20] In such cases, the greatest diagnostic dilemma is distinguishing occupational sources from other causes of asthma, though the periodicity as documented by history or peak expiratory flow records (PEFR) aid in identifying a relation to work. Latex has become a particularly important cause, especially when ren-

dered airborne in association with the use of powdered gloves.[21,22] More troublesome are the low-molecular-weight agents such as toluene-2,4-diisocyanate (TDI) and other isocyanates, for which atopy is not a risk factor.[19,23] Onset is often insidious, with cough and chest discomfort relatively more common than in asthma of other causes. Far more often than with the IgE-mediated agents, symptoms may be delayed some hours after exposure, so patterns may include nocturnal complaints. Once the physiologic hallmarks of asthma are established, the history and PEFR are the keys to specific diagnosis. Studies have shown that detailed histories can be inconclusive; in some cases, objective measurements can establish the diagnosis of occupational asthma.[24] Specific inhalation tests may be valuable, but they should be performed only under medical supervision.

Current evidence suggests that correct diagnosis of occupational asthma makes a difference. People who are removed early from further contact have a better likelihood of reducing their dependence on medication; many will become nonasthmatic over time.[19,20] Most who remain exposed will develop persistent nonspecific bronchial hyperreactivity, as well as possible fixed obstructive changes. These patients will typically fail to recover after they are removed from contact with the agent, and their conditions may even worsen; this is the basis for an aggressive posture toward early evaluation and management.

Acute infectious diseases occur in an extraordinarily wide variety of workplaces, from health care to industrial and agricultural settings. Anthrax and other agents of bioterrorism, as well as emerging infectious diseases such as severe acute respiratory syndrome and influenza A (H5N1) are of particular concern to workers.[25,26]

Allergic alveolitis, with its more benign variants, such as humidifier fever, continues to occur sporadically in a wide range of settings. This disorder was traditionally associated with agricultural exposures to molds and bacilli. Cases are now reported to occur in manufacturing and other industrial settings because of the appearance of a few chemicals that appear capable of inducing the immune response (e.g., plastic resin constituents) and because of the contamination of many industrial processes with microorganisms.[27] The office environment continues to be an occasional source of this condition as well, though the reservoir of causal microbes may be obscure; such organisms may potentially reside in heating and air-conditioning systems remote from the patient's work area.[28]

Chronic Conditions

The pneumoconioses continue to occur, in part because of their very long latency from first exposure and because pockets of very poor industrial conditions continue to exist even in developed countries. Construction activities have been particularly problematic. In general, asbestosis, silicosis, and coal workers' pneumoconiosis are diseases that occur after extensive work exposures. The diagnosis can usually be made on the basis of clinical findings and the history of exposure, once the patient's lifetime job history is obtained.

The granulomatous diseases, including CBD and so-called hard metal disease, are less common but important and increasingly recognized disorders of sensitization. CBD is clinically almost identical to idiopathic sarcoidosis except that all cases involve the lung and that the prognosis—even after the patient is removed from exposure to beryllium metal, compound, or fumes—is generally unfavorable. All patients with sarcoidosis should be asked if they work with metals, and the least suspicion should prompt specific testing; there is a highly sensitive test that can distinguish sarcoidosis from CBD on blood or bronchoalveolar lavage (BAL) fluid.[29] Hard metal disease is a giant cell alveolitis induced through an idiosyncratic reaction in workers exposed to the metal cobalt.[30] Most often, it occurs in workers making or using tungsten carbide, the very hard metal used for machine tools. Onset may be insidious and may include asthmatic symptoms, because cobalt is asthmogenic as well. Recognition of the parenchymal process by BAL or biopsy is crucial because hard metal disease is progressive, often refractory to treatment with steroids, and often lethal; there is anecdotal evidence favoring the use of cytotoxic drugs. Once hard metal disease is diagnosed, the patient should be promptly removed from any further exposure.

In 1998, a novel form of interstitial fibrosis related to an industrial exposure was reported: flock worker's lung, named after the nylon flocking used for making feltlike textiles.[31] Cases of flock worker's lung are distinctive, with pathologic evidence of both parenchymal fibrosis and lymphocytic bronchiolitis. The reporting of flock worker's lung underscores a key principle of occupational medicine: that new occupational diseases and other clinical consequences of work continue to be uncovered.[32]

DERMATOLOGIC DISORDERS

Despite increased recognition of the need to reduce contact between the skin and the chemical and physical environment, dermal conditions remain responsible for significant morbidity in the workplace. Most disorders are caused by direct exposure of the skin to workplace irritants, sensitizers, pigments, carcinogens, and materials that interfere with normal dermal function by disrupting sebaceous and follicular secretions (e.g., oils that cause acne) or solvents that erode protective lipids. Trauma, foreign bodies, ionizing and nonionizing radiation, and extremes of temperature may modify or disrupt skin growth, vascular integrity, or both. On occasion, systemic exposure may have a dermal consequence, as in urticarial responses to inhaled antigens, pigmentary alterations from the deposition of metals (e.g., silver), and the much-described though rarely seen chloracne, a variant of acne induced by dioxins and related chemicals. Workers who are at increased risk for allergic contact dermatitis include tanners, cast-concrete product workers, leather-goods workers, footwear workers, machine and metal product assemblers, electrical and telecommunications equipment assemblers, print-shop workers, and machine and engine mechanics.[33] Several excellent texts of occupational skin diseases are available.[34-36]

Overwhelmingly, the major skin problem in the workplace remains dermatitis, either irritant induced or caused by allergy. Many agents may be responsible, including organic and inorganic chemicals, plastics and rubber, oils and lubricants, metals and construction materials, paints, and coatings.[37] Both allergic dermatitis and irritant-induced dermatitis are more likely to affect persons with atopic conditions, dry skin, or other dermal risk factors. Distinguishing between the two is less important than recognizing occupational precipitants in the first place; both are difficult to differentiate from other commonplace skin disorders, such as eczema. The key to correct diagnosis is the history of skin contact and the temporal relation between contact and manifestations. Unfortunately, there is seldom a perfect or obvious correlation between the two, and some sleuthing is necessary, especially to discern the extent to which chemical contact

may spread to places like the groin or areas where hand contact occurs. Airborne exposure may cause lesions in apparently untouched areas, such as the face; such occurrences are signs of likely hypersensitivity. Vexingly, symptoms do not always abate dramatically over weekends or during short periods in which exposure is avoided; removing the patient from the toxin for a week or two may be necessary to observe response. This, combined with observation of the patient during reexposure, is often the most valuable diagnostic test. Patch testing, performed by an experienced clinician aware of the exposures of concern, may be useful in difficult cases, though the clinician should keep in mind that irritants may yield false negative results and that even many healthy atopic persons will experience reactions to common contactants, such as nickel.[38] Often, complete isolation from offending agents is economically infeasible, and materials that previously were well tolerated become sources of irritation and exacerbation. Combinations of work modification, aggressive treatment of flares and complications, and careful attention to routine skin care are necessary to control disease.

DISORDERS OF THE URINARY TRACT

Although innumerable toxins are known to cause acute injury to the kidney, exposures to chemical and physical agents at concentrations found in the workplace rarely cause such effects (exceptions include cases involving overwhelming accidental overexposure or ingestion). Of far greater concern are recurring exposures to agents at more typical workplace exposure levels that have subclinical effects but can lead to late nephropathy. Although there remains a vast burden of unexplained nephropathology in the population and despite epidemiologic data suggesting an occupational cause,[39,40] chronic renal injury resulting from workplace exposures remains poorly characterized.

The best-established effects on the urinary tract are those caused by exposure to heavy metals, especially lead, mercury, and cadmium; each of these metals is associated with a unique pattern of effects. Workers whose jobs entail exposure to lead include traffic police, hazardous-waste incineration workers, industrial workers, and furniture strippers; workers at risk for exposure to mercury include gold-mine workers, workers at chloralkali plants, workers exposed to hazardous waste, and construction workers; workers at risk for exposure to cadmium include those involved in the manufacture of batteries. Long-standing heavy-lead exposure results in a pattern of injury difficult to distinguish pathologically and clinically from the effects of hypertension; signs and symptoms include nephrosclerosis and evidence of both glomerular and tubular defects. The ability to clear urate is impaired early in the course and may be a clue; saturnine gout may occur a decade later. There is debate about the possibility of low-level or brief exposures to lead predisposing to hypertension or enhancing the degree of renal injury associated with essential hypertension or gout.[41,42] Proponents of this view stress the importance of assessment of lead exposure in patients with mild chronic renal insufficiency.[43]

Long-term occupational exposure to inorganic mercury—principally through exposure to mercury vapor—may result in renal alterations involving the tubules and glomeruli. The monitoring of urinary mercury is useful for controlling such risk.[44]

Cadmium exposure in jewelry making, battery production, and other metal-processing operations leads to bioaccumulation of cadmium in the kidney, which results in proximal tubular injury with excessive excretion of β_2-microglobulin and other tubular proteins. Later, a pattern of renal tubular acidosis may occur, which subsequently may lead to the development of renal insufficiency. Because the tubular dysfunction is only partially reversible,[45] it is important to carefully monitor cadmium exposure, which is best done with regular blood and urine cadmium testing.[46] Renal damage can occur at relatively low levels of cadmium exposure.[47]

Organic solvents have been implicated in renal tubular and renal parenchymal injury[48]; despite uncertainty of their role in renal toxicity, growing evidence suggests the need for evaluation of these substances in all new cases of unexplained nephropathy.

LIVER DISEASE

The liver is highly sensitive to effects of numerous organic and inorganic substances used in the workplace [*see Table 1*]. Despite the impressive potential for harm, often at exposure levels not uncommon in the workplace, occupational liver diseases are rarely recognized except during outbreaks.[49] This is almost certainly because the clinical presentation is nonspecific, most often consisting of unsuspected elevations of hepatocellular enzymes occasionally associated with mild gastrointestinal symptoms. The single exception to this is the now extremely rare vascular disorder resembling veno-occlusive disease that is caused by vinyl chloride.

The more common hepatic effects of occupational hazards—steatosis and nonspecific hepatocellular injury—have numerous causes and are prevalent in the general population; a given case may be readily attributed to infection, alcohol use, drug toxicity, biliary tract disease, diabetes, obesity, or weight change. When persistent elevations of hepatic enzymes prompt more extensive workup with radiographic studies and biopsy, results rarely provide specific evidence of an occupational cause. Only high suspicion of a workplace culprit, combined with evidence of exposure to a suspect agent, serves to distinguish etiology.

CENTRAL AND PERIPHERAL NERVOUS SYSTEMS

Most pesticides,[50] organic solvents,[51] and many metals[52] are neurotoxic at doses that may be seen in the workplace [*see Table 1*]. A handful of other chemicals used in plastics, lubricating fluids, and chemical operations are also neurotoxic; most cases occur after accidental or unusual exposures. In addition, persons exposed to asphyxiants, such as carbon monoxide and cyanide, may present with acute or recurring central nervous system symptoms. Both acute and late effects may occur—the former typically occurring immediately after an intense exposure, the latter often after prolonged periods of exposure. Importantly, the late or chronic effects usually result from prolonged periods of bioaccumulation or recurrent mild or subclinical acute exposures or as sequelae of acute intoxication. A direct consequence of this toxicologic fact is that neurotoxicity almost invariably presents during the time of occupational exposure to the offending agent and not long afterward, as may occur with carcinogenic substances or dusts causing pneumoconiosis.

Because of the extraordinarily diverse range of clinical symptoms that may herald CNS toxicity, including subtle changes in cognitive and affective function, the evaluation of suspected cases follows the general principles for all occupational disease, with increased attention given to recent exposures. The acute disorders usually occur as mild alterations of CNS function,[53] often with associated GI or other systemic effects; they are often recurrent, cycling with periods of work exposure, as might be seen in a painter (through exposure to solvents) or a pest-control worker. The key to recognition is the temporal pattern, with re-

mission of symptoms occurring over a course of time consistent with the metabolism of the toxin. There may also be evidence of symptoms associated with withdrawal, similar to the effects associated with ethyl alcohol. For the subacute and chronic effects, the key to diagnosis is identification of evidence of substantial exposure occurring over a course of time consistent with the evolving neurotoxic picture. None of the neurologic disorders appear to involve allergy or idiosyncrasy; thus, the doses of exposure involved must be substantive.

In many cases, the exposure to the agent can be biologically confirmed with measurement of the levels of metal in the urine or blood, measurement of cholinesterase levels, or identification of a metabolite of an organic chemical in urine. There may also be some clinical or pathophysiologic clues. For example, the constellation of cerebellar ataxia, personality change, and salivary gland hypersecretion should prompt consideration of inorganic mercurialism, possibly with associated renal effects. An asymmetrical motor neuropathy should always raise the specter of lead poisoning. Insidious symmetrical distal sensory neuropathies, on the other hand, are far more common with solvents and acrylamide; electrophysiologic or pathologic evaluation reveals almost pure axonal degeneration, with minimal secondary demyelination—an important differential feature. Highly localized neuropathies, either unilateral or bilateral, should raise the possibility of a compressive etiology, not uncommon with repetitive work activities [*see* Musculoskeletal Disorders, *below*].[54]

Although diagnosis may be straightforward once the possibility of a workplace agent is considered, management remains challenging. Treatment of acute disorders involves ending the exposure and providing support where clinically necessary. Several hazards, such as certain cholinesterase inhibitors and cyanide, have specific antidotes that should be administered under medical supervision. The subacute and chronic conditions all require removal from further exposure. In addition, patients with heavy-metal exposure may be given chelation therapy when signs and symptoms of severe intoxication are evident; this, too, must be done under very close supervision in view of the risk of enhancing CNS effects early in treatment. Moreover, the possibility of rebound effects from reequilibration of metal into the nervous system must be anticipated when chelation is stopped. Most important, whatever strategy is chosen, physician and patient must be aware that the prognosis for full recovery from all but the most acute effects is somewhat guarded. Axons regrow very slowly, and higher integrative functions, such as affective or cognitive functions of the CNS, resolve even more slowly or not completely. Early efforts at functional rehabilitation, as may be used for trauma or stroke patients, are indicated when impairments limit work or other major life activities.

Possibly the most challenging diagnostic situation in occupational neurology is the worker who presents with CNS-related complaints that exhibit a temporal pattern consistent with a workplace origin but who does not have substantial exposure to neurotoxic agents. Such symptoms are a common part of the so-called sick-building syndrome, now referred to as nonspecific building-related illness, and are universal among persons who have acquired intolerance to low levels of chemicals (multiple chemical sensitivities).[55] It is important to recognize early that these syndromes are different from the neurotoxic disorders discussed here with regard to evaluation, prognosis, and treatment. They are discussed more fully later in this chapter [*see* Clinical Problems Associated with Low-Level Environmental Exposures, *below*].

MUSCULOSKELETAL DISORDERS

There has been a marked increase in the awareness of the role that work factors play in musculoskeletal disorders, ranging from such well-defined clinical problems as arthropathies and nerve compression syndromes to the less well characterized ailments causing pain of the trunk and extremities.[54,56] In developed countries, such disorders account for billions of dollars of costs in medical care and lost productivity. The overwhelming bulk of this epidemic relates to suspected consequences of physical stressors and trauma that occur at work. A number of systemic occupational disorders may also have expression in the muscles, bones, joints, and connective tissues; important examples of such disorders are the arthralgias and gouty consequences of lead intoxication, bony pain in association with systemic fluorosis, and the apparent increased risk of scleroderma in miners.[57]

It is clinically useful to divide potential occupational musculoskeletal disorders into those that have a well-defined anatomic structure of involvement, such as carpal tunnel syndrome, and those that lack such a clear-cut pattern, such as low back pain.[58,59] Although extensive data suggest that physical aspects of work, such as overall force, repetition, awkward posture, and vibration, contribute in a cumulative fashion to the development of both localizable and nonspecific symptoms, the approach to diagnosis and treatment is somewhat different for each. There is also evidence that factors other than physical strain, such as work stress, work fatigue, and adverse relationships in the workplace, may be important contributory factors, partially explaining high rates of musculoskeletal disorders among certain white-collar workers.[60,61]

For disorders of new onset involving the trunk or extremities or for clinically mild disorders, the initial approach should be short-term palliation with minimal workup. Rest from physically demanding tasks, use of nonsteroidal anti-inflammatory drugs or other nonnarcotic pain relievers, reassurance, and follow-up after a few days of treatment are suggested; further evaluation is indicated only if suggested by physical findings. If conservative steps fail to alleviate symptoms rapidly, additional examination and laboratory evaluation may be appropriate to rule out an anatomically discrete lesion that could be amenable to treatment. Where specific lesions are identified, such as compression of a nerve or disk or tenosynovial inflammation, longer-term efforts at elimination of strain in the affected region combined with anti-inflammatory drugs or other therapies are appropriate, followed by surgical intervention should these fail. In such cases, it is crucial to remember that the work-related stressors that caused the problem will complicate recovery unless they are modified.[62-64]

The most perplexing problem is the management of patients whose complaints cannot be specifically localized by physical examination or, when necessary, electrophysiologic or radiologic evaluation. Such complaints are no less real than those that are more readily understood and treated. Modification of work activities is often necessary but is rarely sufficient to resolve the problem. Pain may be persistent and refractory to treatment, and the value of physical therapy or pain medications is questionable. Rather, it is important for the treating physician to establish early that the symptoms are troublesome but not the result of a progressive process and that the patient may have to adapt to them despite discomfort. Expectation of cure often leads to unnecessary treatment, prolonged (and clinically unhelpful) loss of work time, and, ultimately, frustration on the part of the employer, the insurance company, the patient, and the physician.

HEMATOLOGIC DISORDERS

A host of disturbances of red cell function, survival, and production have been attributed to workplace exposures, including acute, subacute, and chronic processes [*see Table 1*]. Effects involving other cell lines have seldom been reported and will not be discussed. In clinical practice, the biggest concerns are the risk of acute hemolysis in workers exposed to nitrogen-containing oxidant chemicals in pharmaceutical, chemical, and explosives manufacturing; the effects of lead, which remains ubiquitous in the work environment; and the potential for solvent-induced marrow injury. The problem of oxidant stressors is somewhat difficult. Although workers with marked deficiency of glucose-6-phosphate dehydrogenase (G6PD) should probably avoid significant contact with such chemicals, there is not a clear relation between any of the measurable enzyme levels and risk. It is prudent to periodically screen all exposed workers for subclinical evidence of hemolysis, as well as for subclinical accumulation of methemoglobin, which is often induced by the same agents; workers who show evidence of early effects should probably be removed from harm's way, irrespective of identifiable factors.[65]

The hematologic effects of lead are widely misunderstood.[66,67] Although there is a dose-related inhibition of heme synthetase by lead that can be readily quantified by determining the accumulation of the precursor protoporphyrin (usually measured as whole blood zinc protoporphyrin), this biochemical effect of lead on blood hemoglobin or hematocrit is minimal until very high levels are reached, and there is almost no impact on red cell volume. In other words, anemia associated with hypoproliferation of red cells is very rare, and the absence of anemia should never be used to exclude a role for lead in causing toxicity to organs and systems that are far more sensitive, such as the nervous system and renal tubules. Furthermore, microcytosis can only occasionally be attributed to lead alone; when it is seen, especially in children, it most often signifies coincident iron deficiency. On the other hand, rapid accumulation of lead in acute lead poisoning, typically heralded clinically by the onset of abdominal pain, is almost always associated with evidence of rapid hemolysis; reticulocyte counts are in the range of 5% to 20%. In this setting, the notorious basophilic stipples are frequently seen as well, though they are by no means pathognomonic for lead toxicity. In general, this syndrome will occur only after lead levels have exceeded 60 mg/dl in whole blood. The hemolysis tends to abruptly stop after effective chelation therapy, which is usually indicated in this acute symptomatic form of lead poisoning.

The bone marrow effects of workplace chemicals are only slowly being unraveled, but certain conclusions seem warranted. Benzene, the aromatic constituent of petroleum products, was once widely prevalent in the work environment as a solvent and a component of gasoline. It can cause hypoplastic injury to the marrow, which may directly progress to a chronic blood dyscrasia (i.e., myelodysplasia or leukemia), or dyscrasia may occur after apparent recovery.[68] In other words, an exposed worker may show depressed cell counts, be removed from the source of toxicity, improve, and years later (possibly long after exposure ceases) develop myelodysplasia or a myeloproliferative syndrome. It is likely that some workers will develop the obviously more serious dyscrasias without direct marrow injury having been recognized while exposure was ongoing. There are no hallmark features of either the hypoplastic state (occurring during ongoing exposure) or the myelodysplastic state (occurring later) that distinguish benzene toxicity from other causes of such disorders; this differentiation depends on the history of substantial benzene exposure, because the disorders are not believed to be idiosyncratic but dose related. Although there is some evidence that a few other solvents, such as the glycol ethers that are widely used in paints and coatings,[69] may cause such injury, the vast majority of solvents, including many benzene congeners such as toluene and xylene, do not appear to have potential for marrow injury. For this reason, most products that formerly contained benzene that are used in developed countries have been modified, and benzene is not used directly except for specific purposes in the manufacture of chemicals and pharmaceuticals. Obviously, exposed persons should be carefully monitored for hematologic effects, the presence of which would be clear evidence of overexposure.

ENDOCRINE AND REPRODUCTIVE EFFECTS

Despite an exceptional upsurge in interest in the endocrine-disrupting effects of environmental contaminants, there is little evidence that occupational exposures to chemical hazards cause clinically relevant endocrinopathies in adults.[70] Lead has been shown to impair hypothalamic–pituitary axis secretions and probably testosterone regulation in men heavily exposed, but the clinical relevance of these observations is unclear. Several compounds used in the pharmaceutical industry and other industries have been shown to have estrogenic activity, with predictable clinical consequences in both men and women.

The effects of work on male and female reproduction are a more formidable concern.[71] Although data are far from complete because many chemicals have never been studied adequately, several substances at occupational levels of exposure have been proved to cause infertility and decreases in sperm counts; such substances include lead, the pesticides 1,2-dibromo-3-chloropropane (DBCP) and ethylene dibromide (EDB), ethylene glycol ethers, and carbon disulfide. Heat and ionizing radiation have also been associated with infertility and decreased sperm counts. In addition, a host of other metals, anesthetic agents, and plastic reagents have been shown to cause worrisome gonadal effects in toxicologic experiments on male animals. For this reason, infertile men should be carefully questioned about work exposures; they should be observed for signs of improvement for about 9 months (which equals four cycles of spermatogenesis) should suspicion of an occupational cause be entertained.

Female reproduction is harder to study for lack of a single body fluid to analyze and because of the absence of a simple animal model. There is evidence that several common exposures, including waste anesthetic gases, lead, glycol ethers, ethylene oxide, and antineoplastic drugs, have the potential to increase the risk of miscarriage. Lead, organic mercury, polychlorinated biphenyls (PCBs), heat, and ionizing radiation are established teratogens; organic solvents are also suspect on the basis of animal studies and new epidemiologic reports.[72] Most of the agents that cause human cancer [*see Table 3*] are considered likely fetal hazards as well. In most cases, there is risk of adverse effects at doses considered acceptable in the workplace, because regulations have not traditionally been developed on the basis of reproductive concern. To a disturbing degree, knowledge of the reproductive effects of thousands of additional chemicals is unknown. Even the effects of hard physical work during pregnancy remain unclear, though there is evidence that excessive lifting and standing late in the third trimester may induce prematurity.

With the majority of women of reproductive age now in the workforce, many are questioning the safety of work during pregnancy, and clinicians are being confronted with trade-offs between fetal risks and the worker's economic security. Although each case must be studied individually, a reasonable guideline is to rigorously protect patients from the established teratogens or ensure the levels of exposure below those established for pregnancy. For others, reasonable steps can be taken to minimize exposure, including job transfer if the patient prefers and the employer has alternative work. For the patient for whom any risk represents an unacceptable psychological impediment, transfer or removal is probably in the best interest of all parties.

CLINICAL PROBLEMS ASSOCIATED WITH LOW-LEVEL ENVIRONMENTAL EXPOSURES

One of the most common problems emerging in developed countries is the constellation of respiratory and systemic complaints that are appearing with increasing frequency in office workers and others in what are traditionally considered safe jobs.[73,74] Typical symptoms of sick-building syndrome, or nonspecific building-related illness, include upper and lower respiratory symptoms, often combined with neurologic problems, such as fatigue, headache, and cognitive deficits, as well as rashes and other nonspecific complaints.[74] Usually, the patient will relate that others in the environment are experiencing similar difficulties and that the symptoms improve when the patient is away from work and return upon reexposure. Although in a minority of cases, investigation may reveal a specific allergy (e.g., in patients with asthma, rhinitis, or allergic alveolitis) or a specific hazard (e.g., fibrous glass released during a renovation or from a ventilation duct, causing pruritus), in the majority of cases, the environment is usually best described as poorly ventilated.[74,75] At present, there is no specific treatment of this syndrome other than palliative care and reassurance that it is neither progressive nor life threatening.[76,77] Expensive testing of either the patient or the work environment is rarely necessary or beneficial.[74] Ideally, remediation of both should be undertaken as soon as more dire possibilities are excluded by history and a walk-through of the workplace by an industrial hygienist or comparable environmental professional. In the vast majority of cases, improvement of ventilation will result in symptomatic improvement for most workers.[74]

On occasion, a patient in an affected building will start to experience similar discomfort in other situations, such as driving behind a bus, being in a store, or using a perfume or detergent.[55] The net impression is that the patient has become reactive to everything that has an odor. Many also have fatigue or other asthenic symptoms between exposures. Symptoms reminiscent of those in panic disorder may also occur. Dubbed multiple chemical sensitivities (MCS), this disorder is not associated with measurable abnormalities of organ system function but may be highly disabling.[55] Although there are many physical and psychological theories regarding the origin of MCS, present knowledge is limited. Patients do not easily tolerate pharmacologic agents and usually do not respond to treatment for anxiety or depression. Avoidance is equally fruitless, with shorter and more trivial exposures causing problems in those who quit work and minimize human contact. At present, the recommended treatment is supportive care coupled with moderate life modifications to avoid the most provocative exposures while preserving everyday functioning, including work if possible. Unrealistic expectations of cure or remission are as harmful as unwarranted fears of deterioration; neither outcome appears common among patients followed for many years.

VII HEALTH ADVICE FOR INTERNATIONAL TRAVELERS

PETER F. WELLER, M.D.

The provision of health advice and the administration of prophylactic measures can help reduce the morbid and, at times, mortal risks of infectious illnesses that may be acquired during international travel. The Centers for Disease Control and Prevention (CDC) publishes *Health Information for International Travel*, which provides information on required and recommended vaccinations and malaria prophylaxis, as well as general advice.[1] *Health Information for International Travel 2003–2004* is available for purchase on the Internet, at http://bookstore.phf.org/cat24.htm, or by phone, at 1-877-252-1200. Other information regarding international travel is readily available on the CDC Web site (http://www.cdc.gov), such as the Green Sheet, which provides reports of cruise-ship sanitation inspections; detailed guidelines on the need for yellow fever immunizations; guidelines on international health issues for travelers by country; recently recognized disease outbreaks; and general guidelines on immunizations and other medical issues for travelers. Information may also be obtained from state public health departments, local physicians or clinics catering to travelers, the embassies of individual countries, and Internet-based advisory services. Even the most up-to-date information sources, however, may not be able to provide precise information on specific diseases prevalent in specific locales, because mechanisms for recognizing and reporting diseases are often lacking in developing areas.

Pretravel Evaluation and Immunizations

Medical consultation should be obtained at least 1 month before international travel to allow time for immunizations [*see Table 1*]. A general patient medical history should be obtained to define pertinent underlying medical conditions. For instance, splenectomy predisposes a person to more severe malaria, babesiosis, and infections with encapsulated bacteria, including meningococcal infections. A history of allergies to antimicrobial agents or to other components of vaccines should be determined. Knowledge of the duration and purpose of a trip, as well as of the countries and locales to be visited, can help in estimating the risks of exposure to endemic diseases. In addition, specific groups of travelers—including pregnant women; persons with HIV; persons with chronic diseases such as chronic obstructive pulmonary disease, diabetes mellitus, hypercoagulable states, and cardiovascular disease; and health care workers—may require more time before travel to address their potentially altered needs for immunization and prophylaxis.

Table 1 Guidelines for Immunizations for Travelers

	Asia	*Eastern Mediterranean, North Africa*	*Middle East*	*Sub-Saharan Africa*	*Pacific Islands*	*Caribbean, Mexico, Central and South America*	*North America, Europe, Japan, Australia, New Zealand*
Yellow fever				X (some countries)		X (some South American countries)	
Cholera*							
Polio	X (some countries			X (some countries			
Tetanus/diphtheria (booster every 10 yr)	X	X	X	X	X	X	X
Measles (if born after 1957 and not recipient of 2 doses of vaccine)	X	X	X	X	X	X	X
Typhoid	X	X	X	X	X	X	
Rabies (for prolonged visits)	X	X	X	X		X	
Hepatitis A	X	X	X	X	X	X	
Hepatitis B (especially for prolonged visits)	X	X	X	X	X	X

Japanese encephalitis	X†						

*Only if required by a country.
†Prolonged visits to some regions.

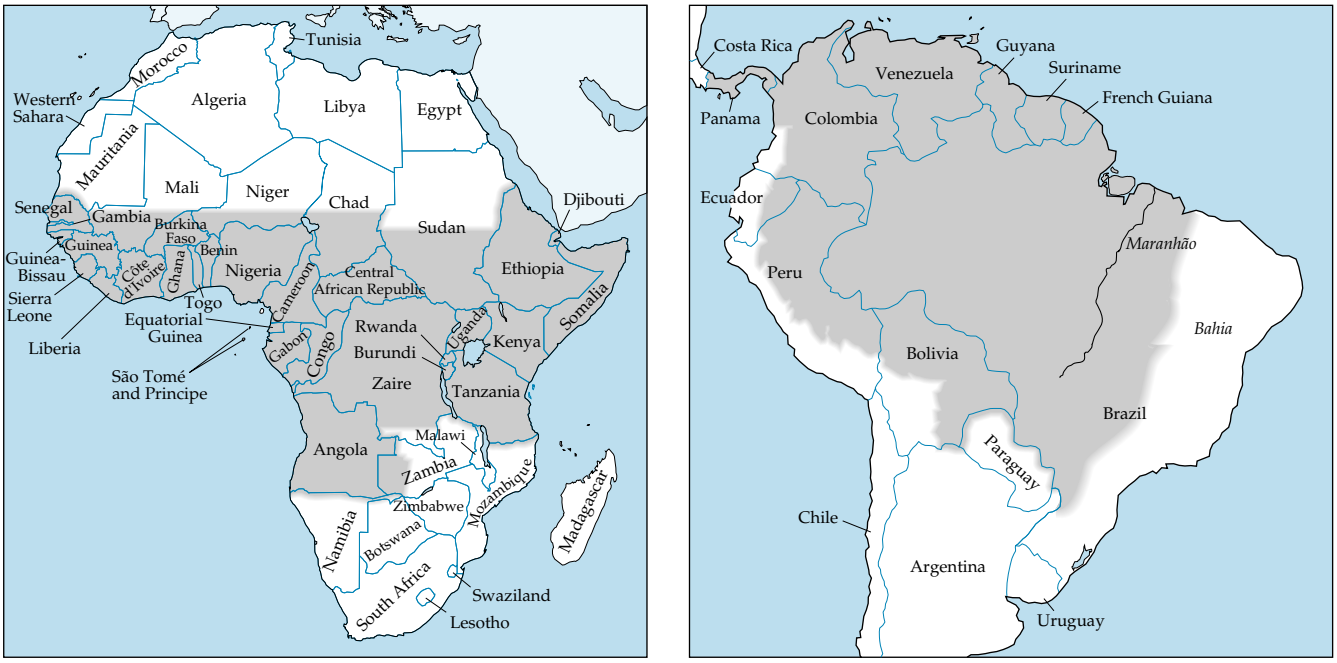

Figure 1 **Yellow fever (gray areas) is endemic in parts of Africa (left) and South America (right). Several countries consider these zones infected areas and require an International Certificate of Vaccination against yellow fever from travelers from these zones.**

REQUIRED IMMUNIZATION

The only immunization legally required for entrance into specific countries is that for yellow fever.

Yellow Fever

Yellow fever is a mosquito-transmitted viral infection, whose severity may range from an influenzalike illness to potentially fatal hepatitis and hemorrhagic fever. Yellow fever occurs only in equatorial Africa and in areas of tropical South America [*see Figure 1*].[1] Persons older than 6 months visiting countries where yellow fever is known to exist should be immunized. In addition, those traveling outside of urban areas in countries that are in the yellow fever endemic zones but are not officially reporting the infection should be immunized because the disease may be underrecognized. Some countries, especially in Asia, may require yellow fever immunizations for entry, especially for persons who have traveled in potentially endemic countries.[1] Yellow fever vaccine, a live virus vaccine grown in chick embryos, is effective.

Although generally safe, yellow fever vaccines are uncommonly associated with encephalitis (referred to as yellow fever vaccine–associated neurotropic disease [YEL-AND]) and a potentially fatal multiorgan system failure (referred to as yellow fever vaccine–associated viscerotropic disease [YEL-AVD]). In the United States, estimated rates of these two complications are four to six cases per million doses for encephalitis and three to five cases per million doses for multiorgan failure.[1] However, the risks of illness and death due to yellow fever in an unvaccinated traveler are greater, estimated to be one per 1,000 and one per 5,000 a month, respectively.[1] Thus, for those entering yellow fever endemic areas, yellow fever vaccination is indicated; however, vaccine use should be limited to those who are truly at risk. This is especially true for travelers older than 60 years, because they appear to be at greater risk for developing YEL-AVD.[2] For these travelers, vaccine may be indicated only if the risk of potential exposure is high (e.g., when travel in endemic areas outside urban centers is anticipated). A history of thymus disorders appears to be a contraindication for vaccine. In an analysis of 23 vaccinated persons who developed YEL-AVD, four (17%) had a history of thymus disease.[2] Travelers with a history of thymus disorders or dysfunction, including myasthenia gravis, thymoma, thymectomy, or DiGeorge syndrome, should not receive yellow fever vaccine. If travel to yellow fever–endemic regions cannot be deferred, persons with thymus disorders should be advised to use N,N-diethyl-m-toluamide (DEET) and permethrin to reduce mosquito bites [*see* Insect Repellents and Avoidance, *below*].[2]

Initially, a single subcutaneous dose of 0.5 ml is given. A booster dose is required every 10 years. Immunizations, which are recorded on the International Certificate of Vaccination, are available only from designated physicians and centers, an updated listing of which can be found on the Internet at http://www2.ncid.cdc.gov/travel/yellowfever. Yellow fever vaccine, which contains both egg proteins and gelatin, rarely causes anaphylaxis.[3] For those persons allergic to egg proteins or gelatin, skin testing with yellow fever vaccine (per directions included on the package insert) may help determine whether vaccine can be given safely.

Because yellow fever vaccine is a live virus vaccine, cautions and potential contraindications to its use apply to those who are pregnant, lactating, or immunocompromised. In these persons, if the sole indication for administration of yellow fever vaccine is to satisfy legal requirements for entry, a physician's letter documenting the contraindications to vaccination can be provided to the traveler; in addition, advice should be sought from the embassy or consulate of the country or countries to be visited.

Influenza

Travelers are at increased risk for influenza infection.[1] Influenza, like hepatitis A, has become one of the more common infections in travelers that are preventable by vaccine. In temperate countries, influenza is prevalent in the winter months; whereas in the tropics, influenza transmission occurs year-round. For travelers to the Northern Hemisphere, the risk is greatest during December through February; and for travelers to the Southern Hemisphere, the risk is greatest from April through September. Summertime outbreaks of influenza have occurred on cruise ships in the Northern and Southern hemispheres. For travelers to tropical countries, the risk of influenza exists throughout the year.[1]

Persons at high risk for influenza, including those older than 50 years, should receive influenza vaccine (1) if influenza vaccine was not received during the preceding fall or winter, (2) if travel is planned to the tropics, (3) if travel is planned with large groups of tourists (e.g., on cruise ships), or (4) if travel is planned during seasons in which influenza is prevalent.[1,4] In North America, travel-related influenza vaccination should be administered in the spring, if possible, because vaccine may be unavailable in the summer.

Cholera

Cholera is caused by toxigenic *Vibrio cholerae* groups 01 and 0139. Although the number of cases of cholera seen in the United States has increased in recent years, many of the cases have been the result of the illness being imported into the United States by travelers from other countries; tourists from the United States visiting other countries have only rarely been infected. Cholera is acquired by ingestion of contaminated water, ice, or food, including raw or undercooked fish and shellfish. Travelers in endemic regions should be advised of the precautions to be followed to minimize risks of acquiring cholera and other enteric infections [*see* Travel-Related Illness, *below*] and of the importance of rehydration in the treatment of cholera. Dietary precautions include consuming only boiled or treated water, eating thoroughly cooked food, avoiding all fruit not peeled by onself, and avoiding undercooked or raw fish or shellfish, including seviche.

Routine immunization is not recommended for travelers.[1] In the unlikely event that a locale requires immunization for cholera, immunization would need to be obtained outside the United States in countries in which current cholera vaccine is available. Currently, no country requires proof of cholera immunization as a condition for entry, and the World Health Organization recommends against such a requirement. Some local authorities, however, may require immunization (to determine local requirements, travelers may consult the embassies of the countries to which they will be traveling). The only cholera vaccine licensed for use in the United States is no longer manufactured. In other countries, two cholera vaccines (Dukoral, from Biotec AB, and Mutacol, from Berna) have been licensed for use, but neither of these vaccines is indicated for most travelers.[1] Travelers who are at risk for cholera and who expect to travel to areas remote from medical care should take with them packets of oral rehydration salts. Antimicrobial agents often employed for therapy for traveler's diarrhea, such as ciprofloxacin, are usually very effective in helping terminate cholera infections.[5]

Poliomyelitis

Travelers to countries in which polio is endemic or in which there is a current epidemic are at risk for the disease and should be immunized. Countries considered to be free of wild poliovirus are all countries in the Western Hemisphere, the Western Pacific Region (which includes China), and the European region.[1] Polio transmission continues in some developing countries, including Afghanistan, India, Pakistan, Nigeria, and Niger, although efforts to achieve global eradication of polio are ongoing.

Travelers who were immunized previously should receive one booster dose of polio vaccine. Oral live virus vaccine is no longer recommended for immunizations in the United States.[6] The inactivated vaccine is preferred to avoid the small risk of paralytic disease from the oral vaccine. Patients with an altered immune status should receive inactivated vaccine. Children who have not been immunized should receive a full series of immunizations with inactivated polio vaccine. Adults who have not been immunized should receive a series of three doses of enhanced-potency inactivated vaccine.[1] If there is insufficient time before travel for at least three doses of inactivated vaccine to be given at intervals of 1 to 2 months, the following alternatives are recommended[1]: if less than 1 month is available before travel, a single dose of inactivated vaccine is given; if between 1 and 2 months is available before travel, two doses of inactivated vaccine are administered 4 weeks apart. Travelers who were incompletely immunized previously should receive the remaining required doses of vaccine.

Tetanus and Diphtheria

A tetanus-diphtheria booster should be administered every 10 years [*see 7:V Anaerobic Infections*].[1] Older persons and women are more likely to lack the tetanus and diphtheria antibodies and thus are more likely to require boosters.[7,8]

Pneumococcal Infections

There are no data on the risk to travelers of acquiring pneumococcal infections; however, those at risk, including those older than 65 years [*see 7:I Infections Due to Gram-Positive Cocci*], are recommended as candidates to receive pneumococcal vaccinations.

Measles

Because of the declining prevalence of measles in the United States, disease imported by immigrants and by returning residents accounts for an increasing proportion of cases in this country. Measles may be acquired during travel in developed countries, including those in Europe and Asia, as well as in less developed countries.[1] Most persons who were born before 1957 are immune because of natural exposure and do not require vaccination. Persons who were born after 1956 who either have not been immunized or were immunized before 1980 and who have neither serologic evidence of infection nor a history of physician-diagnosed measles should be immunized with a single subcutaneous dose of measles vaccine before travel. Measles vaccine is contraindicated for both pregnant and immunodeficient patients. HIV-infected patients, unless they are severely immunocompromised, should be immunized before travel because measles can be severe and even fatal in persons with HIV infection.[1,9]

Typhoid

Salmonella typhi infection is prevalent in many areas of Asia, Africa, and Latin America. Typhoid is acquired from contaminated food or water. Although the overall risk of acquiring typhoid during travel remains low (2.3 million cases per million

travelers),[10] foreign travel accounted for 74% of 1,393 cases of typhoid reported to the CDC between 1994 and 1999.[11] The risk was greatest for those traveling to the Indian subcontinent (India, Pakistan, and Bangladesh) and Haiti. Of note, even those traveling for no more than a couple of weeks were at risk of acquiring typhoid. Given the safety of current typhoid vaccines, typhoid vaccination should be considered for short-term travel in high-risk areas, as well as for any travel to areas off the usual tourist itinerary.[11]

Two typhoid vaccines are available for use in the United States. One typhoid vaccine is an oral vaccine (Vivotif Berna, from Berna) that uses the attenuated Ty21a strain of *S. typhi;* this vaccine does not cause the local and systemic side effects frequently produced by the older, parenteral vaccine. The oral vaccine is supplied as a packet of four enteric-coated capsules that must be refrigerated. Patients need explicit guidance on refrigerating the vaccine because failure to do so might compromise its efficacy.[12] At least 2 weeks before departure, the traveler takes one capsule every other day until all four capsules have been taken. Because mefloquine and antibiotics inhibit the growth in vitro of *S. typhi* strains, including Ty21a, it is prudent to separate the oral administrations of mefloquine and antibiotics and of Ty21a vaccine by 24 hours.[1] It is recommended that a booster dose of Ty21a vaccine, consisting of four capsules taken on alternate days, be given every 5 years to persons who continue to be at risk for exposure to typhoid. The safety of the oral vaccine has not been established for patients with deficient humoral or cell-mediated immunity, and thus, patients with congenital or acquired immunodeficiencies should not receive it. It may be given to children 6 years of age or older.

The second typhoid vaccine is a capsular polysaccharide vaccine for parenteral use (Typhim Vi, from Aventis Pasteur). Primary vaccination consists of one I.M. dose of 0.5 ml; the same dose is administered as a booster every 2 years. The vaccine is well tolerated but, like the oral vaccine, protects only 50% to 80% of recipients.[1,13] This vaccine is safe for immunocompromised persons, including HIV-infected patients.[1] The only contraindication to its use is a history of serious reactions to the vaccine. It may be given to children 2 years of age and older.

Rabies

Rabies vaccine—either human diploid cell rabies vaccine (HDCV), purified chick embryo cell vaccine (PCEC), or rabies vaccine adsorbed (RVA)—is an inactivated viral preparation. Immunizations with either of the three vaccine preparations consists of three I.M. doses, 1 ml each, administered on days 0, 7, and 21 or 28.[1] Preexposure immunization with rabies vaccine is not indicated for most travelers but should be strongly considered for persons who anticipate contact with wild animals or who are living for a month or more where rabies is endemic. Dog rabies is present in most countries of Asia, Africa, and Central and South America and is prevalent in parts of Brazil, Bolivia, Mexico, El Salvador, Guatemala, Colombia, Ecuador, Peru, India, Nepal, the Philippines, Sri Lanka, Thailand, and Vietnam.[1] Preexposure immunization does not eliminate the need for postexposure immunization but abbreviates its course and eliminates the need to administer rabies immune globulin. If left untreated, rabies is fatal, and postexposure rabies immune globulin and postexposure vaccine are frequently unavailable in many areas of the world.

Plague

Plague vaccine is no longer commercially available. Vaccination against plague is not indicated for most travelers.[1] However, prophylaxis should be considered for travelers to areas in which plague is epidemic or actively epizootic. For adults, tetracycline or doxycycline is appropriate prophylactic therapy; for children younger than 8 years, trimethoprim-sulfamethoxazole is recommended.[1]

Hepatitis A

Hepatitis A is prevalent in many less-developed countries [*see Figure 2*] and is the most common infection acquired by travelers that is preventable by vaccine. In visitors to developing countries, even those staying in luxury hotels, the incidence of hepatitis A in unprotected travelers is about 3 per 1,000 travelers per month of stay, and this rate rises to 20 per 1,000 travelers per month for those eating or drinking under poor hygienic conditions.[14]

Immunization for hepatitis A is recommended for persons who will be traveling or working in countries with intermediate or high endemicity for hepatitis A infection.[1] Although hepatitis A previously was prevented solely by the administration of immune globulin, two monovalent inactivated hepatitis A vaccines and a combined hepatitis A and hepatitis B vaccine are now available. The monovalent vaccines, HAVRIX (GlaxoSmithKline) and VAQTA (Merck), have proved safe and highly effective.[15] For adults, two I.M. 1.0 ml doses should be administered in the deltoid muscle at 0 and 6 to 12 months. For persons between 2 and 18 years of age, two doses, 0.5 ml each, should be administered at 0 and 6 to 12 months. VAQTA contains no preservative, whereas HAVRIX contains 2-phenoxyethanol. The bivalent hepatitis A and hepatitis B vaccine, TWINRIX (GlaxoSmithKline), is likewise safe and effective and is administered to those 18 years of age or older in three I.M. 1.0 ml doses at 0, 1, and 6 months. TWINRIX contains 2-phenoxyethanol.

With the monovalent vaccines, many persons who have been vaccinated will have detectable antibody responses within 2 weeks after the first dose; 94% to 100% of persons treated will have protective levels of antibody by 1 month after the first dose. The second dose of vaccine provides longer-term protection. If the immunization schedule is unduly interrupted, it is not necessary to restart the full regimen; the second dose may simply be administered. A vaccination series started with one brand of vaccine may be completed with the same or the other brand of hepatitis A vaccine. Travelers who receive vaccine less than 2 weeks before travel are at risk for acquiring hepatitis and should also receive immune globulin, given at an injection site different from the one for vaccine.

For travelers who are allergic to vaccine components or who opt not to receive the vaccine, immune globulin should be administered. Administration of immune globulin should begin shortly before departure in a dose of 2.0 ml I.M. for adults (1.0 ml for patients, including children, weighing 23 to 45 kg; 0.5 ml for those weighing less than 23 kg). If the stay is to be longer than 3 months, the adult dose is 5.0 ml (2.5 ml for patients weighing 23 to 45 kg; 1.0 ml for those weighing less than 23 kg). If the duration of stay is prolonged, the latter dosage schedule should be repeated every 4 to 6 months. Immune globulin should be given at least 2 weeks after measles, mumps, or rubella live virus vaccines. Conversely, these vaccines should be given at least 3 months after immune globulin. Immune globulin does not interfere with the immune response to killed virus vaccines or to yellow fever or polio vaccines.

Because immune globulin has been in limited supply and because the hepatitis A vaccines have proved to be highly effective against hepatitis A infection, which is frequent in travelers, immunization with hepatitis A vaccine has become the principal approach for preventing hepatitis A infection in travelers. The hepatitis A vaccines are safe in pregnancy and immunosuppression.

Hepatitis B

The risk to travelers of acquiring hepatitis B is generally low, compared with the risk of acquiring hepatitis A. The risk increases, however, in regions where hepatitis B is highly prevalent [*see Figure 3*], if there is contact with blood or bodily secretions, if sexual contact with infected persons occurs, or if travel is prolonged.[1] Immunization for hepatitis B, which is recommended for all persons who work in health care fields with potential exposure to human blood, is especially important for medical workers traveling in countries with high or intermediate hepatitis B endemicity. Hepatitis B immunization should be considered for persons residing for more than 6 months in regions where hepatitis B is endemic and for persons with potential contact with blood (including those receiving tattoos or body piercing), potential sexual contact, or potential need for medical or dental procedures.

Two monovalent hepatitis B vaccines are available, both of which include recombinant HBsAg (hepatitis B surface antigen) protein produced in yeast. Except for rare hypersensitivity reactions to vaccine components, including yeast proteins, the two recombinant vaccines are safe and efficacious; there are no other medical contraindications, including pregnancy and immunosuppression, for administration of these vaccines. The two vaccines, Recombivax HB (Merck) and Engerix-B (GlaxoSmithKline), are administered in three I.M. doses: at 0, 1, and 6 months. Engerix-B may also be given in four doses: at 0, 1, 2, and 12 months. Immunization should start 6 months before travel, but if this schedule is not feasible, some protection is afforded by one or two doses administered before travel. Full protection will be achieved in most cases by completion of the three-dose or four-dose schedule.[1] For travelers who will depart before the recommended series can be completed, an accelerated regimen, involving doses given on days 0, 7, and 14, can be administered; the accelerated regimen is not approved by the Food and Drug Administration. Travelers receiving the accelerated course should receive a booster at least 6 months later to provide long-term immunity.[1]

An additional vaccine for hepatitis B is TWINRIX, a combined hepatitis A and hepatitis B vaccine. Primary immunization with TWINRIX consists of three doses administered at 0, 1, and 6 months. The bivalent vaccine can be used to complete immunization series started with monovalent hepatitis A and B vaccines.

Meningococcal Disease

Although acquisition of meningococcal disease is uncommon in travelers from the United States, immunization should be considered for travelers to areas with recognized epidemics or to regions where such disease is hyperendemic, especially if prolonged contact with the local populace is anticipated. Epidemics of meningococcal disease are frequent in the area of sub-Saharan Africa extending from Guinea in the west to Ethiopia in the east [*see Figure 4*]. Vaccination against meningococcal disease is legally required only for pilgrims who make the Hajj pilgrimage to Mecca, Saudi Arabia. Routine immunization is also indicated for persons who have either deficiencies of terminal complement components or functional or anatomic asplenia. The currently available quadrivalent vaccine is composed of meningococcal

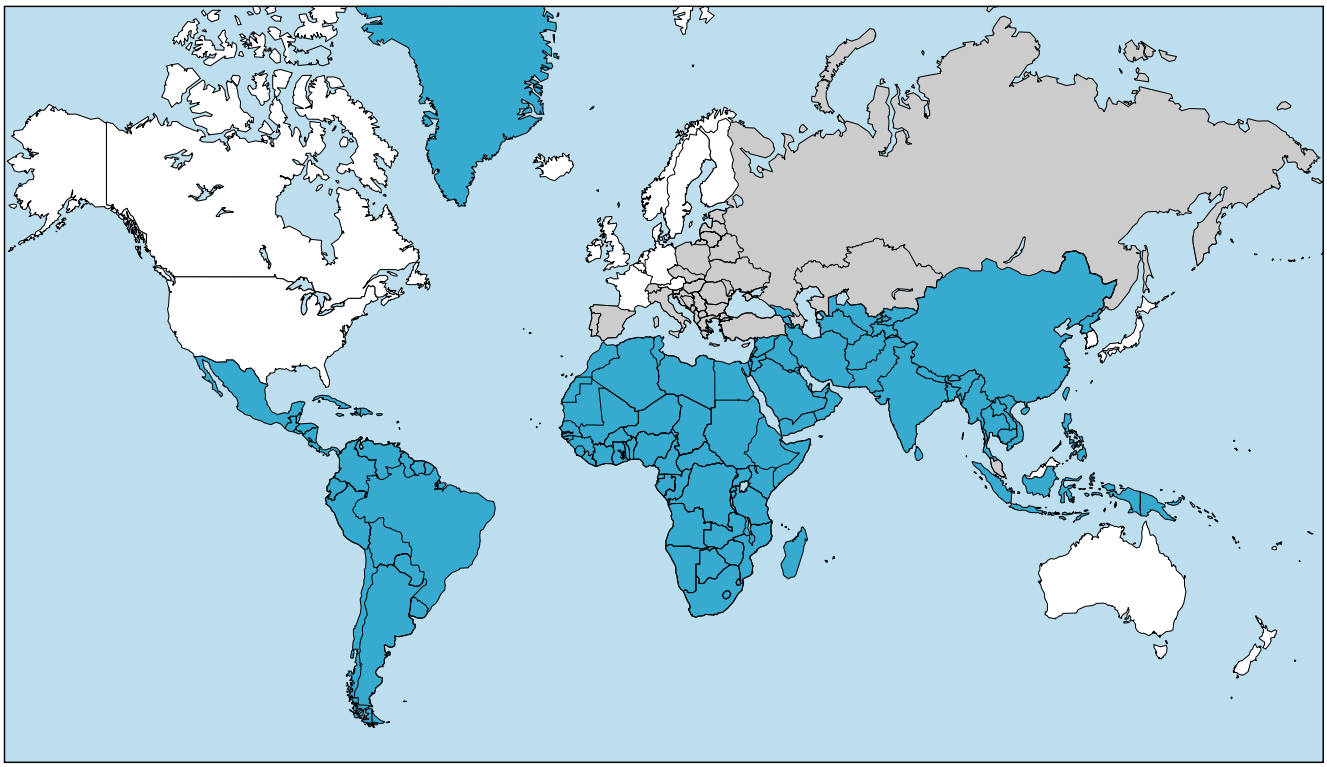

Figure 2 **The prevalence of hepatitis A is high in those countries shaded blue, intermediate in those shaded gray, and low in the white areas of the map.**

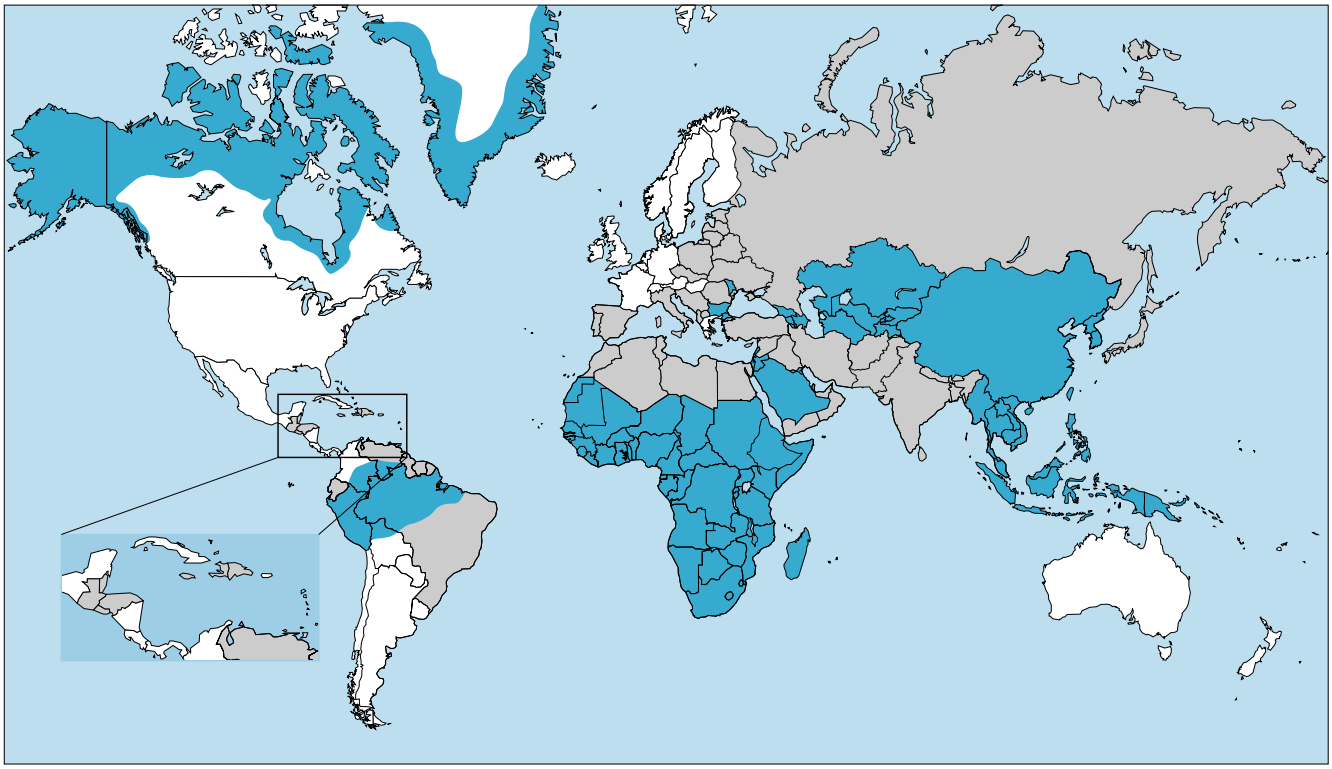

Figure 3 **Hepatitis B is highly endemic in those countries shaded blue (prevalence > 8%). Those regions shaded gray, where the prevalence is 2% to 7%, are considered to be of intermediate endemicity. The prevalence of hepatitis is less than 2% in the white areas of the map.**

polysaccharides from *Neisseria meningitidis* serogroups A, C, Y, and W-135. A single 0.5 ml subcutaneous dose of vaccine is administered to both adults and children and will induce an antibody response in 10 to 14 days.[1] Duration of immunity is at least 3 years.

Japanese Encephalitis

Japanese encephalitis, an arboviral infection transmitted by mosquitoes, may occur in epidemics during the late summer and autumn in northern tropical areas and temperate regions of some countries. The risk of acquiring Japanese encephalitis infection varies by season and geographic area [*see Table 2*].[1] The disease rarely occurs in Hong Kong or Japan. Persons at highest risk are those who live for extended periods in endemic or epidemic areas. The risk for short-term travelers to urban centers is low, and in temperate countries, the risk for travelers to either an urban or a rural area is negligible during the winter.

Although Japanese encephalitis is highly uncommon, prevention is important for those traveling specifically to epidemic or endemic areas [*see Table 2*], because the risk of serious neurologic sequelae is high. Exposure to mosquitoes should be minimized by the use of insect repellents, protective clothing, and mosquito screens. Also, vaccination should be considered for persons traveling during summer monsoon months, for those visiting rural areas, and for those planning to stay more than 1 month in urban or rural areas.

Vaccination is not usually recommended for travelers to Singapore or Hong Kong, urban Japan or China, or high-altitude regions in Nepal. An effective formalin-inactivated, mouse-derived vaccine (JE-Vax, Aventis Pasteur) has been licensed by the FDA. Primary immunization for persons older than 3 years consists of three doses, 1 ml each, administered subcutaneously on days 0, 7, and 30. An abbreviated schedule of 0, 7, and 14 days can be used if there is insufficient time before travel to administer the standard immunization. A booster dose of 1 ml may be administered after 2 years. About 20% of recipients of JE-Vax vaccine experience local reactions and mild systemic side effects (e.g., fever, headache, myalgias, and malaise).[1]

Allergic reactions, including generalized urticaria, angioedema, respiratory distress, and anaphylaxis, have developed in about six per 1,000 recipients; at times, the onset of allergic reaction is delayed for hours or even a week after vaccine administration. Those with a history of urticaria and allergies (including hay fever and reactions to hymenoptera venom) appear to have a greater risk of developing allergic reactions to the vaccine. Reactions have been responsive to epinephrine, antihistamines, steroids, or a combination of these agents.[1,16] Because of late-developing allergic reactions, immunizations should be completed 10 days before travel; vaccine recipients need to be advised to remain accessible to emergency medical care.

Tick-Borne Encephalitis

Tick-borne encephalitis is a viral infection of the central nervous system that is transmitted by ticks. The disease occurs in Scandinavia, western and central Europe, and countries of the former Soviet Union. The disease is transmitted principally from April through August, when the tick vector, *Ixodes ricinus,* is most active. Infections may also be acquired by consumption of unpasteurized dairy products from infected cows, goats, or sheep. Effective vaccines are available in Europe and in many travel clinics in Canada; vaccines are not available in the United States. Vaccination should be considered for travelers who anticipate extensive outdoor exposure (e.g., camping or related activities) in the endemic regions during the spring and summer months.[1]

VACCINE CONTRAINDICATIONS

Vaccines that contain live attenuated viruses (i.e., oral polio, measles, mumps, rubella, and yellow fever vaccines) should not be given to pregnant women or to persons who have known or potential immunodeficiencies (e.g., leukemia, lymphoma, or a generalized malignant disorder) or who are receiving corticosteroids, alkylating agents, antimetabolites, or irradiation. Oral polio vaccine, which is no longer recommended in the United States, should not be given to a patient if an immunodeficient person resides in the same household. If a pregnant woman cannot defer travel to areas of high risk for yellow fever, yellow fever vaccine may be given.[1] For travelers infected with HIV, immunization with live oral polio and attenuated oral typhoid vaccines should be avoided in favor of killed parenteral vaccines. The risks of live yellow fever vaccine have not been defined for HIV-infected persons, but persons with asymptomatic HIV infection who cannot avoid exposure in areas endemic for yellow fever should be offered the choice of immunization.[1] Because measles can be severe in patients with HIV, measles immunization should be provided, unless the patient is severely immunocompromised (i.e., total $CD4^+$ T cell count < 200 µl).[9]

Contraindications to vaccination also include hypersensitivity to components of the vaccine. Neomycin and gelatin are present in some vaccines. Persons who have immediate hypersensitivity reactions to neomycin, gelatin, or preservative agents should avoid vaccines containing these substances. Yellow fever vaccine, which contains egg proteins and gelatin, may be contraindicated in patients who have allergic reactions to these proteins. In general, there is a poor correlation between a history of egg sensitivity and skin-test reactivity to egg antigen. The most reliable predictor of reactions to egg-containing vaccines is skin testing with the vaccine itself.[1] If travel plans cannot be changed, persons who have positive skin tests or known egg hypersensitivity (i.e., urticaria, oropharyngeal swelling, bronchospasm, or hypotension) should be given a letter documenting the contraindication to immunization and obtain a waiver before travel from the embassy of any country requiring yellow fever immunization.

INSECT REPELLENTS AND AVOIDANCE

To reduce the risk of all mosquito-borne infections (e.g., malaria, yellow fever, and dengue fever), travelers should be instructed about the importance of minimizing the potential for insect bites. The most effective insect repellents contain DEET.[17,18] DEET is available in many products in concentrations ranging from 25% to more than 75% and repels mosquitoes, ticks, fleas, and biting flies. Protection lasts for several hours but is shortened by losses from swimming, washing, rainfall, sweating, and wiping. A long-acting formulation, which contains polymer to limit the losses of DEET that result from dermal absorption and evaporation, has been developed by the military and is available in the United States as Ultrathon (3M).

The absorption of DEET through the skin can cause such adverse reactions as dermatitis, allergic reactions, and neurotoxicity. Potential toxicity can be avoided by using solutions of 30% to 35% DEET and following instructions for its use. The repellent should be applied sparingly to clothing and exposed skin only. The product should be applied carefully to avoid introducing it into the eyes, to avoid contact with wounds and sensitive skin, and to prevent inhalation or ingestion. Clothing and bed netting can also be treated with permethrin for protection against mosquitoes and ticks.[19] Treated clothing will effectively repel mosquitoes for more than 1 week even with washing and field use. Permethrin is available, often in outdoor supply stores, as a nonstaining aerosol clothing spray (e.g., Permanone Tick Repellent).

Figure 4 **Epidemics of meningococcal disease are frequent in the area of sub-Saharan Africa that extends from Guinea in the west to Ethiopia in the east.**

Table 2 Risk of Japanese Encephalitis by Country, Region, and Season[1]

Country	*Affected Areas*	*Transmission Season*
Australia	Islands of Torres Strait	Probably year-round transmission
Bangladesh	Few data, probably widespread	Possibly July through December
Bhutan	No data	No data
Brunei	Presumed to be sporadic-endemic, as in Malaysia	Presumed year-round transmission
Myanmar (Burma)	Presumed to be endemic-hyperendemic countrywide	Presumed to be May through October
Cambodia	Presumed to be endemic-hyperendemic countrywide	Presumed to be May through October
India	Reported cases from many states	South India: May through October in Goa, October through January in Tamil Nadu, and August through December in Karnataka Andhra Pradesh: September through December North India: July through December
Indonesia	Kalimantan, Bali, Nusa, Tenggara, Sulawesi, Mollucas, Irian, Jaya, and Lombok	Probably year-round risk (varies by island); peak risks associated with rainfall, rice cultivation, and presence of pigs Peak periods of risk are November through March and, in some years, June through July
Japan	Rare, sporadic cases on all islands, except Hokkaido	June through September; Ryukyu Islands (Okinawa), April through October
Korea	Sporadic in South Korea; endemic with occasional outbreaks	July through October
Laos	Presumed to be endemic-hyperendemic countrywide	Presumed to be May through October
Malaysia	Sporadic-endemic in all states of Malay Peninsula, Sarawak, and probably Sabah	No seasonal pattern; year-round transmission
Nepal	Hyperendemic in southern lowlands (Terai)	July through November
People's Republic of China	Hyperendemic in southern China; periodically epidemic in temperate areas	Northern China: May through September Hong Kong and southern China: April through October
Pakistan	May be transmitted in central deltas	Presumed to be June through January
Philippines	Presumed to be endemic on all islands	Uncertain
Russia	Far eastern maritime areas south of Khabarovsk	Peak period July through September
Singapore	Rare cases	Year-round transmission; April peak
Sri Lanka	Endemic in all but mountainous areas; periodically epidemic in northern and central provinces	October through January; secondary peak of enzootic transmission May through June
Taiwan	Endemic-sporadic cases island-wide	April through October; June peak
Thailand	Hyperendemic in north; sporadic-endemic in south	May through October
Vietnam	Endemic-hyperendemic in all provinces	May through October

Malaria Chemoprophylaxis

The provision of appropriate malaria chemoprophylaxis is the most important preventive measure for travelers to malarious areas. Several hundred United States civilians contract malaria each year,[1] and infections from *Plasmodium falciparum* are potentially lethal and do cause deaths in travelers [*see 7:XXXIV Protozoan Infections*].[20] Morbidity and mortality are largely avoidable with chemoprophylaxis. Malaria is prevalent in parts of Mexico, Haiti, Central and South America, Africa, the Middle East, Turkey, the Indian subcontinent, Southeast Asia, China, the Malay archipelago, and Oceania. Chloroquine-resistant *P. falciparum* (CRPF) malaria occurs in most areas [*see Figure 5*]. Details on the prevalence by country and regions within countries of both malaria and CRPF malaria are reported annually by the CDC and may be accessed online (www.cdc.gov/travel/yb/index.htm).[1] Because even brief exposures to infected mosquitoes can transmit malaria infections, travel in malarious regions, no matter how brief, mandates the use of chemoprophylaxis. When uncertainty exists over the need for chemoprophylaxis, it should be initiated. If a traveler can ascertain that malaria is not a risk after arriving in an area, prophylaxis can be terminated as long as further travel into malarious areas is not planned.

Travelers should be advised that it is possible to acquire malaria despite prophylaxis and regardless of the prophylactic regimen used. Symptoms can begin as early as 8 days after infection or as late as several months after departure from a malarious area. Travelers should be cautioned to seek medical attention promptly for any febrile illness and to inform the physician of their prior itinerary. The wisdom of general protective measures against mosquito bites should also be stressed for all travelers to malarious areas. Because the vector mosquitoes usually feed at night, it is advisable to diminish exposure between dusk and dawn by remaining in screened areas; using mosquito net-

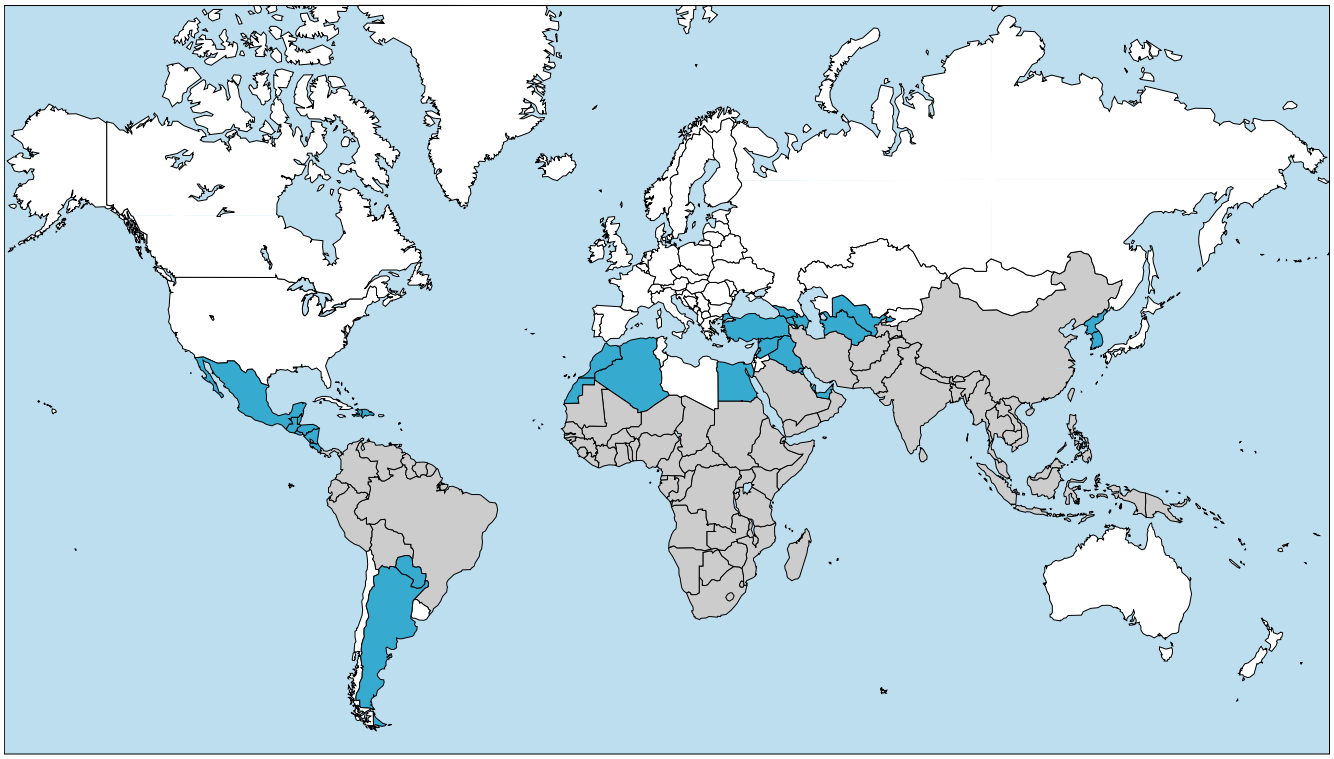

Figure 5 **This map displays the distribution of the chloroquine-resistant malaria (gray areas) and chloroquine-sensitive malaria (blue areas) in the Americas and in Asia, Europe, and Africa.**

ting, ideally treated with permethrin; covering exposed skin with clothing; and using insect repellent.

The choice of appropriate chemoprophylactic agents against malaria depends on the geographic areas to be visited and, importantly, whether these areas are endemic for CRPF [*see Figure 5*]. If travel is not to include areas where CRPF has been reported (e.g., Central America and the Caribbean), chloroquine remains the chemoprophylactic agent of choice. For most of the world, however, alternatives to chloroquine are required. Mainline alternatives to chloroquine include mefloquine and atovaquone-proguanil (Malarone).

Chloroquine

For those limited geographic regions not yet experiencing CRPF [*see Figure 5*], the chemoprophylactic agent of choice is chloroquine, given as either chloroquine phosphate (Aralen) or hydroxychloroquine sulfate (Plaquenil).[1] Chloroquine phosphate, 500 mg (300 mg of chloroquine base), or hydroxychloroquine sulfate, 400 mg (310 mg of hydroxychloroquine base), should be taken once weekly beginning 1 to 2 weeks before travel and continuing during the stay and for 4 weeks after departure from malarious areas. Minor side effects, including gastrointestinal disturbances, dizziness, blurred vision, and headache, may be alleviated by taking the drug after meals. Serious side effects are rare. Specifically, retinal injury, which can occur when high doses of chloroquine are used to treat rheumatoid arthritis, does not occur with the weekly dosages used for malaria prevention, even when such a regimen is continued for 5 years. However, deaths from malaria have occurred among tourists from the United States who avoided chloroquine prophylaxis out of a misguided concern for ocular toxicity.

Mefloquine

Mefloquine (Lariam) is active against CRPF and against *P. falciparum* that is resistant to sulfadoxine with pyrimethamine (Fansidar). With the now-widespread geographic prevalence of CRPF [*see Figure 5*], either mefloquine or atovaquone-proguanil is for many travelers the mainstay of malarial chemoprophylaxis. Strains of *P. falciparum* that are resistant to mefloquine, however, have been recognized in Africa and along the border between Thailand and Cambodia. Mefloquine, 250 mg, is taken once a week, beginning 1 to 2 weeks before travel and continuing during the stay and for 4 weeks after departure from a malarious area.[1] (This schedule is similar to that for chloroquine.) For travelers who will be immediately arriving in malarious areas, a loading dose of mefloquine (250 mg daily for the first 3 days) is advisable.

Despite the benefits of mefloquine to travelers in regions with CRPF malaria, mefloquine has acquired an unsalutary reputation. Mefloquine causes side effects, including nausea, dizziness, vertigo, light-headedness (described as an inability to concentrate), bad dreams, seizures, and psychosis. These reactions occur principally when the drug is given at therapeutic doses, which are higher than those given for prophylaxis. The incidence of psychosis or seizures has been about one per 10,000 travelers treated with chemoprophylactic mefloquine, which is comparable to the incidence associated with chloroquine use.[21] Other controlled trials have demonstrated that mefloquine is reasonably well tolerated in groups receiving this agent.[22-24] Thus, the uncommon and self-limited, but bothersome, side effects of mefloquine are to be weighed against the very real risks of serious and fatal malaria in many nonimmune travelers.

Mefloquine use has also been associated with sinus bradycardia and prolongation of the QT interval. Therefore, mefloquine

probably should not be used by persons with cardiac conduction abnormalities but may be used by patients without arrhythmias who are taking beta blockers.[1] Other contraindications to mefloquine include a history of serious neuropsychiatric disorders or seizures. Mefloquine appears to be safe and effective for young children.[25] Studies indicate that use of mefloquine in pregnancy during the second and third trimesters is not associated with adverse fetal or pregnancy outcomes; more limited data suggest that mefloquine is probably safe during the first trimester.[26-28] Mefloquine has no deleterious effects on fine motor skills, such as those required by airplane pilots.[29]

Atovaquone-Proguanil

Atovaquone-proguanil (Malarone) is available in many countries, including the United States, for the chemoprophylaxis of malaria. Atovaquone-proguanil is formulated as a fixed-dose tablet in adult strength (250 mg atovaquone/100 mg proguanil) and in pediatric strength (62.5 mg atovaquone/25 mg proguanil). For prophylaxis, one tablet is taken daily, beginning 1 to 2 days before travel and continuing for the duration of travel and for 1 week after departure from malarious areas. One, two, or three pediatric-strength tablets are taken by children weighing 11 to 20 kg, 21 to 30 kg, or 31 to 40 kg, respectively.

Atovaquone-proguanil is well tolerated; side effects, which are uncommon, are abdominal pain, nausea, vomiting, headache, and rash. Atovaquone-proguanil is safe and efficacious for prophylaxis of *P. vivax* and *P. falciparum* malaria, including CRPF. For *P. vivax* and *P. ovale* malaria, atovaquone-proguanil, like mefloquine and chloroquine, does not prevent development of hepatic hypnozoite stages, so treatment with primaquine (so-called terminal prophylaxis) may be necessary to prevent relapses with these species [*see* Primaquine, *below*]. Atovaquone-proguanil, therefore, is an alternative to mefloquine for malaria chemoprophylaxis[1] in regions of Thailand, Myanmar (Burma), and Cambodia where mefloquine-resistant *P. falciparum* malaria is present.

Doxycycline

Doxycycline, taken alone, is an alternative chemoprophylactic agent.[1] It should be taken in a dosage of 100 mg daily, beginning 1 to 2 days before travel and continuing for 4 weeks after departure from malarious areas. The use of doxycycline is appropriate for persons who are intolerant of sulfonamides, pyrimethamine, chloroquine, or mefloquine and for persons who are planning short-term visits in forested areas of Thailand, Myanmar (Burma), or Cambodia, where strains of malaria that are resistant to chloroquine, mefloquine, and sulfadoxine with pyrimethamine (Fansidar) are present.[1] Doxycycline may cause photosensitivity skin reactions and is contraindicated in pregnant women and in children younger than 8 years.

Proguanil

Proguanil (Paludrine) is not available in the United States but is available in Canada, Europe, and much of Africa. This agent, like pyrimethamine, is a dehydrofolate reductase inhibitor, and some strains of malaria are resistant to it. Proguanil (200 mg) is taken daily in combination with a weekly dose of chloroquine. The combination of proguanil and chloroquine, however, is much less effective than mefloquine or atovaquone-proguanil against chloroquine-resistant *P. falciparum* malaria and hence is not recommended.[1,30]

Primaquine

Primaquine may be used either as a single agent taken daily for chemoprophylaxis against all species of malaria or as an agent to eradicate residual intrahepatic stages of *P. vivax* and *P. ovale*. For the latter purpose, primaquine is administered during the last weeks of or just after a course of prophylaxis with either chloroquine or mefloquine. When intended as terminal prophylaxis, primaquine may be administered as 30 mg of the base daily for 14 days. Such terminal prophylaxis is generally reserved for persons who have had more than a casual potential exposure to *P. vivax* or *P. ovale*; other persons may be followed clinically and evaluated if they become symptomatic. For use as a primary chemoprophylactic agent, 30 mg of primaquine base is taken daily starting 1 day before travels and continuing for 2 days after departure from a malarious area.[31]

Because primaquine can cause severe hemolysis in patients who have glucose-6-phosphate dehydrogenase (G6PD) deficiency, this disorder must be excluded before the drug is administered. As a chemoprophylactic agent, primaquine is reserved for the rare individual who is unable to take other recommended chemoprophylactic regimens. CDC suggests primaquine be used only after consultation with malaria experts, including those at the CDC Malaria Hotline (1-770-488-7788).[1]

Sulfadoxine with Pyrimethamine

For chemoprophylaxis in areas where CRPF malaria occurs, it was formerly recommended that a single tablet of Fansidar, which contains 500 mg of long-acting sulfadoxine and 25 mg of pyrimethamine, be taken once a week along with chloroquine beginning 1 to 2 weeks before arrival in an endemic area and continuing for 4 weeks after departure from such an area. However, severe mucocutaneous reactions, including erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis, have developed after the use of two or more doses of Fansidar. These reactions produced fatalities with an incidence of about one per 11,000 to 20,000 travelers from the United States. Moreover, *P. falciparum* malaria is increasingly resistant to antifolate agents. Consequently, Fansidar is not recommended for chemoprophylactic use.

PROPHYLAXIS DURING PREGNANCY

Malaria infections represent a major health hazard to the mother and fetus.[32,33] Infections are potentially more serious during pregnancy and increase the risks of stillbirths, abortions, and other adverse pregnancy outcomes. For pregnant women who cannot defer travel or residence in malarious areas, chloroquine, which is without established teratogenicity, may be used.[1] Mefloquine appears to be safe in pregnancy.[26-28] For the pregnant traveler in regions with CRPF malaria, the benefits of effective mefloquine chemoprophylaxis need to be balanced with any potential, but as yet not recognized, adverse effects of mefloquine in pregnancy. Sulfadoxine should be avoided before delivery because of the risk of neonatal jaundice. Pyrimethamine, which is teratogenic in animals because it interferes with folate metabolism, is generally avoided but probably could be used. Doxycycline should not be used during pregnancy because of the effects of tetracyclines on the fetus, which include dental discoloration and dysplasia and inhibition of bone growth. To avoid the risk of inducing hemolytic anemia in utero in a G6PD-deficient fetus, primaquine should not be taken during pregnancy. The safety of malarone in pregnancy has not been established.

Travel-Related Illness

In a study of more than 10,000 Swiss who had traveled in developing countries for less than 3 months, 15% experienced health problems, and 3% were unable to work for an average of 15 days.[34] Infections with the greatest incidence per month abroad included giardiasis (seven cases per 1,000 months abroad), amebiasis (four cases per 1,000), hepatitis (four cases per 1,000), and gonorrhea (three cases per 1,000). Malaria, syphilis, and helminthic infections occurred at a lower incidence (fewer than one case per 1,000). No cases of typhoid fever or cholera were reported. The most common modes of acquisition of infection were enteral and sexual. Travelers should be cautioned about sexual contacts, especially in areas where hepatitis B or HIV is prevalent, and be advised to use condoms and barrier protection during sexual encounters.

Because of the global prevalence of HIV, postexposure antiretroviral prophylaxis may be germane for travelers who may have occupational exposures (e.g., health care workers) and for students and workers who are traveling and may be at risk for HIV exposure. The availability of local postexposure prophylactic medications should be ascertained at overseas work or study sites. Options for two- or three-drug regimens of postexposure antiretroviral therapy are discussed elsewhere [*see 7:XXXIII HIV and AIDS*]. If selected antiretroviral therapy is not assuredly available at work or study sites, sufficient medication should be carried by the traveler to ensure that a 28-day course of antiretroviral therapy is available.

Stays at major resorts and first-class hotels are associated with less risk than stays in less frequented locales or rural dwellings or encampments. In areas where sanitation and personal hygiene may be poor, it is prudent to be careful of food and water, although such care does not necessarily diminish the risk of diarrheal disease. Fruit that is peeled by the traveler is safe, whereas vegetables may be contaminated with fecally passed organisms in the soil and should not be consumed raw. Unpasteurized dairy products should be avoided, as should inadequately cooked fish or meat. If water is of uncertain quality, travelers should avoid drinking it or using ice made from it. Boiling will render water safe. Chlorination will kill most bacterial and viral pathogens, but protozoal cysts of *Giardia lamblia* and *Entamoeba histolytica* may survive. Carbonated beverages, beer, wine, and drinks made from boiled water are safe.

In areas where schistosomiasis is prevalent, swimming in freshwater should be avoided, although swimming in chlorinated or saltwater is safe. Even short exposures to infested water during rafting or swimming have caused the onset of acute schistosomiasis.

Most infections acquired during travels will present within weeks of travel, but some may not manifest themselves until much later; hence, knowledge of a patient's travel history is important.

ALTITUDE ILLNESS

Altitude illnesses may develop in travelers who arrive at heights between 6,000 and 8,000 ft (1,829 and 2,438 m) above sea level.[1] Travelers may arrive at these altitudes rapidly by flying into an airport at these elevations or more slowly by driving or climbing. Altitude illness includes three syndromes: acute mountain sickness (AMS), high-altitude pulmonary edema (HAPE), and high-altitude cerebral edema (HACE). AMS, the most common form of altitude illness, may occur at altitudes between 4,000 and 6,000 ft. Symptoms include headache, fatigue, loss of appetite, nausea, and, sometimes, vomiting. AMS usually develops 6 to 12 hours after arrival at the higher altitude. HACE is a progression of AMS characterized by extreme lethargy, confusion, and an ataxic gait during a tandem gait test.

HAPE may develop alone or in conjunction with HACE. Symptoms include increasing breathlessness. HAPE is more likely than HACE to be fatal. Travelers who develop HACE or HAPE must immediately descend to lower altitudes. Travelers to elevated altitudes need to be cautioned about the symptoms of these syndromes [*see 14:X Pulmonary Edema*], advised about the gravity of HACE and HAPE, and admonished not to delay descent to lower altitudes if these potentially lethal syndromes develop.

Three medications can be used to prevent and treat altitude illnesses. Acetazolamide can prevent AMS if taken before ascent; it also can hasten recovery. Dosing is 125 mg every 12 hours beginning the day of ascent. Dexamethasone (4 mg every 6 hours) can be used to prevent and treat AMS and HACE. Some investigators recommend relying on acetazolamide for prophylaxis and reserving dexamethasone for treatment of symptoms.[1] Persons who have experienced HAPE are at increased risk of its recurrence. If travel to high altitudes is unavoidable, nifedipine (10 to 20 mg every 8 hours) can prevent and ameliorate HAPE in those prone to experience this syndrome.

TRAVELER'S DIARRHEA

Diarrhea is the most common illness of travelers.[35] Infectious agents, primarily bacterial but also viral and parasitic pathogens, are responsible for traveler's diarrhea. Over 75% of cases of traveler's diarrhea are caused by bacteria, with enterotoxigenic *Escherichia coli* being the most frequent cause. Other common bacterial causes of traveler's diarrhea include *Shigella* species, *Campylobacter jejuni*, *Aeromonas* species, *Plesiomonas shigelloides*, *Salmonella* species, and noncholera *Vibrio* species.[35] Rotavirus and Norwalk agent are the most common viral causes; *Giardia, Cryptosporidium, Cyclospora,* and, less commonly, *Dientamoeba fragilis, Isospora belli, Balantidium coli, Strongyloides stercoralis,* and *E. histolytica* are parasitic causes.

In addition to exercising caution about food and water,[36] travelers may take either of two approaches: chemoprophylaxis and postonset treatment.

Chemoprophylaxis

The benefits of chemoprophylaxis may be offset by the risks of taking chemoprophylactic agents. Side effects of short-term prophylactic doses of bismuth subsalicylate may include tinnitus, blackening of the stool and tongue, and impaired absorption of doxycycline, which is important if doxycycline is used as daily antimalarial chemoprophylaxis. Side effects of antibiotics may include skin rashes and vaginal candidiasis, photosensitivity skin eruptions (especially with doxycycline), and, in rare instances, potentially life-threatening bone marrow suppression, mucocutaneous reactions, or anaphylaxis. Although these potential side effects temper the routine use of chemoprophylaxis, specific needs or wishes of travelers may dictate its use. Patients with underlying medical conditions that may be aggravated by a serious diarrheal illness, including active inflammatory bowel disease, type 1 (insulin-dependent) diabetes mellitus, and heart disease in the elderly, as well as patients whose activities during travel cannot tolerate interruption by an episode of diarrheal illness, should consider chemoprophylaxis. Several regimens are available [*see Table 3*]. Bismuth subsalicylate, which should not

Table 3 Chemoprophylaxis and Treatment of Traveler's Diarrhea

Drug	*Dose*
Prophylaxis	
Bismuth subsalicylate	Two 262 mg tablets chewed q.i.d. with meals and at bedtime
Quinolone antibiotics	
Norfloxacin	400 mg/day
Ciprofloxacin	500 mg/day
Ofloxacin	300 mg/day
Levofloxacin	500 mg/day
Doxycycline	100 mg/day
Treatment	
Loperamide	4 mg loading dose, then 2 mg after each loose stool, to a maximum of 16 mg/day
Quinolone antibiotics	
Norfloxacin	400 mg b.i.d. for up to 3 days
Ciprofloxacin	500 mg b.i.d. for up to 3 days
Ofloxacin	300 mg b.i.d. for up to 3 days
Levofloxacin	500 mg/day for up to 3 days
Azithromycin	1,000 mg single dose or 500 mg/day for 3 days
Rifaximin	200 mg t.i.d. for 3 days

be taken by persons with peptic ulcer disease, coagulopathies, or allergies to salicylates, is not as completely effective as quinolone antibiotics but has fewer side effects and enables the use of quinolone antibiotics, if they are needed for therapy. Resistance among bacterial causes of traveler's diarrhea is not common at present for the quinolone antibiotics (except for quinolone-resistant *Campylobacter* infection prevalent in Thailand) but is quite common for trimethoprim-sulfamethoxazole and doxycycline, limiting their efficacy. Chemoprophylactic medications should be started on the first day of arrival and continued for 1 to 2 days after returning home but not for more than 3 weeks.

Postonset Treatment

A generally preferable alternative to chemoprophylaxis is early therapy for traveler's diarrhea [*see Table 3*]. Because of the likelihood of bacterial resistance, trimethoprim-sulfamethoxazole is less effective than regimens employing quinolone antibiotics. Antibiotics will shorten the duration of traveler's diarrhea to a range of 16 to 30 hours, compared with a range of 59 to 93 hours in those not receiving antibiotics. The use of loperamide, which diminishes intestinal motility and fluid and electrolyte losses, together with antibiotics can further abbreviate symptoms. In a study of patients with dysentery caused by *Shigella* or enteroinvasive *E. coli*, the use of loperamide with ciprofloxacin, in comparison with ciprofloxacin alone, led to briefer (median, 19 hours versus 42 hours) and milder (median, two stools versus 6.5 stools) diarrheal illness, without untoward effects.[37] Loperamide has not been studied in children, and adults with prolonged fever or bloody stools should be advised to cease loperamide use and seek medical attention. Azithromycin is an alternative to quinolone antibiotics that can be used by pregnant patients; it is the agent of choice where quinolone-resistant *Campylobacter* infection is prevalent. Rifaximin (Xifaxan, from Salix), a nonabsorbable agent, is approved by the FDA for traveler's diarrhea caused by noninvasive strains of *Escherichia coli*.[38] Rifaximin should not be used if dysentery is suspected (i.e., if symptoms include fever and bloody stools) or if other causes of diarrhea (e.g., *Campylobacter*, *Shigella*, or invasive *E. coli*) are possible or isolated.

For any diarrheal illness, maintenance of hydration is of cardinal importance and can often be achieved by oral replacement of lost fluid and electrolytes. Convenient and inexpensive packets of oral rehydration salts formulated according to World Health Organization recommendations (i.e., 3.5 g of sodium chloride, 1.5 g of potassium chloride, 20 g of glucose, and 2.9 g of trisodium citrate in each packet) are available in both developed and developing countries. Each packet of oral rehydration salts is added to a liter of boiled or treated water and should be consumed or discarded within 12 hours if kept at ambient temperature or within 24 hours if kept refrigerated.

MEDICAL ISSUES DURING TRANSIT

Cruise ships that dock at ports in the United States are inspected for sanitation by officials from the CDC. Inspections are aimed at minimizing the potential for outbreaks of gastrointestinal disease on board. Travelers may obtain information on whether specific cruise ships meet sanitation standards from travel agents, state health departments, or the CDC.[1] Outbreaks of influenza have occurred aboard cruise ships in the past 10 years in various regions, including Alaska and the Yukon Territory. Travelers older than 50 years should consider influenza vaccination.

Because jet aircraft are not pressurized to sea level, passengers will be exposed to high-altitude environments. The atmospheric pressure maintained within the cabin of an airplane flying at 27,000 to 42,000 ft is equivalent to the pressure at an altitude of 3,000 to 8,000 ft, so that at a cruising altitude of 35,000 ft, the cabin pressure is about 600 mm Hg. Because of the decreased pressure, the arterial oxygen tension (P_aO_2) of normal persons will fall to about 68 mm Hg. In patients with chronic obstructive lung disease, the P_aO_2 will fall even lower. However, despite a fall in P_aO_2, patients may not show symptoms of hypoxia. Although hypoxia occurs in pregnant women, jet air travel has no deleterious effects on them or their fetuses. It is difficult to establish precise criteria for the use of supplemental oxygen for air travelers. Caution is indicated, however, for patients with impaired cardiopulmonary function: supplemental oxygen may be administered during flights at altitudes higher than 22,500 ft.

Scuba divers should wait 12 to 48 hours, depending on the length of their diving exposures, before boarding a commercial aircraft. This measure is important for avoiding the occurrence of aeroembolism, commonly known as the bends, which could develop in an underpressurized cabin if nitrogen gas dissolved in the person's fat cells is mobilized.

In patients with upper respiratory tract infections, differential air pressures between blocked eustachian tubes or sinuses and the cabin may develop on ascent or descent and impair hearing or cause pain in the ears or sinuses; symptoms can be relieved by the use of decongestants. Persons prone to motion sickness should take a prophylactic medication. Prolonged immobilization during flight may cause venous thrombosis in persons with preexisting thrombotic or venous disease [*see 1:XVIII Venous Thromboembolism*]. The exact risks and rates for developing venous thromboembolism during air travel are not yet defined.[39] Leg exercise and walking during the flight and use of below-the-knee stockings have been suggested to be beneficial, but evidence is lacking.

The author has received grant or research support from and is an advisor to GlaxoSmithKline.

VIII QUANTITATIVE ASPECTS OF CLINICAL DECISION MAKING

Brian Haynes, m.d., ph.d.
Harold C. Sox, m.d.

An increasing amount of very useful quantitative evidence from health care research is available to practitioners. New research findings continually expand the knowledge base of what does more good than harm for patients, and institutional forces, both professional and financial, are accelerating the adoption of research findings. More and more information is available on issues related to such important clinical topics as screening and diagnostic tests, preventive and therapeutic interventions, prognosis and clinical prediction, risk of adverse outcomes, improvement in quality of care, and cost-effectiveness of tests and treatments. Clinical application of this evidence has lagged, however, for a number of reasons.[1] First, evidence from research is often not definitive or covers only some aspects of practice. Second, clinicians are often slow to adopt research findings, even those that are well validated. Third, resources may be inadequate or too poorly organized in the local setting to permit implementation. Fourth, clinicians may be unfamiliar with the concepts that lie behind the application of quantitative reasoning to clinical care. This chapter addresses the last of these barriers: principles and methods for quantitative reasoning.

Lack of precision in clinical thinking is beginning to yield to several encouraging developments—in particular, clinicians increasingly applying principles of critical appraisal to evidence in the medical literature; formulation of methods for medical decision analysis; increasing clinical comfort with terms such as sensitivity, specificity, likelihood ratio, number needed to treat, and confidence interval (CI); and creation of print and electronic resources that minimize the effort that clinicians must make to find and interpret valid quantitative evidence when it is needed. These developments notwithstanding, the possibility of miscommunication is still considerable. A 2003 study of primary care physicians reported that just over 50% of respondents were able to answer questions about critical appraisal of methods and interpretation of results of studies focusing on treatments and diagnostic tests.[2] Patients are entitled to expect clearer thinking from their physicians, especially because many patients have difficulty themselves interpreting information about risks, benefits, and prognoses provided by their doctors.[3] Moreover, the current health care environment increasingly demands that physicians be able to justify clinical policies and decisions with an evidence-based, quantitative approach.

We have two principal goals in this chapter. The first is to provide a basic explanation of the measurements used in critical appraisal of the literature and the ways in which physicians interpret these measurements in evidence-based clinical decision making. With the advent of electronic access to MEDLINE and its clinical subsets, specialized compendia of studies (e.g., Clinical Evidence[4] and Physicians' Information and Education Resource [PIER][5]), systematic reviews of studies (e.g., the Cochrane Library[6]), and alerting services for new, clinically relevant evidence (e.g., bmjupdates+[7] and MEDSCAPE Best Evidence alerts[8]), the current best evidence for clinical practice is becoming more and more accessible to clinicians.

The second goal is to introduce the topic of medical decision analysis. Clinicians use decision analysis in two ways. One way is essentially indirect: reliance on products of decision analyses conducted by others. For example, practice guidelines increasingly influence many of the quick, straightforward decisions that occur in daily practice. Many of these guidelines are based on formal decision analyses. The second way of employing decision analysis is more direct: using the tools of decision analysis to assist in making major decisions about the care of an individual patient. Although few physicians spend the hours required to conduct a formal decision analysis from scratch, some tools of decision analysis (e.g., likelihood ratios of test results) are easy to apply; moreover, some decision analyses are accessible on a desktop or palmtop computer and only require the clinician to enter the clinical findings required by the decision tree.

It is important to understand the intent of this effort to achieve precision and quantitation in measurement and decision making: to enhance the quality of care by making it more tailored to the individual patient. Anything that can be measured, even if only qualitatively, can be counted and turned into a clinically useful quantitative measure. For example, a study might classify clinical outcomes only qualitatively (e.g., as satisfactory or unsatisfactory), but if the numbers of participants in the study who fall into one or the other of the two outcome states are counted, the result then becomes quantitative. If physicians can define individual states and measure them quantitatively (e.g., by using a continuous scale to assess functional status), they can describe individual patient status more precisely and therefore can make finer distinctions between groups of patients. By placing patients in distinctive groups, physicians can achieve one of the great goals of patient care: to inform patients of the choices between alternative treatments by the known predictors of response to those treatments.

What is the role of the individual practitioner in retrieving and evaluating evidence from research and incorporating it into individual clinical decisions? The answer to this innocuous question distills the angst of contemporary health care. In some settings, the practitioner has the freedom to act as circumstances dictate, whereas in others (e.g., certain managed care settings), someone else tries to dictate how to translate research results into patient care. We believe that practitioners cede their responsibility for clinical decision making to others at great risk to their patients and themselves, because any clinical decisions must take into account not only the evidence available and the guidelines in force but also the patient's unique circumstances and individual wishes. In today's world, the freedom to determine the content of one's practice is increasingly precious. To use this freedom responsibly, practitioners must have ready access to information that is based on current best evidence, must understand the basic principles of quantitative decision making and decision analysis, must be able to determine whether others have applied these principles appropriately in published works or in practice,

Table 1 Abbreviated Users' Guides for Appraisal of Medical Journal Articles

Purpose of Study	*Source of Data*	*Method of Arriving at Findings*	*Method of Reducing Bias of Findings*
Diagnosis	Clearly identified comparison groups, all suspected of having the disorder, but one of which is free of the disorder	Objective or reproducible diagnostic standard applied to all participants	Blinded assessment of test and diagnostic standard
Therapy	Random allocation of patients to comparison groups	Outcome measure of known or probable clinical importance	Follow-up of ≥ 80% of subjects
Prognosis	Inception cohort, early in the course of the disorder and initially free of the outcome of interest	Objective or reproducible assessment of clinically important outcomes	Follow-up of ≥ 80% of subjects
Causation	Clearly identified comparison group for those who are at risk for, or for those having, the outcome of interest	Blinding of observers of outcome to exposure; blinding of observers of exposure to outcome	—
Review	Comprehensive search for relevant articles	Explicit criteria for rating relevance and merit of studies	Inclusion of all relevant studies

and must be able to understand how to use evidence from research to make decisions in clinical practice.

How to Critically Evaluate Research Reports

To use numbers wisely in making decisions about patients, the physician must have some way of determining whether the numbers are derived from sound research. Detailed users' guides for interpreting the medical literature are available[9]; in an effort to simplify this issue, we have provided an abbreviated set of such guides [*see Table 1*].[10] Physicians may find these guides especially useful when reading research reports in the primary literature. However, when physicians are not getting and interpreting evidence themselves, they should look to evidence-based publications, such as *Clinical Evidence* and *PIER*; systematic review articles, such as those from the Cochrane Collaboration and clinical journals; and practice guidelines that use explicit criteria for evaluating evidence [*see Table 1*].

How to Apply Research Results to Patient Care

Once a physician is satisfied that the quantitative results from the relevant research were derived through sound methods, he or she can interpret them in light of the patient's circumstances and use them to help determine the best way to proceed with management. The interpretation of research results takes five main forms: (1) measures of disease frequency, (2) measures of diagnostic certainty, (3) measures of diagnostic test performance and interpretation, (4) measures of the effects of treatment, and (5) measures of treatment outcomes adjusted for quality of life.

Measures of Disease Frequency

Clinically useful measures of disease frequency include incidence, prevalence, the case-fatality rate, the *P* value, and the CI [*see Table 2*]. The use of such terms is illustrated in more detail elsewhere (see below).

Measures of Diagnostic Certainty: Use of Probabilities

When asked how sure they are of their diagnoses, most physicians express their degree of certainty in words rather than numbers. A classic study illustrates the difficulty of this approach.[11] The authors examined pathology and radiology reports and recorded various terms expressive of the probability of a disorder, such as "compatible with," "consistent with," "likely," "probably," and "pathognomonic." They then asked a group of clinicians to assign numerical probabilities to all of these terms. For each term (even "pathognomonic"), the range of probabilities stretched over half the scale. For example, to one physician, "likely" meant there was a 45% chance that the disease in question was present, whereas to another, "likely" meant the probability was higher than 90%. When diagnostic-test specialists were asked on two different occasions what they meant by these terms, the earlier and later answers were highly consistent for each individual specialist but highly inconsistent from one specialist to the next.

An alternative to using words to express the degree of diagnostic certainty is to use a number—namely, the probability that the diagnosis is present. A probability is a number between 0 and 1 that expresses the likelihood that an event will occur; 0 represents certainty that it will not occur, and 1 represents certainty that it will. Using probability to express diagnostic certainty has two key advantages. First, it facilitates precise communication. Comparison of probability estimates is a far more precise method of comparing degrees of diagnostic certainty than ex-

Table 2 Clinically Useful Measures of Disease Frequency

- Incidence: the proportion of new cases of a disorder occurring in a defined population during a specified period of time, typically 1 year.
- Prevalence: the proportion of cases of a disorder at a designated point in time in a specified population.
- Case-fatality rate: the proportion of cases of a specified disorder that are fatal during a specified period of follow-up (typically 1 yr) from the onset of the disorder.
- Quality-adjusted life year (QALY): a measure of survival in which each year of a patient's survival is discounted according to a measure (usually an index) of the patient's quality of life.
- *P* value: the probability of obtaining the observed data, or more unlikely data, when the null hypothesis is true. The *P* value does not indicate the magnitude of the effect of interest, or even its direction, nor does it indicate how much uncertainty is associated with the results.
- Confidence interval (CI): the range of values of a true effect that is consistent with the data observed in a study. A common (although not entirely correct) interpretation of a 95% confidence interval is that 95% of the time, the true value lies within the stated range of values.

changing verbal assessments. Second, there exists an accurate method of calculating changes in the likelihood of disease as new information (e.g., a test result) becomes available. This method, Bayes' theorem, should be one of the central principles that underlie medical practice. This claim may seem audacious to some readers, but we all recognize that the interpretation of new information about the patient moves us either away from or closer to a diagnosis and, therefore, away from or closer to the decision to use a specific treatment.

The probability of an event is not precisely the same thing as the odds of an event occurring, even though the two are mathematically equivalent ways of expressing diagnostic uncertainty. Habitués of the racetrack are reputed to use odds directly, but most clinicians are likely to find probabilities easier to use. Each of these measures can be readily converted to the other, as follows:

$$\text{Odds} = \frac{\text{probability}}{1 - \text{probability}}$$

$$\text{Probability} = \frac{\text{odds}}{1 + \text{odds}}$$

To use a test result quantitatively, a physician must first estimate the pretest probability of the disease. Unaided, physicians are not particularly good at this task. In a 1982 study, when primary care physicians were given clinical scenarios and asked for their estimates of the probabilities of given disorders, they provided estimates—quite confident ones—but their estimates did not agree with those of their fellow clinicians.[12] Indeed, when individual physicians were tested subsequently with the same scenarios, their later estimates did not agree with their initial ones.

How does a physician estimate the probability that a patient's chief complaint is a manifestation of a particular disease? The first step is to take a careful history and do a physical examination. From this point, the physician may take any of three basic approaches to estimating the probability of a disease[13]: (1) subjective estimation, (2) estimation based on the prevalence of disease in other patients with the same syndrome, or (3) application of clinical prediction rules.

Subjective Estimation

In principle, the physician can draw on personal experience with similar patients and use the estimated frequency of the disease in those patients. In practice, this approach is little more than a semiquantitative guess and is prone to error because of defective recall, as well as to bias in the application of the heuristics (i.e., the rules of thumb) for estimating probability. Examples of such heuristics are representativeness, by which one estimates a probability on the basis of the similarity of the patient's signs and symptoms to the features of the classic description of the disease, and availability, by which one estimates a probability partly on the basis of how easy it is to recall similar cases. One very useful heuristic is anchoring and adjustment, by which one establishes an initial estimate (e.g., the prevalence of pulmonary embolism in 100 patients presenting to the emergency department with pleuritic chest pain) and then adjusts the estimate upward or downward by taking into account the patient's findings (e.g., hypoxemia, unilateral leg swelling, or a history of cancer). Physicians can, in principle, calculate the extent of such adjustments by using Bayes' theorem (see below).

Estimation Based on the Prevalence of Disease in Other Patients with the Same Syndrome

One antidote to the failures of subjective probability estimation is to base the estimate on accurate diagnoses established in a series of patients with the same clinical syndrome as the patient under consideration. The best example is the diagnosis of suspected coronary artery disease in patients with chronic chest pain. On the basis of the clinical history, the physician can place the patient in one of three categories: typical angina pectoris, atypical angina, or nonanginal chest pain. Many published studies have reported the frequency of angiographically proven coronary disease in patients with these syndromes. These studies have shown, for example, that in a man with atypical angina, the probability of significant coronary artery disease is approximately 0.70 (see below).

Application of Clinical Prediction Rules

Clinical prediction rules describe the key clinical findings that predict a disease and show how to use these findings to estimate the probability of disease in a patient. Such rules are based on analysis of a standardized set of data, including clinical findings and the final diagnosis, for each of many patients with a diagnostic problem. One type of clinical prediction rule uses regression analysis to identify the best clinical predictors and their diagnostic weights. The sum of the diagnostic weights corresponding to a patient's findings is a score, and the probability of disease for each patient is equivalent to the prevalence of disease among patients with a similar score. A well-known example of this approach is the rule for estimating the probability of cardiac complications from noncardiac surgery.[14] Another interesting example showed that the prevalence of coronary artery disease in patients with similar chest pain scores varied systematically according to the overall prevalence of coronary artery disease in several study populations.[15] This study suggested that the probability of disease corresponding to a patient's clinical history varies depending on whether the setting of care is a primary care practice or a referral practice. *Diagnostic Strategies for Common Medical Problems*[16] is an excellent source of pretest probabilities, as is *Evidence-Based Physical Diagnosis*.[17]

MEASURES OF DIAGNOSTIC TEST PERFORMANCE AND INTERPRETATION

Clinically useful measures of diagnostic test performance include sensitivity, specificity, and the likelihood ratio; clinically useful measures of test interpretation include pretest odds, pretest probability, probability after a positive test result, and probability after a negative test result [*see Table 3*]. Physicians should memorize and internalize the definitions of these terms to avoid becoming muddled when attempting to use information from diagnostic tests in decision making.

In the past, articles usually described the performance of a diagnostic test only in terms of sensitivity and specificity. These familiar terms do not directly describe the effect of a test result on the probability of disease. To correct this shortcoming, many articles now use the likelihood ratio (LR), which is the amount by which the odds of a disease change with new information. This value is calculated as follows:

$$\text{LR} = \frac{P\,[\text{test result if disease present}]}{P\,[\text{test result if disease absent}]}$$

Because physicians often express test results as either positive or negative, there is a likelihood ratio for a positive test re-

Table 3 Definitions of Clinically Useful Measures of Diagnostic Test Performance and Interpretation

The typical approach to evaluation of most diagnostic tests, particularly those with so-called binary outcomes (e.g., a positive or a negative test result, with no other categories), makes use of a 2 × 2 table, as follows:

Diagnostic Test Result	*Presence or Absence of Disease on a Reference Test (Gold Standard)*		*No. of Patients with Given Test Result*
	Present	*Absent*	
Positive	*a*	*b*	*a* + *b*
Negative	*c*	*d*	*c* + *d*
Total	*a* + *c*	*b* + *d*	

Measures of diagnostic test performance, defined below, are calculated from this table.

- Sensitivity: the proportion of people with a disease of interest who are detected by a diagnostic test; calculated as $a/(a+c)$.
- Specificity: the proportion of people who do not have a disease who are correctly identified by a negative result on a diagnostic test; calculated as $d/(b+d)$.
- Likelihood ratio: the amount by which the odds of having a disease change after a test result; calculated as $[a/(a+c)]/[b/(b+d)]$ for a positive test result and as $[c/(a+c)]/[d/(b+d)]$ for a negative test result.
- Pretest probability: the proportion of people with the disorder of interest in a group suspected of having the disorder; calculated as $(a+c)/(a+b+c+d)$.
- Odds: calculated as probability/(1 – probability).
- Probability: calculated as odds/(1+ odds).
- Posttest odds: calculated as pretest odds × likelihood ratio.
- Probability after a positive test: the proportion of people with a positive test result who have the disease of interest; calculated as $a/(a+b)$.
- Probability after a negative test: the proportion of people with a negative test result who have the disease of interest; calculated as $c/(c+d)$.

sult (LR^+) and a likelihood ratio for a negative test result (LR^-). The formula for the likelihood ratio for a positive test result is as follows:

$$LR^+ = \frac{\text{sensitivity}}{1 - \text{specificity}}$$

The formula for the LR for a negative test is as follows:

$$LR^- = \frac{1 - \text{sensitivity}}{\text{specificity}}$$

The likelihood ratio is generally a better descriptor than sensitivity or specificity because it more directly describes the effect of a test result on the odds of disease. The probability after obtaining new information is an application of Bayes' theorem. The most useful form of Bayes' theorem for this purpose is the odds ratio format:

$$\text{Posttest odds} = \text{pretest odds} \times \text{likelihood ratio}$$

This form of Bayes' theorem illustrates a very powerful concept that clinicians often overlook: new information has meaning only in context. Operationally, the statement means that a physician should never interpret a test result in isolation but should always take into account the individual patient's pretest probability. Simply stated, the posttest probability after a positive test result will be greater if the pretest index of suspicion was high than if the pretest index of suspicion was low. The most important practical application of this reasoning is to be suspicious when a test result is negative in a patient whose clinical findings strongly point toward a disease—that is, the probability of the disease may still be high, even after the negative test. One should also be suspicious when a test is positive in a patient for whom the likelihood of disease is very low.

The evaluation of suspected pulmonary embolism (PE) is a good example of the practical use of these statistical terms and methods. A 37-year-old woman presents to the emergency department (ED) with pleuritic chest pain and new dyspnea. She has a low-grade fever and has no cough or hemoptysis, but the ED physician believes it necessary to rule out PE. The patient has none of the other known risk factors for PE (e.g., recent surgery or prolonged bed rest, previous deep vein thrombosis [DVT], coagulopathy, malignancy, pregnancy, and use of oral contraceptives), and physical examination reveals no evidence of DVT. The arterial oxygen tension (P_aO_2) is 92 mm Hg on room air. The patient is quite distressed. The ED physician orders a chest x-ray and a helical CT scan. The CT scan is interpreted as negative for PE. The resident wishes to explain this result to the patient and then to take the appropriate next steps.

A useful flowchart for working up patients with suspected PE is provided elsewhere [*see 1:XVIII Venous Thromboembolism*]; however, this chart provides no guidance on how to estimate the clinical probability of PE. It is instructive to examine how the results of a quantitative, evidence-based approach to this patient's case relate to the recommendations outlined in the flowchart.

The initial step is to estimate the pretest probability of PE by one of two approaches. The first is to use the anchoring and adjustment heuristic. The anchor, or starting point, is the prevalence of PE in adults who present to the ED with pleuritic chest pain. One very careful study found that 21% of such patients (36/173) had a positive pulmonary angiogram.[18] The physician should use this 21% initial probability as the starting point (the anchor) for the patient under discussion and adjust it on the basis of the history and the physical examination. As noted, this patient has no predisposing factors for PE and no evidence of DVT, and her P_aO_2 is greater than 90 mm Hg. Using this approach, the ED physician concludes that the probability of PE before helical CT is quite low, perhaps 10%.[19]

The second approach is to use a clinical prediction rule.[20] This model places patients into three categories on the basis of clinical findings (typical for PE, atypical for PE, severe PE), the likelihood of alternative diagnoses, and the presence of risk factors for DVT. The prevalence rates of PE in the three categories are 3.4%, 27.8%, and 78.4%, respectively. The algorithm for placing patients into one of the three categories is somewhat complex but is easy to use when represented on the screen of a palmtop computer. Assuming that the ED physician did not identify an alternative diagnosis that seemed more likely than PE, the patient's pretest probability of PE was 28%, considerably higher than the ED physician's subjective probability.

With an estimate for the pretest probability of PE, the next step is to obtain the likelihood ratio for a negative helical CT scan. The sensitivity and specificity of the helical CT scan have varied considerably among studies. A recent meta-analysis of studies of diagnostic tests for pulmonary embolism found the likelihood ratio for a positive chest CT scan to be 24.1 (95% CI,

12.4 to 46.7). The likelihood ratio for a negative scan was 0.04 (95% CI, 0.03 to 0.06).[21]

To calculate the posttest odds of PE, the ED physician must combine the patient's pretest odds with the test's likelihood ratio by means of the odds ratio format of Bayes' theorem mentioned earlier (posttest odds = pretest odds × likelihood ratio). An alternative to converting the pretest probability to odds and doing the calculation of posttest odds is to use a nomogram [*see Figure 1*]. To estimate posttest probability, anchor a straightedge at a pretest probability of 28% (corresponding to the clinical predictive rule's estimate of pretest probability) in the left-hand column; then pass the straightedge through a likelihood ratio for a negative helical CT scan, 0.04, in the middle column. Read the posttest probability from the right-hand column: about 1.5%. The math for this estimate is as follows, with the 0.28 pretest probability of PE first needing to be converted to pretest odds:

$$\begin{aligned}\text{Pretest odds} &= \text{pretest probability}/(1 - \text{pretest probability})\\ &= 0.28/(1 - 0.28)\\ &= 0.28/0.72\\ &= 0.39\end{aligned}$$

Now, the post–helical CT scan odds of PE for this patient must be determined by multiplying the pretest odds of PE, 0.39, by the likelihood ratio for a negative helical CT, 0.04:

$$\begin{aligned}\text{Posttest odds} &= \text{pretest odds} \times \text{likelihood ratio}\\ &= 0.39 \times 0.04\\ &= 0.0156\end{aligned}$$

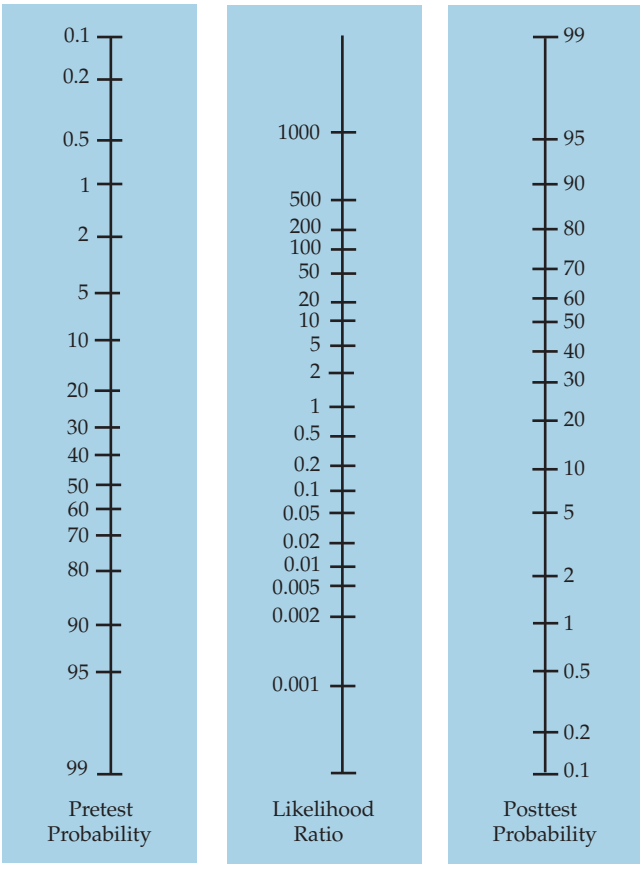

Figure 1 **Nomogram for converting pretest probabilities to posttest probabilities when test results are presented as likelihood ratios.**

Table 4 Definitions of Clinically Useful Measures of Treatment Effects from Clinical Trials

Like evaluation of diagnostic tests, evaluation of treatment effects often makes use of a 2 × 2 table, as follows:

Treatment Group	*Treatment Outcome*		*No. of Patients in Treatment Group*
	Bad	*Good*	
Experimental	*a*	*b*	*a* + *b*
Control	*c*	*d*	*c* + *d*
Total	*a* + *c*	*b* + *d*	

Measures of treatment effects when treatment reduces the risk of bad outcomes are calculated from this table.

- Experimental event rate (EER): the rate of an adverse clinical outcome in the experimental group; calculated as $a/(a+b)$.
- Control event rate (CER): the rate of an adverse clinical outcome in the control group; calculated as $c/(c+d)$.
- Absolute risk reduction (ARR): the absolute arithmetic difference in outcome rates between control and experimental groups in a trial; calculated as CER – EER, or $[c/(c+d)] - [a/(a+b)]$.
- Relative risk reduction (RRR): the proportional reduction in the rate of an adverse clinical outcome in the experimental group in comparison with the control group in a trial; calculated as ARR/CER, or (CER – EER)/CER, or $\{[c/(c+d)] - [a/(a+b)]\}/[c/(c+d)]$.
- Number needed to treat (NNT): the number of patients to whom one would have to give the experimental treatment to prevent one adverse clinical outcome; calculated as 1/ARR, or $1/\{[c/(c+d)] - [a/(a+b)]\}$, and reported as a whole number rounded to the next highest integer.
- Odds ratio: the odds that an experimental patient will experience an adverse event relative to the odds that a control subject will experience such an event; calculated as $(a/b)/(c/d)$.

Convert the posttest odds to the posttest probability, as follows:

$$\begin{aligned}\text{Posttest probability} &= \text{posttest odds}/(1 + \text{posttest odds})\\ &= 0.0156/(1 + 0.0156)\\ &= 0.0154\end{aligned}$$

At a posttest probability of PE of 1.5%, only 15 patients per 1,000 would have PE. Anticoagulating patients with a 1.54% probability of PE would mean exposing 65 patients (i.e., 1/0.0154) to the harms of anticoagulation to benefit one patient with a PE. Most physicians would follow this patient closely without giving specific treatment for PE. This same logic can be applied to all screening and diagnostic tests for PE, including D-dimer testing (high sensitivity and low specificity), which is therefore more useful for ruling out PE (when it is negative) than ruling it in (when it is positive).[22] D-dimer tests can also be used for calibrating clinical observations to enhance the quantitation of pretest probabilities.[23]

MEASURES OF TREATMENT EFFECTS

One of the most important tasks of clinicians is to advise patients about the current best treatment for their condition. Such advice should be based on the best evidence available. Clinically useful measures of treatment effects reported in clinical trials include the experimental event rate (EER), the control event rate (CER), relative risk reduction (RRR), absolute risk reduction (ARR), the number needed to treat (NNT), and the number needed to harm [*see Table 4*]. These measures can be effective tools for quantifying the magnitude of treatment benefits and

risks, provided that there is a statistically significant difference in the clinical event rate between experimental subjects and control subjects (i.e., between the EER and the CER).

Again, we illustrate the practical application of these terms by a specific example. A 69-year-old hypertensive male smoker has experienced a partial left hemispheric stroke, with good recovery of function. He has a 75% ipsilateral internal carotid artery stenosis. One option would be to give this patient aspirin or clopidogrel and manage his risk factors for cerebrovascular disease; another would be to offer him carotid endarterectomy in addition to medical treatment. The question is, how and on what evidentiary basis does the clinician choose one treatment over another? It is tempting to think of treatments in black-and-white terms, as either working or not working, but the reality is rarely so absolute; often, the choice is between two or more treatments, each of which works after a fashion in certain situations. To apply the available evidence to the decision-making process in the most effective manner, the clinician must interpret it quantitatively, offering accurate, relevant figures instead of gut feelings when the patient asks what his chances are with each therapeutic approach.

Three randomized, controlled trials of carotid endarterectomy for symptomatic carotid artery stenosis[24-26] can inform our choice of treatment in this hypothetical patient. Examination of the North American Symptomatic Carotid Endarterectomy Trial (NASCET)[24] in the light of the users' guides discussed earlier [*see Table 1*] reveals that this study meets the three criteria for a study focusing on therapy. First, patients with symptomatic hemispheric transient ischemic attacks or partial strokes and ipsilateral carotid stenoses of 70% to 99% were randomly assigned to either an experimental group that underwent carotid endarterectomy or a control group that did not. All patients received continuing medical care, with special attention given to risk factors for cerebrovascular disease. Second, the study assessed the effect of carotid endarterectomy on important clinical events—namely, recurrence of stroke or perioperative stroke or death. Third, none of the patients were lost to follow-up. Consequently, the data from the study are likely to be valid guides in determining which treatment is best for this patient.

In the NASCET report, the risk of major or fatal ipsilateral stroke within a 2-year follow-up period was 2.5% in the group that underwent carotid endarterectomy and 13.1% in the control group. The absolute risk reduction, therefore, was 13.1% – 2.5%, or 10.6% ($P < 0.001$; CI, 5.5% to 15.7%), and the relative risk reduction was 10.6%/13.1%, or 81%. The number needed to treat was 10 (1/0.106); that is, 10 patients (CI, 7 to 18) would have to be treated with carotid endarterectomy (rather than medical treatment alone) to ensure that one major or fatal ipsilateral stroke would be prevented. The NASCET report indicates that this benefit is somewhat lower for patients with less severe stenosis (70% to 79%) and somewhat higher for patients with multiple risk factors for cerebrovascular disease—circumstances that offset one another in the case of the patient under consideration here.

Having determined the NNT, the next question is whether an NNT of 10 for major or fatal stroke over a 2-year period is a small benefit or a large one. By contrast, treatment of elevated diastolic blood pressures that do not exceed 115 mm Hg is associated with an NNT of 167 to prevent one stroke over a 5-year period.[25] Thus, for patients who have symptomatic, severe carotid artery stenosis, carotid endarterectomy is highly beneficial.

Given this conclusion, the next question is, do these research results apply to a specific patient, hospital, and surgeon? For example, the NASCET data reflect operative procedures performed by highly competent surgeons in specialized centers. One would have to know the perioperative complication rates for local surgeons to be able to assess a patient's level of risk if referred to any of those surgeons. If the local surgeons' perioperative complication rates for carotid endarterectomy are lower than 7%, the results are comparable to the NASCET results. On the other hand, patients with a stenosis of less than 70% are at substantially less risk for subsequent stroke to begin with. Potential benefit is similar to potential harm for patients with stenoses of 50% to 70%; for patients with stenoses of less than 50%, current evidence indicates that carotid endarterectomy would not yield any net reduction of this risk, even when the procedure is done by a highly skilled surgeon.[26,27]

MEASURES OF TREATMENT OUTCOME, ADJUSTED FOR QUALITY OF LIFE

Measures of treatment outcome, such as reduction in mortality, are important in deciding whether to start a medication or perform an operation, but they do not answer a question that is important to many patients: How much longer can they expect to live if treatment is started? One way of responding is to frame the answer in terms of life expectancy, the average length of life after starting treatment, which has a simple relation to the annual mortality in patients undergoing treatment.[13]

Although life expectancy is a useful measure of treatment outcome, it has one shortcoming: it places the same value on years in perfect health as on years in poor health. Arguably, a year with partially treated chronic disease is not equivalent to a year in perfect health. A solution to this problem is to adjust life expectancy for the quality of life that the patient experiences during a year of poor health by multiplying life expectancy by a number, expressed on a scale of 0 to 1, that reflects how the patient feels about the quality of life experienced during an illness. This number is usually called a utility. When life expectancy, expressed in years, is multiplied by a utility, the result is a quality-adjusted life year (QALY). One QALY is equivalent to a year in perfect health.

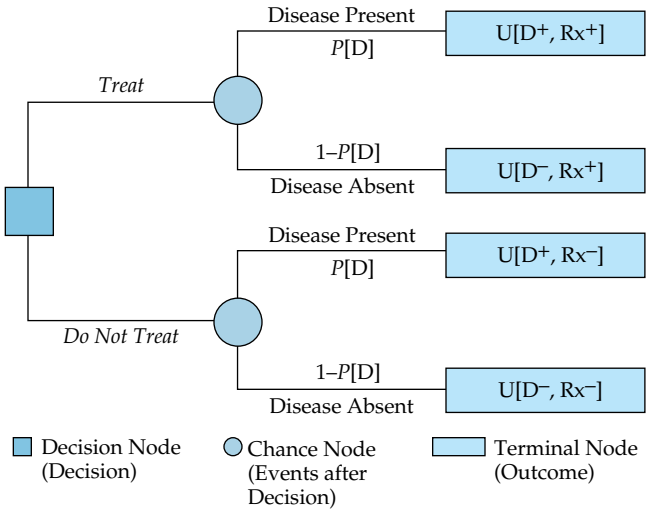

Figure 2 **Shown is a decision tree for calculating the treatment threshold probability in a patient who is a possible candidate for carotid endarterectomy. (D—disease; U—utility)**

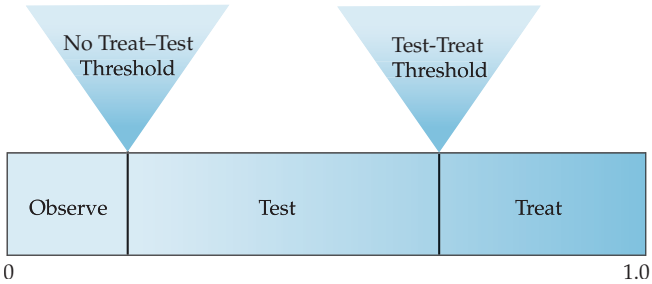

Figure 3 **Probability scale showing the ranges of probability corresponding to different actions following the initial history and physical examination.**

Medical Decision Analysis

Clearly, there is more to clinical decision making than simply collecting numbers that measure treatment effects. Reports of treatment effects in randomized, controlled trials are important starting points that help determine whether a treatment has merit in its own right, but the actual decision whether to offer a given patient a particular treatment is complex and must take into account each patient's specific clinical circumstances and individual wishes. For example, if the patient has significant comorbidity that would result in an especially high risk of perioperative complications, surgical therapy might not be the best choice. Even if the patient is well enough to undergo operation, individual preferences and values must be taken into account: the patient might be strongly averse to the immediate risks posed by surgery or might lack the resources to pay for the procedure.

THE THRESHOLD MODEL OF DECISION MAKING

At the conclusion of every history and physical examination, the clinician must choose one of three options: to treat, to observe, or to obtain more information. The optimal approach to making this choice starts with the assumption that the physician will seek more information (i.e., order diagnostic tests) only if the results may alter the treatment decision. Although occasional exceptions are easily justified, this rule is a good guiding principle for a lean style of practice. It is also the central assumption behind the threshold model of decision making.

When a diagnosis is uncertain, the decision whether to start treatment depends on the probability of the diagnosis. If the probability is 0, no one would start treatment; if the probability is 1, everyone would start treatment. Therefore, there must be a probability between 0 and 1 at which a physician would have no preference between treating and not treating. This probability is called the treatment threshold probability.

The treatment threshold probability is a key to solving the important decision-making problem of whether to treat, to observe, or to obtain more information. The most elegant way of obtaining the treatment threshold probability is to construct a decision tree that represents the choice between starting treatment and withholding treatment [*see Figure 2*]. In a decision tree, decisions are represented by squares (decision nodes), and the chance events that follow a decision are represented by circles (chance nodes). The probabilities of the events after a chance node must total 1.0. A terminal node (represented by a rectangle enclosing the name of the state) represents a state in which there are no subsequent chance events. Each terminal node has a value, which is a measure of the outcome associated with the event.

In a decision tree for starting or withholding treatment, each branch of the two chance nodes ends in a terminal node whose value is the utility (U) for being in the state specified. For example, $U[D^+, Rx^+]$ is the utility for having the disease (D) and being treated for it, which one could calculate by representing that state as a tree with chance nodes and terminal nodes. To obtain the treatment threshold probability, one sets the expected utility of treatment at a value equal to the value for the expected utility of no treatment and then solves for the probability of disease. The general solution to the equation is as follows:

$$\text{Treatment threshold probability} = \frac{\text{harm}}{\text{harm} + \text{benefit}}$$

where harm is the net utility of being treated when disease is absent ($U[D^-, Rx^+] - U[D^-, Rx^-]$) and benefit is the net utility of being treated when disease is present ($U[D^+, Rx^+] - U[D^+, Rx^-]$). This relationship between harms and benefits of treatment is fundamental to solving the common decision problem of deciding about treatment when the diagnosis is not known with certainty. Because the treatment threshold depends on the benefits and harms of the treatment, it will vary from treatment to treatment. When the benefits of a treatment exceed harms, which is usually the case, the treatment threshold probability must be less than 0.50.

To make the choice between treating, not treating, and ordering tests to obtain additional information, the physician needs to know the range of probabilities of disease within which testing is the preferred action. The probability scale can be divided into three ranges [*see Figure 3*], one of which is the test range. The first step in defining the test range is to establish the treatment threshold probability. For the next step, we must invoke the principle that the physician should seek more information only if the results might alter the treatment decision. Translated to the threshold model, this principle takes the following form: testing is indicated only if the result of the test might move the probability of disease from one side of the treatment threshold (the do-not-treat side) to the other (the treat side). A physician can use this principle to decide whether to obtain a test in an individual patient. If the patient's pretest probability is below the treatment threshold and therefore in the do-not-treat zone, the physician should order the test only if the posttest probability of disease after a positive test result would be higher than the treatment threshold probability.

To obtain the test range, we must extend this example to a more general solution, which is to use the test's likelihood ratio and Bayes' theorem to calculate the pretest probability at which the posttest probability is exactly equal to the treatment threshold probability [*see Figure 3*]. This probability is called the no treat–test threshold probability. Clearly, if the pretest probability is lower than the no treat–test threshold probability, the test should not be done, because the posttest probability will be lower than the treatment threshold probability (i.e., a positive result will not change the management decision); conversely, if the pretest probability is higher than the no treat–test threshold probability, the test should be done, because the posttest probability will be higher than the treatment threshold probability (i.e., a positive test result would change the management decision from do not treat to treat).

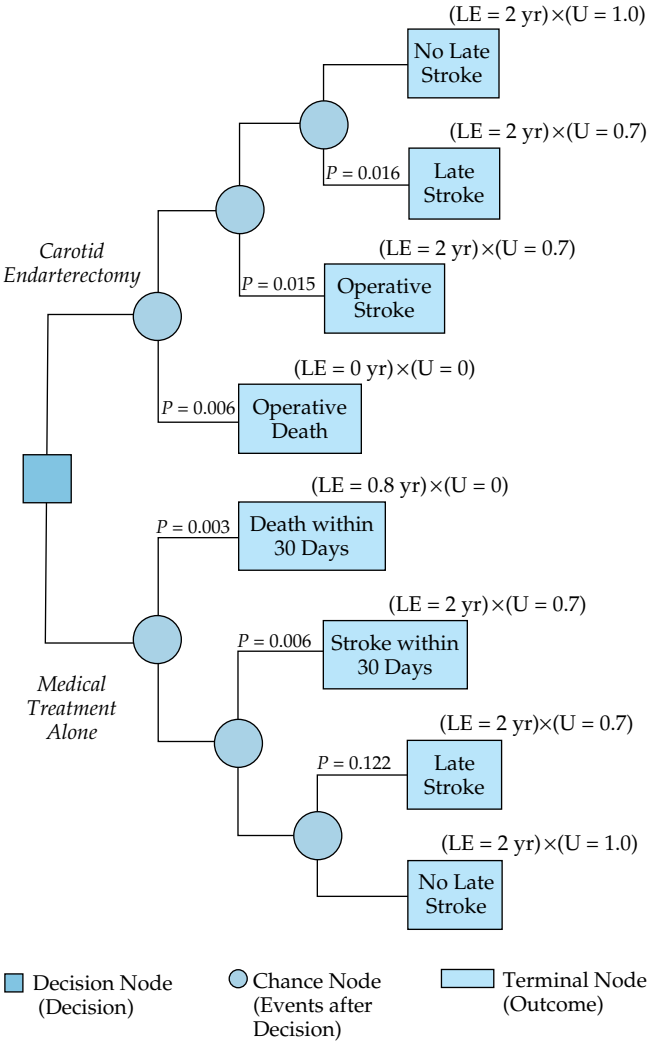

Figure 4 **Shown is a decision tree depicting the application of expected-outcome decision analysis to the same patient referred to in Figure 2. (LE—life expectancy; U—utility)**

The size of the test range depends on the likelihood ratios reported for the test. If LR^- is close to zero and LR^+ is much greater than 1.0, the test range will be very wide. In general, the better the test, the larger the test range. If the posttest probability falls within the treat zone, the physician must then decide which treatment to offer. The choice among treatments offers a good opportunity to explore the principles of decision making under conditions of uncertainty.

MEASURES OF EXPECTED-OUTCOME DECISION MAKING: THE TREATMENT DECISION

The purpose of decision analysis is to help with those decisions for which the outcome cannot be foretold (e.g., the decision whether to treat carotid artery stenosis surgically). Even when randomized trial results indicate that one treatment generally gives better results than another, some degree of uncertainty remains: individual patients may still exhibit idiosyncratic outcomes or may experience unusual but serious side effects of treatment. Faced with this uncertainty, most physicians choose the treatment that gives the best results averaged over a large number of patients. In so doing, they become, perhaps unwittingly, what are known as "expected-value decision makers." Expected value is the value of an intervention when the outcomes of that intervention are averaged over many patients. A more general term might be "expected-outcome decision maker," which would denote a physician who chooses the treatment that gives the best outcome when averaged over many patients. This concept is the basis of expected-outcome decision analysis, which is a method of framing a decision problem in terms of the expected outcome of each decision alternative. Thus, in a patient with stable angina, the physician would decide between medical management, coronary angioplasty, and coronary artery bypass surgery by first calculating a patient's life expectancy, expressed in years in good health, after undergoing each of these treatment options; then, the physicial would choose the treatment with the highest life expectancy.

We can illustrate the application of expected-outcome decision making by returning to the example of the 69-year-old man who has recovered from a hemispheric stroke and has a 75% carotid stenosis. The question to be answered is the same: Should the patient be offered carotid endarterectomy in addition to best medical treatment? The first step is to represent the problem by a decision tree [*see Figure 4*]. Each of the terminal nodes in this decision tree is associated with a life expectancy, as well as a utility representing the value of life in the outcome state, represented by the terminal node. As noted earlier [*see* How to Apply Research Results to Patient Care, Measures of Treatment Outcome Adjusted for Quality of Life, *above*], life expectancy by itself is not a sufficiently precise measure: clearly, 2 years of life after a major stroke is not equivalent to 2 years in perfect health. The decision maker needs a quantitative measure of the patient's feelings about being in an outcome state. The physician can obtain the patient's utility for that state by asking the patient to indicate the length of time in perfect health that he would consider equivalent to his life expectancy in a disabled state (e.g., after a major stroke). This technique is called time trade-off. Other techniques used to obtain this utility include linear scaling and the standard reference gamble.[13]

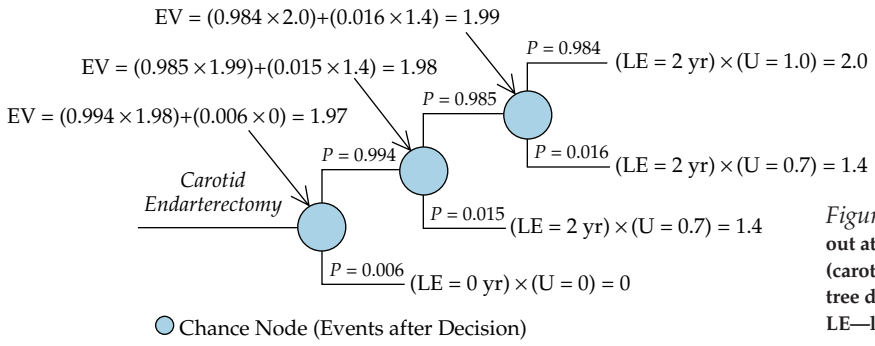

Figure 5 **Illustrated is the process of averaging out at a chance node, as applied to the upper (carotid endarterectomy) portion of the decision tree depicted in Figure 2. (EV—expected value; LE—life expectancy; U—utility)**

To calculate the expected value of surgical management, the decision maker starts at the chance nodes that are farthest from the decision node (the tips of the branches of the decision tree), multiplies the probability of each event at each chance node by the value of the event, and sums these products over all the events at the chance node. This calculation is known as averaging out at a chance node [*see Figure 5*]. The value obtained for each chance node by means of this process becomes the outcome measure for the next step, which is to repeat the averaging-out process at the next chance node to the left.

With either therapeutic option—aspirin combined with carotid endarterectomy or continued management with aspirin alone—there is a chance of death within 30 days, stroke within 30 days, or stroke within 2 years [*see Figure 4*]. As noted [*see* How to Apply Research Results to Patient Care, Measures of Treatment Effects, *above*], reliable data on the probabilities of these adverse events are available in the NASCET report.[24] To simplify the presentation of the decision analysis, we measure survival only within the 2-year time frame addressed in the NASCET report, and we assume that all late strokes occur at the start of this 2-year period. Further, we assume that a patient would value 2 years of disability resulting from a stroke as equivalent to 17.5 months of healthy life, which means that the utility representing the state of having experienced a major stroke is 0.70.

The decision analysis indicates that the decision maker should prefer surgical treatment to medical treatment. The expected value of carotid endarterectomy for this patient is 1.96 QALY, whereas the expected value of medical treatment is 1.91 QALY. Admittedly, this difference is not very large, indicating a close call, and it is reasonable to ask how high the operative mortality would have to be to make medical treatment the favored approach. Sensitivity analysis, one of the most powerful features of decision analysis, shows that the operative mortality would have to increase considerably before medical treatment would become preferable. The baseline figure for operative mortality in the NASCET report was 0.6%. The sensitivity analysis indicates that medical treatment would have a higher expected value than surgical treatment only if the operative mortality were 3.2% or higher, which might be the case if considerable comorbidity were present or if the surgeon seldom performed carotid endarterectomy. Although most physicians would not have the time or expertise to carry out this decision analysis, storing the appropriate decision tree in a palmtop computer would make it possible to do the decision analysis easily in the office setting, using values specific to the clinical setting and the patient.

cost-effectiveness analysis

Cost-effectiveness analysis is a method for comparing the impact of expenditures on different health outcomes. Cost-effectiveness analysis assesses the trade-off between added benefit and added cost by examining costs and benefits at the margin (i.e., comparing one intervention with another or with no intervention). The cost-effectiveness of one intervention (A) versus another (B) is calculated as follows:

$$\text{Cost-effectiveness (A vs. B)} = \frac{\text{cost A} - \text{cost B}}{\text{effectiveness A} - \text{effectiveness B}}$$

In the carotid endarterectomy example, the costs would include all costs associated with a subsequent stroke. If we assume that the average lifetime cost associated with carotid endarterectomy is $10,000 and the average lifetime cost associated with medical treatment is $8,000, then the cost-effectiveness of surgical treatment, as compared with medical treatment, would be calculated as follows:

Cost-effectiveness (surgery vs. no surgery)
= ($10,000 – $8,000)/(1.96 –1.91 QALY)
= $2,000/0.05 QALY
= $40,000/QALY

One may then ask, is a treatment choice that costs $40,000 for each extra QALY cost-effective? There is no absolute answer to this question. In practice, a physician compares the cost-effectiveness of carotid endarterectomy with that of other interventions. How this information should affect the decision whether to offer surgical treatment to any given patient is an even more difficult question. Indeed, most experts would say that cost-effectiveness is a technique for deciding policies that would apply to many patients. An organization with limited resources would choose policies that prescribe interventions with the lowest cost per added QALY. The organization would not offer interventions that have a high cost relative to the magnitude of the anticipated benefit.

Conclusion

Quantitative approaches to clinical reasoning are still evolving. By combining better evidence from health care research with today's burgeoning information technology, physicians can apply evidence effectively to individual patient care. As requirements for efficiency and accountability continue to increase, physicians are under more and more pressure to adopt a quantitative, evidence-based approach to patient care. Physicians who can back up their decisions with sound research and sound reasoning will be in a better position to provide their patients with optimal care.

IX PALLIATIVE MEDICINE

Cynthia X. Pan, m.d.

One unanticipated result of the advances in health care during the past century has been the emergence of chronic illness as the leading cause of death [*see Table 1*]. At the same time, the enhanced ability to significantly extend life for patients with chronic diseases has blurred the boundary between curable illnesses and illnesses that inevitably result in death. As a result, over the course of the 20th century, Western society increasingly attributed near-miraculous powers to medical science—and increasingly avoided the subject of death. Many patients and physicians came to regard the prolongation of life and the cure of disease as the fundamental and exclusive goals of modern medicine. Viewed from this perspective, death is a medical failure.

Recent decades, however, have seen a growing recognition that this view is unrealistic and potentially harmful. This recognition has supported the emergence of the field of palliative care. Unlike curative care, which focuses on the disease process, palliative care focuses on the patient, striving to minimize the patient's burden and maximize the patient's quality of life. A distinguishing feature of palliative care is that it openly acknowledges dying as part of living and does not consider death an enemy.[1]

This chapter describes the general concepts of palliative care, reviews the clinical skills needed to provide competent palliative care to patients who are chronically ill or near the end of life, and discusses some of the challenging legal and ethical issues often encountered in palliative and terminal care.

History and Rationale

Palliative medicine was first recognized as a medical specialty in Great Britain in 1987. This discipline grew out of the hospice care movement, a special interdisciplinary system of comprehensive care for the dying and for their families.[1] Over time, the palliative care model has been extended. It now applies not only to patients who are clearly at the end of life but also to those with chronic illnesses that, although not imminently fatal, cause significant impairment in function, quality of life, and independence. Palliative medicine for patients with serious illness thus should no longer be seen as the alternative to traditional life-prolonging care. Instead, it should be viewed as part of an integrated approach to medical care. Palliative care is not characterized by less care or by withdrawal of care. On the contrary, palliative care may involve intensive and highly sophisticated medical interventions, albeit ones intended to relieve suffering or improve quality of life.

Table 1 Leading Causes of Death in the United States: 2000[46]

Rank	*Condition*	*Percent of Total Deaths*
1	Heart disease	29.6
2	Malignant neoplasm	23.0
3	Cerebrovascular diseases	7.0
4	Chronic lower respiratory tract diseases	5.1
5	Accidents	4.1
6	Diabetes mellitus	2.9
7	Influenza and pneumonia	2.7

Note: These conditions account for approximately 75% of all deaths.

Settings for Delivery of Palliative Care

Palliative care may be delivered in a variety of settings, including a hospital, nursing home, hospice, or private home. In some cases, the level of care required will dictate the choice of setting. For the most part, however, palliative care depends more on the attitude of the clinician than on the setting.

HOSPITALS

Increasing numbers of hospital-based palliative care programs have been developed in recent years to meet the needs of people who are chronically and critically ill and eventually die in hospitals.[2] A national Center to Advance Palliative Care has been created to provide technical support and resources for hospitals that want to establish such programs [*see Sidebar* Palliative Care Information and Resources on the Internet].

HOSPICE

Hospice is one way to deliver palliative care [*see Table 2*]. Hospice care traditionally has been characterized as low tech, high touch. Hospice provides home nursing, support for the family, spiritual counseling, pain treatment, medications for the illness that prompted the referral, medical care, and some inpatient care. The National Hospice and Palliative Care Organization (NHPCO) estimates that in the United States, hospices admitted 775,000 patients in 2001 (compared with approximately 340,000 persons in 1994) and that, in 2000, one in four persons who died of all causes were receiving hospice care at the time of death.[3]

Palliative care and hospice share similar philosophies, and both are delivered by an interdisciplinary team of health care professionals. Palliative care differs from hospice care in that palliative care can be provided at any time during an illness and in a variety of settings, may be combined with curative treatments, and is independent of the third-party payer. In the United States, hospice is paid through the Medicare Hospice Benefit. Medicare requires that recipients spend 80% of hospice care days at home, which means that to qualify for hospice, the patient must have a home and have caregivers (e.g., family members) capable of providing care. In addition, primarily for financial reasons, Medicare requires that recipients have an estimated survival of 6 months or less and that their care be focused on comfort rather than cure.[4] These eligibility rules were created at a time when hospice programs principally served patients with cancer or AIDS, in which the trajectory of dying is relatively predictable; in 1994, for example, 80% of hospice patients had cancer, and the average patient enrolled about 1 month before death.[5] Because hospice increasingly serves pa-

Provides a comprehensive national education program to develop a core of expert nursing educators and to coordinate national nursing efforts in end-of-life care.

Growth House
http://www.growthhouse.org
Gateway to international resources for life-threatening illness and end-of-life care; intended to improve the quality of care for dying people through public education and global professional collaboration; includes links and search engine on reviewed resources for end-of-life care.

National Hospice and Palliative Care Organization (NHPCO)
http://www.nhpco.org
Nonprofit membership organization representing hospice and palliative care programs and professionals in the United States. Offers information in Spanish and English on local hospice and palliative care programs across the country. Toll-free telephone number: 800-658-8898.

Project on Death in America (PDIA)
http://www.soros.org/death
Strives to increase understanding and transform the culture and experience of dying and bereavement through initiatives in research, scholarship, the humanities, and the arts, and to foster innovations in the provision of care, public education, professional education, and public policy.

tients with chronic conditions in which prognostication remains inaccurate, these eligibility rules now limit access to care.[6,7] Asking patients and families to choose between curative care and palliative care is difficult for all concerned and is inconsistent with the current model of care, which views palliative care on a continuum with life-prolonging therapy [*see Figure 1*].[8] Also, this either/or situation contributes to late referrals and underutilization of hospice services.[9]

Palliative care can be provided in nursing homes, and increasing numbers of nursing homes strive to do so. Policies governing the coordination of palliative care in nursing homes vary according to reimbursement venues and availability of trained staff. Many nursing homes coordinate palliative care through local hospices, taking advantage of the skilled hospice nurses and other health care professionals.

Demographics of Death and Dying in the United States

Most people in the United States can now expect to die in old age. Of the over 2 million deaths per year in the United States, 73% occur in persons 65 years of age or older: 49% in persons 65 to 84 years of age, and 24% in persons 85 years of age or older. In 2001, the estimated life expectancy at birth reached 77.2 years, compared with less than 50 years in 1900.[10]

The median age of death in the United States is 77 years of age; of persons who survive to 65 years of age, median age at death is 84 years for women and 80 years for men.[11] Persons 65 years of age or older constitute an increasingly large number and proportion of the United States population, and those persons 85 years of age or older constitute the most rapidly growing segment. In 1999, persons 65 years of age or older accounted for about 13% of the population; this proportion is projected to rise to 20% by the year 2030.[12]

The elderly population is extremely heterogeneous, varying in socioeconomic status, educational level, and cultural and ethnic background. This diversity is likely to increase in the coming years. For example, African Americans 65 years of age and older numbered 2.5 million in 1990 (constituting 8% of the population of persons older than 65 years), and their number is expected to more than triple, to 8.4 million (or 10.5% of that population) by 2030. Similarly, there were approximately 1.1 million Hispanic elderly persons in 1990 (3.5% of the population of persons older than 65 years), but by 2030 this number will skyrocket to 12.5 million (15.6% of that group).[12]

Compared with the current elderly population, elderly baby boomers will be far more knowledgeable about health care and far more demanding of health care providers. Their expectations are likely to lead them to challenge the health care profession to deliver high quality end-of-life care tailored to patients' individual need and to provide that care in a culturally sensitive manner.

Although most deaths occur in the elderly, people can become critically ill at any point in their lives and can die at any age. In fact, the persons whose cases were the basis for establishing important precedents for ethical and legal decisions related to death and dying were young adults: 26-year-old Nancy Cruzan,[13] whose case involved the issue of artificial feeding of patients in a persistent vegetative state; and 21-year-old Karen Ann Quinlan,[14] whose case involved the withdrawal of artificial ventilation from patients in a persistent vegetative state.

LEADING CAUSES AND SETTINGS OF DEATH

The three leading causes of death in adults in the United States in 2001 were heart disease, malignant neoplasm, and stroke.[10] Chronic obstructive pulmonary disease (COPD), pneumonia, and accidents each accounted for less than 10% of all deaths. Most adult deaths in the United States occur in hospitals (56%), followed sequentially by deaths occurring at home (21%), in nursing homes (19%), and in other settings (4%).[15] These statistics vary substantially according to geographic site, primarily because of regional variations in hospital, hospice, and nursing home bed supply.

Table 2 Comparison of Hospice and Palliative Care

Feature	*Hospice*	*Palliative Care*
Initiation	Prognosis of < 6 mo survival	Any time during illness
Clinical focus	Comfort care; no curative care	May involve both comfort care and curative care
Third-party payment	Medicare hospice benefit	Independent of payer
Personnel	Volunteers integral and required	Health care professionals
Setting	> 90% provided at home; inpatient hospice for acute deterioration, very short life expectancy (e.g., < 2 wk), or high symptom burden	Anywhere (hospital, home, nursing home)
Do not resuscitate (DNR) orders	Not required	Not required

Prognosis and Palliative Care

Traditionally, palliative care has been narrowly conceptualized as an alternative to standard life-prolonging therapy and has been provided to patients whose disease no longer responds to curative treatment. Although this model may be appropriate for patients dying of metastatic cancer, in which prognosis is relatively predictable and response to treatment is typically well defined, fewer than a quarter of persons in the United States die of cancer; the majority die of chronic diseases (e.g., heart disease) in which the prognosis is often uncertain, functional decline is nonlinear, and life-prolonging therapies coexist with or are identical to therapies directed at palliation and comfort (e.g., diuresis for fluid overload in heart failure).

One of the barriers to initiating palliative care is the uncertainty of predicting prognosis in these complex, chronic medical illnesses. For example, timing of death in heart failure is far less predictable than in many other fatal disorders. A patient dying of colon cancer usually has a long period of functional stability, then several months of progressive functional decline and weight loss just before death. In contrast, most heart failure patients experience a lengthy decline in daily function, with periodic bouts of severe symptoms and disability and multiple hospital admissions for exacerbation and for adjustment of therapy. Death may occur during a severe exacerbation but often occurs suddenly and relatively unpredictably from cardiac arrhythmia [*see Figure 2*]. In the SUPPORT project (Study to Un-

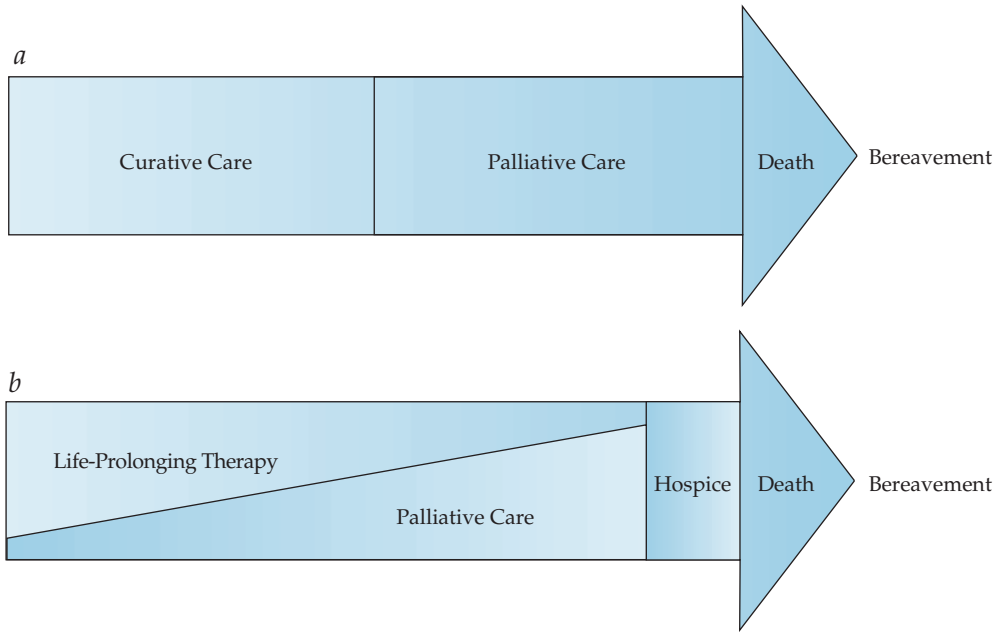

Figure 1 **(*a*) Formerly, curative care and palliative care were viewed as mutually exclusive; when death became inevitable, curative care was abandoned and palliative care begun. This model of care is now outdated, because prognosis is so difficult to determine. (*b*) The current model views palliative care on a continuum with life-prolonging therapy, with palliative care assuming increasing importance as the patient's illness progresses and curative options are exhausted. Also, many chronic and life-threatening illnesses have no cures; the goals of treatment are to contain the illness and maintain an acceptable level of function and quality of life.**

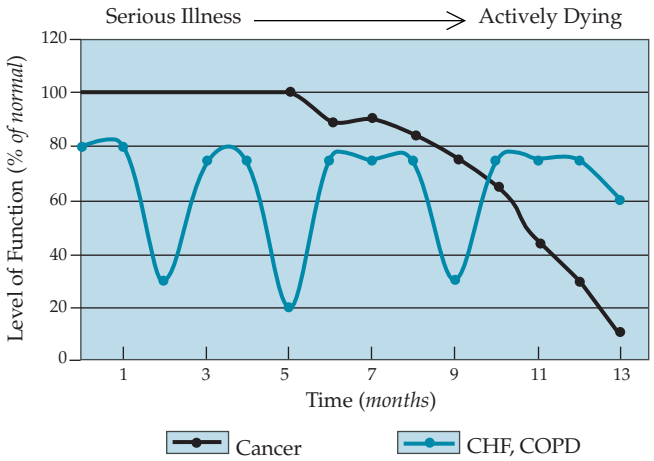

Figure 2 **Prognosis is relatively predictable in metastatic cancer; these patients typically have a long period of functional stability, then several months of progressive functional decline and weight loss just before death. In contrast, prognosis can be difficult to predict in diseases such as chronic heart failure (CHF), chronic obstructive pulmonary disease (COPD), and Alzheimer disease; these patients typically experience a lengthy decline in daily function, with periodic bouts of severe symptoms and disability and multiple hospital admissions for exacerbation and for adjustment of therapy. Death may occur during a severe exacerbation, but—especially in CHF—often occurs suddenly and relatively unpredictably from cardiac arrhythmia.**

derstand Prognoses and Preferences for Outcomes and Risks of Treatments),[16] heart failure patients were given surprisingly long prognoses even up to the day before death. The median prognosis on the day before death was a 50% chance of living 2 months.[17] Dementia is another condition that often progresses over years rather than months.

To help clinicians assess prognosis in various nonneoplastic conditions, the NHPCO has compiled guidelines describing factors associated with poor prognosis; these guidelines can promote discussion about preferences for care and advance care planning.[18] However, SUPPORT data indicate that for seriously ill, hospitalized patients with advanced COPD, heart failure, or end-stage liver disease, recommended clinical-prediction criteria cannot reliably identify those patients whose survival prognosis is 6 months or less.[19] Because it is not possible to consistently and accurately predict the timing of death, palliative care interventions should be incorporated early in a patient's course of illness, even in the face of substantial uncertainty about prognosis. As disease progresses, the goals of care should change accordingly, with the balance shifting from curative to palliative.

Clinical Skills

Caring for dying patients and for those who suffer from chronic and severe illnesses with uncertain prognoses requires an interdisciplinary approach and specific clinical skills. In particular, the clinician who provides palliative care must be competent in clinical communication, management of symptoms (physical, emotional, and psychological), and planning for continuity of care.

COMMUNICATION

The ability to communicate well with both patient and family is paramount in palliative care. In the beginning, it enables the physician to deliver bad news, assess the patient's and the family's knowledge and understanding of the disease process, determine the factors that they consider important to quality of life, and discuss goals and preferences for future care. As the illness progresses, regular communication about the course of illness and the patient's needs and expectations enables the physician to provide the most appropriate care for the patient and support for the family. Communication continues to be important after the patient's death, because the period of bereavement poses major challenges and increased risks of medical and psychiatric illness for family members.[1]

Patients whose cultural background and language differ from that of the physician present special challenges and rewards and need to be approached in a culturally sensitive manner [*see* Accounting for Cultural Differences, *below*]. Physicians also need to communicate effectively with colleagues and interdisciplinary team members to achieve optimal care for their patients. Communication in palliative care is discussed in detail elsewhere [*see CE:XI Management of Psychosocial Issues in Terminal Illness*].

SYMPTOM MANAGEMENT

Symptom management in palliative care encompasses the assessment and treatment not only of physical symptoms but of emotional and psychological symptoms as well. Physical symptoms that can contribute to discomfort, disability, and dependence include pain, dyspnea, constipation, nausea and vomiting, delirium, fatigue, and anorexia. Emotional and psychological symptoms include depression, anxiety, delirium, cognitive impairment, fear, and agitation or sedation, as well as spiritual and existential angst.

Pain is the most common symptom of terminal illness, reported by 84% of patients with cancer and 67% of patients dying of other causes.[11] Surprisingly, the leading cause of physical distress in patients dying of heart failure is also pain, followed by fatigue and shortness of breath. Other common symptoms reported by dying patients include trouble with breathing (49%), nausea and vomiting (33%), sleeplessness (40%), depression (36%), loss of appetite (47%), and constipation (36%). Apart from illness, symptoms that become more prevalent with increasing age include mental confusion, loss of bladder and bowel control, difficulty seeing and hearing, and dizziness.

At present, the identification and management of many symptoms, including pain, remain suboptimal. Undertreatment of symptoms is common in elderly patients whether they have cancer[20] or other chronic conditions, whether they reside in long-term care settings (45% to 80% prevalence)[21,22] or in the community, and whether they are white or are members of minority groups.[20,23] Undertreatment of pain in the elderly may be more common in patients who are women, are members of minority groups, or have mild to moderate cognitive impairment.[24] Clinicians may contribute to undertreatment of pain through lack of proper pain-assessment procedures, misconceptions regarding both the efficacy of nonpharmacologic pain-management strategies and the attitudes of the elderly toward such treatments,[25] and legitimate concerns about drug interactions and side effects.

Education and involvement of the patient and family as partners in care are key to the successful management of symptoms. Specific strategies for symptom management include both pharmacologic and nonpharmacologic measures. These

strategies are discussed in detail elsewhere [*see CE:IX Symptom Management in Palliative Medicine and 11:XIV Pain*].

ACCOUNTING FOR CULTURAL DIFFERENCES

The United States is a culturally heterogeneous country. Culture can broadly include race and ethnicity, as well as country of origin, religion, spirituality, and profession.[26] Medicine has its culture as well, with its attendant values, beliefs, behaviors, and language. Thus, in some cases, patients may be encountering two unfamiliar cultures: that of the United States mainstream and that of Western medicine.

Cultural traits may have a far-reaching impact on a patient's views on illness, preferences, and ultimate decisions.[27] Compared with patients from mainstream United States culture (most of whom are whites of European descent), people from other cultural backgrounds may be less willing to discuss resuscitation status,[27] less likely to forgo life-sustaining treatment,[27-29] and more reluctant to complete advance directives.[30]

Although many individual variations exist, some frequently encountered examples of cultural differences include the following:

(1) Hindus traditionally respect the doctor's medical opinion and may request the physician, rather than a family member, be appointed as health care proxy. They may prefer to die at home, preferably on the floor near the earth. After death, the relatives may want to wash the body themselves and dress it in new clothes. Autopsy is not forbidden but is considered distasteful, and cremation is usual.

(2) Traditional Chinese (and some other Asian) families usually will ask the clinician not to inform the patient about a terminal diagnosis (especially cancer) for fear that the patient will lose hope and die. In these cultures, the patient ideally will be informed after a period of adjustment. Decision-making is often entrusted to the eldest child, usually a son. Patients may seek traditional therapies, such as acupuncture and herbal medicine, often in conjunction with allopathic care.

(3) African Americans may decline participation in research studies, because of their long history of abuse as experimental subjects in research. Because of their history of receiving inappropriate undertreatment, they may continue to request aggressive care, even in terminal illness.[31]

With patients who do not speak English, it is extremely helpful to have access to a trained interpreter who can provide an objective translation and shift the translation burden from family members. This can prevent awkward and inappropriate situations, such as having to ask a male teenager to interpret for his mother who has cervical cancer. Translators may also be able to provide valuable information about patients' cultural attitudes and expectations.

Although it is important to learn about and respect different cultural practices, it is even more important not to stereotype or assume that membership in a group determines preferences. Instead, the physician should treat each patient as an individual. When in doubt, ask: "I have had patients from your cultural group who told me…. Does this apply to you?" Or, "I don't know much about medical practices or beliefs in your culture; can you tell me more about this?"

Advance Directives

Public opinion polls have revealed that close to 90% of adults in the United States would not want to be maintained on life-support systems without prospect of recovery. Yet a survey of emergency department patients found that 77% did not have advance directives, and of those patients who had one, only 5% had discussed their advance directive with their primary care physician.[32] A survey of community-dwelling older adults found that only about 16% had written advance directives.[33] In a survey of adult outpatients, most felt that discussions about advance directives should take place at an earlier age, earlier in the course of the disease, and earlier in the patient-physician relationship; most subjects also agreed that it was the physician's responsibility to initiate the discussion.[34]

Primary care physicians are in an excellent position to speak with patients about their care preferences because of the therapeutic relationship that already exists between patient and doctor. Conversations about preferences of care should be a routine aspect of care, even in healthy older patients. Determination of the patient's preferences can be made over two or three visits and then updated on a regular basis (e.g., annually). Reevaluation is indicated if the patient's condition changes acutely. In general, it is preferable that a close family member or friend accompany the patient during these discussions, so that these care preferences can be witnessed and any potential surprises or conflicts can be explored with the family.

Such discussions have particular urgency in patients who are showing early signs of cognitive impairment, because advancing impairment may render these discussions impossible. In older persons with existing cognitive impairment, it is important to assess both their current degree of decision-making capacity and any evidence, written or verbal, of previously stated preferences.

Decision-making capacity refers to the capacity to provide informed consent to treatment. This is different from competence, which is a legal term; competence is determined by a court. Any physician who has adequate training can determine capacity. It does not need to be determined by a psychiatrist. Primary care physicians often have more insight and knowledge about their patients than a psychiatrist, who might be seeing the patient for the first time.[35] The more complicated and serious the decision, the more stringent the requirements for understanding. For instance, a demented patient may have the capacity to appoint a trusted family member to serve as health care proxy but may not have the capacity to decide whether to have a permanent feeding tube placed.

A patient must meet three key criteria to demonstrate decision-making capacity: (1) the ability to understand information about diagnosis and treatment; (2) the ability to evaluate, deliberate, weigh alternatives, and compare risks and benefits; and (3) the ability to communicate a choice, whether verbally, in writing, or with a nod or gesture.

In eliciting patient preferences, the clinician should explore the patient's values—what is important to the patient and what makes life worth living or what makes life intolerable. The clinician should help the patient identify and set realistic goals, then direct treatment decisions according to these goals. More specifically, it is important to evaluate whether the patient would prefer to focus on length of life or quality of life if faced with a serious illness. In older persons who have chronic conditions that are not immediately life threatening, there is more time to explore these issues and to modify decisions over time. Outlining the available treatment options (e.g., probability and extent of response to treatment, duration and quality of extended life, anticipated side effects), identifying patients' short- and long-term

goals and needs, uncovering their expectations about therapy, evaluating their coping strategies, and identifying their support networks are critical components of this discussion.

Discussions of care preferences should cover specific life-sustaining treatments such as cardiopulmonary resuscitation (CPR), artificial nutrition and hydration, and mechanical intubation and ventilation. Physicians should review with the patient the potential indications for such therapies and, if possible, offer an explicit appraisal of the outcome in their situation. A helpful strategy is to ask patients how long they think they would want a particular treatment to be continued if it did not seem to be helping. For example, the physician might ask, "If you had a brain injury that left you in a coma and the neurologists determined that only a miracle would restore your brain function, how long would you want to stay on treatments that were keeping you alive?" Some patients may specify a week, some a month, and still others, a year. Such discussions help clarify the patient's preferences and tolerance for uncertainty.

In eliciting patient preferences for care, it is critical to consider the person's cultural, ethnic, and religious background.[26] For example, it is fairly well known that Jehovah's Witnesses will not accept blood transfusions, even in the face of life-threatening conditions, but may want all other invasive treatments. Such differences can make a patient unwilling to accept a physician's recommendations and can make a physician angry at the patient's resistance to those recommendations. With patience and training, however, it is usually possible to uncover these beliefs and negotiate treatment plans that are acceptable to all concerned.

TYPES OF ADVANCE DIRECTIVES

There are three types of advance directives: (1) do not resuscitate (DNR) orders, (2) directives involving health care proxies, and (3) living wills. All are legal instruments. The federal Patient Self-Determination Act of 1990 requires hospitals, skilled nursing facilities, home health agencies, hospice programs, and health maintenance organizations to maintain written policies and procedures guaranteeing that every adult receiving medical care be given written information concerning advance directives. Although forms for designating health care proxies and living wills are completed by patients themselves, physicians may wish to secure copies of the forms used in their state and assist their patients in completing these forms.

A health care proxy is a person appointed by the patient to make health care decisions in the patient's stead, in the event that the patient loses the capacity to make those decisions. In general, it is preferable for the physician to speak to the patient first, ask the patient to think about appointing a health care proxy, and then ask the patient to bring the potential proxy to a follow-up meeting. The proxy should be aware of and advised about the patient's goals of care and preferences and should be able and willing to assume the responsibilities of serving as proxy. Typically, an alternative proxy is also appointed.

A living will is a document that directs health care personnel to withhold or withdraw life-sustaining treatment in the event that the patient is in an incurable or irreversible condition with no reasonable expectation of recovery. Not all states have statutes recognizing living wills. However, courts have recognized and upheld the use of living wills as long as these documents provide "clear and convincing evidence" of a competent patient's wishes.

Ethical Issues in Palliative Care

Chronic illness and end-of-life care bring into focus some compelling ethical issues. These include limiting life-sustaining treatments, physician-assisted suicide, and euthanasia. Guidelines and principles on these issues have been established to enable patients, families, and physicians to reach medically sound, ethical treatment decisions in cases of irreversible illness. As a result, and despite widespread physician feeling to the contrary, these treatment decisions are almost devoid of litigation danger. Nevertheless, physicians should work with their hospital attorneys to clarify the status of legislation and case law on these issues in their particular jurisdiction.

LIMITING TREATMENT (REFOCUSING GOALS OF CARE)

In the discussion of treatment goals and plans with patients or family members, the language a physician uses can make a tremendous difference. If the physician says, "It is time to stop [or limit] the treatments," the patient or family will likely feel abandoned and hopeless and therefore ask for more interventions that may not be appropriate or useful. However, if the physician says, "It is time to refocus our efforts; let's strive to maximize comfort and dignity rather than prolong the dying process," the patient and family are more likely to feel validated and reassured. Similarly, if the physician refers to mechanical ventilation, dialysis, or artificial nutrition as "life-sustaining" treatments, it is a rare individual who will elect to forgo them. Rather, the physician should refer to them as medical interventions used to achieve specific goals. For example, one might speak of instituting mechanical ventilation to support breathing, in the hope that the patient will regain spontaneous breathing; if this hope is not realized, it is then time to discuss what the goals of care are and whether they need to be modified.

Ordinarily, discussions of goals of care involving limitation of life-sustaining treatment occur in three categories of patients. The first category includes patients whose illness is judged irreversible and who are moribund; these patients usually do not benefit from aggressive medical interventions, which can become invasive and burdensome. For patients who will die with or without treatment, such as a patient with advanced metastatic cancer or a patient with end-stage cardiomyopathy for whom a transplant is not possible, interventions often pose more burdens and risks than benefit. The second category consists of patients with capacity who are not moribund but have an irreversible illness, such as amyotrophic lateral sclerosis or multiple sclerosis. These patients often wish to discuss their ultimate goals of care and their right to refuse medical treatments so as to retain control over their health care as their disease progresses. The third category includes patients with capacity who have a reversible illness. As with any patient with capacity, the principle of autonomy guarantees these patients the right to refuse any treatment, even a lifesaving one, although physicians obviously will question these refusals much more vigorously than refusals in cases of irreversible and progressive illnesses.

An important caveat here is that although supreme autonomy of the patient is valued by mainstream culture in the United States, it is not the guiding value of many other cultures. In fact, most ethnic groups in the United States (e.g., Hispanic Americans, Asian Americans, Orthodox Jews, African Americans) favor a family-based decision-making process. Furthermore, autonomy does not always mean that the patient must be informed or must participate in decision making. Autonomy

means that patients should be asked whether they wish to be informed or participate in decision making; they may refuse to do either.

In some cases, a limited trial of life-prolonging treatment may clarify the patient's chances of recovery. The treatment can be stopped if it becomes clear that health (or the extent of recovery acceptable to the patient) cannot be restored. However, sometimes it is psychologically more difficult to stop such a treatment once it has been started, even if its original justification no longer applies.

When the patient does not have capacity, there are several ways to resolve treatment decisions. Advance directives are the most helpful. Otherwise, common sense should be followed, and the patient's next of kin should be asked to provide a substituted judgment about what the patient would have wanted or what decision would be in the patient's best interest.

Ethically and legally, there is no difference between forgoing or withholding a medical treatment (such as mechanical ventilation) and stopping or withdrawing it. However, family members and health care providers may feel that withholding and withdrawing interventions are emotionally different. It is therefore critical to counsel families and health care professionals that the decisions about any medical treatment should be guided by overall goals of care. Consultation with the hospital's palliative care service or ethics committee may be valuable for resolving conflicts over life-prolonging treatments.

FUTILE TREATMENT

Conflicts that require arbitration often center on treatments that either the family or the treatment team regard as futile or ineffective. Futility is a narrowly applied term that is used in the setting of CPR to describe a resuscitation attempt that would not succeed in resuscitating the patient or that, if successful, would likely be followed shortly afterward by another arrest. In many cases, when a patient is irreversibly ill and dying, CPR would be futile. Application of it is contrary to the standards of medical practice; it is unethical and inhumane. In such a case, the physician does not have a duty to consult anyone before writing a DNR order but should inform the family that a DNR order is being implemented. This is an opportunity for the physician to remind the family just how severe the illness is and to refocus attention to meeting other needs of the patient and the family.

Defining futility is currently a major goal of medical ethics.[36] The negative right of refusal has become transformed by some into a positive right to demand of physicians any life-sustaining treatment. Others argue that physicians have a duty not to offer or provide treatments that are ineffective.[37] Because most risk-versus-benefit considerations of life-sustaining treatment involve value judgments and because the principle of autonomy requires that the patient's values come first, some argue that so-called objective standards for futility are impossible to formulate and that physicians should make no such judgments.[38] However, for patients in an irreversible coma and, increasingly, for those in a persistent vegetative state, life-sustaining treatments are seen to be futile.

Controversial questions about defining treatments as futile will most likely be resolved city by city by a panel of experts set up to judge whether a treatment is futile after hearing all evidence presented by the family, the medical team, and others. This was the approach used by the Houston citywide consortium of hospitals.[39]

THE REQUEST FOR ASSISTED SUICIDE OR EUTHANASIA

In the United States, the public increasingly accepts physician-assisted suicide and euthanasia as moral practices and believes that these practices should be legal.[40] These views can be seen as the public's condemnation of at least two things: the way hospitals and physicians overtreat sick patients in their last days, making death a painful journey; and medicine's inadequate and ineffective treatment of suffering. These views also reflect a demand for more control in decisions about the end of life. Some people equate physician-assisted suicide with euthanasia, but they are different concepts. In physician-assisted suicide, the patient requests the physician's help in dying, usually in the form of a prescription of a lethal dose of medication to be taken at home. Euthanasia occurs when there is no patient request but the physician (or other health care professional) decides to hasten the patient's dying process in order to relieve suffering (the patient's or the physician's).

In June 1997, the United States Supreme Court ruled that there is no constitutional right to physician-assisted suicide.[41] This opinion did not remove the authority of individual states to outlaw or decriminalize physician-assisted suicide, however; and in November 1997, Oregon voters confirmed their acceptance of the Death with Dignity Act, which allows terminally ill Oregon residents to obtain from their physicians and to use prescriptions for self-administered, lethal medications. The act states that ending one's life in accordance with the law does not constitute suicide, and it specifically prohibits euthanasia (i.e., direct administration of a medication to end another person's life).

Many, if not most, of those patients who want physician-assisted suicide want it not to relieve suffering as ordinarily understood but to maintain control over their dying.[42] As of 1999 (2 years after legalization of physician-assisted suicide in Oregon), a survey of Oregon physicians found that they granted about one in six requests for a prescription for a lethal medication and that one in 10 requests actually resulted in suicide. Substantive palliative interventions led some—but not all—patients to change their minds about assisted suicide.[43,44] As of 2002, a total of 129 people had committed physician-assisted suicide in Oregon, corresponding to a rate of 8.8 per 10,000 deaths from any cause in the state.[45] Compared with Oregon residents who died of similar underlying causes, rates of physician-assisted suicide decreased with age and were higher among those who had been divorced and among those with higher levels of education. The rate of physician-assisted suicide was also higher among those afflicted with amyotrophic lateral sclerosis and cancer. The majority of patients using physician-assisted suicide were non-Hispanic whites, but a significant minority were Asian Americans. Overall, the number of Oregon residents using physician-assisted suicide has increased over the years, but it remains a very small minority relative to overall deaths.

Regardless of legal issues, however, when a patient requests a prescription for enough medication to commit suicide or to hasten death, the physician has the ethical responsibility to try to learn why. What is it that now makes death seem a better option than life? What is it that the patient feels must be avoided? From what is the patient trying to escape? Is the patient depressed? Why does the patient feel that that he or she can no longer be someone who matters? Are there financial considerations—that is, does the patient fear becoming a financial burden, a burden to care for, or both? Has any of this been discussed with the fam-

ily? How would the family understand the patient's requests and be affected by them? If the patient considers life to be devoid of value and meaning, does the patient's life still have meaning for other persons? Does this affect the patient? Has the patient made any effort to achieve consensus so that his or her death can be a meaningful, shared family experience?

FEAR OF LEGAL REPRISAL

When a physician makes a reasonable clinical judgment of irreversible illness and decides to forgo or stop life-sustaining treatment—whether on the wish of the patient or, if the patient is incompetent, with the agreement of the patient's proxy or surrogates—fear of litigation is neither a reasonable nor a legitimate excuse not to proceed. The courts have made it clear that these decisions are valid and that the persons involved in those decisions should not be brought to trial. It is irrational to demand guarantees that no litigation will follow, however. It is hoped that physicians' energies will be spent doing the best they can for the patient, in accord with the patient's wishes. Should litigation follow an action taken in accord with the above guidelines, the physician will be well prepared to defend the decisions in court.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

X SYMPTOM MANAGEMENT IN PALLIATIVE MEDICINE

Maria Torroella Carney, m.d.
Jennifer Rhodes-Kropf, m.d.

The goal of palliative care is to provide comfort and support for both patient and family through the course of a life-threatening illness. Symptom control is essential to meeting that goal. This chapter discusses symptoms that commonly contribute to patients' suffering in terminal illness: pain; respiratory, gastrointestinal, mouth, and skin problems; and delirium.

Although this chapter focuses on physical and psychological symptoms, achieving symptom control requires the physician to address the patient's suffering in all its aspects: physical, psychological, social, and spiritual. Physical distress cannot be effectively treated in isolation from the emotional and spiritual components that contribute to it, nor can these sources of suffering be addressed adequately when patients are in physical distress. The various components of suffering must be addressed simultaneously [*see Clinical Essentials: XI Management of Psychosocial Issues in Terminal Illness*].

Symptom Assessment

A full and formal symptom assessment is necessary before effective treatment can be instituted.[1] Symptoms are inherently subjective[2]; therefore, patient self-reporting must be the primary source of information, and the clinician must believe what the patient says. If the patient is unable to report, a family member or professional can provide a surrogate assessment. However, several studies have demonstrated that observer and patient assessments are not well correlated.[3,4]

To compensate for this inherent subjectivity, researchers have developed symptom measurement systems that are intended to quantify patients' perceptions in a manner that is valid and reliable. Often, these measurement systems have taken the form of symptom checklists.[5,6] For example, the Edmonton Symptom Assessment Scale[5] comprises 14 questions that evaluate eight physical and psychological symptoms [*see Table 1*]. This scale has been extensively employed in palliative care research, in part because of its ease of use. Although the scale yields a numeric score (the higher the score, the more severe the patient's condition), the formal scoring mechanism is used only in research. In clinical practice, the scale can be used informally to evaluate a patient's status and follow it over time.

The Memorial Symptom Assessment Scale[7] characterizes 32 physical and psychological symptoms in terms of intensity and frequency, as well as the level of distress from the symptoms [*see Table 2*]. Although the Memorial Symptom Assessment Scale provides a greater range of information than the Edmonton Symptom Assessment Scale, the former is correspondingly more time consuming to use.

Physical Symptoms

PAIN

Diagnosis

Management of pain begins with a careful and detailed assessment [*see 11:XIV Pain*]. The goal of this assessment is to determine the location and character of the pain, define its cause (or causes), and develop a plan of care.

Pain cannot be measured objectively, and several studies have shown that medical care providers' estimates of patients' pain severity are significantly lower than the patients' self-reports.[8,9] Pain is independent of age, gender, marital status, physical function, and cognitive function.[10] Therefore, the central guiding principle of pain assessment is to ask the patient and believe the patient's description of pain.

Pain assessment in the elderly is often complicated by coexistent cognitive impairment. The cognitively impaired patient may be unable to express pain adequately or request analgesics and, therefore, is at increased risk for undertreatment of pain.[11,12] As with cognitively intact patients, the first step in the assessment of pain in demented patients is to ask them about their pain. Although patients with severe dementia may be incapable of communicating, many patients with mild or moderate impairment can accurately localize and grade the severity of their pain,[13] and these self-reports should be regarded as valid.

Untreated pain can result in agitation and disruptive behavior, and it may worsen or precipitate delirium, particularly in cognitively impaired patients.[14,15] When delirium prevents communication with the patient, the physician may have to infer that pain is present and proceed with treatment.

Treatment

Opioids are the standard choice for treating pain in terminally ill patients. The physician who provides palliative care needs to have the confidence and competence to prescribe opioids at whatever dose is needed to control pain, as well as the skill to determine when adjuvant analgesics (e.g., antidepressant or antiseizure medication) are needed to manage certain types of pain.[16,17] Terminally ill patients are a special population, often suffering chronic pain and taking pain medications over longer periods of time and at higher dosages.[18] Indeed, tolerance to opioids may require that they be used in amounts that would be fatal to the opioid-naive patient.

In a multisite study of terminally ill patients in the United States, Weiss and colleagues[19] found that half of terminally ill patients experienced moderate to severe pain but that less than one third wanted additional pain treatment from their primary care physician. Reasons for not wanting additional therapy included dislike of analgesic side effects and not wanting to take more pills or injections. Some patients, however, mentioned fear of addiction. This is a common—and unwarranted—concern not only of patients but of some medical personnel, as well.

As the goals of care change in the course of a life-threatening illness, higher dosages of pain medication may be needed to achieve comfort. In the last days of life, relief of suffering may require sedation to the point of unconsciousness, a technique referred to as palliative sedation (see below).

RESPIRATORY SYMPTOMS

Dyspnea

Shortness of breath has been described in 70% of cancer patients during the last 6 weeks of life[20] and in 50% to 70% of patients dying

Table 1 Modified Edmonton Symptom Assessment Scale[5]

1a. Please rate your *pain* now.
- 1. ☐ No pain
- 2. ☐ Mild pain
- 3. ☐ Moderate pain
- 4. ☐ Severe pain

1b. Please rate your *pain* over the past 3 days.
- 1. ☐ No pain
- 2. ☐ Mild pain
- 3. ☐ Moderate pain
- 4. ☐ Severe pain

1c. Is your *pain control* acceptable to you?
- 1. ☐ Very acceptable
- 2. ☐ Acceptable
- 3. ☐ Not acceptable

2. How would you describe your *activity level* over the past 3 days?
- 1. ☐ Very active
- 2. ☐ Somewhat active
- 3. ☐ Minimally active
- 4. ☐ Not active

3. How would you describe your amount of *nausea* over the past 3 days?
- 1. ☐ Not nauseated
- 2. ☐ Mildly nauseated
- 3. ☐ Moderately nauseated
- 4. ☐ Very nauseated

4a. How would you describe your level of *constipation* over the past 3 days?
- 1. ☐ No constipation
- 2. ☐ Mild constipation
- 3. ☐ Moderate constipation
- 4. ☐ Severe constipation

4b. When was your *last bowel movement*?
- 1. ☐ Today
- 2. ☐ Yesterday
- 3. ☐ 2–3 days ago
- 4. ☐ More than 4 days ago

5. How would you describe your feelings of *depression* over the past 3 days?
- 1. ☐ Not depressed
- 2. ☐ Mildly depressed
- 3. ☐ Moderately depressed
- 4. ☐ Very depressed

6. How would you describe your feelings of *anxiety* over the past 3 days?
- 1. ☐ Not anxious
- 2. ☐ Mildly anxious
- 3. ☐ Moderately anxious
- 4. ☐ Very anxious

7. How would you describe your level of *fatigue* over the past 3 days?
- 1. ☐ Not fatigued
- 2. ☐ Mildly fatigued
- 3. ☐ Moderately fatigued
- 4. ☐ Very fatigued

8. How has your *appetite* been over the past 3 days?
- 1. ☐ Very good appetite
- 2. ☐ Moderate appetite
- 3. ☐ Poor appetite
- 4. ☐ No appetite

9. How would you describe your sensation of *well-being* over the past 3 days?
- 1. ☐ Very good sensation of well-being
- 2. ☐ Moderately good sensation of well-being
- 3. ☐ Not very good sensation of well-being
- 4. ☐ Poor sensation of well-being

10. How *short of breath* have you been over the past 3 days?
- 1. ☐ No shortness of breath
- 2. ☐ Mild shortness of breath
- 3. ☐ Moderate shortness of breath
- 4. ☐ Very short of breath

11. How has your *physical discomfort* been over the past 3 days?
- 1. ☐ No physical discomfort
- 2. ☐ Mild physical discomfort
- 3. ☐ Moderate physical discomfort
- 4. ☐ Severe physical discomfort

of other illnesses.[21] Ventafridda and colleagues[22] observed "horrible and unpleasant" dyspnea in 10% of cancer patients dying in a palliative care unit. Like pain, dyspnea is a subjective symptom that may not correlate with any objective signs of respiratory compromise,[23] and hence, its management can be challenging.

It is important to diagnose and treat any underlying reversible causes of dyspnea. For example, dyspnea caused by congestive heart failure will require diuretics and inotropic support [*see 1:II Congestive Heart Failure*].

When therapy specific to the underlying cause is unavailable or ineffective, several techniques may alleviate breathlessness. Simple measures include pursed-lip breathing and diaphragmatic breathing, leaning forward with arms on a table, cool-air ventilation (from a fan or an open window), and nasal oxygen.

Opioids have been shown in numerous studies to be highly effective in the amelioration of dyspnea.[24,25] In one study,[24] morphine in doses sufficient to relieve dyspnea had no measurable adverse effect on respiratory rate or effort, oxygen saturation, and carbon dioxide concentration. Therefore, morphine is the drug of choice for treating otherwise refractory dyspnea in terminal illness.

Lorazepam and other benzodiazepines are also widely used, especially in terminally ill patients whose dyspnea has an anxiety component, although evidence to support this practice is limited.[26] In addition, steroids and oxygen therapy may be of benefit [*see Table 3*].

Cough

Cough can be an annoyance or can develop into a major source of suffering by causing muscle strain, increasing fatigue, and interrupting sleep. In one study of lung cancer patients, cough was the most common symptom, affecting 80% of patients until just before death.[27] Because the causes of cough are varied, the optimal treatment is treatment of the underlying problem, if possible. When such treatment is not possible, management depends on whether the cough is productive [*see Figure 1*].[28] A productive cough may improve with chest physiotherapy, oxygen, humidity, and suctioning. Antibiotics for infection, *N*-acetylcysteine, bronchodilators, and guaifenesin are also effective.[29,30] Opioids, antihistamines, and anticholinergics decrease mucus production, which can decrease the stimulus for cough. Cough suppressants can be harmful if used in patients with productive coughs by causing mucus

retention,[29,30] which may lead to the formation of mucous plugs and airway obstruction. A patient with a nonproductive cough may benefit from a cough-suppressing agent such as a local anesthetic (e.g., nebulized bupivacaine), bronchodilators, opioids, or a soothing agent such as a lozenge. Benzonatate, steroids, and opiates are effective treatments. Opioids act centrally and are one of the most effective agents against cough. Nonopioid antitussives, such as dextromethorphan, may work synergistically with opiates.[30]

GASTROINTESTINAL SYMPTOMS

Anorexia, nausea and vomiting, constipation, bowel obstruction, and diarrhea are common and potentially devastating in terminal illness.

Anorexia

Anorexia is nearly universal in patients with a terminal illness.[31] Evaluation of anorexia should be concentrated on finding a reversible or treatable cause. It is important to note that cognitive impairment, which is also highly prevalent in advanced disease, may cause a person to be misdiagnosed as anorexic, because the person may be unable to obtain, prepare, or eat meals.[32] Often in terminal disease, however, the patient simply loses the desire to eat.

Patients themselves may complain of anorexia, in some cases because they find the resulting cachexia unacceptable. In those cases, the decision to treat is straightforward. However, anorexia can often be of more concern to family, friends, and medical staff than to patients themselves. The family may be concerned because loss of appetite is seen as a certain sign of impending death.[33] Concern about anorexia may also be rooted in the emotional and psychological meanings that surround food and its consumption: not feeding the patient may be considered equivalent to not caring about the patient. The family should be reassured that anorexia in terminal disease is usually not associated with suffering; especially at the end of life, patients rarely feel hunger or thirst, and many patients who stop eating experience analgesia and even euphoria. Excessive proteins and lipids can induce nausea and vomiting in such cases, and excessive hydration can result in edema and dyspnea.[34]

In the early stages of terminal illness, however, studies have shown that the treatment of anorexia with appetite stimulants may improve patients' quality of life.[35,36] Treatment can begin with simple measures. The patient should be encouraged to eat without any restrictions on sugar, salt, or fats, when possible. Alcohol has appetite-stimulating properties, so patients may wish to consider a cocktail or glass of wine before the evening meal.[37]

Appetite stimulants with proven efficacy in palliative care include dexamethasone, in dosages of 2 to 20 mg/day (recommended because its long half-life permits once-daily dosing and because it has minimal mineralocorticoid effects); megestrol acetate (beginning with 200 mg every 8 hours and titrating to 800 mg/day); and cannabinoids (e.g., tetrahydrocannabinol [THC]), starting with a small dose and titrating to effect and tolerability. Dexamethasone and megestrol tend to be used more often than cannabinoids because of the restricted availability of cannabinoids.

Anorexia in patients with dementia Because Alzheimer disease destroys higher brain function while sparing the other major organ systems, many patients with Alzheimer disease progress to a stage at which they are unable to eat on their own or even chew and swallow reliably but may survive for years if artificial hydration and nutrition are provided. Deciding whether to insert a gastrostomy tube in such patients can be challenging. Complications of tube feeding are common and include repeated infections, whose treatment may require needle sticks, transfer to a hospital, and restraints; these are especially burdensome for a confused patient who cannot understand the reason for such interventions.[38] In addition, patients with advanced neurologic impairment are at high risk for pneumonia from a variety of causes, including but not limited to aspiration. There is no evidence that tube feeding reduces the risk of pneumonia in such patients; it may even increase the risk.[39] One may ask what is to be gained with artificial nutrition and hydration in such cases.

Because of the terminal and irreversible nature of end-stage dementia and the substantial burden that continued life-prolonging care may pose for these patients, they may be better served by palliative care that focuses predominantly on their comfort. Comfort care is viewed as preferable to life-prolonging

Table 2 Memorial Symptom Assessment Scale[14]

For physical symptoms, patients are instructed to check off all symptoms experienced during the past week and the degree to which the symptom bothered or distressed them. Categories and scores are as follows: Not at all (0), A little bit (1), Somewhat (2), Quite a bit (3), and Very much (4). Patients may also add symptoms not listed and rate them on the same scale. For psychological symptoms, patients are instructed to check off all symptoms experienced during the past week and how often each occurred. Categories and scores are as follows: Rarely (1), Occasionally (2), Frequently (3), and Almost constantly (4). Patients may also add symptoms not listed and rate them on the same scale.

Physical Symptom	*Severity*				
	0	*1*	*2*	*3*	*4*
Difficulty concentrating					
Pain					
Lack of energy					
Cough					
Changes in skin					
Dry mouth					
Nausea					
Feeling drowsy					
Numbness or tingling in hands and feet					
Hair loss					
Constipation					
Swelling of arms or legs					
Psychological Symptom	*Frequency*				
	0	*1*	*2*	*3*	*4*
Feeling sad					
Worrying					
Feeling irritable					
Feeling nervous					

Table 3 Drug Treatment for Dyspnea[33]

Drug (Trade Name)	*Dosage*	*Comment*
Oral morphine	2.5–5 mg p.o., q. 4 hr while awake	Doses for opiate-naive patients
I.V. morphine	0.5 mg/hr; titrate to relief	Once dose requirement established, switch to long-acting oral opiate or fentanyl patch
Nebulized morphine	2.5–10 mg injectable in 2 ml NS	—
Nebulized hydromorphone	0.25–1 mg injectable in 2 ml NS	—
Nebulized albuterol	0.083% (3 ml)	Possible adjunct to opioid
Nebulized methylprednisolone (Solu-Medrol)	10 mg	Possible adjunct to opioid
Dexamethasone	Day 1: 16 mg p.o.; days 2–3: 8 mg b.i.d.; days 3–4: 4 mg b.i.d.; subsequent: 2 mg b.i.d.	Possible adjunct to opioid
Prednisone	40 mg b.i.d. for 5–7 days	Possible adjunct to opioid
Lorazepam (Ativan)	1–10 mg/day in two or three divided doses; usual dose, 2–6 mg/day in divided doses. Elderly: 0.5–4 mg/day	For patients whose dyspnea has an anxiety component
Oxygen	2 L/min by nasal cannula; titrate to relief	—

NS—normal saline

measures by a substantial proportion of nursing home patients and family members.[40] Families should be reassured that it is never unethical to withhold nutrition and hydration if they are not helping the patient.

Nausea and Vomiting

Nausea and vomiting occur in up to 62% of patients with terminal cancer[41] and 27% of patients dying of other causes. There are multiple potential causes for both nausea and vomiting [*see Table 4*].[37] Once the cause has been determined, symptomatic relief is relatively easy to achieve with the appropriate medications [*see Table 5*].[28] Without an understanding of the underlying etiology, it may be impossible to find the most beneficial form of treatment.

The central nervous system and the gastrointestinal tract are particularly important in nausea and vomiting.[42] The gastric lining, the chemoreceptor trigger zone in the base of the fourth ventricle, the vestibular apparatus, and the cortex are all involved in the physiology of nausea. Stimulation of the vomiting center in the brain from one or more of these areas is mediated through the neurotransmitters serotonin, dopamine, acetylcholine, and histamine. Serotonin seems to be important in the gastric lining and the CNS, whereas acetylcholine and histamine are important in the vestibular apparatus. Cortical responses are mediated via both neurotransmitters and learned responses (e.g., nausea related to anxiety or anticipatory nausea with chemotherapy).

The major causes of nausea and vomiting can be classified by the mechanisms' principal site of action. Dopamine-mediated nausea is probably the most common form of nausea and the most frequently targeted one for initial symptom management. Antidopamine medications are phenothiazines and butyrophenone neuroleptics (metoclopramide and prochlorperazine). They may cause drowsiness and extrapyramidal symptoms. Haloperidol is a highly effective antinausea agent and may be less sedating. Antihistamines such as diphenhydramine can be used to control nausea, but they may cause sedation. Antihistamines also have anticholinergic properties. Serotonin has been implicated in chemotherapy-associated nausea. Antiserotonin medications (e.g., odansetron) can be effective, but they are expensive.

Nausea can also result from slow gastric and intestinal motility, so-called squashed stomach syndrome from mechanical compression of the stomach, and constipation. Hence, prokinetic agents (e.g., metoclopramide) and aggressive fecal disimpaction and institution of a bowel regimen (see below) should be considered as therapeutic modalities. In some patients, hyperacidity and mucosal erosion may also be associated with significant nausea. In these patients, consider the use of antacids, histamine$_2$ blockers, proton-pump inhibitors, and misoprostol [*see 4:XIV Gastrointestinal Motility Disorders*].

Constipation

Constipation can lead to serious complications, such as bowel obstruction, ulceration, or perforation, as well as delirium. Because constipation is so common in terminal illness, appropriate management includes the institution of preventive measures in patients at high risk for this complication.

Diagnosis Assessment of constipation begins with inquiry about the frequency and consistency of stools; possible contributing factors, such as medications, reduced mobility, and a low-fiber diet; and any accompanying symptoms that suggest complications, such as nausea, vomiting, abdominal pain, distention, and discomfort.[43] As with any symptom, the search for a reversible cause is primary. A plain x-ray can be useful to evaluate for ileus or bowel obstruction. Invasive evaluation with colonoscopy should be considered in difficult, refractory, or complicated cases.

Many medications can contribute to constipation. These include beta blockers, calcium channel blockers, anticholinergic agents, and diuretics.[43,44] First and foremost, however, are opioid analgesics: constipation is a universal side effect of opioid therapy, especially in the terminally ill. For that reason, every terminal-

ly ill patient who is placed on opioids should also be started on a preventive regimen for constipation. The bowel regimen in these patients starts with stool softeners and stimulant laxatives and progresses through hyperosmotic agents and enemas, as necessary [*see Table 6*].[45] This regimen can also be utilized for treatment of constipation from other causes, once intestinal obstruction is ruled out.

Treatment Treatment of constipation is with oral agents, rectal suppositories, or enemas and can focus on softening the stool, enlarging stool volume, or promoting bowel peristalsis. Laxative categories include detergents, stimulants, osmotic agents, prokinetic agents, lubricant stimulants, and large-volume enemas [*see Table 7*]. Polyethylene glycol solution (GoLYTELY) or powder (MiraLax) is an osmotic agent that is marketed as a bowel cleanser to prepare patients for colonoscopy, but it is often effective in relieving constipation and may cause less cramping than other laxatives. Whichever laxative is chosen, the clinician should prescribe the maximum therapeutic dose of the agent before switching to another one.

Fecal impaction Although impaction of stool in the rectum is a complication of constipation, the typical clinical manifestation is so-called overflow diarrhea from leakage of unformed stool around the obstruction. A digital rectal examination may confirm fecal impaction in the distal rectum, but abdominal x-rays may be required for the diagnosis of more proximal impaction. Treatment of fecal impaction is from below, utilizing digital disimpaction and rectal laxatives (suppositories, enemas, or both); only if those fail should oral treatment be attempted.[43]

Bowel Obstruction

The prevalence of bowel obstruction is as high as 40% in bowel and pelvic cancers.[46] Constipation and fecal impaction are the most common causes of bowel obstruction in terminal illness. Symptoms of bowel obstruction include anorexia, confusion, nausea and vomiting, constipation, and pain. Diagnosis is made on the basis of the clinical presentation and abdominal x-rays.

Consultation with a surgeon is advisable to establish a treatment plan. In addition to aggressive measures to prevent or treat constipation and fecal impaction (see above), treatment of bowel obstruction may involve surgical relief of obstruction, nasogastric suction, and pharmacologic measures. Colicky or cramping pain may respond to dicyclomine, opioids (parenteral or rectal), and warm soaks to the abdomen. The obstruction and associated nausea and vomiting may respond to metoclopramide, haloperidol, or dexamethasone. Parenteral octreotide is also useful in this setting to decrease the volume of bowel secretions.

Diarrhea

Diarrhea, which is often secondary to fecal impaction or antibiotic-associated colitis, is a particularly distressing and exhausting symptom in the terminally ill patient.[43] Once impaction, overgrowth, and other causes (e.g., gastrointestinal bleeding, malabsorption, and medications) have been ruled out, kaolin-pectin, psyllium, loperamide, or tincture of opium may be tried.

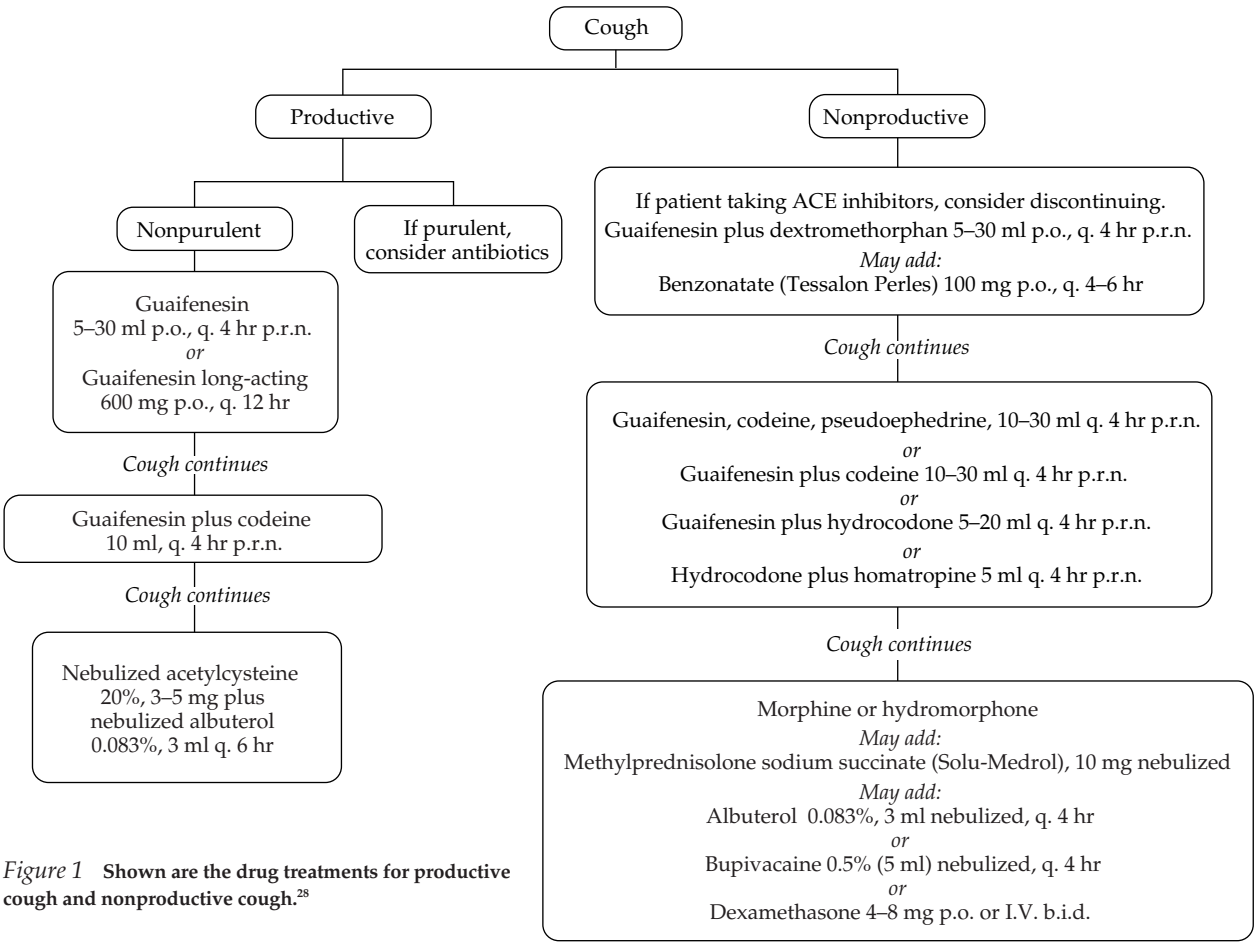

Figure 1 **Shown are the drug treatments for productive cough and nonproductive cough.[28]**

Table 4 Management of Nausea and Vomiting[37]

Etiology	*Pathophysiology*	*Therapy*
Mechanical obstruction—intraluminal	Constipation, obstipation	Laxatives; disimpaction
Mechanical obstruction—extraluminal	Tumor, fibrotic stricture	Surgery, fluid management, steroids, octreotide, scopolamine
Medications—chemotherapy	Chemoreceptor trigger zone, GI tract	Antiserotonin, antidopamine, steroids
Medications—NSAIDs	GI tract irritation	Cytoprotective agents, antacids
Medications—opioids	Chemoreceptor trigger zone, vestibular effect, GI tract	Antidopamine, anticholinergic, prokinetic agents, stimulant cathartics
Medications—other	Chemoreceptors	Antidopamine, antihistamine
Meningeal irritation	Increased intracranial pressure	Steroids
Mentation (e.g., anxiety)	Cortical	Anxiolytics
Metabolic—hypercalcemia	Chemoreceptor trigger zone	Antidopamine, antihistamine
Metabolic—hyponatremia	Chemoreceptor trigger zone	Antidopamine, antihistamine
Metabolic—hepatic/renal failure	Chemoreceptor trigger zone	Rehydration, steroids
Metastases—cerebral	Increased intracranial pressure	Steroids, mannitol
	Chemoreceptor trigger zone	Antidopamine, antihistamine
Metastases—liver	Toxin buildup	Antidopamine, antihistamine
Microbes—gastroenteritis	GI tract	Anti-infectives, antacids
Microbes—sepsis	Chemoreceptor trigger zone	Antidopamine, antihistamine, anti-infectives
Movement	Vestibular stimulation	Anticholinergic
Mucosal irritation	GI hyperacidity, GERD	Cytoprotective agents, antacids
Myocardial—ischemia, CHF	Vagal stimulation, cortical, chemoreceptor trigger zone	Oxygen, opioids, antidopamine, antihistamine, anxiolytics

CHF—congestive heart failure GERD—gastroesophageal reflux disease NSAIDs—nonsteroidal anti-inflammatory drugs

Octreotide (see above) is an effective means of reducing gastrointestinal secretions.

MOUTH SYMPTOMS

Oral problems can cause altered taste, pain, and difficulty swallowing, which may lead to reduced food and fluid intake. Good hydration, hygiene, and regular observation can keep oral problems to a minimum. The patient's teeth should be brushed twice daily with toothpaste. Daily observation of the oral mucosa is recommended.

Dentures also require regular cleansing. Dentures may cease to fit properly in patients who lose a significant amount of weight. Some of those patients may wish to have their dentures refitted; others (especially those nearing death) will choose to forgo this arduous process.

Key questions to ask regarding the mouth include the following: Is the mouth dry? Is infection present? Is the mouth dirty? Is the mouth painful? Are oral ulcerations present? [*see Table 8*][47]

Dry Mouth

The presence of saliva is usually taken for granted, but the lack of it can seriously damage the quality of life. Xerostomia (the subjective sensation of dry mouth) may result from salivary gland disease or systemic conditions such as Sjögren syndrome, Parkinson disease, AIDS, or diabetes[48]; it may also be a side effect of medications, including those with anticholinergic action, benzodiazepines, diuretics, and interleukin-2.[49] Regardless of the cause, xerostomia almost always requires symptomatic treatment. The goal of therapy is to moisten the oral mucosa, and the best, simplest way is for the patient to sip water frequently. However, mouth moisteners and artificial salivas exist and may be preferred by some patients.[47,49] Pilocarpine tablets may be used, at a dosage of 5 to 10 mg every 8 hours, if the above measures fail. Side effects may include nausea, diarrhea, urinary frequency, and dizziness. Other nonpharmacologic treatments include eating ice chips and sucking on hard candy.

Oral Ulcers/Mucositis

Oral infection can have multiple causes. Aphthous ulcers are common and can be eased by topical corticosteroids, tetracycline mouthwash, or thalidomide. Oral candidiasis usually presents as adherent white plaques but can also present as erythema or angular cheilitis. Nystatin suspension is the usual treatment, but a 5-day course of oral ketoconazole, 200 mg daily, can also be used. Severe viral infection (herpes simplex or zoster) requires treatment with acyclovir, 200 mg every 4 hours for 5 days. Malignant ulcers are often associated with anaerobic bacteria and may respond to metronidazole, 400 to 500 mg orally or rectally every 12 hours or as a topical gel.[47]

Pressure Ulcers

Pressure ulcers typically result from both intrinsic and extrinsic factors [*see Table 9*]. Major sites of pressure ulcers in terminally ill patients include the ear and the skin overlying the spine (apex of kyphosis), sacrum, greater femoral trochanter, head of the fibula, and malleolus. Prevention should emphasize these sites and should include daily visual inspection of them in patients at risk for pressure sores.

Prevention and treatment of pressure sores require targeting risk factors and minimizing them. Caregivers need to minimize pressure by turning and repositioning the patient frequently and avoiding shear (sliding movement) and friction. They should be

Table 5 Medications for Nausea and Vomiting[28]

Administration	*Category*	*Drug (Trade Name)*	*Dosage*
Oral	Corticosteroid	Dexamethasone	2–8 mg q. 6–12 hr
	Antidopamine	Haloperidol (Haldol)	0.5–5 mg q. 6–8 hr
		Prochlorperazine (Compazine)	5–10 mg q. 4–6 hr
		Prochlorperazine SR	10–15 mg b.i.d.
	Antihistamine	Diphenhydramine (Benadryl)	25–50 mg q. 4–6 hr
		Hydroxyzine (Atarax)	25–50 mg t.i.d.–q.i.d.
		Promethazine (Phenergan)	12.5–25 mg t.i.d.–q.i.d.
	Anticholinergic	Hyoscyamine (Levsin)	0.125–0.25 S.L. q. 4 hr
		Meclizine (Antivert)	12.5–25 mg b.i.d.–q.i.d.
	Anxiolytic	Lorazepam (Ativan)	1–2 mg q. 2–4 hr
	Prokinetic	Metoclopramide (Reglan)	10–40 mg q.i.d.
	Antiserotonin	Ondansetron (Zofran)	8 mg p.o., t.i.d.–q.i.d.
	Other	Dronabinol (Marinol)	2.5–10 mg b.i.d., t.i.d.
		Thiethylperazine (Torecan)	10 mg q.d.–t.i.d.
		Trimethobenzamide (Tigan)	250 mg t.i.d.–q.i.d.
Rectal suppositories	Antidopamine	Prochlorperazine (Compazine)	25 mg q. 6 hr
	Antihistamine	Promethazine (Phenergan)	12.5, 25, 50 mg t.i.d.–q.i.d.
	Other	Trimethobenzamide (Tigan)	200 mg t.i.d.–q.i.d.
Continuous intravenous infusion	Corticosteroids	Dexamethasone	8–100 mg/24 hr
	Antidopamine	Haloperidol (Haldol)	2.5–10 mg/24 hr
	Anticholinergic	Hyoscyamine (Levsin)	1–2 mg/24 hr
		Scopolamine	0.8–20 mg/24 hr
	Antiserotonin	Odansetron (Zofran)	0.45 mg/kg/24 hr
	Prokinetic	Metoclopramide (Reglan)	20–80 mg/24 hr
Intermittent intravenous infusion	Corticosteroids	Dexamethasone	2–8 mg q. 4–6 hr
	Antidopamine	Haloperidol (Haldol)	0.5–2 mg q. 4–6 hr
		Prochlorperazine (Compazine)	5–10 mg q. 4–6 hr
	Antihistamine	Diphenydramine (Benadryl)	25–50 mg q. 6 hr
	Anxiolytic	Lorazepam (Ativan)	1–2 mg q. 6–8 hr
	Prokinetic	Metoclopramide (Reglan)	10–20 mg q. 6 hr
	Antiserotonin	Ondansetron (Zofran)	4–8 mg q. 8 hr
		Granisetron (Kytril)	10 µg/kg q.d.
	Other	Dronabinol (Marinol)	5 mg/m^2 q. 4 hr (maximum, six doses/day)

aware that even crumpled bedclothes can impair circulation. How a patient moves or is moved by caregivers needs to be assessed and monitored. Even with regular turning and careful lifting and positioning, special pressure surfaces or mattresses are sometimes needed.[47] Fragile skin that is at risk for breakdown should be covered with clear, occlusive dressings; pressure points should be covered with thin, hydrocolloid dressings.

Caregivers must keep the patient's skin clean and dry. Absorbent surfaces, urinary catheters, and rectal tubes may be helpful, but they must be used carefully because of their attendant complications.[37]

Nutrition is an important factor in both prevention and treatment. Good hydration, a diet that is high in protein and carbohydrates, and vitamin C supplements help maintain skin integrity and encourage healing.

If pressure ulcers develop, they should be covered with gel or colloid dressings, which keep the area moist, reduce pain, and can be left in place for several days. The pain of dressing changes can be eased by extra analgesia before each change.[47] The clinician should instruct caretakers to give oral pain medication one-half hour before the dressing change. The dose is determined by whether or not the patient is on regular opioid medications. If the patient is not on regular pain medications, start with 15 mg of immediate-release morphine. If the patient is on a regular opioid regimen, the predressing dose should be the same as the rescue dose.

Pressure ulcer management needs to be consistent with the overall goals of care. If maintenance or improvement of function is the goal and the patient's life expectancy is weeks to months, the ulcer should be treated according to the usual management guidelines. If life expectancy is very limited (e.g., days), the intent should be to optimize quality of life and minimize pain and discomfort (such as from excessive dressing changes or debridement).

Malignant Ulcers

For uncomplicated malignant ulcers, pain relief and wound care are managed in the same way as pressure ulcers. Malignant wounds can present special problems, however, which may include bleeding, exudate, infection, odor, and disfigurement. A bleeding malignant ulcer should be treated with radiation therapy, topical sucralfate, or topical tranexamic acid. Dirty ulcers should be debrided, which can be accomplished chemically. Altered body image from disfiguring wounds can be lessened with cavity foam dressings. Furthermore, empathetic listening is often therapeutic in itself. Anxiety, anger, or depression needs specific support, however[47] [*see Clinical Essentials: XI Management of Psychosocial Issues in Terminal Illness*].

Foul-Smelling Wounds

Odors may be very distressing to patients, families, and caregivers and may lead to poor quality of care, as even professional caregivers tend to avoid sickening smells. Odors are usually due to anaerobic infections or poor hygiene. Treat superficial infections with topical metronidazole or silver sulfadiazine. These agents are expensive, however; and if a less costly alternative is required, a diluted hydrogen peroxide solution can be used.[37] For soft tissue infections, add systemic metronidazole to topical management.

To control odors, place a pan containing kitty litter or activated charcoal under the patient's bed, provide adequate room ventilation, place an open cup of vinegar in the room, or burn a candle. Special charcoal-impregnated dressings placed over the odorous wound may also be helpful.[37]

Psychiatric Symptoms

Adjustment disorders, depression, anxiety, dementia, and delirium are the most common psychiatric problems encountered in dying patients.[50,51] Depending on their severity, management of these psychiatric problems may be within the capacity of the primary care physician or may require referral [*see Clinical Essentials: XI Management of Psychosocial Issues in Terminal Illness*].

DELIRIUM

Delirium occurs in roughly 75% of terminally ill patients.[52,53] Symptoms of delirium include inability to maintain attention, waxing and waning of consciousness, psychomotor changes, disturbance of sleep-wake cycle, disorientation, visual or auditory hallucinations, and problems with memory and language.[54] Other terms often used synonymously with delirium include acute confusional state, metabolic encephalopathy, and sundowning. In contrast to dementia, delirium is more rapid in onset (developing over hours to days), fluctuates in severity, is potentially reversible, and is associated with a lesser degree of memory impairment.

Table 6 A Progressive Bowel Regimen for Patients Receiving Opioid Therapy[45*]

Step 1
Docusate, 100 mg b.i.d.
Senna, 1 tablet q.d. or b.i.d.

Step 2
Docusate, 100 mg b.i.d.
Senna, 2 tablets b.i.d.
Bisacodyl rectal suppositories, 1–2 after breakfast

Step 3
Docusate, 100 mg b.i.d.
Senna, 3 tablets b.i.d.
Bisacodyl rectal suppositories, 3–4 after breakfast

Step 4
Docusate, 100 mg b.i.d.
Senna, 4 tablets b.i.d.
Lactulose or sorbitol, 15 ml b.i.d.
Bisacodyl suppositories, 3–4 after breakfast

Step 5
Sodium phosphate or oil-retention enema; if no results, add a high-colonic tap-water enema

Step 6
Docusate, 100 mg b.i.d.
Senna, 4 tablets b.i.d.
Lactulose or sorbitol, 30 ml b.i.d.
Bisacodyl rectal suppositories, 3–4 after breakfast

Step 7
Docusate, 100 mg b.i.d.
Senna, 4 tablets b.i.d.
Lactulose or sorbitol, 30 ml q.i.d.
Bisacodyl rectal suppositories, 3-4 after breakfast

*The bowel regimen is started at the time of or before the initiation of opioid therapy, and it should be continued for the duration of opioid therapy. The clinician should start with step 1 and progress through higher steps until an effective regimen is found.

Table 7 Treatments for Constipation

Laxative type	*Mechanism*	*Agent*	*Dosage*	*Comment*
Stimulant	Irritate the bowel and increase peristaltic activity	Prune juice	120-240 ml q.d. or b.i.d.	
		Senna	1–2 tablets p.o., q.h.s.	Titrate to effect; ≤ 8 tablets b.i.d.
		Bisacodyl	10–15 mg p.o., h.s.; or 10 mg p.r., after breakfast	Titrate to effect
Osmotic	Draw water into the bowel lumen, increase overall stool volume	Lactulose	30 ml p.o., q. 4–6 hr	Titrate to effect
		Sorbitol, 70% solution	2 ml/kg, up to 50 ml p.o., q.d.–t.i.d.	
		Milk of magnesia	1–2 tbsp, q.d.–t.i.d.	
		Magnesium citrate	1–2 bottles p.r.n.	
		Polyethylene glycol solution	1–4 L p.o.	Drink 8 oz q. 10 min until consumed
		Polyethylene glycol powder	17 g (1 tbsp) powder in 8 oz water, q.d.	2–4 days may be required to produce a bowel movement; increase dose as needed
Detergent (stool softeners)	Increase water content in stool by facilitating the dissolution of fat	Docusate sodium	1–2 capsules p.o., q.d.–b.i.d.	Titrate to effect
		Docusate calcium*	1–2 capsules p.o., q.d.–b.i.d.	Titrate to effect
Prokinetic agents	Stimulate the bowel's myenteric plexus, and increase peristaltic activity and stool movement	Metoclopramide	10–20 mg p.o., q. 6 hr	
Lubricant stimulants	Lubricate the stool and irritate the bowel, increasing peristaltic activity and stool movement	Glycerin suppositories	Daily	
		Mineral oil or peanut oil enema	Daily	
Large-volume enemas	Soften stool by increasing its water content; distend the colon and induce peristalsis	Warm-water enema	Daily	Addition of soapsuds irritates bowel wall to induce peristalsis
High-colonic enemas	Utilize gravity to bring fluid to more proximal parts of bowel	2 L of water or saline warmed to body temperature, hung on I.V. pole at ceiling level	Run in over 30 min, repeat q. 1 hr	

*Not available in the United States.

Delirium is a multifactorial syndrome, involving preexisting risk factors and precipitating factors that occur during hospitalization. Factors that predispose a patient to delirium include vision impairment, severe illness, cognitive impairment, and dehydration.[55] In older patients, cognitive impairment that is so mild as to be inapparent when they are well may nevertheless increase the risk of delirium. Precipitating factors include the use of physical restraints, malnutrition, taking more than three drugs, bladder catheter use, and any iatrogenic event.[55] Prevention of delirium can be accomplished by targeting risk factors.[55]

Management of delirium in the terminally ill patient includes correction of the cause and provision of symptomatic relief. Identification and treatment of underlying diseases or conditions is paramount—for example, give antibiotics for sepsis or oxygen for shortness of breath. In patients with underlying dementia, the possibility of untreated pain deserves special consideration. In the past, physicians were taught that the use of narcotic analgesics is dangerous in patients with dementia because those agents cause delirium. That is not true of a demented patient who becomes agitated or belligerent because of pain, however; in those cases, a dose of a narcotic analgesic may calm the patient within an hour or so. The risk of undertreating severe pain should be of greater concern, both medically and ethically, than the risk of worsening delirium with analgesic medications.

Additional means of treating delirium include minimizing any sensory impairments by providing appropriate eyeglasses or hearing aids and maintaining a quiet, familiar, and reassuring

Table 8 Local Measures for Oral Problems[47]

Dry mouth
- Semifrozen fruit juice
- Frequent sips of cold water or water sprays
- Petroleum jelly rubbed on lips

Dirty mouth
- Regular brushing with soft toothbrush and toothpaste
- Pineapple chunks
- Cider and soda mouthwash

Infected mouth
- Tetracycline mouthwash, 250 mg every 8 hr (one capsule dissolved in 5 ml water)

Painful mouth
- Topical corticosteroids: betamethasone, 0.5 mg in 5 ml water, as mouthwash; or triamcinolone in carmellose paste
- Coating agents: sucralfate suspension as mouthwash, carmellose paste, carbenoxolone
- Topical anesthesia: benzocaine or lozenges containing local anesthetics

setting. It is important to maintain communication with the patient, using frequent reorientation; familiar objects, places, and people; and avoidance of stimulus overload or deprivation.[56]

Pharmacologic symptom relief is best achieved with the use of an antipsychotic agent such as haloperidol or risperidone [*see Table 10*]. Benzodiazepines or sedatives should be used only if antipsychotic agents fail.[57]

Terminal Delirium

Delirium may be an irreversible part of the dying process. Many terminally ill patients have escalating restlessness, agitation, or hallucinations that can be relieved only with sedation.[58] When death is imminent, reversing the underlying causes of delirium is not possible. Instead, the clinician should focus on the management of the symptoms associated with the terminal delirium and bring comfort to the patient and family.

Benzodiazepines are widely used in the management of terminal delirium because they are anxiolytics, amnestics, skeletal muscle relaxants, and antiepileptics. Oral lorazepam (1 to 2 mg as an elixir, or the tablet predissolved in 0.5 to 1.0 ml of water and administered against the buccal mucosa) should be given every hour as needed; it will settle most patients at a daily dose of 2 to 10 mg. The lorazepam can then be given in divided doses, every 3 to 4 hours, to keep the patient settled. For a few extremely agitated patients, high doses of lorazepam—20 to 50 mg or more per 24 hours—may be required. A midazolam infusion (1 to 5 mg S.C. or I.V. every 1 hour, preceded by repeated loading boluses of 0.5 mg every 15 minutes to effect) may be a rapidly effective alternative.[37]

Palliative sedation When terminal delirium cannot be adequately controlled despite aggressive efforts to identify a tolerable therapy that does not compromise consciousness, it may be necessary to resort to palliative sedation. Most physicians define palliative sedation as the act of purposely inducing and maintaining a pharmacologically sedated and unconscious state, without the intent to cause death.

Once palliative sedation is initiated, the dosage of the sedative agent should not be increased unless the patient awakens or becomes restless, tachypneic, or tachycardic. Increasing the level of sedation in the absence of a clinical indication might imply that the physician is intending to hasten death, which if true would cross the line between palliative sedation and physician-assisted suicide or euthanasia [*see Clinical Essentials: IX Palliative Care*].[59]

Table 9 Risk Factors for Pressure Ulcers

Intrinsic	*Extrinsic*
Malnutrition	Pressure
Protein	Shear
Vitamin C	Trauma
Zinc	Friction
Diminished mobility	Crumpled bedclothes
Tissue fragility	Restraints
Anemia	Bed rails
Dehydration	Poor hygiene
Hypotension	Hospital equipment
Poor peripheral perfusion	Oxygen tubing
Incontinence	Heart monitor wires
Neurologic deficit	
Sensory	
Motor	
Older age	
Coma	
Moribund state	

Table 10 Drug Treatment for Agitation or Delirium[28]

Acute	Haloperidol, 0.5–5 mg p.o., p.r., I.M., I.V., or S.C.; titrate until calm
	Chlorpromazine, 1 mg I.V. q. 2 min until calm
Chronic	Haloperidol, 0.5–5 mg p.o. or p.r., b.i.d. (maximum dose, 100 mg/day)
	Thioridazine, 10–25 mg p.o., b.i.d. (maximum dose, 800 mg/day)
	Risperidone, 0.5 mg p.o., b.i.d.; increase by 0.5 mg b.i.d. q. 24 hr (maximum dose, 6 mg/day)
	Chlorpromazine, 10–50 mg p.o. or p.r., b.i.d. (maximum dose, 500 mg/day)
	Olanzepine, 2.5–15 mg p.o., q.d.

Terminal Wean

Mechanical ventilation is often tried in patients with respiratory distress, when there is hope that their condition will improve. This is best referred to as a time-limited trial. If reversal of the acute medical condition proves unsuccessful, the physician needs to discuss discontinuance of ventilation with the family.

Terminal ventilation withdrawal should be approached with attention to ensuring the patient's comfort and to enhancing the family's access to the bedside. Miles[60] recommends a 10-step protocol, which applies to unconscious patients dependent on a ventilator:

1. Shut off and remove all monitors and alarms from the patient's room.
2. Remove equipment that impedes access to the patient's hands (e.g., intravenous lines, pulse oximeter, restraints). Hands are for holding.
3. Remove encumbering or disfiguring devices from the bedside.
4. Invite the family to be with the patient.
5. Quietly and personally request that pressors be turned off and that intravenous infusions be set to keep veins open.
6. Watch for distressing symptoms, such as agitation, tachypnea, or seizures; treat appropriately (e.g., with diazepam) if they appear.
7. Turn the fraction of inspired oxygen (F_IO_2) down to 20% and observe the patient for respiratory distress.
8. If the patient appears comfortable, remove the endotracheal tube with a clean towel in hand.
9. Educate and debrief the house staff and nursing staff about the process.
10. Consider contacting the family during the bereavement period, whether by letter or visit.

The goal is for a peaceful, pain-free death for the patient and a supportive, comfortable environment for the family and friends. It is important to warn family that a patient removed from the ventilator may live for hours to days afterward and to reassure them that all measures necessary to ensure comfort during the dying process will be used.

Symptom Management in the Last Hours of Life

The final hours of living can be some of the most important ones for the patient and for family. Managed well, they can lead to a peaceful death and healthy grief and bereavement.[37]

During the final hours, patients usually need skilled care around the clock. Ideally, the environment will allow family and friends both easy access to their loved one and privacy. All who are present should presume that the unconscious patient hears everything.[37]

It is important to be knowledgeable about the normal physiologic changes that occur in the last hours and to educate the patient's family about them. Reassure the family that dehydration in the final hours of living does not cause distress and may stimulate endorphin release that adds to the patient's sense of well-being. Moaning and groaning, although frequently misinterpreted as pain, is often terminal delirium (see above). Decreased hepatic and renal function lead to the accumulation of metabolites, which may cause terminal delirium. Use only essential medications and dose them accordingly.[37]

In the final hours of life, many persons in semiconscious or unconscious states are unable to swallow saliva reflexively or to cough up mucus. This inability to clear secretions from the oropharynx and trachea results in the so-called death rattle—noisy respiration as the secretions move up and down with expiration and inspiration. Explain the reason for the death rattle to the family and administer an anticholinergic drug to reduce pharyngeal secretions (e.g., hyoscine, as a single parenteral dose or by continuous infusion, or scopolamine by patch).[61] At times, it may be necessary to reposition the patient or to suction the airway gently with a soft catheter. Reassure the family that despite the way the breathing sounds, the patient is not uncomfortable.

The removal of the body too soon after death can be even more upsetting to the family than the moment of death, so give the family time with the body.[37] After the patient has died, follow-up with the family is important to ensure that grief and bereavement are progressing normally [*see CE: X Management of Psychosocial Issues in Terminal Illness*].

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XI MANAGEMENT OF PSYCHOSOCIAL ISSUES IN TERMINAL ILLNESS

Jennifer Rhodes-Kropf, m.d.
Ned H. Cassem, m.d.

Like all good medical care, palliative care addresses patients' needs at many levels. The physical deterioration as death approaches can challenge the ingenuity and equanimity of health care professionals [*see CE:IX Palliative Medicine* and *CE:X Symptom Management in Palliative Medicine*]. Yet symptom management is only one aspect of the care that these patients need; the psychosocial and spiritual problems that arise at the end of life also require attention.

A fatal illness—such as untreatable heart disease, terminal cancer, or AIDS—brings with it not only physical pain but also emotional suffering. Fear is prominent. The body, once regarded as a friend, may seem more like a dormant adversary programmed for betrayal. Even innocuous bodily changes may be interpreted as ominous. Patients become fearful before disease symptoms occur. Cancer patients, for example, fear pain, shortness of breath, nausea and vomiting, anorexia, dyspnea, and isolation.[1] Well before the terminal stages of an illness, patients fear the unknown, losing autonomy, disfigurement, dementia, and, last but not least, becoming a burden to their families.

The stress of terminal illness may manifest itself in many ways. Patients may deny or be unable to accept diagnosis or treatment; they may have unrealistic hopes of being cured, and they may persistently ask why there is no improvement. They may express anxiety, often extreme, with near panic and unspecified fears about dying. They may experience intense feelings of ambivalence and guilt regarding their personal relationships.

Considering the severe distress that is frequently involved, it is remarkable how well most patients do cope with a terminal illness and its treatments. The unique set of coping mechanisms that they have used to maintain self-esteem and stability in the past plays a vital role in this process. Religion and spirituality may be most helpful to patients and families at the end of a patient's life and should therefore be recognized and encouraged.

When a patient is dying, the entire family is the appropriate focus of treatment. A family member may be the first to notice a symptom, such as a personality change, in the patient or in another family member and can thus serve as an indispensable historian. The physician must also contend with the psychosocial forces that can lead to family fragmentation and interfere with care. A family member may have more difficulty than the patient in coping with the illness; this may irritate and distract caregivers and ultimately disrupt the relationship between the physician and the family. For example, the physician may be inclined to schedule visits to the patient so as to avoid encounters with the family. This could seriously jeopardize the patient's treatment and the chance to make the patient's death meaningful and dignified. After the patient's death, the survivors may experience abnormal grieving patterns that deserve medical attention.

Most of the psychosocial aspects of palliative care are within the capability of the primary care physician. In some cases, however, psychiatric consultation may be necessary to help the dying patient cope with major depression, personality disorders, continuous treatment-resistant pain, substance abuse, or grieving.

Preliminary Considerations

BREAKING BAD NEWS

Psychosocial care of the patient with terminal illness begins with delivery of the diagnosis. Because there are so many possible reactions a patient may have when informed of the diagnosis, it is helpful to have some plan of action in mind that will permit the greatest range and freedom of response by the patient. Guidelines have been developed for communicating bad news.[2] When the diagnosis is made and it is time to inform the patient, the physician should meet with the patient in a private place. The spouse (and sometimes the family) should be included in the discussion, unless there is a good reason not to do so. If possible, the patient should be informed ahead of time that after all the tests are completed the physician will review the results and discuss treatment plans in detail. With inpatients, the physician should sit down at the bedside to deliver bad news. Standing while conveying bad news may be regarded by a patient as unkind and expressive of wanting to leave as quickly as possible. If the patient is tested as an outpatient and returns home before the results are known, he or she should be told that the diagnostic information is too important to convey by phone, and a meeting to discuss the results should be arranged. Relaying bad news by phone may be perceived by patients as thoughtless, even though they may have asked for information. A physician must also be prepared to respond to a patient who wishes no or minimal information about the diagnosis.

When the findings are life threatening (e.g., a biopsy positive for malignancy), how can the news best be conveyed? A good opening statement is one that is (1) rehearsed so that it can be delivered calmly, (2) brief (three sentences or less), (3) designed to encourage further dialogue, and (4) reassuring of continued attention and care. A typical delivery might go as follows: "The tests confirmed that your tumor is malignant. I have therefore asked the surgeon (or radiotherapist or oncologist) to speak with you, examine you, and make recommendations for treatment. After this, we can discuss how we should proceed." Silence and quiet observation at this point will yield more valuable information about the patient than any other part of the exchange. What are the emotional reactions? What sort of coping is seen at the very start? While observing, one can decide how best to continue with the discussion. Just sitting with the patient for a period of time, however, is the most important part of this initial encounter with a grim reality that both patient and physician will continue to confront together, possibly for a long time.

TELLING THE TRUTH

Given the difficulties that can follow the disclosure of a life-threatening illness, it may be tempting to avoid telling the patient the diagnosis. This tactic has ancient roots: Hippocrates himself recommended concealing bad news from patients, lest they become discouraged.[3] Nevertheless, most empirical studies in which patients were asked whether they wanted to be told the truth about malignancy have indicated an overwhelming desire in the affirmative. Of 740 patients in a cancer-detection clinic who were asked before diagnosis whether they wanted to be told their diagnosis, 99% said that they did.[4] Another group of

patients in this clinic were asked the same question after the diagnosis was established, and 89% of them replied affirmatively, as did 82% of patients in still another group who had been examined and found to be free of malignancy.

Truth telling entails eliciting the patient's concerns. Studies indicate the clinician's use of specific communication skills enhances a patient's disclosure of his or her concerns.[5] Such communications skills include making eye contact with the patient, asking open-ended questions, responding to the patient's affect, and demonstrating empathy. The desire for truth telling may vary among different ethnic groups.[6] In a study of elderly persons in the United States, Korean Americans and Mexican Americans were less likely than African Americans and European Americans to believe that a patient should be told the diagnosis of metastatic cancer.[7] However, a population study in Hong Kong reported that the majority of persons canvassed would want to know if they had terminal cancer; this finding is at odds with the cultural preference of many Chinese, who usually prefer to withhold diagnostic information from terminally ill family members.[8] This study emphasizes that cultural preferences give only general indications of a patient's readiness to hear bad news; truth telling ultimately depends on the physician's assessment of what the patient wants to know and is prepared to know about the diagnosis. Socioeconomic factors may also be involved in a patient's willingness to hear bad news: younger age and higher income and education make patients more likely to want detailed diagnostic information.[9]

Is the truth harmful? Gerle and colleagues[10] studied 101 patients who were divided into two groups, with one group, along with their families, being told the frank truth of their diagnoses and the other group being excluded from discussion of the diagnosis (although the patients' families were informed). Initially, there appeared to be greater emotional upset in the group of patients and families who were informed together. The investigators observed in follow-up, however, that the emotional difficulties of the families of the patients who were shielded from the truth far outweighed those of the patients and families that were told the diagnosis simultaneously. In general, empirical studies support the idea that the truth about the diagnosis is desired by terminally ill patients and does not harm those to whom it is told. Honesty sustains the relationship with a dying person rather than jeopardizing it.[11] Individual variations in willingness to hear the initial diagnosis are extreme, however, and diagnosis is entirely different from prognosis. Many patients have said that they were grateful to their physician for telling them they had a malignancy. Very few, however, reacted positively to being told that they were dying. In our experience, "Do I have cancer?" is a common question, whereas "Am I dying?" is a rare one. The question about dying is more commonly heard from patients who are dying rapidly, such as those in cardiogenic shock.

Honest communication of the diagnosis by no means precludes later avoidance or even denial of the truth of the diagnosis. In two studies, patients who had been explicitly told their diagnosis (using the words cancer or malignancy) were asked 3 weeks later what they had been told: in both studies, about 20% of the patients sampled denied that their condition was cancerous or malignant.[12,13] Croog and colleagues[14] interviewed 345 men 3 weeks after myocardial infarction; 20% of those patients said they had not had a heart attack. All had been explicitly told their diagnosis. For a person to function effectively, truth's piercing voice may be muted or even excluded from awareness. Denial can reduce psychological distress, and preliminary evidence suggests that in women with nonmetastatic breast cancer, it may be associated with prolonged survival.[15] However, information-seeking behavior and fighting spirit have been more consistently associated with higher rates of recurrence-free survival 5 and 10 years after diagnosis of breast cancer.[16,17] Communicating a diagnosis honestly, though difficult, is easier than the labors that lie ahead. Telling the truth is merely a way to begin, but it provides a firm basis on which to build a relationship of trust.

COMMUNICATING WITH THE PATIENT

The most important component of communication is listening. The real issue is not what you tell your patients but, rather, what you let your patients tell you.[1] Most people are afraid to let dying patients say what is on their minds. If a patient who is presumed to be 3 months from death says, "My plan was to buy a new car in 6 months, but I guess I won't have to worry about that now," a poor listener might say nothing or, "Right. Don't worry about it." A better listener might ask, "What kind of car were you thinking about?" In a study of 126 patients with incurable cancer, 98% wanted their physicians to be realistic about their health status, to provide an opportunity to ask questions, and to acknowledge them as an individual when discussing prognosis.[18]

It is essential to get to know the patient as a person. The best way to recognize and acknowledge the person's worth is to learn those features of his or her history and nature that make him or her unique. Encourage dying persons to tell their stories. Learn about significant areas of the patient's life—such as family, work, or school—and chat about common interests. This is the most natural way to give the patient the sense that she or he is known and appreciated.

Patients occasionally complain about professionals and visitors who regard them as "the dying patient," not as a unique person. The physician can help dissolve communication barriers for staff members by showing them the remarkable qualities of each patient. Comments such as, "She has 34 grandchildren," or, "This woman was an Olympic sprinter," convey information that helps other members of the health care team appreciate their patient and to find something to talk about with them. Listen for the patient's own conversational cues whenever possible. Awkwardness subsides when a patient is appreciated as a real person and not merely "a breast cancer patient." This rescue from anonymity is essential to prevent a sense of isolation. The most important communication is often not verbal. A pat on the arm, a wave, a wink, or a grin communicates important reassurances. Back rubs and physical examinations can also be an opportunity to convey reassurance.

Psychosocial Support during Terminal Illness

The diagnosis of a terminal illness impacts the patient's relationships with family, friends, and coworkers and can thus undermine the patient's sense of self. Although death is a natural part of life, the adjustment to diminished function and role in relationships can be stressful, both for the patient and the patient's family.

FAMILY AND FRIENDS

Family members and friends must be helped to support the patient and one another. To provide this help, the physician must get to know both the patient and the family members. When patients are permitted to give support to their families, they often feel they are less of a burden.

One must appreciate the fact that for family and close friends, a fatal illness of a loved one may be the only event important enough to resolve long-standing conflicts. Peacemaking should be a priority. Specific plans for the family are important. The writing of wills, the clarification of family history, the review of memorable family gatherings and achievements, the carrying out of such family projects as trips or photo-album reviews, and planning a funeral or memorial service are all important activities.

The care of a dying person can be a process of mutual growth for the patient and the family. Just as the deterioration of a person with a fatal disease can be threatening (family members may feel both horrified at the prospect of the same thing happening to them and helpless to assist), the response of the dying person to the challenge may be not only edifying but also an invaluable lesson in coping. Indeed, family members who act as caregivers report strong positive emotions regarding the opportunity to express their love through care. Those caregivers may experience extreme grief after the patient's death, however, and may require special support and attention from health care providers at that time.[19]

Near the end of life, a patient may be too weak to communicate by speech, and sometimes, consciousness itself may be difficult to assess. Most patients who have lost the ability to communicate have a period when they can still hear or perceive those in attendance. Family feelings of helplessness can be minimized by reading especially meaningful passages to the dying person (e.g., the daily headlines, articles by favorite authors or columnists, poetry, passages from the Bible, the Dow-Jones average, sports scores, and letters new and old). Conversations should make natural reference to the person as though hearing and understanding were intact. Singing favorite songs, playing favorite music, or praying aloud may increase the sense of unity and purpose for the family. Although the patient may never be able to tell us how important that time is, an occasional incident will do so dramatically, as when a supposedly unconscious person suddenly smiles appropriately, gestures, or even speaks. Often, this conveys gratitude for the attention given to him or her, which is very rewarding for the loved ones in attendance.

The end of life is an opportunity to educate the younger generation. Whenever possible, children should be included in all the planning, meetings, discussions, activities, and care, as well as the final attendance at death. Children can learn that death need not be violent or terrifying and that we face our losses best when we face them together.

Investigators have consistently learned that the visits of children are as likely as any other intervention to bring consolation and relief to the terminally ill patient. How can one determine whether a particular child should visit a dying patient? No better approach has been found than asking the child directly whether he or she wants to visit.

Ideally, this mutual work at the end of life will confirm the dying person's sense of self. It also can give family, friends, and caregivers the wonderful feeling that they have provided good care and safe passage.

OCCUPATION AND WORK

Work is critical for the self-esteem of many people. Many people begin to feel less valuable when work ceases or they retire, and the approaching end of life may intensify a sense of failure. The continuation of work for as long as feasible, as well as continued contact with work colleagues, can remind the dying of who they are and what they have accomplished. It encourages the belief that they are remembered and respected, regardless of their illness. Similarly, continued involvement in recreational activities can be very satisfying.

Near the end of life, a person is often too disabled to get around or to contact colleagues and friends. Wherever possible, such contact should be arranged for and encouraged.

RELIGION AND SPIRITUALITY

Studies find that people who have a strong internalized faith possess a resource that helps significantly in coping with a fatal illness.[1,20-23] It is a well-documented finding that religious persons usually belong to a community that can be unusually thoughtful and generous in providing support. However, the community may not know of the patient's plight and may need to be contacted. Thus, the appreciation of a person's religion or spirituality is extremely important.

The Physician's Psychological Role in Patient Care

The first responsibility of the caregiver, as Saunders[24] points out, is "above all to listen." A suffering person often wants to communicate just how awful a fatal illness is. Words from the caregiver may be irrelevant: "When no answers exist," says Saunders, "one can offer silent attention."

It is important to be aware of the impact that patients' feelings can have on one's own mood and the amount of time spent with the patient. The relentless approach of death from cancer or AIDS may leave a patient with feelings of terror, hopelessness, and despair. Those feelings tend to be contagious, intensifying our feelings of impotence. A caregiver's own helplessness and despair may result in neglect or avoidance of the patient or feelings that the patient would be better off dead. Sensing that a patient is burdensome to caregivers can be devastating to the patient who looks to a doctor or nurse for some sense of hope.[25] In one study of terminal cancer patients, the majority of patients (87%) indicated that seeing their physician nervous or uncomfortable in their presence did not promote hope.[16] Thus, it is of the utmost importance that caregivers remain empathetic and reassure patients that they will continue to be there for them at all stages of their illness and that caregivers learn to live with negative feelings and resist the urge to avoid certain patients—attitudes that could convey that care of a patient is difficult for us or that the patient no longer matters to us.

COMPASSION

Of all attributes in physicians and nurses, none is more highly valued by terminally ill patients than compassion. Although they may never convey it precisely by words, some physicians and nurses are able to tell the patient that they are genuinely touched by his or her predicament. Although universally praised as a quality for a health professional, compassion exacts a cost that is usually overlooked in professional training. This cost is conveyed by its two Latin roots: *com*, meaning with, and *passio*, from *pati*, meaning to suffer—that is, to suffer with another person. It is important for caregivers to have a source of support for themselves—such as colleagues, friends, and family—so that they can continue to be there for their patients.[26]

CHEERFULNESS

The possessor of a gentle and appropriate sense of humor can bring relief to all parties involved. Often, patients provide this, and their wit may soften many a difficult incident. Humor needs

to be used sensitively, however: forced or inappropriate mirth with a sick person can increase feelings of distance and isolation.

CONSISTENCY AND PERSEVERANCE

Dying patients have a realistic fear of progressive isolation. The physician or nurse who regularly visits the sickroom provides tangible proof of continued support and concern. A brief visit is far better than no visit at all; the patient may not even be able to tolerate a prolonged visit. Do continue to visit: patients are quick to identify those who show interest at first but gradually disappear from the scene. Stay the course even if this means that you must listen to repeated or irrelevant complaints.

The Patient's Psychological Response to Terminal Illness

Any serious illness inflicts some loss on the patient. A diagnosis itself, with no change in subjective symptoms, can cause a feeling of loss, as concepts of self and plans for the future are swept away.

The emotional reactions to a myocardial infarction serve as a model for the reactions of a person who has experienced physical loss. In a series of 149 coronary patients whose emotional difficulties were severe enough to warrant psychiatric consultation, the majority of problems during the first 2 days stemmed from fear and anxiety. These patients generally showed a sequence of emotions beginning with anxiety, followed shortly thereafter by denial (at this stage, a few wanted to sign out of the hospital) and then by despondency, which sometimes persisted. A final group of management problems, related mostly to dependency or personality disorders, rounded out the sequence.[27]

In essence, this reaction pattern suggests that the most common difficulty for a patient immediately after admission is fear. The patient fears imminent death, the presence or return of pain or breathlessness, or some vague but ominous threat to well-being. As symptoms stabilize or subside, the patient is likely to imagine that admission symptoms were false alarms and, in some cases, to insist on signing out of the hospital. When the diagnostic tests confirm the presence of myocardial infarction, however, the patient is confronted with the reality of the illness and feels demoralized. As hospitalization continues, any personality flaws (e.g., passive aggression) further complicate interactions between the patient and the hospital personnel. The sequence of acute onset of illness, fear, stabilization, denial, confirmation of illness, and depression provides a convenient framework for assessing the mental state of an individual hospitalized for any serious illness.

FEAR

Anxiety and despondency are the most common emotional reactions to illness. Panic distorts personality as nothing else does. Yet fear assumes many guises. If a patient seems impossible to deal with on the first day of hospitalization, the reason very likely is underlying fright. However, if difficult behavior continues after 4 or 5 days in the absence of new events that are frightening, it is probably because of the patient's personal style. Excessive talkativeness or mute withdrawal is a typical sign of fear in the acute phase.

Medication, quiet reassurance, or both can relieve a patient's fear and anxiety. Minor tranquilizers are the agents most commonly employed, but explanation and reassurance can be even more effective than medication.

When the physician senses that the patient is afraid, it is safe to assume that the patient regards the illness as an overwhelming threat to well-being. This threat is based on what the patient already knows or presumes about the disease. The physician, therefore, may ask questions designed to uncover erroneous concepts about the patient's condition, such as, "Have you ever known anyone with this disease?" or, "What is your notion of this disease?" If any family member has died of the disease, his or her age at death may also contribute heavily to the patient's fear of the same fate.

After false notions have been corrected, it is important to emphasize the positive aspects of the treatment plan. Even when the prognosis is grave, a calm statement of the treatments planned to counteract and contain the disorder is of value to the anxious patient. The more ominous the prognosis, the more important it is to encourage the patient to specify the fear, so that correspondingly true reassurances (e.g., "the medication can control pain") can be given. False comfort is not recommended. It robs the physician of credibility and, therefore, of the ability to reassure the patient as the illness progresses. An empathetic yet silent presence can sometimes be more helpful than well-meant counsel.[28]

DENIAL AND PANIC

Denial is a common defense mechanism in the initial stage of life-threatening illness. The ability to minimize or to completely deny the threatening implications of the disease ("There's nothing to worry about; I'll be all right.") is essential for controlling panic. When panic sets in, denial fails and people want to flee. Panic is the most common reason why acutely sick patients sign out of a hospital. Although it may simply mean that the patient does not take his or her illness seriously enough, the threat to sign out should be considered a panic reaction. The patient's panic conviction is, "I'll die if I don't get out of here."

Because patients who are experiencing a panic reaction are feeling desperate, they may become antagonistic to efforts to detain them. A gentle approach is essential. For example, the doctor, seated if possible, may begin with "Mr. Jordan, I'm not here to force you to do anything; I just ask that you hear me out." Then the patient needs to hear the truth—that he is seriously ill—expressed in direct but reassuring terms. To quiet the panic, it is most important to explain that the illness is manageable. As the patient calms down, other questions designed to reduce fear can be asked. Even if calmed, however, an anxious patient will not remain calm for long and should be promptly medicated. Family members should also be mobilized and informed.

ANXIETY

Anxiety disorders may or may not intensify during a terminal illness, but they clearly require psychiatric attention when they do. The four most common anxiety-provoking fears associated with death are (1) helplessness or loss of control, (2) being considered bad (guilt and punishment), (3) physical injury or symbolic injury (castration), and (4) abandonment.[29]

In the clinical examination, a severely anxious patient usually does not know what it is about death that is so frightening. Increased anxiety may result from specific memories and associations related to the death of parents or others with whom one identifies; patients may picture the same fate for themselves (e.g., agonizing pain or excessive use of technology). Memories of someone who died of the same illness (e.g., a woman with breast cancer who had relatives who died of breast cancer or a patient

with AIDS who tended to a lover dying of AIDS) or particular associations with the illness may produce specific reasons for anxiety (e.g., the disease will be disfiguring). For the sake of the patient's mental health, it is important to explore these issues.

Pharmacologic therapy with an antidepressant such as a selective serotonin reuptake inhibitor (SSRI) or benzodiazepine may be warranted for patients with moderate levels of anxiety. The effect of benzodiazepine is immediate, whereas the therapeutic effect of an SSRI is delayed, occurring 2 weeks after initiation of treatment. Benzodiazepines (e.g., lorazepam and clonazepam) are therefore the preferred class of drug. Lorazepam (0.5 to 2 mg, given orally two to four times a day) peaks in 1 to 6 hours and is available in tablet, elixir, sublingual, rectal, or I.V. formulations. Clonazepam (0.25 to 0.5 mg, given orally two to four times a day) has a slightly longer half-life; it is available in tablet formulation. Patients who have anxiety in the setting of dyspnea respond well to morphine [*see CE:X Symptom Management in Palliative Medicine*].[30] If psychotic symptoms accompany anxiety, a neuroleptic agent such as haloperidol (0.5 to 5 mg, given orally, I.V., or S.C. every 2 to 12 hours) is helpful.[31]

DESPONDENCY

Despondency—a mixture of dread, bitterness, and despair—is the result of an attack on the patient's self-image. The patient feels broken, scarred, and ruined. Work and personal relationships appear jeopardized. It may seem too late to realize cherished goals. The patient is haunted by disappointment with both what has been done and what has been missed. He or she may feel old and that life has been a failure.

Despondency is a contagious feeling, and in most cases, the physician can sense that the patient is depressed. Simply asking about the depression is helpful: "You look a bit blue today. What's on your mind?" The patient is likely to respond with the feelings already described. The patient should be told that such feelings are a normal part of any serious illness. It is important to remind even those who deny despondency that there is nothing unusual about feeling low from time to time in the struggle with any illness and that these feelings are time-limited. When the patient has acknowledged feelings of depression, even in the first few days of illness, it is very helpful if the physician describes future plans for medical treatment.

DEPRESSION

The more seriously ill a patient becomes, the more likely it is that a major depression will develop.[32] In a review of the literature, major depression was reported to affect as many as 29% of palliative care patients[33]; however, this figure may be low. Researchers identified depression in 62% of patients in a palliative care unit in Winnipeg, Canada.[34] Standard depression inventories (e.g., Beck) are not as useful for diagnosing depression in terminal patients, because some of the physical symptoms of depression that these inventories target can occur in terminal illness without depression. At present, there is no validated instrument to assess depression in patients with terminal illness, although research is under way. Emotional symptoms remain helpful, however.[35] These include anhedonia, depressed mood, suicidal thoughts, and guilt.

Patients in pain have a significantly higher rate of depression than comparable patients without pain.[36] Extreme depression and hopelessness are the strongest predictors that patients may develop a desire for hastened death.[29] Ganzini and colleagues[37] documented that severely depressed patients make more restricted advance directives when depressed and change them when the depression is in remission.

Dignity therapy, a novel psychotherapeutic intervention, may hold promise as a treatment for depression in palliative care patients. As part of the intervention, patients are asked to discuss issues that matter most to them or that they most want remembered by their families; these discussions are recorded and transcribed for the patients and their families. In a multicenter study, the majority of patients who received dignity therapy reported a heightened sense of dignity (76%) and an increased sense of purpose (68%) after the intervention.[38] These results suggest dignity therapy may be useful in treating depression and distress common in palliative care patients.

Pharmacologic options for depression in palliative care extend beyond the traditional agents [*see Table 1*]. Because standard antidepressant medications typically require several weeks to take effect, psychostimulants such as methylphenidate (Ritalin) and pemolin (Cylert) are increasingly being used for short-term treatment of depression for terminally ill patients in pain. They may be used instead of traditional antidepressants, in patients whose life expectancy is less than 3 weeks, or as an interim measure until traditional antidepressants take effect.[39] They

Table 1 Antidepressant Medications Used in Patients with Advanced Disease[37,56]

Class	*Agent (Trade Name)*	*Dosage*
Tricyclic antidepressants	Amitriptyline (Elavil)	10–150 mg p.o./I.M./p.r., q.d.
	Clomipramine (Anafranil)	10–150 mg p.o., q.d.
	Desipramine (Norpramin)	12.5–150 mg p.o./I.M. q.d.
	Doxepin (Sinequan)	12.5–150 mg p.o./I.M. q.d.
	Imipramine (Tofranil)	12.5–150 mg p.o./I.M. q.d.
	Nortriptyline (Pamelor)	10–125 mg p.o., q.d.
Second-generation antidepressants	Bupropion (Wellbutrin)	200–450 mg p.o., q.d.
	Citalopram (Celexa)	10–60 mg p.o., q.d.
	Fluoxetine (Prozac)	10–60 mg p.o., q.d.
	Fluvoxamine (Luvox)	50–300 mg p.o., q.d.
	Mirtazepine (Remeron)	15–45 mg p.o., q.d.
	Paroxetine (Paxil)	10–60 mg p.o., q.d.
	Sertraline (Zoloft)	25–200 mg p.o., q.d.
	Trazodone (Desyrel)	25–300 mg p.o., q.d.
	Venlafaxine (Effexor)	37.5–225 mg p.o., q.d.
Psychostimulants	Dextroamphetamine (Dexedrine)	2.5–20 mg p.o. in the morning and at noon*
	Lithium carbonate	600–1,200 mg p.o., q.d.
	Methylphenidate (Ritalin)	2.5–20 mg p.o. in the morning and at noon*
	Pemoline (Cylert)	37.5–75 mg p.o. in the morning and at noon*

*Give last dose at noon to avoid insomnia at night.

are also useful to counteract opiate-induced sedation and may potentiate opiate analgesia.

Of the antidepressant agents, the selective serotonin reuptake inhibitors (SSRIs) are associated with fewer side effects than traditional tricyclic agents, which are associated with a high incidence of anticholinergic toxicity, including constipation, urinary retention, confusion, and altered cardiac conduction. The SSRIs (fluoxetine, sertraline, and paroxetine) are effective antidepressants and are generally well tolerated. Major side effects include anorexia, nausea, restlessness, and insomnia. Antidepressants with demonstrated efficacy as adjuvant therapy for treatment of pain include the tricyclic antidepressants and paroxetine.

PERSONALITY DISORDERS

Seriously ill people share common objectives with their physician: the relief of suffering and, as far as possible, the restoration of health. Dysfunctional personality traits (e.g., passive, hysterical, obsessive, dependent) that are the residue of past problems, such as parental conflicts, can distract both patient and doctor from those shared objectives. The doctor has enough to do to care for the physical illness and its normal emotional consequences to the patient (e.g., fear, anger, or despondency) without trying to alter personality traits. If reasonable efforts do not suffice, further intervention is best left to a consulting psychiatrist.

Preparation for the End of Life

THE CHOICE OF WHERE TO DIE

Where a person wishes to spend the end of his or her life is a very personal decision. The options are to remain at home, to move to an inpatient hospice [*see CE:IX Palliative Medicine*], or to die in the hospital. Factors that influence this decision include the degree of support at home to care for the patient (emotional and physical), how comfortable the caretakers are with the care of a person who is dying, financial resources, and the technical support needed to keep the patient comfortable. In most cases, special equipment and services can be set up in the home, but this can be prohibitively expensive.

If it is anticipated that the patient has less than 6 months before death, this is an appropriate time to discuss hospice, whether inpatient or at home [*see CE:IX Palliative Medicine*].

Health care providers frequently overlook the financial burden for patients and families resulting from terminal illness. Financial costs can be devastating. It is important to address this issue with patients and families and to refer them to appropriate financial counseling. Social workers can provide invaluable assistance in facilitating the provision of the home services to which patients are entitled under Medicare or Medicaid, and they can usually tell the patient and family what services will have to be paid for out of pocket.

Remember that while patients are in the hospital, caregivers surround them. When they return home, they often feel isolated and abandoned. Every effort should be made to maintain channels of communication among patients, family, and home health care workers.

ADVANCE DIRECTIVES

It is a mistake to delay the discussion of advance directives until the patient is in the terminal stages of illness. Rather, this issue should be dealt with soon after the diagnosis of terminal illness [*see CE:IX Palliative Medicine*].

FINAL CLOSURE

The end of life is the opportunity for closure in relationships with loved ones. Relationship completion comprises five types of communications: I forgive you; forgive me; thank you; I love you; and good-bye.[40] These messages are vital to the peace of mind of the patient and the patient's family and should be encouraged by the physician as an aspect of standard palliative care.

Other actions that help with life's closure are a discussion of personal preferences for a memorial service, the settlement of financial affairs, and, if applicable, the completion of a plan for care of the children.

The physician should instruct the family in practical considerations concerning their loved one's death. For instance, the family should be told that there is no need to call 911 when the patient dies; instead, they should contact the funeral director. If a patient is dying at home and the family panics and calls 911, it is important that they have a "Do Not Resuscitate (DNR)" form in the home. Otherwise, the emergency medical services in some states are required to automatically intubate the patient.

Grief and Bereavement

In one respect, life can be described as one loss after another. The degree of recovery from each loss determines whether an individual regains a stable life or remains disabled. When losses occur, the resulting sadness can eventually give way to a process of reorganization that restores the person's ability to function normally. For example, the death of a parent can cause a child to become self-reliant. Some persons maintain a satisfying, productive life despite seemingly overwhelming losses, whereas others never recover from less severe losses. What makes the difference?

NORMAL GRIEVING

Grief is the psychological process by which an individual copes with loss, struggles to understand it, regains perspective, and goes on with life. Causes of grief include not only the loss of a loved one, of valued possessions, or of employment but also the loss of good health that occurs with major illness or injury. Serious illness or injury challenges personal integrity; it could be said, for example, that every myocardial infarction causes an ego infarction. Therefore, recovery from major illness is not complete until the patient has also recovered from the accompanying emotional damage to the self.

Surrounded daily by the sick and injured, physicians see grief-work in process. It is important for the physician to realize that grief is a normal reaction serving an important restitutive function, that it follows a typical pattern, and that marked deviation from this pattern may be a sign that psychological intervention is required.

The normal grieving process follows a similar course in individuals suffering from any serious loss. Several prominent features of normal grieving have been identified.[41,42] Because these features are often mistakenly labeled as pathologic, familiarity with their correlation to grief can prevent well-meaning but misguided efforts to intervene in a necessary process.

Somatic symptoms of grieving may be prominent, including sighing respirations, exhaustion, gastrointestinal symptoms of all kinds, restlessness, yawning, and choking. Feelings of guilt, especially early in the wake of loss, seem to be universal. "What more could I have done?" or other references to unresolved emotional conflicts are common expressions of these feelings.

Preoccupation with the image of the deceased person, often seeming bizarre even to the griever, is a sure sign that normal mourning is under way. The intense focus on the deceased may be manifested in several ways: by continual mental conversations with the dead person; by a sense of the dead person's presence so vivid, especially at night, that the griever hears, sees, or is touched by the person; or by the simultaneous feeling that all other persons are emotionally distant.

Hostile reactions and irritability also seem to be the rule, combined with a disconcerting loss of warm feelings toward others. Some disruption of normal patterns of conduct is present, such as a desire to be alone, uncharacteristic procrastination, and indecisiveness toward others. The style, traits, mannerisms, or even the physical symptoms of the dead person may alarmingly appear in the mourner; such identification phenomena signify only that grief is in process. Finally, it is routine for the griever to feel that part of the self has been destroyed or mutilated.

How long will it take for the acute symptomatology of grieving to subside? Although the usual estimate is 1 to 3 months, many factors affect the actual time required. They include the number of strong remaining relationships, the intensity and duration of the bond with the lost person, the number and severity of any unresolved conflicts, the degree of dependence on the lost person, and how much of the survivor's mental life habitually assumed the dead person's physical or emotional presence. The main signs of resolution of acute grief are the reappearance of normal functioning, the capacity to experience pleasure, and the ability to enter new relationships.

The acute phase is followed by the disorganization phase. In this phase, the pain of the experience becomes foremost in the person's consciousness. Turmoil, emptiness, despair, and thoughts about the pointlessness of life and the reasonableness of suicide are common. Social interaction seems impossible and is avoided, even though solitude itself is dreaded and intolerable.

Finally, there is reorganization, characterized by a return of normal functioning and behavior. Reversals during this time are the rule, and reappearance of the earlier two phases should be expected. The bereaved person is caught off guard by sudden reminders of the lost person (e.g., a special coat discovered in storage) or by new and painful realizations (e.g., no more shared holidays) that reopen the wound of loss.

The grieving process is often delayed when death follows a prolonged and difficult illness. In such circumstances, death is entirely acceptable, even welcomed as the end of suffering. Later, especially when returning to a scene that sharply evokes the memory of the dead person when healthy, death becomes unacceptable, and feelings of protest or resentment spontaneously emerge.

ABNORMAL GRIEVING

Preexisting personality traits in survivors can interfere with the normal grief process. Additionally, survivors are at heightened risk of abnormal or complicated bereavement if the loved one died suddenly or unexpectedly, if the death was violent, or if no bodily remains were found. Because grief serves an important restitutive function, failure to grieve normally may result in serious psychological symptoms.

Some markers of abnormal grief are evident immediately; others do not appear for 3 months or longer after the loss. An inability to grieve immediately after the loss, typically manifested by absence of weeping, is the best predictor of later problems. Prolonged hysterical grieving that is defined as excessive by the individual's own subcultural norms (not those of the physician) is an equally ominous prognostic sign. Overactivity without a sense of loss is an early sign of distorted grieving. Furious hostility against specific persons—for example, the doctor or hospital staff—which may assume true paranoid proportions, can be regarded as a sign of abnormality when the individual dwells on it to the exclusion of the other concerns of normal grief. A suppression of hostility to the degree that the person's affect and conduct appear frozen (masklike appearance, stilted robotlike movements, and no emotional expressiveness) and self-destructive behavior (giving away belongings, foolish business deals, or other self-punitive actions with no attendant guilt feelings) are also early indicators of abnormal grieving.

Ultimately, it may become apparent that social isolation has become progressive, with a lasting loss of interpersonal initiative. When symptoms of the deceased person appear in the survivor as conversion symptoms or have become the focus of hypochondriacal complaints overshadowing all other manifestations of grief, pathologic grief is likely. Unresolved grief can also be suspected when the dead person is portrayed either as a saint who had no shortcomings or as one who never occasioned the least feeling of anger, burden, or disagreement in the survivor. In such cases, the mourner usually harbors intense feelings that are in conflict with those feelings outwardly expressed, and fear that these feelings will be discovered immobilizes the grieving process.

The result of prolonged grieving may be prolonged sadness, social isolation, somatic complaints, or loss of ability to function. A few sessions with a psychiatrist, aimed at helping the patient bring his or her own feelings into the open so that the process of grieving can be completed, often provide great relief.

Helping the Bereaved

Mourners tend to be outcasts from society. Their presence is painful to many around them, and efforts to silence, impede, or stop the manifestations of their grief are common. Allowing the grieving person to express feelings is essential, however. Most important is avoidance of maneuvers that negate grieving, such as clichés ("It's God's will"), efforts to distract ("After all, you've got three other children"), and outright exhortations to stop grieving ("Cheer up, life must go on").

Seeing the body of the deceased facilitates grieving, probably by establishing the irrevocable fact of death.[39] Permitting survivors to express their feelings and reminders that grief is a normal process are helpful. Gentle review of the deceased person's last days of life, last conversations, and final exchange of words, as well as talking about the deceased's general lifestyle, help initiate grieving. The memories most obstructive of grieving are those of hostile interactions with the deceased and any other interactions that leave the survivor feeling guilty. The more negative these interactions were, the longer it takes to begin recalling and discussing them.

In helping the bereaved, presence means more than words. Someone who can remain calm and accepting in the presence of a weeping, angry, or bitter mourner is highly valued. A hand on the shoulder can be just what is needed. Over time, helping the griever complete memories of the deceased also facilitates mourning. Old photograph albums and letters can be helpful in this regard. Anniversaries are key points in the grieving process, and special attention to the bereaved on these days is a basic element in the care of mourners.

A return to a job is an essential feature of the recovery process because it brings the mourner back into contact with concerned fellow workers. In addition, the therapeutic effects of work on self-esteem play an important part in alleviating the narcissistic component of the response to the loss. Most bereaved persons benefit from returning to work within 2 to 4 weeks after the death of a loved one.

Self-help groups can be extremely effective for permitting expression of emotion, showing that grief is universal, and supplying the compassion and respect necessary for rebuilding self-esteem. Books that recount events such as losing a spouse or that give instructions for the surviving spouse and children may be helpful.

SPECIFIC TYPES OF LOSS

Each type of loss carries specific challenges to mourners, and each type has a specific literature that can be helpful.[43] Loss of a parent by an adult, although a nearly universal occurrence, is not trivial, and loss of the second parent may leave the bereaved feeling particularly alone and vulnerable. Loss of a parent by a child invariably worries the adult survivors responsible for the child's care because successful mourning in a child is a more complex process than in an adult.[44,45] For example, the child may face adjustment to parental surrogates, to a parent stressed by the responsibility of raising the child alone, to the loss of a gender role model, or, eventually, to the replacement of the deceased parent by remarriage and competition for the affection of the surviving parent. However, studies of bereaved children from stable families have shown optimistic results: 8 weeks after the death of a parent, children 5 to 12 years of age were similar to nonbereaved children in school behavior, interest in school, peer involvement, peer enjoyment, and self-esteem.[46]

Research on loss of a sibling appears to be lacking, but the available data indicate that death of a sibling forces surviving siblings to reorganize their roles and relationships with their parents and with one another.[43]

Loss of a spouse, ranked on life-event scales as the most stressful of all possible losses,[47] is more detrimental for men than for women and leads to increased morbidity and mortality in elderly men.[48] The bereaved spouse is left with sole responsibility for children, finances, management, and planning; faced with possible loss of income; and forced to cope with a changed social role in the community.

Each year, about 800,000 parents lose a child younger than 25 years. This loss is particularly traumatic because it is so contrary to life-cycle expectancies.[49]

Sudden death, such as death in an emergency ward, stillbirth, sudden infant death, accidental or traumatic death, cardiac arrest, or death during or after surgery, inflicts a uniquely intense trauma on the survivors. Shock is dramatically intensified. Guilt is likely to be a much more serious problem than it is with nonsudden death because of the total absence of preparation. Violence or disfigurement further intensifies the survivor's feelings.

General rules for dealing with the bereaved also apply here, with certain specific emphases. The chance to view the body, even when mutilated, should be offered to the family members. If there is severe mutilation, the family should be warned. The need to view the body, an aid to normal mourning, is greater when death is sudden.

Suicide is an especially difficult way to lose a loved one. Feeling abandoned and rejected, the survivor often experiences unsettling anger or, if the relationship had been hostile and stormy, equally unsettling relief. The bereaved scours through memories for an action that might have caused or prevented the suicide. Guilt is such an inevitable consequence of suicide that even casual acquaintances wonder what they might have done that contributed to the death. Shame can cause avoidance of others, falsification of the event as an accident, or unwillingness to let others know that a family member has died. A scapegoat may be sought, such as the deceased's therapist, spouse, or boss or the medical examiner who labeled the death a suicide.[50]

Loss by homicide also produces especially intense grief reactions.[51] Flashbacks of the violent death are unavoidable. Survivors tend to avoid locations associated with the death and to stop watching television news because of possible reports of violence. Rage and desire for proportional revenge may cause intense discomfort for the bereaved, if suppressed, or for those around the bereaved, if excessively expressed. Children who witness the murder of one parent by another are afflicted with traumatic intrusive memories of the parents, massive conflicts of loyalty, and the intense need for secrecy because of the stigmatizing nature of their loss. They may inadvertently become so-called neglected victims and are at risk for perpetuating an intergenerational cycle of violence.[52,53]

Patience and gentleness with the family's prolonged numbness and shock are essential features of caring for bereaved family members. Physical acts of kindness may be the only avenue of communication at first. Leading the family to a quiet room, providing comfortable seats, bringing beverages, and making sure that all possible members are included are all helpful and may lay the groundwork for dialogue.

Immediately after imparting the news of death, the physician may be able to bring the family together and start a dialogue by offering to give them as detailed an account as possible. Teamwork is usually required to get everyone present and seated with beverages, ashtrays, and any other comforts that seem appropriate. Survivors may benefit from very gentle questions about the last hours of the deceased: Were there any prodromal syndromes? Any premonitions? Who saw the deceased last? Families who do not wish to explore these crucial questions at this time should not be pushed, however.

A chaplain, nurse, or other team member with counseling skills, present from the time the physician begins communicating the bad news, may be able to address sensitive issues that arise. Family members or other supportive figures (e.g., family doctor or clergyman) who are absent should be notified and asked to come to the hospital when appropriate. When the family members are too shaken to sit down or participate in any dialogue, it is important to leave them a telephone contact at the hospital should any questions arise.

MEDICATIONS AND BEREAVEMENT

Treatment of bereavement-related major depressive episodes has recently been shown to be beneficial. In one trial, persons who had lost their spouses within 6 to 8 weeks and met the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) criteria for a major depressive episode were treated with sustained-release bupropion. Improvement was noted in both depression and grief intensity.[54] In another study, persons with major depressive episodes that began within 6 months before or 12 months after the loss of a spouse were randomly assigned to a 16-week double-blind trial of one of four treatments: nortriptyline plus interpersonal psychotherapy, nortriptyline alone in a medication clinic, placebo plus interpersonal psy-

chotherapy, or placebo alone in a medication clinic. Nortriptyline proved superior to placebo in achieving remission of bereavement-related major depressive episodes, but the combination of medication and psychotherapy was associated with the highest rate of treatment completion. The investigators concluded that the results support the use of pharmacologic treatment of major depressive episodes in the wake of a serious life stressor such as bereavement.[55]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XII COMPLEMENTARY AND ALTERNATIVE MEDICINE

Bimal H. Ashar, m.d., f.a.c.p.
Adrian S. Dobs, m.d., m.h.s.

Definitions

The term alternative medicine encompasses a spectrum of approaches to medical conditions not routinely used by conventional practitioners. Historically, the term has been associated with negative conceptions about medical practices that did not conform to accepted standards of care. The term complementary medicine has since evolved to describe a more positive, symbiotic relationship between unconventional medicine and conventional medicine. The field of complementary and alternative medicine (CAM) now encompasses a multitude of different approaches and beliefs that are generally linked by their emphasis on so-called natural modalities of healing and wellness. More and more, the term integrative medicine is being used, suggesting that CAM should be integrated into conventional care. This chapter describes modalities that are complementary to conventional medicine in the United States; in other countries, many of these modalities are part of mainstream medical practice.

Classification

Patient demand, media attention, and the growth of an approximately $40 billion industry[1] have stimulated leaders in governmental agencies and academic medicine to recognize and categorize CAM and to direct research initiatives on the subject. Although there is currently no universally accepted classification of CAM modalities, the National Center for Complementary and Alternative Medicine (NCCAM) has grouped CAM practices into five domains [*see Table 1*]. It should be recognized that these categories are not mutually exclusive. Certain practices will overlap (e.g., qigong is considered an energy therapy but is part of Chinese medicine, which is an alternative medical system). Also, as evidence emerges regarding mechanisms of action, safety, and efficacy, certain modalities will naturally move beyond the CAM label and become part of mainstream medicine.

Use of CAM

Prevalence and demographics

The widespread use of CAM by the public has been well documented. In 2002, about 62% of adults in the United States reported using at least one form of alternative medicine within the previous year.[1] It has been estimated that 75% of people in the United States have used at least one CAM therapy over their lifetime.[1] Public-opinion surveys have suggested similar overall patterns of use in European countries, although the popularity of specific CAM modalities varies greatly from country to country.[2] Patients across all demographic groups use alternative medicine. However, some surveys have noted that predictors of CAM use may include female gender, white race (as opposed to African-American or Hispanic), higher socioeconomic status, and higher levels of education.[3,4] Many CAM users have chronic, non–life-threatening medical conditions,[3,5] and they may have an interest in spirituality.[6] A number of diagnosis-based surveys suggested exceptionally high usage of alternative medicine in patients with cancer,[7] HIV infection,[8] fibromyalgia,[9] and inflammatory bowel disease.[10]

Public perception

The alternative-medicine movement has clearly been a public-driven process that has spanned decades. It was initially thought that this movement was primarily the result of dissatisfaction with conventional medicine.[11] Subsequent studies have shown that this is not the case[6,12] and that patients continue to see their conventional health care practitioners while using CAM therapies; however, about 27% of CAM users believe that conventional medicine will not help their health care problem.[1] Two disturbing observations are that most patients do not disclose their use of alternative therapies to their physicians and that such patients are never asked about CAM use by their physicians.[13] Furthermore, many patients feel no need to communicate their CAM use to their physicians because they believe that their physicians would be unable to understand and incorporate that information into their treatment plan.[12,14] On the other hand, current data suggest that about one quarter of patients who use CAM do so on the advice of a conventional medical professional.[1]

A number of other factors have stimulated public use of alternative medical therapies. The fact that many CAM modalities emphasize natural forms of healing seems to form the fundamental basis for its use. Many patients desire a more holistic approach to their medical care.[6] They may feel that conventional medicine focuses excessively on suppression of symptoms (e.g., pharmacologic lowering of elevated blood pressure) rather than addressing the root cause of symptoms. They believe that so-called natural products are better and safer than synthetic medications. In many cases, they may turn to alternative medical practices to get relief from chronic conditions that have not responded to conventional symptomatic therapy. Additionally, media hype, direct-to-consumer advertising, and the wide-

Table 1 NIH/NCCAM Classification of Complementary and Alternative Medicine Practices

Category	*Examples*
Alternative medical systems	Ayurveda (traditional Indian medicine), traditional Chinese medicine, homeopathy
Mind-body interventions	Biofeedback, hypnosis, meditation, prayer
Biologic-based therapies	Dietary therapy, herbal medicine, megavitamins, shark cartilage
Manipulative and body-based methods	Chiropractic, massage therapy, craniosacral therapy
Energy therapies	Therapeutic touch, qigong, bioelectric field manipulation, reiki

NIH/NCCAM—National Institutes of Health/National Center for Complementary and Alternative Medicine

spread availability of information over the Internet have all played a role in the popularity of CAM and have served to expand the public's health care choices. Of concern to many physicians is that these choices are frequently based on insufficient basic science or clinical evidence.

Research Concerns

SCIENTIFIC ISSUES

One of the defining characteristics of alternative medicine is the paucity of definitive evidence supporting mechanism of action, efficacy, and safety. Although a number of clinical trials on CAM have been published, the overall quality of those trials is quite poor, primarily because of inadequate sample size, randomization, and blinding.[15,16] Additionally, publication bias may be common in the international literature. Critical reviews of published studies on CAM therapies from a number of countries have shown that the studies almost universally report positive findings pertaining to CAM. This suggests that studies reporting negative findings may never make it to press.[17,18]

There are a number of barriers to the proper evaluation of CAM studies. First, the establishment of adequate control groups is frequently very difficult. Studies on acupuncture, for example, have attempted to incorporate a placebo control by stimulating nonacupuncture points, stimulating actual points unrelated to the treated condition, or applying pressure instead of inserting needles. Some critics argue that so-called sham acupuncture is an inadequate placebo that does not preserve subject blinding. Proponents of acupuncture may argue that such control methods are still potentially therapeutic because of their possible positive effect on the flow of subtle energy through the body. Similar pitfalls are inherent in mind-body research. In the study of personal prayer, of prayer groups, or of intercessory prayer that occurs in the presence of the patient, the intervention group can be compared with those who do not partake in organized prayer. Such a design clearly does not lend itself to adequate blinding. Additionally, any positive results could reflect aspects of prayer that are unrelated to its spiritual qualities (e.g., relaxation), making definitive conclusions difficult.

Another major problem with interpreting CAM research stems from inconsistencies in the intervention groups. Drawing meaningful conclusions from herbal-medication studies is difficult because extracts are not standardized. For example, although positive effects have been seen in a number of published clinical trials with the plant genus *Echinacea* for treatment of upper respiratory tract infections, definitive conclusions cannot be drawn because of variation in the species of plant studied, the part of the plant utilized (root, leaf, or flower), and extraction methods.[19] In addition, the manufacturing processes within and between companies vary widely, so that the concentration of active product in an over-the-counter preparation is rarely known.

Lack of standardization is also a flaw in acupuncture research. Many different types of acupuncture are practiced around the world, and each type may utilize a completely different set of points for the same condition. Even among providers who practice the same type of acupuncture, variation in point selection is common because approaches differ on the basis of the patient's history and physical examination and on the acupuncturist's personal style. This individualization of therapy is alluring to patients, but the unwillingness of practitioners to agree on what constitutes acceptable technique challenges conventional study methodology. CAM practitioners often criticize the typical scientific model that employs randomized clinical trials because in clinical practice, there are multiple interventions, such as mind-body and herbal treatments, that occur simultaneously. Thus, any research in the area may have to be multidimensional.

FINANCIAL ISSUES

Unlike conventional pharmaceutical and medical-device research, large-scale studies in CAM derive their funding almost exclusively from government sources. Modalities such as prayer, acupuncture, and massage therapy are not lucrative enough endeavors to support large, privately funded trials. Dietary supplements, such as herbs, may have a significant profit potential, but the incentive for research is weakened by the fact that herbs, like other natural substances, cannot be patented. In addition, the rules and regulations under which foods and natural products are regulated differ from those for pharmaceuticals, which must meet stringent standards of efficacy and safety.

In an effort to boost CAM research, the United States Government set up NCCAM (http://nccam.nih.gov), under the National Institutes of Health (NIH). With an annual working budget of about $120 million, NCCAM has funded a number of individual projects, as well as specialty centers around the country [*see Table 2*].

Specific CAM Modalities

ALTERNATIVE MEDICAL SYSTEMS

Traditional Chinese Medicine

Acupuncture Acupuncture has been used for centuries as a component of traditional Chinese medicine (TCM). It involves the insertion of thin needles into specific points on the skin to facilitate the movement of energy (qi). Chinese medicine posits that qi (pronounced *chee*) flows along distinct channels (called meridians) in the body and that balanced circulation of qi is a prerequisite for good health. A block in the flow of qi can result in either a deficiency or an excess of qi along a meridian; those imbalances can be corrected by accurate needle placement (or pressure, in the case of acupressure) at specific points on the body. Acupuncture practitioners often enhance the effect of the needles by electrical stimulation; manual manipulation (e.g., twirling); or moxibustion, which involves burning mugwort (*Artemisia vulgaris*) on the acupuncture point or the end of the needle. Practitioners of TCM frequently combine acupuncture with other modalities, including herbal remedies, to achieve the desired physiologic response. Each treatment is individualized on the basis of the patient's history and physical examination, including pulse and tongue examinations. Many types of acupuncture are practiced today; a few examples are traditional Chinese acupuncture, five-elements acupuncture, and auricular acupuncture.

To date, no clear physical mechanism of action has emerged to explain the potential therapeutic response to acupuncture. Changes in blood flow and biologic mediators (e.g., hormones, neurotransmitters, and endorphins) have been shown to occur with needle manipulation.[20-23] There are numerous published clinical studies on acupuncture treatment for a variety of ailments. Most are small in size and have methodologic flaws that make consensus difficult. Nevertheless, in 1997, an NIH consensus panel concluded that there is clear evidence to support the use of acupuncture for postoperative, chemotherapy-induced, and prob-

ably pregnancy-associated nausea and vomiting.[23] Although the data are less compelling, evidence also suggests a positive effect of acupuncture on idiopathic headache,[24] fibromyalgia,[25,26] and osteoarthritis of the knee.[27] Current evidence does not support its use for smoking cessation,[28] asthma,[29] or low back pain.[30]

If done correctly, acupuncture is quite safe.[31] Rare case reports of serious adverse events, including skin infections, hepatitis, pneumothorax, and cardiac tamponade, seem to stem from inadequate sterilization of needles and practitioner negligence.[32,33] To prevent transmission of infection, most practitioners now use disposable needles. Minor side effects, including insertion-site pain or bleeding, fatigue, and vasovagal syncope, are probably more common.[34]

Table 2 Government-Funded Specialty Centers for Research into Complementary and Alternative Medicine

Specialty	*Center and Location*
Acupuncture—addiction	Minneapolis Medical Research Foundation, Minneapolis; New England School of Acupuncture, Watertown, Massachusetts
Acupuncture—neuroimaging	Massachusetts General Hospital, Charlestown
Aging and women's health	Columbia University, New York
Antioxidants	Oregon State University, Corvallis
Arthritis	University of Maryland, Baltimore
Botanical treatment of age-related diseases	Purdue University, West Lafayette, Indiana
Botanical dietary supplements for women's health	University of Illinois, Chicago
Botanical dietary supplements	UCLA, Los Angeles
Cancer	Johns Hopkins University, Baltimore
Cancer and hyperbaric oxygen	University of Pennsylvania, Philadelphia
Cardiovascular diseases	University of Michigan, Ann Arbor
Cardiovascular disease and aging in African Americans	Maharishi University of Management, Fairfield, Iowa
Chiropractic	Palmer Center for Chiropractic Research, Davenport, Iowa
Craniofacial disorders	Kaiser Foundation Hospitals, Portland, Oregon
Frontier medicine (biofield science)	University of Arizona, Tucson
Frontier medicine (therapeutic touch)	University of Connecticut, Farmington
Neurodegenerative diseases	Emory University School of Medicine, Atlanta
Neurologic disorders	Oregon Health Sciences University, Portland
Pediatrics	University of Arizona Health Sciences Center, Tucson
Phytomedicine	University of Arizona, Tucson
Phytonutrient and phytochemical studies	University of Missouri, Columbia

Homeopathy

Homeopathy is one of the most controversial modalities in CAM, primarily because of its theoretical implausibility. The roots of homeopathy trace back to the 1700s, when it was first described by Samuel Hahnemann. Homeopathic principles revolve around two basic tenets: the law of similars and the principle of serial dilutions. According to the law of similars, substances that cause symptoms in healthy people can cure those same symptoms in people who are sick. A number of examples of this principle exist in conventional medicine. Digoxin is used to treat the same arrhythmias that it is capable of inducing. Similarly, methylphenidate, which is a stimulant, has been used to treat attention-deficit/hyperactivity disorder.[35]

The principle of serial dilutions (or the minute dose) is another controversial aspect of homeopathy. According to this principle, medications can have a biologic effect even if diluted to levels at which the original substance is undetectable (a so-called homeopathic dose).

A homeopath's approach to patients differs from that of the conventional physician. Homeopaths concentrate almost exclusively on subjective symptoms and sensations. They choose medications on the basis of the patient's symptomatology, rather than on the objective medical diagnosis. This results in the use of a wide array of different medications for any one conventionally diagnosed condition. A number of homeopathic encyclopedias (*materia medica*) are available that describe symptoms induced by different remedies when given to healthy individuals (provings). These provings are matched to a patient's symptoms to determine the therapeutic regimen. Patients are typically followed closely so that the homeopath can titrate dosing schedules.

Meta-analyses of a number of trials of homeopathic remedies have suggested an effect superior to placebo.[36,37] However, many studies and reviews on specific medications have shown negative or inconclusive results.[37-39] Given the conflicting clinical data and the lack of evidence regarding mechanism of action, it is difficult to support the general use of homeopathy until more high-quality research is available.

Because homeopathic remedies typically contain little or no detectable active ingredients, serious side effects are rare. Homeopathic preparations are generally marketed as over-the-counter remedies and are usually exempt from government requirements for finished product testing or expiration dating. In the United States, the Food and Drug Administration requires that all homeopathic remedies list the indications for their use, the ingredients, instructions for safe use, and dilutions. Dilutions in a ratio of 1:10 are labeled with an X, and dilutions in a ratio of 1:100 are labeled with a C. For example, a 3X product has been diluted 1:10 three times; a 3C product has been diluted 1:100 three times. It should also be noted that these remedies are not restricted to the 10% alcohol limit of conventional drugs.[40]

MIND-BODY INTERVENTIONS

The relationship between psychological stress and physical health has been studied extensively over the past 30 years. Despite positive results from some trials, interventions designed to alter the stress response have not become part of mainstream medical practice. The reluctance of physicians to incorporate

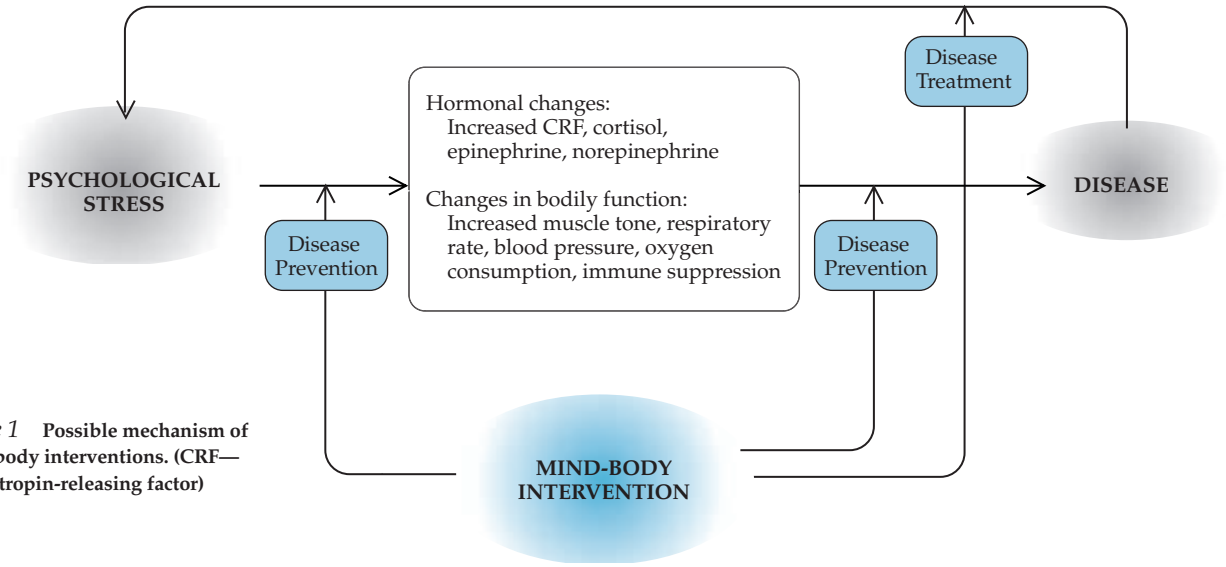

Figure 1 **Possible mechanism of mind-body interventions. (CRF—corticotropin-releasing factor)**

mind-body strategies into their therapeutic armamentarium likely stems from their unfamiliarity with such interventions; time constraints; and the lack of a clear mechanistic pathway to disease. Furthermore, many physicians may feel that these therapies need to be patient driven rather than physician driven, because they require significant changes in self-care.

The proposed theory of mind-body medicine stems from work done in the early 1900s. The fight-or-flight response was described as physiologic preparation for combating or fleeing an external threat.[41] Stimulation of the hypothalamus and increased sympathetic nervous system activity lead to neurohormonal stimulation and increases in blood pressure, heart rate, respiratory rate, and muscle tension. This response has historically been protective, ensuring survival in the face of physical danger. In today's society, however, we are continually faced with innumerable stressors that can elicit the fight-or-flight response, yet fighting or running away is inappropriate or impossible. The body is primed for action but can take none. This chronic physiologic stimulation is thought to increase the likelihood of disease. Furthermore, the development of a chronic disease may stimulate the response through a feedback mechanism, potentially worsening the condition. The effect of the chronic fight-or-flight response on immunosuppression and cytokine and hormone production needs greater elucidation.

Mind-body interventions can elicit a relaxation response that may prevent or aid in the treatment of a number of medical ailments[42] [*see Figure 1*]. A number of modalities can be used for this purpose. Many people have incorporated yoga, meditation, or self-hypnosis into their daily self-care regimen. Several clinical studies have suggested that there are positive results from mind-body modalities for many conditions [*see Table 3*]. As with other CAM interventions, however, limitations in study methodology and sample size, as well as lack of an adequate control, make definitive conclusions difficult.

The mind-body category also encompasses techniques for which a mechanism is not even remotely understood. No physical explanation for distant healing modalities—such as intercessory prayer, spiritual healing, and mental healing—is currently accepted, despite some evidence for positive treatment effects.[43] No harmful effects are seen when most mind-body interventions are used as an adjunct to conventional care. However, there is concern that patients might choose exclusive use of one or more of these methods in lieu of appropriate diagnosis and therapy.

BIOLOGIC-BASED THERAPIES

Biologic therapy is the most popular of all fields of CAM. Its popularity stems from its similarity to the process of using conventional medications. Some people consider biologics to be a possible quick fix for their ailments, without the need for physician visits or potentially harmful prescription medications. Others turn to biologics in the hope of preventing potentially serious diseases through the use of so-called natural substances.

Dietary supplements, including herbal and nonherbal products, make up the preponderance of medications in this category. The supplement industry has become a billion-dollar business, largely as a result of the loosening of federal regulations. The Dietary Supplement Health and Education Act (DSHEA) of 1994 expanded the definition of dietary supplements to include vitamins, amino acids, herbs, and other botanicals. Furthermore, under DSHEA, supplements no longer require premarket testing for safety and efficacy. Supplements are assumed to be safe unless proved otherwise by the FDA. Given the number and variety of products currently available, the FDA's ability to effectively regulate all products after they have been marketed is limited. An example of the regulatory process was the banning of products containing ephedra. The FDA first expressed concern over the herb in 1997, when it proposed limitations on its use. The General Accounting Office viewed these limitations as inappropriate, because of insufficient evidence proving harm. It took 7 years (and a few high-profile deaths) for the FDA to be able to effect a ban on ephedra.[44] Although most dietary supplements are well tolerated and are associated with few adverse effects, the potential for harm from the lack of regulation can be seen from examples of misidentification of plant species,[45] contamination with heavy metals, and addition of pharmaceutical agents.[46,47]

Overall, there is only limited evidence supporting the use of most dietary supplements. Most clinical trials have been small, nonrandomized, or unblinded. In general, physicians and patients should view herbs as medications. Physicians should advise patients to be wary of products for which grandiose claims are made, because misleading advertising is common.[48] The potential for significant toxicity and drug interactions does exist.

The list of currently used supplements is immense, and this chapter can touch on only the most popular [*see Tables 4 through 6*]. More comprehensive resources for dietary supplements (and other CAM modalities) are now available [*see Table 7*].

MANIPULATIVE AND BODY-BASED THERAPIES

Chiropractic

Many would argue that chiropractic medicine should not be considered alternative therapy. Patients, physicians, and insurance companies have all shown some degree of support for chiropractic care in recent years. Between 10% and 20% of the population have used chiropractors.[6] Health care insurance plans, including Medicare, cover many of the services performed during chiropractic visits. Most chiropractor visits are for musculoskeletal problems, including low back pain, neck pain, and extremity pain. However, a small proportion of patients currently seek out chiropractic care for a variety of other conditions, as well as general health concerns.[49] The tenets of chiropractic medicine place the spinal cord and nervous system at the center of a person's well-being. The nervous system is thought to control and influence all other bodily systems. Malalignments (subluxations) of the vertebrae are thought to cause or perpetuate disease. Once these subluxations are identified and corrected (via manipulation), the body uses its natural healing abilities to restore physiologic balance and health. Chiropractors typically look for spinal pain, asymmetry, impaired range of motion, or abnormalities in tone, texture, and temperature when evaluating patients.[50] Laboratory testing, including x-rays, electromyography (EMG), and ultrasonography, may be used to aid in diagnosis. Actual spinal manipulation is performed by direct or indirect delivery of thrusts to the spine. Frequently, the patient will experience a cracking noise. Some chiropractors may use adjunctive therapies, including massage, heat, and trigger-point injections.[50]

Chiropractic manipulation has been touted as treatment for a number of conditions, including hypertension, asthma, pelvic pain, and fibromyalgia. Very little data exist to support its use for these conditions.[51,52] Use of chiropractic therapy for neck pain and headaches is also weakly supported.[53,54] Much of the current use of chiropractic care stems from its utility in cases of low back pain. A number of controlled trials on chiropractic treatment for low back pain have been done, with conflicting results. A meta-analysis concluded that spinal manipulation appears to be more effective than sham therapy or treatments previously judged to be ineffective, but not to be superior to other standard treatments for acute or chronic low back pain, such as analgesics, physical therapy, or exercises.[55] Patient satisfaction also seems to be high with such therapy.[56]

Serious complications from lumbar spinal manipulation seem to be uncommon, although there are reports of cauda equina syndrome.[57] Many patients, however, experience mild to moderate side effects, including localized discomfort, headache, or tiredness. These reactions usually disappear within 24 hours.[58] Brain stem or cerebellar infarction, vertebral fracture, tracheal

Table 3 Selected Mind-Body Interventions

Modality	*Description*	*Potential Applications*	*Comments*
Aromatherapy	The use of essential oils (e.g., jasmine, chamomile, lavender) to enhance physical or psychological well-being; often combined with massage	Anxiety, agitation	Long-term efficacy data (independent of massage) are lacking[71]
Biofeedback	Voluntary control of physiologic processes—e.g., brainwaves, smooth muscle contraction, vasodilation—learned and reinforced with the aid of instrumentation (EEG, EMG, skin temperature/sweat monitors)	Asthma, ADHD, back pain, fibromyalgia, headache, hypertension, incontinence, neuromuscular disorders, Raynaud disease	Effective for fecal incontinence[72]; techniques utilized may vary between patients and practitioners; learning process can be slow, requiring multiple sessions with therapist and regular practice by patient
Guided imagery	Use of the imagination to positively stimulate the senses to bring about emotional and physiologic change	Chronic pain, perioperative management, headaches, nausea, posttraumatic stress disorder	Small studies suggest a positive impact on surgical and cancer treatment outcomes[73]
Hypnotherapy	The induction of a trancelike state to induce relaxation and susceptibility to positive suggestion; used as a diagnostic and therapeutic tool	Anesthesia, headache, irritable bowel syndrome, smoking cessation	Success of therapy may depend on patient susceptibility and attitude toward hypnosis; no conclusive data on most conditions
Intercessory prayer	Request to God (or other spiritual beings) for the benefit of others; can take place in the presence of the patient or at a distance	Cardiac disease, HIV infection, RA	Studies are conflicting and inconclusive[74]; mechanism is unclear
Meditation	Release of the mind from attachment to discursive thought, typically aided by focusing on the breath or a mantra	Anxiety, chronic pain, hypertension, substance abuse	Many types of meditation exist; large-scale studies are needed to prove the absolute impact of this simple intervention on health
Music therapy	Use of music to improve psychological, physical, cognitive, or social functioning	Anxiety, dementia, chronic pain, Parkinson disease	Treatment is guided by a trained music therapist; may have a short-term effect on anxiety and mood during treatments or procedures[75]
Writing therapy	Creative writing exercise about an emotionally traumatic event	General emotional health, asthma, RA, HIV infection	Short-term studies show positive response in asthma and RA[76,77]

ADHD—attention-deficit/hyperactivity disorder EEG—electroencephalography EMG—electromyography RA—rheumatoid arthritis

Table 4 Commonly Used Herbal Dietary Supplements

Herb	*Suggested Uses*	*Potential Toxicity*	*Potential Drug Interactions*	*Comments*
Black cohosh (*Cimicifuga racemosa*)	Menopausal symptoms	Gastrointestinal discomfort	None known	Scant efficacy data, long-term safety unknown[78]
Chaste tree berries (*Vitex agnus-castus*)	Premenstrual syndrome, mastodynia	Pruritus	May have dopaminergic activity; therefore, avoid with use of dopamine-receptor antagonists (e.g., neuroleptics)	Small, short-term studies suggest efficacy[79]
Cranberry (*Vaccinium macrocarpon*)	Urinary tract infections	Nephrolithiasis (with cranberry concentrate tablets)[80]	Possible interaction with warfarin[81]	No clear role in treatment of UTIs; may be effective for prophylaxis[82]
Dong quai (*Angelica sinensis*)	Menopausal symptoms	Rash	Increased INR in patients taking warfarin	No clinical evidence of efficacy[78]
Echinacea (*E. purpurea, E. pallida, E. angustifolia*)	Upper respiratory infections	Hypersensitivity reactions	Theoretically, may antagonize the effect of immunosuppressive medications	Variations in plant species studied, part of plant used, and extraction methods make conclusions regarding efficacy difficult[83]
Ephedra (*E. sinica,* mahuang)	Asthma, congestion, weight loss	Hypertension, arrhythmia, myocardial infarction, stroke	Interaction with monoamine oxidase inhibitors and cardiac glycosides; potential for serious toxicity when combined with other stimulants	Banned by the FDA, effective April 2004, but still available internationally over the Internet
Evening primrose (*Oenothera biennis*)	Eczema, irritable bowel syndrome, mastalgia, premenstrual syndrome, rheumatoid arthritis	Nausea, vomiting, diarrhea, flatulence	Possible lowering of seizure threshold in patients taking antiepileptic medications[84]	Conflicting efficacy data for a number of conditions
Feverfew (*Tanacetum parthenium*)	Migraine prophylaxis	Hypersensitivity reactions	Theoretical risk of increased bleeding when combined with anticoagulants	No clear evidence to support efficacy[85]
Garlic (*Allium sativum*)	Cardiovascular protection	Gastrointestinal upset, bleeding	Theoretical risk of increased bleeding when combined with anticoagulants	Possible short-term improvement in cardiovascular risk factors, but impact on disease unknown; active ingredient unclear[86]
Ginger (*Zingiberis rhizoma*)	Nausea, motion sickness, dyspepsia	None known	Theoretical risk of increased bleeding when combined with anticoagulants	May be useful for nausea and vomiting of pregnancy[87]

rupture, internal carotid artery dissection, and diaphragmatic paralysis are rare but have all been reported with cervical manipulation.[59] Given the lack of efficacy data and the risk (although small) of catastrophic adverse events, it is difficult to advocate routine use of this technique for treatment of neck or headache disorders. Physicians should also recognize potential contraindications to chiropractic therapy. Patients with coagulopathy, osteoporosis, rheumatoid arthritis, spinal neoplasms, or spinal infections should be advised against such treatments.[59]

Massage Therapy

A number of different types of massage are in practice today. Many therapists combine aspects of Swedish massage (stroking and kneading), shiatsu (pressure-point manipulation), and neuromuscular massage (total body, deeper therapy) to relieve stress, anxiety, and muscle tension, as well as improve circulation. Frequently, aromatic oils are employed to enhance the relaxation response. A number of small studies have suggested a potential beneficial effect of massage on fibromyalgia, headaches, and anxiety,[60] although the paucity of data precludes definitive conclusions. Massage therapy does seem to be effective for subacute and chronic back pain.[30] No significant adverse effects are seen with properly performed massage, although caution must be advised for patients with coagulation disorders.

Structural integration (rolfing) is a system of deep-tissue manipulation that involves stretching of the fascial planes. In this system, the fascia is thought to be the key supporting structure for bones and muscles. When injury or stress occurs, the fascia tends to become shorter and thicker. Manipulation of the fascia with fingers, thumbs, and elbows is supposed to relieve tension, restore structural integrity, and improve physiologic and psychological function. Limited data exist to support the efficacy of rolfing for any particular condition.

ENERGY THERAPIES

Many traditional cultures describe the physical body as existing within a field of energy. Such energy is called prana by Indians and qi by the Chinese; English terms include subtle energy, vital energy, and life energy. Many ancient and modern CAM techniques involve the manipulation of this energy or the transfer of additional energy into the patient's field in an effort to restore or maintain balance. Because the field extends beyond the body, energy therapies do not always involve physical contact between practitioner and patient. Further, the presumed connec-

Table 4 (*continued*)

Herb	*Suggested Uses*	*Potential Toxicity*	*Potential Drug Interactions*	*Comments*
Ginkgo biloba	Dementia, claudication, tinnitus	Gastrointestinal upset, headache, dizziness, bleeding, seizure	Theoretical risk of increased bleeding when combined with anticoagulants	May have modest effects on cognitive performance and functioning in patients with Alzheimer disease or multi-infarct dementia[88]; no evidence to support prevention of memory loss or dementia
Ginseng (*Panax* species; Asian ginseng, Korean ginseng, American ginseng)	Fatigue, diabetes	Generally considered safe; rare reports of hypertension, insomnia, headache, and mastalgia	May interact with monoamine oxidase inhibitors and warfarin (decreased prothrombin time)	Currently, little data to support its use[89]
Kava kava (*Piper methysticum*)	Anxiety	Rash, sedation, liver toxicity	May potentiate effects of benzodiazepines; best to avoid with other anxiolytics or alcohol because of risk of excess sedation	Studies suggest efficacy for short-term treatment of anxiety[90]; no data on addiction potential; banned in many European countries because of cases of hepatic failure
Kola nut (*Cola nitida*)	Fatigue	Irritability, insomnia	Caution when used with other stimulants	Contains caffeine
Milk thistle (*Silybum marianum*)	Chronic liver disease	Rare mild laxative effect, gastrointestinal upset	None known	Appears to be safe and well tolerated; efficacy data too limited to exclude a substantial benefit or harm[91]
Saw palmetto (*Serenoa repens*)	BPH	Mild gastrointestinal effects	None known	Short-term studies show improvement in symptoms[89,92]; no evidence for prevention of BPH or its complications, or prevention of prostate cancer
St. John's wort (*Hypericum perforatum*)	Depression, anxiety	Headache, insomnia, dizziness, gastrointestinal irritation	Can decrease levels of cyclosporine, digoxin, oral contraceptives, theophylline, and indinavir; serotonin syndrome can occur when combined with prescription SSRIs	May be effective for mild to moderate depression[89,93]
Valerian (*Valeriana officinalis*)	Insomnia	Headaches	Avoid use with benzodiazepines because of sedation	Efficacy data inconclusive[94]; theoretical risk of addiction with prolonged use

BPH—benign prostatic hyperplasia FDA—Food and Drug Administration INR—international normalized ratio SSRI—selective serotonin reuptake inhibitor UTI—urinary tract infection

tion of these individual fields with a universal field is believed to permit the use of some of these therapies at a distance.

Qigong

Qigong is a branch of traditional Chinese medicine designed to affect the flow of energy (qi) to preserve health. This system combines relaxation techniques with movement to achieve a meditative state designed to ensure mental and physical health. Tai chi (tai chi chuan) is a type of movement-oriented qigong that utilizes a sequence of slow, dancelike maneuvers to enhance the flow of qi through the body. In the course of a tai chi session, the person shifts body weight constantly from one foot to the other. Studies of tai chi in elderly persons have shown that long-term regular practice may improve balance, flexibility, and cardiovascular fitness and, possibly, decrease the risk of falls in older individuals.[61,62] Meditative qigong is accomplished without movement and is intended to establish inner harmony. Breathing exercises can also be part of qigong. They are designed to enhance circulation of qi and expel negative energy. Qigong has been used extensively in China for a number of conditions, including hypertension, anxiety, asthma, and nausea and vomiting.[63] Data to support use for any individual condition are lacking, despite historical successes. Although the principles of qigong seem simple, it involves a complex set of processes that are not clearly understood. Inappropriate training has reportedly been associated with physical and mental disturbances.[64]

Yoga

Yoga is an ancient Indian philosophical practice that uses postures or stretching exercises (asanas), breathing exercises (pranayama), and meditation to help unite the body and the mind. It was developed as a means of enlightenment through self-realization and self-mastery. Only recently, with its migration to the West, has yoga come to be seen as a means to heal illness or reduce anxiety. As with most CAM modalities, there are limited data for or against the use of yoga for particular conditions. Studies on the use of yoga in patients with carpal tunnel syndrome seem promising.[65] Yogic breathing exercises may have

Table 5 Commonly Used Nonherbal Dietary Supplements

Supplement	*Common Uses*	*Potential Toxicity*	*Potential Drug Interactions*	*Comments*
Coenzyme Q10	Heart failure, hypertension, angina, Parkinson disease	Nausea, heartburn, diarrhea	Decreased INR in patients on warfarin	Data inconclusive for treatment or prevention of cardiovascular disease[95]; early data promising for slowing the progression of Parkinson disease[96]
Glucosamine and chondroitin	OA	Hyperglycemia in diabetic patients	Theoretical risk of increased bleeding in patients taking chondroitin and anticoagulants	Current data suggest symptomatic improvement for OA of the hips and knees,[97] with a slowed progression of joint space narrowing[98]
Melatonin	Jet lag, insomnia	Fatigue, drowsiness, headache	Theoretical risk of bleeding in patients taking anticoagulants	Data suggest efficacy for jet lag[99]; no data on long-term use
SAMe (S-adenosylmethionine)	OA, depression, liver disease	Nausea, abdominal discomfort	Can lead to serotonin syndrome when used with tricyclic antidepressants	Early data promising[100]; poor oral bioavailability; very expensive; marketed doses are much lower than studied doses

INR—international normalized ratio OA—osteoarthritis

some beneficial effect on the symptoms of asthma and may reduce bronchodilator use, but they do not decrease airway reactivity or improve lung function.[66]

Therapeutic Touch

Therapeutic touch is the use of the hands, without actual physical touching, to influence or direct life energy throughout the body in an effort to promote healing. Therapeutic touch was codeveloped by a nurse, Dolores Krieger,[67] and many of its practitioners are nurses who use the technique for hospital inpatients.

In a therapeutic-touch session, which generally lasts 20 to 30 minutes, the practitioner enters a meditative state (centering) and then assesses the patient's energy field. To do so, the practitioner holds his or her hands a few inches from the patient's body and moves from head to foot. Downward sweeping movements are then used to remove any blockages of energy and correct any energy-field imbalances. The practitioner then transfers energy to the patient's field and finishes the session by smoothing the field.

A number of small trials have suggested a positive effect of therapeutic touch on conditions such as osteoarthritis, tension headache, and anxiety.[43] However, most of these trials are quite small and suffer from methodologic weaknesses that make definitive conclusions difficult.[68] A critical evaluation of relevant trials concluded that the data did not support the hypothesis that therapeutic touch promoted wound healing.[69] More vigorous trials need to be performed to determine the true efficacy of this technique.

CAM and the Practicing Physician

The field of research in CAM is in its infancy. Current levels of evidence are insufficient to support or disprove a majority of CAM modalities. Despite these limitations, the public continues to embrace CAM therapies as alternatives or adjuncts to conventional care. Given that many patients currently do not inform their physician of their use of CAM, it is imperative that physicians take the lead in inquiring about such therapies. Open dialogue needs to be established to uncover the types of modalities being utilized, reasons for pursuing such therapy, and patient experiences. From there, a discussion of the current data on level of efficacy and toxicity can follow. Ultimately, primary care physicians may need to develop referral networks of trusted CAM practitioners who are open to reciprocal communication.

Table 6 Popular Uses for Common Dietary Supplements*

Use	*Supplement*
Anxiety	Kava kava, St. John's wort, valerian
Benign prostatic hyperplasia	Saw palmetto, *Pygeum africanum*
Claudication	*Ginkgo biloba*
Dementia	*Ginkgo biloba*, pyridoxine
Depression	SAMe, St. John's wort
Diabetes	Aloe vera, chromium picolinate, ginseng, *Gymnema sylvestre*
Fatigue	Ginseng, licorice root
Heart failure	Coenzyme Q10, hawthorn extract
Hypercholesterolemia	Fenugreek, garlic, guggulipid, red yeast rice
Hypertension	Coenzyme Q10, garlic
Insomnia	Melatonin, valerian
Irritable bowel syndrome	Acidophilus, aloe, evening primose, peppermint oil
Jet lag	Melatonin
Liver disease	Milk thistle, SAMe
Menopausal symptoms	Black cohosh, dong quai, red clover, soy
Migraine prophylaxis	Butterbur root, feverfew, riboflavin
Nausea and vomiting	Ginger, pyridoxine
Osteoarthritis	Ginger, glucosamine and chondroitin, SAMe
Premenstrual syndrome	Calcium, chaste tree berries, evening primrose, pyridoxine
Tinnitus	*Ginkgo biloba*
Upper respiratory infections	Ascorbic acid, *Echinacea*
Urinary tract infections	Ascorbic acid, cranberry
Weight loss	Chitosan, chromium picolinate, *Garcinia cambogia*

*See Tables 4 and 5 for potential toxicity, drug interactions, and comments.

Table 7 Sources of Information on Complementary and Alternative Medicine

Medium	*Listing*	*Description (Price)*
Internet	Natural Medicine Comprehensive Database www.naturaldatabase.com	Monographs on a multitude of natural products ($92/year)

	National Center for Complementary and Alternative Medicine http://nccam.nih.gov/index.htm	Describes ongoing CAM research; contains links to governmental resources on popular modalities and supplements (free)
	United States Pharmacopeia (USP) www.usp.org	Dietary supplement verification program identifies ingredients and absence of contaminants of specific brands that undergo testing (free)
	ConsumerLab.com www.consumerlab.com	Tests individual supplements and reports on purity and accuracy of labeling ($24/year)
	National Cancer Institute PDQ Cancer Information Summaries: Complementary and Alternative Medicine www.cancer.gov/cancertopics/pdq/cam	Overviews of selected CAM products used in cancer treatment (free)
Print	Essentials of Complementary and Alternative Medicine. Jonas W, Levin J, Eds. Lippincott Williams & Wilkins, Philadelphia, 1999	Concise overview of popular CAM therapies
	Herbal Medicine: Expanded Commission E Monographs. Blumenthal M, Goldberg A, Brinckmann J, Eds. American Botanical Council, Austin, Texas, 2000	Expanded English translation of the German compendium on herbs
	Evidence-Based Herbal Medicine. Rotblatt R, Ziment I, Eds. Hanley & Belfus, Philadelphia, 2001	Pocket-sized handbook that contains a summary of clinical trials as well as a rating of efficacy, evidence, and safety levels of common herbs

These steps should serve to strengthen the physician-patient relationship while limiting the potential for adverse outcomes.

Specific emphasis should be placed on the role of dietary supplements, which pose a risk of significant toxicity and drug interactions. To ensure patient safety, the medication history should include specific questioning about what vitamins, herbs, or other supplements the person is taking. Unfortunately, supplements are often sold as combination products that are identified only by their catchy trade names. Patients should be encouraged to bring in all new medications and supplements at each visit. Depending on their side-effect profile or potential for drug interactions, certain supplements should be discontinued in the perioperative period.[70] Finally, any suspected adverse reactions or drug-supplement reactions should be reported to the FDA's MedWatch program at their web site (http://www.fda.gov/medwatch) or by calling them at 1-800-FDA-1088.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XIII PERFORMANCE MEASUREMENT IN CLINICAL PRACTICE

Stephen D. Persell, m.d., m.p.h.
David W. Baker, m.d., m.p.h., f.a.c.p.
Kevin B. Weiss, m.d., m.p.h., f.a.c.p.

Performance in health care is the degree to which desirable objectives are accomplished. Performance measurement can inform quality-improvement activities and allow health care consumers and commercial health care purchasers to hold physicians and health care organizations accountable for the services they provide. Over the past decade, the methodology supporting performance measurement has matured. With this maturity has come an increasing array of performance measures covering a range of care settings and specialties; the increasing information has given rise to an expanded interest in the application of performance measurement. The Centers for Medicare and Medicaid Services (CMS) and large commercial health care purchasers now pay close attention to publicly released performance data. At present, the vast majority of patients in the United States who are enrolled in managed care organizations or Medicare receive health care from health plans, hospitals, nursing homes, or ambulatory care centers for which publicly reported performance data are available; the trend toward the public release of performance information is likely to accelerate in coming years. Physicians may increasingly find themselves the targets of efforts to profile the care provided by group practices or individual physicians. It is likely that the trend toward performance measurement will have increasingly noticeable effects on the ways in which health care is delivered and physicians are compensated.[1]

Why Measure Performance?

Ideally, individual health care professionals would be able to deliver high-quality care as a matter of course, and performance measurement would be unnecessary. Unfortunately, the best practices often are not followed, and patients frequently do not receive indicated services for acute problems, chronic illnesses, and preventive health care.[2] Measurement of clinical performance is needed to assess the quality of care and to compare what is achieved with what is desired. This information can then serve the related but distinct purposes of internal and external quality review. First, measurement can enable internal quality improvement—in other words, deficiencies in health care can be identified and physicians and health care organizations can implement changes to improve quality and track their progress.[3] Second, the public release of performance information can increase accountability of health care providers by (1) allowing health care purchasers and consumers to make informed health care choices and (2) permitting regulators responsible for licensure or accreditation to evaluate the quality of care offered by specific health care organizations. Both purposes figure prominently in the Institute of Medicine's Strategic Framework for a national quality measurement and reporting system.[4]

Performance Measures

In the past, performance measurement was often conducted through the use of implicit review to assess the quality of care provided. In this method, a physician reviewed patient records and judged whether appropriate care had been provided. This approach to performance measurement is poorly reproducible because implicit review involves a level of subjectivity, and physician reviewers frequently do not agree.[5] Currently, the most widely used quality measures define explicit criteria against which performance is judged. Although no performance measure is ideal, well-developed measures share three characteristics[6]: (1) they are based on strong clinical evidence; (2) they depict uncontroversial clinical practices that have broad consensus among physicians; and (3) they incorporate agreed-upon standards for determining satisfactory performance.

For performance measurement to be undertaken, it must be feasible to collect the necessary data. Methods of data collection that are too burdensome limit a measure's utility. When used for comparisons of health care providers, performance measures should be attributable to the physician or organization being assessed. Furthermore, sufficient numbers of patients should be assessed to allow for meaningful statistical comparisons; if required, statistical adjustments should be made to account for confounding variables in the collected data.[6] Several measures are used to assess the quality of health care; these include measures of clinical performance, measures of patient experience, and measures of efficiency.

Measures of Clinical Performance

Measures of clinical performance can assess health care structures, processes, and outcomes.[7] Structural measures are not measures of clinical performance per se; rather, they describe characteristics of physicians, hospitals, or other health care organizations. Structural characteristics are selected for assessment because they are perceived to be associated with favorable clinical outcomes. Examples of structural measures include the ratio of nurses to patients in the hospital,[8] whether a board-certified critical care physician is available in the intensive care unit of a hospital 24 hours a day,[9] whether a hemodialysis center is operated as a not-for-profit facility,[10] and whether a hospital has a computerized drug-order entry system.[11,12]

Process measures assess specific components of the encounters between physicians and patients: Was a screening test for colon cancer obtained? Was a beta blocker prescribed to a patient with a myocardial infarction? Did a patient who was hospitalized for a mental illness receive an outpatient appointment promptly after discharge?[13]

Outcome measures are direct assessments of patients' health status. Examples include whether a nursing-home patient has a pressure ulcer and whether death occurs within 30 days after coronary artery bypass graft surgery.[14,15]

Structure and process measures have some advantages over outcome measures. Because they are to a greater degree under the control of a single health care organization or individual physician, structure and process measures are less likely than outcome measures to require adjustment for confounding differences between patient groups—a statistical correction referred to as case-mix adjustment, or risk adjustment [*see* Case-Mix Adjustment, *below*]. In addition, structural measures often require very little data collection, as compared with other measures.

Conversely, a limitation of both structure and process measures is that they need to be causally related to desirable health outcomes to be valid measures of health care quality. If structure or process measures are not directly related to desirable health outcomes, efforts made to improve these measures may merely increase the costs of care without improving patients' health status. An advantage of outcome measures is that they directly measure the ultimate objectives of health care—clinical outcomes; however, they are often dependent on the characteristics and actions of individual patients. Observed differences in outcomes may be largely driven by factors that are not under the control of physicians or health care organizations. Patients who receive excellent care may still have bad outcomes, and physicians caring for patients of lower socioeconomic status or educational attainment, who are known to be at higher risk for disease severity and who lack access to care because of mechanisms such as cost sharing of copayments and high deductibles, may falsely appear to be providing inferior care.[16-19]

PATIENT EXPERIENCE AND SATISFACTION MEASURES

Although expert-derived clinical measures may best assess the technical aspects of care, consumers of health care are in the best position to evaluate their own experience and level of satisfaction with the services they receive. Furthermore, care that is timely and well received by patients may lead to better health outcomes. Examples of patient experience measures include the ease with which medical advice can be obtained by phone, the number of times a patient must wait more than 30 minutes past an appointment time to see a physician, and the rating of a personal physician on a scale of 0 to 10.[20] The Consumer Assessment of Health Plans Survey (CAHPS) is a widely used series of surveys to assess patients' experience of health care.[21] CAHPS captures patient satisfaction with the delivery of care occurring during office visits, the level of assistance obtained from health-plan customer service, the perceived accessibility and timeliness of medical and reimbursement services, and the clarity and timeliness of health advice provided by the physician. CAHPS is one form of evaluation used by the National Committee for Quality Assurance (NCQA) to evaluate health plans.[14]

EFFICIENCY MEASURES

Efficiency measures focus on the costs of delivering health care. When combined with measures of clinical performance, efficiency measures assess the value of health care (i.e., the quality of care delivered per unit cost). The methodology for assessing efficiency is less well developed than that of quality measurement.[22] Common units of efficiency measurement (e.g., cost of health plan per member per month and cost per episode of care) do not capture the quality of the care received for that cost.

From Quality Improvement to Accountability

Performance measurement can support quality improvement in several ways. Measuring performance and relaying this information to the physicians who were assessed can produce beneficial, albeit modest, improvements in quality.[23] Within health care organizations, reliable measurements of quality are necessary to assess the impact of quality improvement initiatives such as clinical-reminder systems, disease-management programs, clinical-decision support systems, patient-directed programs, and multimodality interventions. Because they are in a position to implement system-level changes, health care organizations may be in a better position than individual physicians to act on performance data and institute quality improvement.[24,25]

Using performance measurement to hold physicians and organizations accountable for the care they provide is a very different undertaking from that of quality improvement. Although publicly released reports on quality performance may prompt physicians to improve performance, they are intended for an audience external to the health care team.[26] The goal of measurement for accountability is to enable comparisons of different health care organizations. For this reason, the measures used in assessing accountability must be standardized across sites. In the United States, private organizations such as the NCQA, the Quality Consortium of the American Medical Association, the Joint Commission on Accreditation of Healthcare Organizations, and the National Quality Forum (NQF) have taken leading roles in the development of standardized performance measures and the dissemination of performance results. Government agencies, such as CMS, are also a major source of performance data. Consumers and commercial health care purchasers can find comparative information on health plans, hospitals, nursing homes, and hemodialysis centers on the Internet or through health insurers.[13-15]

The use of publicly released performance data is not limited to consumers or purchasers of health care. Increasingly, physicians may find their remuneration influenced by their measured performance. The Institute of Medicine has issued a call for government health care payers to reward high-quality care with increased payments.[1] Nongovernmental organizations also are adopting pay-for-performance (PFP or P4P) plans. For example, the Integrated Healthcare Association, a California consortium of medical groups and health plans, distributed $50 million in bonuses to health care providers on the basis of performance in the first year of the consortium's pay-for-performance initiative.[1,27] In the United Kingdom, the government has instituted an ambitious pay-for-performance initiative in which family practitioners will receive from the government an additional £1 billion ($1.8 billion) more than they ordinarily would have received; this represents a 20% increase over the previous year's family-practice budget. The additional funding will be distributed to family practitioners on the basis of a combination of three factors: their performance on a variety of clinical measures, organizational indicators, and patient surveys.[28] Both positive and negative consequences of pay-for-performance have been predicted,[28] but the full impact of the program remains to be seen.

Aside from influencing payments, performance measurement can also be incorporated into the accreditation process. For example, the American Board of Internal Medicine has incorporated a module on self-assessment of the quality of care provided by the physician as an option by which to meet the 2006 practice-assessment requirement for recertification in internal medicine.[29]

Methodological Issues

As the use of performance measurement increases, continued awareness of its limitations is vital. There remain both methodological and practical limitations to successful performance measurement.

FACTORS AFFECTING DATA UTILITY

Data Collection

Collecting the data required for performance measurement can be labor-intensive and expensive. Measures that rely on data

collected for other purposes (e.g., administrative data) are not burdensome to implement but may not be as reliable as data collected explicitly for quality measurement. Expanded use of clinical computer systems and electronic health records is one way to facilitate the collection of clinical data of high quality,[28] but the implementation of new clinical computer systems is costly.

Use of publicly released data to inform consumer choice or to increase provider accountability also has its drawbacks. One significant problem is that publicly available data may include falsified results. To help maintain the accuracy of data reported to such organizations as the NCQA, auditing is required. Some falsification, however, may be undetectable by audits (e.g., a physician's falsely recording a blood pressure measurement that is below a quality goal). The potential exists for physicians to adjust their performance measures by the selection or dismissal of patients. For example, physicians may dismiss nonadherent or outlier patients (i.e., patients whose data lie far outside the central statistical mass) to improve their measured performance.[30] Physicians who will be judged by clinical outcomes such as mortality following coronary artery bypass graft surgery may avoid taking on patients at high risk for bad outcomes. In one instance, following the release of publicly reported cardiac surgery mortality, cardiologists reported that it became harder to find surgeons willing to operate on high-risk patients who needed surgery.[31]

Sample Size

Another potential problem in performance measurement is insufficient sample size. For any single measure, there may be too few patients for statistically meaningful comparisons, either between providers or between the performances of a single provider over time. An insufficient sample size is frequently a factor when individual physicians are profiled. When statistically meaningful differences cannot be detected because of limited sample size, those who report data should not suggest that providers with statistically insignificant differences in quality scores differ from one another. Combining several years of data is one way to compensate for insufficient sample size; however, this reporting method makes the reported results less timely and may obscure improvements in quality that occur in the short term.

Case-Mix Adjustment

The differences in patient characteristics (referred to as case mix) can introduce systematic biases into quality measurements; case-mix adjustment to correct these biases is an important methodological consideration in the utilization of performance data. Apparent differences in the quality of care received by patients cared for by different physicians may disappear when differences in patients' socioeconomic status or education are taken into account.[16-19] Case-mix adjustment is especially important for measures of clinical outcome or cost efficiency, but it may alter the interpretation of data pertaining to process measures.

Statistical methods can be used to improve the validity of statistical inference when sample sizes are small or when the case mix differs across providers; however, it is not clear whether the methodology to correct for these variables will be generally adopted or, if adopted, applied in uniform ways.[32]

Optional Reporting

Public reporting of performance data may be of limited use to health care purchasers and consumers if poor performers can choose not to report their data. It has been noted that some health plans that participated in the NCQA's Health Plan Employer Data and Information Set (HEDIS) withdrew from HEDIS when they performed poorly.[33]

Internet Resources for Performance Measures

General Information

Agency for Healthcare Research and Quality (AHRQ)
http://www.ahrq.gov/clinic/epcix.htm
A governmental agency and information clearinghouse on issues of quality, safety, efficiency, and effectiveness of health care

Ambulatory Care Quality Alliance (AQA)
http://www.ahrq.gov/qual/aqaback.htm
Initially convened by the American Academy of Family Physicians, American College of Physicians, America's Health Insurance Plans, and AHRQ, the Alliance consists of a large body of stakeholders, including physicians, consumers, health care purchasers, and health plans

Centers for Medicare and Medicaid Services (CMS)
http://www.cms.hhs.gov/quality/hospital
Provides hospital quality information to consumers and others in initiatives designed to improve hospital care in the United States

National Committee for Quality Assurance (NCQA)
http://www.ncqa.org
An independent nonprofit organization that provides information on the quality of managed care plans in the United States

National Quality Forum (NQF)
http://www.qualityforum.org
A private, not-for-profit membership organization created to develop and implement a national strategy for measuring and reporting health care quality

Measures and Tools

National Quality Measures Clearinghouse
http://www.qualitymeasures.ahrq.gov
Public repository for evidence-based quality measures and measure sets

Measuring Healthcare Quality
http://www.ahrq.gov/qual/measurix.htm
Includes National Health Care Quality reports, AHRQ quality indicators, and ambulatory care clinical-performance measures

National Voluntary Consensus Standards for Ambulatory Care
http://www.qualityforum.org/txWEBambreport04-29-05.pdf
Appendix A contains physician standards for ambulatory care pertaining to asthma and respiratory conditions, heart disease, hypertension, prenatal care, and prevention

Quality Profiles
http://www.qualityprofiles.org/quality_profiles/index.asp
Case studies that examine performance measures in such topics as chronic illness, women's health, preventive care, and behavioral health

Quality Improvement Initiative Tools
http://www.qualityprofiles.org/qia_Tools/index.asp
Templates of the tools used by health plans to help implement their health care improvement initiatives

Physician Quality Reports
http://www.ncqa.org/PhysicianQualityReports.htm
Includes measures used to qualify physicians for the Diabetes Physician Recognition Program, the Heart/Stroke Physician Recognition Program, and Physician Practice Connections

Hospital Quality Measures
http://www.qualityindicators.ahrq.gov
Presents hospital quality measures, inpatient quality indicators, and prevention quality indicators

Inadequate Use of Data

Even when public reports of health care quality are available, purchasers and consumers may not put them to good use.[34] Consumers often do not access the performance data that are available and may have difficulty making sense of the information when they find it.[25,35,36]

METHODS TO IMPROVE PERFORMANCE MEASURES

Although all these methodological issues and limitations are formidable, the organizations developing and promoting such measurement seek to identify and promote only those measures meeting clear criteria. An example of this move toward standardization is the recent development by the NQF of a set of voluntary consensus criteria by which to endorse physician-focused ambulatory care performance measures. The NQF's consensus standards include criteria to judge the importance, scientific acceptability, usability, and feasibility of proposed performance measures.[37]

Issues for the Physician

Although encumbered by methodological and practical issues, performance measurement is a reality of modern medical care. Experts caution physicians that they must be leaders in quality measurement and performance improvement or be vulnerable to challenge by economic or political stakeholders and to the potential loss of patient confidence.[38] Because it is likely that we physicians will increasingly be held accountable for the quality of care we provide, it is to our advantage to have a working knowledge of current performance measurement activities in our specialty [*see Sidebar* Internet Resources for Performance Measures]. By understanding the types of measures by which we will be judged and knowing how the data are collected, we may be able to improve our performance—as well as the documentation of the data needed for proper measurement of that performance—without greatly increasing our work.

When possible, individual physicians should assess the quality of the care they provide and correct their own deficiencies. They should consider making systematic changes that facilitate quality measurement and internal quality improvement, such as making use of disease registries, flow sheets, or computer systems, to track the quality of chronic disease management and preventive care. It is unlikely that the costs of implementing these changes will be recovered in the short term; however, if pay-for-performance becomes widespread, physicians and health care organizations that have not prepared for it by routinely measuring their own quality of care will find themselves at a distinct disadvantage in comparison with their competitors who have.

I APPROACH TO THE CARDIOVASCULAR PATIENT

Catherine M. Otto, m.d.
David M. Shavelle, m.d.

The complete evaluation of the cardiovascular patient begins with a thorough history and a detailed physical examination. These two initial steps will often lead to the correct diagnosis and assist in excluding life-threatening conditions. The history and physical examination findings should be assessed in the context of the overall clinical status of the patient, including lifestyle, comorbidities, and expectations. Cardiovascular conditions that frequently require evaluation include chest pain, dyspnea, palpitations, syncope, claudication, and cardiac murmurs. Each of these conditions will be discussed separately, with an emphasis on a diagnostic algorithm and the appropriate use of invasive and noninvasive cardiac testing.

Chest Pain

BACKGROUND

Chest pain is perhaps the most common cardiovascular symptom encountered in clinical practice. Establishing a cardiac origin of chest pain in a patient with multiple cardiovascular risk factors is essential because it allows initiation of appropriate therapy, thereby reducing the risk of myocardial infarction and death. Similarly, excluding a cardiac origin of chest pain in a low-risk patient is no less essential to avoid costly and potentially risky diagnostic testing that will neither add to the care of the patient nor relieve the patient's discomfort.[1] Cardiac disorders that result in chest pain include myocardial ischemia, myocardial infarction, acute pericarditis, aortic stenosis, hypertrophic cardiomyopathy, and aortic dissection. Noncardiac disorders that may result in chest pain include pulmonary embolism, pneumonia, pleural effusion, reactive airway disease, gastrointestinal and biliary disease, anxiety, and musculoskeletal disorders.

Angina most frequently is caused by atherosclerosis of the coronary arteries. Less common causes of angina include coronary artery spasm (e.g., Prinzmetal angina or spasm secondary to drug use, as with cocaine), coronary artery embolism (from aortic valve endocarditis), congenital coronary anomalies, spontaneous coronary artery dissection, coronary arteritis, and aortic dissection when the right coronary artery is involved. Angina may also occur in the presence of angiographically normal coronary arteries and is referred to as syndrome X. The underlying pathophysiology is thought to be related to microvascular dysfunction; the prognosis is generally good despite frequent episodes of chest pain.[2]

HISTORY AND PHYSICAL EXAMINATION

Essential features of the history include an accurate description of the chest pain, including the severity, frequency, location, radiation, quality, alleviating and aggravating factors, and duration of symptoms [*see Table 1*]. Anginal chest pain is often described as pressure or a heavy sensation. Symptoms may be difficult for the patient to describe and may be better characterized as discomfort, not pain. Angina typically is described as substernal with radiation to the left neck, jaw, or arm; is mild to moderate in severity; and lasts for 5 to 15 minutes. Classically, angina occurs with exercise, stress, or exposure to cold weather and is relieved with rest or use of nitroglycerin. Some of the most useful features of the patient history that help establish that chest pain is angina are (1) reproducibility of the pain with a given degree of activity, (2) brief duration, and (3) alleviation of the pain with rest or use of nitroglycerin. In patients with a history of coronary artery disease (CAD), an accurate characterization of the quality and frequency of the pain is essential to determine whether a change in the anginal pattern has occurred (i.e., a patient with chronic stable angina now has unstable angina) or if a noncardiac origin of pain is now present (e.g., a patient with chronic stable angina now has musculoskeletal pain). Elderly patients, diabetic patients, and women experiencing angina often present with atypical symptoms that may appear to be noncardiac in nature.

Anginal chest pain may also be seen in patients with aortic stenosis or hypertrophic cardiomyopathy secondary to the supply-demand imbalance caused by excessive myocardial hypertrophy. Pericarditis commonly results in a sharp type of chest pain that occurs in the substernal region and worsens on inspiration (pleuritic) when the patient is in a supine position and improves when the patient is in an upright position. The pain of aortic dissection is also substernal, but typically, it is described as a tearing or ripping sensation, radiates to the back or interscapular area, begins abruptly, and fails to improve with rest or use of nitroglycerin. Musculoskeletal pain may be located anywhere on the chest wall, is often reproducible with palpation, and frequently worsens with rotation of the thorax. If the pain is musculoskeletal in origin, recent episodes of excessive lifting or activity may be elicited in the history. Esophageal spasm and gastroesophageal reflux disease are frequent causes of noncardiac chest pain.[3]

Cardiovascular risk factors should be reviewed in all patients presenting with chest pain. These risk factors include (1) a history of hypertension, hyperlipidemia, diabetes mellitus, or cigarette smoking,[4] and (2) a family history of CAD (i.e., a first-degree male relative with myocardial infarction or sudden death occurring before 55 years of age or a first-degree female relative with these events occurring before 65 years of age). Relatively uncommon factors that may also result in angina include prior radiation therapy, drug use (e.g., cocaine and amphetamines), and the presence of a systemic disease (e.g., lupus erythematosus, polyarteritis nodosum, or rheumatoid arthritis) that is associated with coronary arteritis.

The physical examination is usually unremarkable in patients presenting with anginal chest pain. However, certain physical findings can be very helpful in supporting the diagnosis of CAD. Elevated blood pressure by cuff sphygmomanometry and retinal abnormalities on fundoscopic examination (e.g., arteriovenous nicking, microaneurysms, arteriolar narrowing, or hemorrhages) may indicate previously undiagnosed hypertension. Xanthomas (cholesterol-filled nodules that occur subcutaneously or over tendons) indicate severe elevations in serum choles-

terol levels. Femoral, carotid, or renal artery bruits and diminished peripheral pulses signify peripheral vascular disease and markedly increase the probability of CAD.[5] Tenderness to palpation of the chest wall, especially at the costochondral and chondrosternal articulations, suggests a musculoskeletal etiology of chest pain. Occasionally, patients with anginal chest pain also have a component of reproducible pain with palpation. A third heart sound and a holosystolic murmur of mitral regurgitation (secondary to ischemia of a papillary muscle) may be present if a patient with CAD is examined during an episode of anginal pain.

Physical examination also is directed toward findings that suggest an alternative cause of chest pain. Asymmetrical peripheral pulses, an early diastolic murmur, and the appropriate clinical history (tearing chest pain with radiation to the back) indicate an aortic dissection. A systolic murmur that radiates to the base of the neck (aortic stenosis) or a systolic murmur that increases in intensity with the strain phase of the Valsalva maneuver (hypertrophic cardiomyopathy) are uncommon but useful findings. A so-called leatherlike or scratchy series of sounds indicates a pericardial rub and supports a diagnosis of pericarditis. The intensity of the rub may increase with inspiration, indicating associated inflammation of the pleura, or pleuritis. Examination of the lung fields may disclose diminished breath sounds associated with dullness to percussion (pleural effusion), rhonchi, and egophony (pneumonia) or expiratory wheezes (asthma).

DIAGNOSTIC TESTS

On the basis of the history, chest pain is characterized as anginal, atypical anginal (some features of angina combined with some noncharacteristic features), or nonanginal. Estimates of the pretest probability of CAD can be accurately derived from a description of the chest pain syndrome and the presence or absence of cardiovascular risk factors.[6,7] The most widely used method for determining pretest likelihood of CAD is the Duke University Database formula, which considers the patient's age, sex, cardiovascular risk factor profile, description of chest pain, and information from the resting electrocardiogram.[8]

Although the diagnostic yield from the baseline ECG is low, it provides useful information on the advisability of pursuing additional diagnostic testing [*see Figure 1*]. Notable findings include Q waves consistent with a prior myocardial infarction and left ventricular hypertrophy that may be secondary to aortic stenosis, hypertrophic cardiomyopathy, or long-standing hypertension. ST segment depression, T wave abnormalities, and arrhythmias may be present if the ECG is obtained during an episode of anginal chest pain. A normal resting ECG predicts normal left ventricular function with a high degree of certainty (i.e., > 95%).

As with the ECG, a routine chest roentgenogram is usually normal. However, the presence of cardiomegaly, a left ventricular aneurysm, significant coronary or aortic calcification, or pulmonary venous congestion would be useful information and may warrant additional diagnostic testing.

Some physicians have started to use portable or handheld echocardiographic devices to evaluate patients with chest pain. Pertinent findings by echocardiography that would assist in establishing the etiology of chest pain include a pericardial effusion (pericarditis), hypokinesis or akinesis of a left ventricular wall segment (acute coronary ischemia), a dilated right ventricle (pulmonary embolism), and calcification and impaired excursion of the aortic valve leaflets (aortic stenosis).

Noninvasive stress testing is most likely to influence clinical decision making when the pretest probability of CAD is in the intermediate range. Patients with a low risk of CAD should not undergo noninvasive cardiac stress testing, because an abnormal test result would likely be a false positive one, and a negative test result would simply confirm the low probability of CAD. However, if patient reassurance is a consideration, a normal test result may be very useful. In addition, exercise stress testing provides information regarding symptom status, exercise capacity, and the hemodynamic response to exercise if the history is unclear (e.g., the patient denies symptoms but has decreased exercise capacity for "other reasons"). Absolute and relative contraindications to exercise testing should be reviewed in all patients before testing is begun [*see Table 2*].[8]

Similarly, patients with a high risk of CAD in general should not undergo noninvasive cardiac stress testing for the purpose of diagnosing CAD, because a negative test result would likely be a false negative one, and a positive result would simply confirm the high probability of CAD. In such patients, coronary angiography should be used to establish a diagnosis of CAD. However, noninvasive cardiac stress testing in certain patients at high risk for CAD may be useful. Indications for noninvasive stress testing in these patients include (1) assessment of the ef-

Table 1 Differentiating Features in the Patient's History of Chest Pain

Condition	*Location*	*Radiation*	*Quality*	*Alleviating Factors*	*Aggravating Factors*	*Duration*
Angina pectoris	Substernal	Jaw, arm	Pressure	Rest, nitroglycerin	Exercise, cold weather	5–15 minutes
Pericarditis	Left-sided, substernal	Neck, trapezius ridge	Sharp	Sitting up and leaning forward	Inspiration, supine position	Hours
Musculoskeletal	Variable over entire chest wall	None	Sharp or aching	Rest, anti-inflammatory or analgesic medications	Movement, palpation	Variable, but usually constant
Aortic stenosis	Substernal	Occasionally to jaw, arm	Pressure	Rest, nitroglycerin	Exercise, cold weather	Minutes
Hypertrophic cardiomyopathy	Substernal	Occasionally to jaw, arm	Pressure	Rest, nitroglycerin	Exercise, cold weather	Minutes
Aortic dissection	Substernal	Back	Tearing	None	None	Minutes to hours

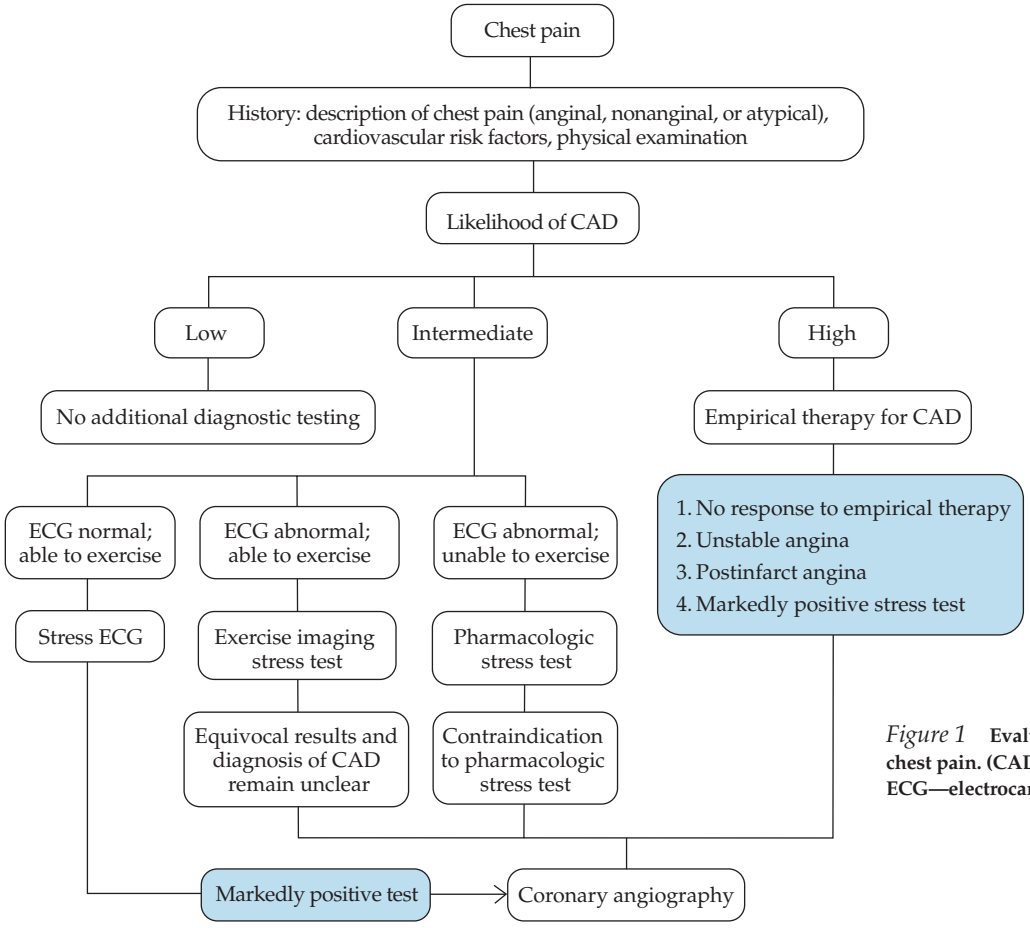

Figure 1 **Evaluation of patients with chest pain. (CAD—coronary artery disease; ECG—electrocardiogram)**

fectiveness of current medical therapy, (2) objective measurement of exercise capacity, (3) evaluation of the extent and location of ischemia or infarction with nuclear or echocardiographic imaging, (4) preoperative risk assessment in patients with known CAD who are undergoing noncardiac surgery, and (5) assessment of prognosis in patients with symptoms consistent with CAD or in patients with known CAD.

To establish the diagnosis of CAD in intermediate-risk patients, a number of noninvasive testing methods are available.[9] The decision whether to perform a specific test is based on various patient characteristics (e.g., body size, associated medical conditions, and ability to exercise), findings on the baseline ECG, and institutional experience with specific testing methods [*see Table 3*].[10-16] The most appropriate noninvasive stress test is chosen on the basis of each of these factors, as indicated in the chest pain algorithm [*see Figure 1*]. For most patients who are able to exercise with a normal baseline ECG, treadmill-ECG stress testing is indicated [*see Table 2*].[14,15,17] Women have a higher incidence of false positive results; therefore, many physicians recommend that, for all women, exercise be combined with an imaging method (e.g., echocardiography or nuclear imaging).[11] In general, to establish the diagnosis of CAD, exercise is preferred over pharmacologic stress agents. For patients who are unable to exercise because of physical limitations (e.g., arthritis or orthopedic problems), severe coexisting pulmonary disease, or general disability, pharmacologic stress agents such as dobutamine, adenosine, or dipyridamole can be employed. Each of these agents has specific contraindications [*see Table 4*].

Coronary angiography is considered the gold standard for the diagnosis of CAD. Although the incidence of major complications is low (< 2%), coronary angiography is costly and has some risk; thus, it is reserved for (1) patients with markedly positive noninvasive tests (i.e., hypotension and significant ST segment depression on ECG stress testing on a treadmill), (2) patients at high risk for CAD in whom a course of empirical antianginal therapy has failed, (3) patients with unstable or postinfarction angina, (4) patients with a contraindication to ex-

Table 2 Absolute and Relative Contraindications to Exercise Testing[8]

Absolute	*Relative*
Recent myocardial infarction (within 48 hr)	Left main coronary stenosis
Unstable angina not previously stabilized with medical therapy	Moderate stenotic valvular heart disease
Uncontrolled cardiac arrhythmias causing symptoms or hemodynamic compromise	Electrolyte abnormalities
Symptomatic severe aortic stenosis	Severe arterial hypertension
Uncontrolled symptomatic heart failure	Tachycardia or bradyarrhythmias
Acute pulmonary embolism or pulmonary infarction	Hypertrophic cardiomyopathy and other forms of outflow tract obstruction
Acute myocarditis or pericarditis	Mental or physical impairment leading to inability to exercise adequately
Acute aortic dissection	High degree of atrioventricular block

Table 3 Diagnostic Testing Methods Available for Evaluating Chest Pain[10-17]

Diagnostic Test	*Indications*	*Information Obtained*	*Limitations*	*Sensitivity*	*Specificity*
Exercise electrocardiographic stress test (stress ECG)	Initial test for most males with chest pain to establish diagnosis of CAD; females have higher rate of false positive test results Assess prognosis and functional capacity in patients with prior MI or known CAD Assess efficacy of current medical therapy in patients with known CAD	Exercise duration and functional aerobic capacity Amount of ST segment depression as indication of extent of ischemia Hemodynamic response to exercise	Normal baseline ECG Ability to exercise (patients who cannot attain adequate cardiopulmonary stress because of respiratory or musculoskeletal problems should receive a pharmacologic stress agent) Contraindications [*see Table 2*] False positives occur with left ventricular hypertrophy, bundle branch block, preexcitation syndromes, electrolyte abnormalities, and digoxin use	68%[1] (females, 61%[2])	77%[1] (females, 70%[2])
Thallium-201 perfusion scintigraphy	Often used when increased diagnostic accuracy for CAD required Can be combined with pharmacologic stress agents such as dobutamine, adenosine, or dipyridamole	Diagnosis of CAD with higher sensitivity and specificity than stress ECG Extent of ischemia Extent of infarction Left ventricular cavity size	Higher cost and longer testing time than stress ECG Imaging artifacts (attenuation) from diaphragm, breast, and intestine Contraindications [*see Table 2 if exercise; see Table 4 if pharmacologic stress agent*]	Ex thall 89%[5] Ph thall 90%[5] Dob thall 88%[4]	Ex thall 76%[5] Ph thall 70%[5] Dob thall 74%[4]
Technetium-99m perfusion scintigraphy	Often used when increased diagnostic accuracy for CAD required Can be combined with pharmacologic stress agents such as dobutamine, adenosine, or dipyridamole	Higher sensitivity and specificity for diagnosis of CAD than stress-ECG Extent of ischemia Extent of infarction Left ventricular cavity size ECG-gated SPECT allows calculation of left ventricular ejection fraction and evaluation of wall motion; evaluation of wall motion reduces false positive scans caused by imaging artifacts (attenuation) Used when excessive body weight precludes thallium imaging	Higher cost and longer testing time than stress ECG Imaging artifacts (attenuation) from diaphragm, breast, and intestine Contraindications [*see Table 2 if exercise; see Table 4 if pharmacologic stress agent*]	Ex tech 89%[5] Ph tech 90%[5] Dob tech 88%[4]	Ex tech 76%[5] Ph tech 70%[5] Dob tech 74%[4]
Exercise or dobutamine echocardiography	Exercise echocardiography often used when patient can exercise and has good-quality echocardiographic images Dobutamine used when exercise not possible	Higher sensitivity and specificity for diagnosis of CAD than stress ECG Left and right ventricular chamber size and function, presence of valve disease and pulmonary arterial pressures	Inadequate image quality may occur in patients with obesity, chronic obstructive pulmonary disease, and chest wall deformities Contraindications [*see Table 2 if exercise; see Table 4 if pharmacologic stress agent*]	Ex echo 85%[6] Dob echo 82%[6]	Ex echo 86%[6] Dob echo 82%[6]
Holter monitoring	Prinzmetal angina	Transient ST segment elevation in presence or absence of chest pain	Difficult to interpret because of baseline abnormalities		
Coronary angiography	Chest pain of unclear etiology despite noninvasive testing Angina not responsive to medical therapy Unstable and postinfarction angina Unclear diagnosis of CAD despite noninvasive stress testing	Anatomic severity of CAD Completely exclude cardiac origin of chest pain—gold standard of diagnostic tests Left ventricular function if left ventricular angiography also performed	Invasive procedure with low (< 2%) but inherent risk of MI, stroke, and death Represents a luminogram; does not evaluate functional significance of arterial narrowing	100%	100%

Table 4 Mechanism of Action, Side Effects, and Contraindications of Pharmacologic Stress Agents

Pharmacologic Stress Agent	*Mechanism of Action*	*Side Effects*	*Contraindications*
Dobutamine	Increase myocardial oxygen demand by increasing heart rate, blood pressure, and myocardial contractility	78% of patients experience side effects: chest pain, palpitations, headache, flushing, malaise, and dyspnea; ventricular and atrial arrhythmias may occur	Severe hypertension at baseline, recent history of ventricular and/or atrial arrhythmias, and current beta-blocker use
Dipyridamole	Coronary artery vasodilatation—indirect response by blocking adenosine uptake and degradation	Increase in heart rate (average, 5–10 beats a minute), decrease in systolic blood pressure (average, 10–15 mm Hg); approximately 50% of patients experience side effects: chest pain, flushing, dizziness, headaches, or nausea; may provoke bronchospasm	Severe reactive airway disease (not contraindicated with chronic obstructive pulmonary disease unless a significant component of reactive airway disease is present), current theophylline use; avoid caffeine use 1 day before testing
Adenosine	Coronary artery vasodilatation—direct response	79% of patients experience side effects (more than with dipyridamole); side effects are chest, throat or jaw pain, headache, flushing, malaise, nausea, and bradyarrhythmias	Similar to dipyridamole; avoid caffeine use 1 day before testing; may cause bradyarrhythmias and is therefore contraindicated with baseline second- or third-degree heart block

ercise or pharmacologic stress testing, and (5) patients with equivocal results on noninvasive stress testing when the diagnosis of CAD remains unclear. Coronary angiography has certain limitations, including the inability to determine (1) the functional significance of a coronary artery stenosis and (2) which coronary plaque is likely to rupture (i.e., the so-called vulnerable plaque) and result in an acute coronary syndrome. Intravascular ultrasound studies have shown that coronary angiography may occasionally underestimate the severity of an area of narrowing, because it represents a so-called luminogram (shadow image) and not the size of the atherosclerotic plaque.[18] Despite these shortcomings, the extent and severity of CAD and measurement of left ventricular function by left heart catheterization are powerful predictors of clinical outcome.[14]

Dyspnea

BACKGROUND

Dyspnea refers to difficulty with breathing and can occur with a wide variety of cardiac, pulmonary, and systemic conditions [*see Table 5*]. Dyspnea can be classified as occurring (1) at rest, (2) with exertion, (3) during the night, awakening a patient from sleep (paroxysmal nocturnal dyspnea), or (4) during episodes of recumbency (orthopnea). Paroxysmal nocturnal dyspnea and orthopnea result from similar mechanisms. Specifically, the recumbent position augments venous return to the right heart. This increase in cardiac filling further increases the pulmonary capillary pressure and results in interstitial (and possibly intra-alveolar) pulmonary edema. Patients find relief by sitting upright, which reduces venous filling and transiently decreases the pulmonary interstitial pressure.

Dyspnea may be acute or chronic. An acute presentation suggests a pulmonary embolism, acute asthma exacerbation, pneumothorax, or rapidly developing pulmonary edema, as occurs with ischemic mitral regurgitation. Chronic dyspnea suggests heart failure resulting from systolic or diastolic dysfunction.

HISTORY AND PHYSICAL EXAMINATION

The history will often exclude less likely conditions and establish the etiology of dyspnea. A history of reactive airway disease, bronchodilator use, or corticosteroid use suggests asthma. Reactive airway disease tends to occur in children and young adults; therefore, in older patients given this diagnosis, a cardiac cause for dyspnea (e.g., new onset of congestive heart failure) should be considered. A significant history of tobacco use, wheezing, chronic cough, and sputum production suggests obstructive airway disease.[19] A recent history of fever, chills, and

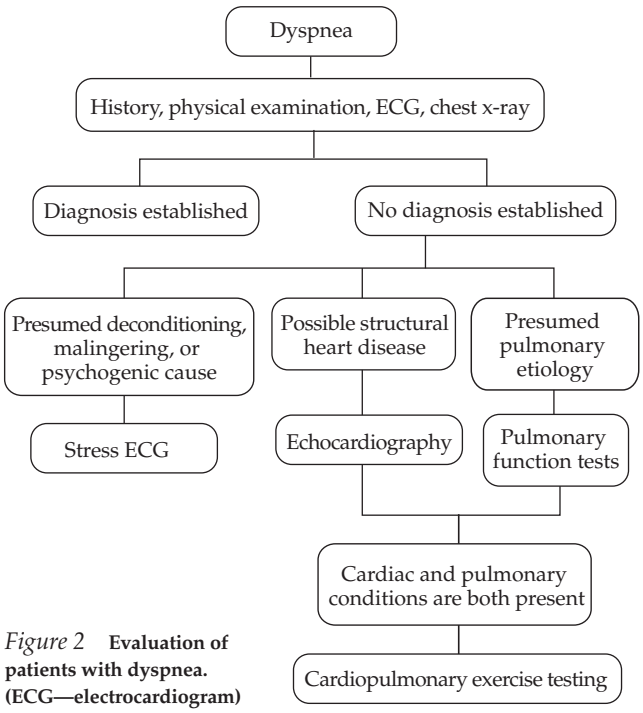

Figure 2 **Evaluation of patients with dyspnea. (ECG—electrocardiogram)**

productive cough may indicate bronchitis or pneumonia. The acute onset of dyspnea associated with pleuritic chest pain after a period of immobilization suggests pulmonary embolism. Paroxysmal nocturnal dyspnea, orthopnea, nocturia, recent weight gain, and lower extremity edema suggest a cardiac cause for dyspnea. Patients with chronic obstructive pulmonary disease may also awaken at night with dyspnea, but they usually have a history of sputum production and expectoration that improves with the patient in the upright position. Occasionally, on the basis of the history alone, it may not be possible to determine whether a cardiac or pulmonary cause of dyspnea is present.[20] In up to one third of patients being evaluated, dyspnea may have more than one cause.[21] In elderly patients, dyspnea may be the only symptom of a myocardial infarction. Hemoptysis may indicate the presence of severe underlying pulmonary disease (e.g., pulmonary embolism or lung cancer) but must be differentiated from hematemesis and nasopharyngeal bleeding.

Several findings on physical examination can assist in excluding a cardiac cause for dyspnea. These findings include a normal level of the jugular venous pressure, a normal point of maximal cardiac impulse, the lack of a third heart sound or cardiac murmurs, the absence of rales on lung examination, and the absence of peripheral edema. Alternatively, elevated jugular venous pressure, a displaced point of maximal cardiac impulse, a third heart sound, a holosystolic murmur of mitral regurgitation, basilar rales, and peripheral edema suggest congestive heart failure. A positive abdominojugular reflux maneuver may also identify dyspnea of cardiac origin.[22]

Obese patients and those with chest wall deformities may experience dyspnea secondary to the increased workload of breathing from the mechanical limitation imposed on the chest wall. Patients with emphysema frequently have an increased anteroposterior chest diameter, prolonged expiratory phase, expiratory wheezes, and diminished breath sounds. Central cyanosis, a normal anteroposterior chest diameter, and expiratory wheezes or rhonchi on lung examination suggest chronic bronchitis. Expiratory wheezing can occur in both cardiac and pulmonary conditions and is therefore not helpful in establishing an etiology. Stridor may result from an upper airway obstruction or vocal cord paralysis and at times may resemble wheezing. Tachypnea, a loud pulmonic component of the second heart sound, and calf tenderness suggest a pulmonary embolism.

DIAGNOSTIC TESTS

An ECG and a chest roentgenogram should be the initial tests in the evaluation of dyspnea. Pertinent ECG findings include Q waves (prior myocardial infarction), a bundle branch block (structural heart disease), left ventricular hypertrophy (aortic stenosis, hypertension), and evidence of atrial chamber enlargement (valvular heart disease). Notable chest roentgenogram findings include an enlarged cardiac silhouette; interstitial or alveolar edema (congestive heart failure); aortic valve calcification (valvular heart disease); lung mass (lung cancer); focal infiltrate (pneumonia); pleural effusion (congestive heart failure, infectious process); and hyperinflation, bullae, and flattened hemidiaphragms (emphysema). Screening laboratory tests may be useful to exclude anemia as a potential cause of dyspnea.

If the diagnosis of dyspnea remains unclear, additional testing can be pursued [*see Figure 2*]. For patients with cardiovascular risk factors, with findings on physical examination that suggest structural heart disease, or with abnormal ECGs, echocardiography is indicated to exclude valvular heart disease and assess systolic and diastolic ventricular function. Patients with a presumed pulmonary etiology for dyspnea that remains undiagnosed should undergo pulmonary function testing to exclude reactive airway and restrictive and chronic obstructive pulmonary disease. Stress-ECG may be useful to objectively evaluate the degree of limitation and may be particularly helpful for patients with presumed deconditioning, malingering, or a psychogenic cause for dyspnea. For patients who may have a component of dyspnea from both a cardiac and a pulmonary source, cardiopulmonary exercise testing can be considered. Serum brain natriuretic peptide (BNP) levels are useful in distinguishing cardiac from noncardiac causes of dyspnea; a BNP greater than 100 pg/ml has a sensitivity of 90% but a specificity of only 73% for establishing the diagnosis of heart failure.[23] Other factors that affect BNP levels include renal failure, acute coronary syndrome, and female gender.

Palpitations

BACKGROUND

Palpitations are a nonspecific symptom associated with severity ranging from an increased awareness of the normal heartbeat to life-threatening ventricular arrhythmias [*see Table 6*]. Although palpitations represent one of the most common complaints requiring evaluation in the outpatient setting,[24] consensus guidelines describing the appropriate evaluation have not yet been established.

For patients with an underlying cardiac disease associated with palpitations, long-term outcome is poor. In contrast, clinical outcome is excellent for those with a noncardiac origin for palpitations, despite a high rate of recurrent episodes.[25] The key, then, in the evaluation of palpitations is to establish or exclude the presence of underlying structural heart disease. This determination can often be made by use of information from the his-

tory, physical examination, and ECG, but it may require additional evaluation with ambulatory ECG monitoring and possibly electrophysiologic testing. Psychiatric illnesses (anxiety, panic, and somatization disorders) account for a certain number of patients who seek medical attention for palpitations[25]; these disorders can initially be screened by use of simple and rapid patient-administered questionnaires. Although an underlying psychiatric illness should be considered in appropriate patients, it does not obviate the need for a complete evaluation to exclude a cardiac origin.[26] A diagnostic algorithm is presented that utilizes a rational approach to diagnostic testing [*see Figure 3*].

Table 6 Causes of Palpitations

General Category	*Prognosis*
Hyperdynamic state	Anemia, thyrotoxicosis, and exercise—all leading to sinus tachycardia
Increase in cardiac stroke volume	Aortic regurgitation, patent ductus arteriosus
Arrhythmia	
Ventricular	Frequent ventricular premature beats, ventricular tachycardia
Supraventricular	Frequent atrial premature beats, atrial fibrillation, atrial flutter, multifocal atrial tachycardia, atrial tachycardia, atrioventricular nodal reentry tachycardia, atrioventricular reentry tachycardia
Psychiatric	Anxiety, panic, or somatization disorder

HISTORY AND PHYSICAL EXAMINATION

Palpitations are often described as a fluttering, a pounding, or an uncomfortable sensation in the chest. Occasionally, patients may complain only of a sensation of awareness of the heart rhythm. Patients may be able to discern whether the episodes are rapid and regular or rapid and irregular. Tapping a finger on the patient's chest in either a regular or an irregular manner may occasionally lead to an accurate description of the events.

A history of palpitations since childhood suggests a supraventricular arrhythmia and possibly an atrioventricular bypass tract, such as in the Wolff-Parkinson-White syndrome. Patients with congenital long QT syndrome typically begin to manifest symptoms in adolescence. A family history of sudden cardiac death, congestive heart failure, or syncope may suggest an inherited dilated or hypertrophic cardiomyopathy.

Knowing the circumstances in which palpitations occur may be useful in determining their origin. Palpitations associated only with strenuous physical activity are normal, whereas episodes occurring at rest or with minimal activity suggest underlying pathology. Episodes associated with a lack of food intake suggest hypoglycemia, and episodes after excessive alcohol intake suggest the toxic effects of alcohol. The resolution of symptoms with vagal maneuvers (breath-holding or the Valsalva maneuver) suggests paroxysmal supraventricular tachycardia. The onset of an episode of palpitations on assuming an upright position after bending over suggests atrioventricular nodal tachycardia.[27] Emotional stress and strenuous exercise may precipitate episodes in patients with long QT syndrome. Palpitations associated with anxiety or a sense of doom or panic suggest, but do not confirm, an underlying psychiatric disorder. An odds-ratio analysis found that regular palpitations, palpitations

experienced at work, and those affected by sleeping were more likely to indicate cardiac origin.[28]

Symptoms associated with an episode of palpitations should also be explored. Syncope or presyncope after an episode suggests ventricular arrhythmias. However, patients with structural heart disease (e.g., severe left ventricular systolic dysfunction) may also experience these symptoms after supraventricular arrhythmias because of dependence on atrial filling. Additional mechanisms of syncope in patients with supraventricular arrhythmias have also been reported.[29] Regardless of the mechanism, syncope and presyncope are worrisome symptoms and merit a complete cardiovascular evaluation. Occasionally, patients may experience an episode of polyuria that follows the palpitations. This condition may suggest supraventricular arrhythmias as the cause of palpitations, although studies have found this to be uncommon.[30]

The physical examination should focus on establishing whether underlying structural heart disease is present. Evidence of cardiac enlargement, third heart sound, and holosystolic murmur of mitral regurgitation suggest an underlying dilated cardiomyopathy. A midsystolic click, often followed by a systolic murmur, indicates mitral valve prolapse, which may be associated with both ventricular and supraventricular arrhythmias. A midsystolic murmur along the left sternal border that varies in intensity with alterations in left ventricular filling (e.g., Valsalva maneuver or changes in body position) is consistent with hypertrophic cardiomyopathy. Although atrial fibrillation is common in hypertrophic cardiomyopathy, ventricular arrhythmias may also occur.

DIAGNOSTIC TESTS

The ECG is the first step in the diagnostic evaluation of a patient with palpitations [*see Figure 3*]. A short PR interval and delta wave (Wolff-Parkinson-White syndrome), prolonged QT interval (long QT syndrome), and left bundle branch block (structural heart disease) are notable findings. Certain medications [*see Table 7*] may result in prolongation of the QT interval (i.e., acquired prolonged QT) and increase the risk of arrhythmias. Extreme voltage amplitudes and Q waves in leads I, aVL, and V4 through V6 are seen with hypertrophic cardiomyopathy. Pathologic Q waves indicate prior myocardial infarction and therefore a substrate for ventricular arrhythmias. Left ventricular hypertrophy or atrial abnormalities are nonspecific findings but suggest underlying structural heart disease. Many pertinent findings for various causes of palpitations can be obtained from the history, physical examination, and ECG [*see Table 8*].

If the cause of palpitations is not apparent after the initial evaluation (history, physical examination, and ECG), additional

Table 8 Diagnosis of the Underlying Etiology of Palpitations

Condition	*History*	*Physical Examination*	*ECG*	*Underlying Etiology of Palpitations*
Congenital long QT syndrome	Symptom onset in adolescence; episodes may be triggered by emotional stress and strenuous exercise	Normal	Prolonged QT interval	Ventricular arrhythmias
Atrioventricular bypass tract (e.g., Wolf-Parkinson-White syndrome)	Childhood episodes of palpitations	Normal	Short PR interval, delta wave	Supraventricular arrhythmias
Inherited dilated cardiomyopathy	Family history of cardiomyopathy, syncope, or sudden cardiac death	Abnormal cardiac impulse, systolic murmur (MR), third heart sound	Atrial enlargement, IVCD, LBBB, ventricular ectopic beats, or Q waves	Supraventricular or ventricular arrhythmias
Hypertrophic cardiomyopathy	Family history of cardiomyopathy, syncope, or sudden cardiac death	Systolic murmur	Increased voltage amplitude (LVH), Q waves in V4-V6, I, aVL	Supraventricular or ventricular arrhythmias
Anxiety, panic, or somatization disorder	Sense of doom, panic, or anxiety associated with episodes; coexisting psychiatric illness	Normal	Normal	Psychiatric
Mitral valve prolapse	Associated fatigue, dyspnea	Midsystolic click, systolic murmur (MR)	Normal or left atrial enlargement	Supraventricular arrhythmias

IVCD—interventricular conduction defect LBBB—left bundle branch block LVH—left ventricular hypertrophy MR—mitral regurgitation

diagnostic testing is indicated for certain patients [*see Figure 3*].[27] Such patients include those with presumed arrhythmias that remain undiagnosed and those with prior myocardial infarction, dilated cardiomyopathy, hypertrophic cardiomyopathy, or significant valvular or congenital heart disease. In addition, patients who desire a specific diagnosis should be considered for additional testing.

Ambulatory ECG devices include Holter monitoring and continuous-loop event recorders. Holter monitors continuously record the heart rhythm for 24 or 48 hours. Patients are asked to maintain a diary documenting the time and describing the symptoms during the monitoring period. The key is to correlate patient symptoms with documented rhythm abnormalities. Patients with significant complaints of palpitations that correlate with periods of normal sinus rhythm should be further evaluated for underlying psychiatric disorders. Event monitors also continuously record the heart rhythm but require the patient to trigger the device to save the information. These devices can be kept by patients for several weeks and are especially useful when symptoms are infrequent. Event monitors are more cost-effective than Holter monitors for evaluating palpitations.[31,32] For patients with underlying structural heart disease and documented ventricular arrhythmias on ambulatory ECG monitoring, additional evaluation is warranted, including determination of left ventricular function and, occasionally, electrophysiologic testing.

Syncope

BACKGROUND

Syncope refers to a transient loss of consciousness accompanied by loss of postural tone. Roughly one third of all persons have an episode of syncope during their lifetime. It is a particularly common problem encountered in emergency departments and accounts for approximately 6% of all hospital admissions.[33] Determining which patients require hospital admission is difficult, given the large number of potential causes of syncope. Although many conditions that result in syncope are life threatening, other common etiologies, such as medication side effects, orthostatic hypotension, and psychiatric disorders, are benign.

Syncope is classified on the basis of the underlying etiology [*see Table 9*]. In elderly patients, the etiology may be multifactorial and related to medication side effects (particularly antihypertensives and antidepressants),[34] orthostatic hypotension, and bradyarrhythmias. Various medications are associated with prolongation of the QT interval and the development of ventricular arrhythmias and resulting syncope [*see Table 7*]. Vasovagal syncope is particularly common in otherwise healthy patients and has a benign prognosis. Episodes often occur in response to injury and are characterized by a sudden decline in blood pressure with or without associated bradycardia.

Establishing the presence of structural heart disease in the evaluation of patients with syncope is essential because such patients may have a 1-year mortality as high as 30%.[35,36] Structural heart disease is usually apparent on the basis of history, physical examination, and information from the baseline ECG. Occasionally, additional diagnostic testing with echocardiography, tilt-table testing, or electrophysiologic testing may be required.

HISTORY AND PHYSICAL EXAMINATION

The first step in establishing the presence of structural heart disease is to obtain an accurate description of the episode of syncope. Key elements of the history include the presence of postural or exertional symptoms; associated chest pain, shortness of breath, or palpitations; and the situation in which the episode occurred (e.g., during micturition). Neurologic symptoms such as focal motor weakness, arm or leg movement, tongue biting, or a postictal state suggest a neurologic rather than cardiac event. However, seizures can occur from cardiac causes if a patient is kept upright during an episode (usually the result of a well-meaning bystander) because of cerebral hypoperfusion. A witness to the episode of syncope may provide a clear description of the event and should be questioned if possible. Medications associated with QT prolongation [*see Table 7*], blood pressure lowering (antihypertensives), and volume depletion (diuretics) should be reviewed. A family history of sudden cardiac death, syncope, or heart failure suggests hypertrophic cardiomyopathy, an inherited dilated cardiomyopathy, or long QT syndrome. A history of myocardial infarction or congestive heart failure raises the possibility of ventricular arrhythmias.

The physical examination focuses on determining whether structural heart disease is present and excluding common causes of syncope. Orthostatic vital signs should be obtained in all patients. Focal neurologic findings such as a motor deficit or a visual-field defect may indicate a neurologic cause for syncope. Pertinent findings on cardiovascular examination include a delayed carotid upstroke (aortic stenosis), an abnormal point of maximal cardiac impulse (cardiomyopathy), an irregular or

bradycardiac rhythm (arrhythmias), a third heart sound (cardiomyopathy), a midsystolic murmur (aortic stenosis, hypertrophic cardiomyopathy), and a holosystolic murmur (mitral regurgitation secondary to left ventricular dilatation). Less common findings include an early diastolic sound (so-called tumor plop, indicating a left atrial myxoma), asymmetrical peripheral pulses (aortic dissection), and a loud second heart sound (pulmonary hypertension secondary to pulmonary embolism). Information from the history and physical examination yields a cause for syncope in approximately 45% of patients.[37]

DIAGNOSTIC TESTS

An ECG is the initial diagnostic test for all patients with syncope. Although the yield of the baseline ECG is low (approximately 5%), a number of potential findings are useful,[37] including bundle branch block, Q waves indicating prior myocardial infarction, left ventricular hypertrophy, prolonged QT interval, or evidence of atrioventricular block. The presence of sinus bradycardia, first-degree atrioventricular block, and bundle branch block suggests bradyarrhythmias as the cause of syncope. Extreme voltage amplitudes and Q waves in leads I, aVL, and V4 through V6 suggest hypertrophic cardiomyopathy and therefore the possibility of ventricular arrhythmias. An uncommon but unique ECG abnormality is the combination of a right bundle branch block, T wave inversions in leads V1 through V3, and an epsilon wave (a positive wave on the terminal portion of the QRS complex)—findings that indicate right ventricular dysplasia, which is associated with ventricular arrhythmias. Ventricular arrhythmias are also seen in the Brugada syndrome, which can be identified on the ECG by an incomplete right bundle branch block and ST segment elevation in leads V1 through V3.[38] A short PR interval and slurring of the initial portion of the

Table 10 Differential Diagnosis of Claudication

Condition	*History*	*Physical Examination*	*Diagnostic Tests*	*Comments*
Peripheral vascular disease	Symptoms occur with exercise and are relieved by rest	Diminished or absent peripheral pulses	ABI, arterial duplex ultrasound	Angiography reserved for those with severe disease who are considering surgical or percutaneous revascularization
Lumbar spinal stenosis	Paresthesias occur with standing and walking Symptoms are relieved by sitting and/or leaning forward History may include chronic low back pain and prior lumbar surgery	Normal peripheral pulses	Computed tomography or magnetic resonance imaging of the lumbar spine	Referred to as pseudoclaudication
Arthritis	Pain localized to the joint area as opposed to adjacent muscles	Normal peripheral pulses	Radiograph of affected joint	
Myalgia	Pain within a muscle group at rest and with exertion No relief with rest	Tenderness to palpation of the affected muscle group; reduced muscle strength	Laboratory evaluation of muscle inflammation with CPK, aldolase	Associated with hypothyroidism and end-stage renal disease; may be related to drug side effect (e.g., HMG-CoA reductase inhibitors)

ABI—ankle-brachial index CPK—creatinine phosphokinase

QRS complex (the delta wave) suggests preexcitation (i.e., Wolff-Parkinson-White syndrome), with the possibility of rapid antegrade conduction via the accessory pathway.

If the etiology of syncope remains unclear after reviewing the history, physical examination, and ECG, additional diagnostic testing should be pursued. For patients with findings suggestive of an underlying cardiac cause, echocardiography and coronary angiography can be performed; for those with a possible neurologic cause, brain imaging (computed tomography or magnetic resonance imaging), neurovascular studies (carotid and transcranial Doppler ultrasound studies), and electroencephalography can be performed; and for those with a presumed pulmonary cause, lung scanning can be considered [*see Figure 4*]. If the diagnosis remains uncertain despite these tests, one of three pathways can be followed.[39]

The first pathway is for patients with structural heart disease or an abnormal ECG, who therefore have an increased likelihood for underlying arrhythmias or valve disease as a cause for syncope. Echocardiography, noninvasive stress testing, and ambulatory ECG monitoring using either a Holter monitor or continuous-loop event recorder should be considered for these patients. Event recorders have been found to be more accurate than Holter monitors in the diagnosis of syncope and presyncope; however, some patients find event recorders difficult to operate correctly.[40] If ambulatory ECG monitoring documents normal sinus rhythm in the setting of reported syncope, psychiatric evaluation and possibly tilt-table testing are warranted.

The second pathway is for patients older than 60 years, who are more likely to have valve disease (aortic stenosis), ischemic heart disease, carotid sinus syncope, cerebrovascular disease (transient ischemic attacks), and situational events (micturition, defecation, postural) as a basis for syncope. Carotid sinus massage (in the absence of carotid bruits, recent myocardial infarction, or stroke) should be the initial diagnostic test for these patients.[41,42] A positive test is defined as asystolic arrest lasting 3 seconds or longer and may identify those with cardioinhibitory hypersensitivity of the carotid sinus who will benefit from pacemaker placement. For those with a negative test result, echocardiography, noninvasive stress testing, and ambulatory ECG monitoring can be performed.

The third pathway is for patients with unexplained syncope and no suspected structural heart disease. For those who have had a single episode, additional evaluation can be deferred until a second episode occurs. In patients with more than one episode, ambulatory ECG monitoring or tilt-table testing and, possibly, psychiatric evaluation should be considered.

Tilt-table testing was initially developed in the 1980s to evaluate patients with presumed vasovagal syncope. The passive portion of the test involves quickly raising a patient from the supine position to an angle of 60° (the tilt angle) for approximately 45 minutes, which causes pooling of venous blood in the lower extremities, a decrease in venous return, compensatory tachycardia, and enhanced ventricular contraction. For individuals with vasovagal syncope, augmented ventricular contraction causes activation of vasodepressor reflexes that result in hypotension, bradycardia, or both. Approximately 49% of patients referred for evaluation of

Table 11 Ankle-Brachial Index (ABI) Values and Accompanying Findings in Peripheral Vascular Disease (PVD)

Condition	*Symptoms*	*Physical Findings*	*ABI*
Normal	None	None	> 1.0
Mild PVD	Mild claudication on exertion	Diminished pulses	0.8–0.9
Moderate PVD	Moderate or severe claudication on exertion	Diminished or absent pulses; nonhealing ulcers or skin wounds	0.5–0.8
Severe PVD	Severe claudication; symptoms may occur at rest	Absent pulses; nonhealing ulcers or skin wounds	< 0.5

vasovagal syncope have positive responses, compared with 9% of control patients.[43] The active portion of tilt-table testing uses an isoproterenol infusion to enhance the vasodepressor reflex.

Claudication

BACKGROUND

Claudication is a condition of muscle pain or weakness associated with compromised blood flow to the extremities. It is a common complaint of patients who have peripheral vascular disease (PVD). Claudication is also a common symptom of CAD, a disease that shares risk factors with PVD. PVD is associated with an increased risk of stroke, cardiovascular death, and all-cause mortality[44]; it is most frequently caused by atherosclerosis. Studies suggest that PVD is infrequently diagnosed and often undertreated in the primary care setting.[45]

Intermittent claudication associated with PVD is a reproducible discomfort of a muscle group that is induced by exercise and relieved by rest. It is frequently manifested during ambulation as pain in the buttocks, upper thighs, and calves. The differential diagnosis of claudication [*see Table 10*] can be challenging and requires a detailed history and physical examination supplemented with diagnostic testing.

HISTORY AND PHYSICAL EXAMINATION

Claudication is described by patients as pain or cramping in the buttocks, thighs, and calf muscles. Symptoms typically occur during ambulation and are relieved by rest. Patients may also describe generalized weakness or a tired sensation within the legs. Depending on the extent of disease, men may experience impotence. Patients with severe disease may experience pain at rest. Patients with pain originating from compression of a nerve root describe an electric shock–like discomfort that frequently involves both legs and may be relieved by sitting down and leaning forward. More than one cause for leg symptoms may exist in a given patient, necessitating careful and clear delineation of each individual patient. Lumbar stenosis is another common cause of these symptoms (i.e., pseudoclaudication). The pain of pseudoclaudication is often poorly localized and may affect the leg from thigh to calf. Additional information that should be elicited from the history include the presence of a nonhealing ulcer or wound and previous manifestations of PVD, such as prior carotid endarterectomy. Risk factors associated with PVD are similar to those associated with CAD and include older age, cigarette smoking, diabetes mellitus, hypertension, and hyperlipidemia.

Physical examination should focus on assessment of all peripheral pulses, including the carotid, femoral, popliteal, dorsal pedis, and posterior tibial. Peripheral pulses should be described as normal, diminished, or absent, and the presence or absence of a bruit should be noted. For patients with severe PVD, the skin distal to the area of occlusion may be cold, and elevation of the legs may result in pallor of the soles of the feet. The presence and location of ulcers, skin wounds, and gangrene should be noted. Auscultation over the neck and abdomen may reveal bruits suggesting carotid artery stenosis and renal artery stenosis, repectively.

DIAGNOSTIC TESTS

The key diagnostic test in the evaluation of claudication is the ankle-to-brachial systolic pressure index (ABI). This involves measuring the systolic blood pressure in the ankle and the upper arm (brachial artery) in the supine position. The ankle systolic pressure is measured with a standard blood pressure cuff placed around the ankle, with the lower edge of the cuff situated above the malleoli. The blood pressure cuff is inflated to approximately 30 mm Hg above the systolic pressure to temporarily occlude flow. As the cuff is slowly deflated, a Doppler probe is used to monitor the signal; the pressure at which the Doppler flow signal is heard is recorded as the systolic pressure. A normal ABI is greater than 1.0; a value of less than 1.0 indicates the presence of PVD [*see Table 11*]. In addition to establishing the diagnosis of PVD, the ABI gives an assessment of disease severity and has prognostic implications for future cardiovascular and cerebrovascular events.[46,47] Additional noninvasive imaging to evaluate the extent and severity of PVD may include an arterial duplex ultrasound. The vasculature from the abdominal aorta to the distal tibial arteries can be imaged to localize the area of stenosis and assess hemodynamic significance using the Doppler flow signals or Doppler velocity spectra.

Diagnostic angiography involves the use of cineangiographic imaging and radiographic contrast to image the peripheral vessels. Because angiography is an invasive procedure that carries a 1% risk of vascular complications, it is usually reserved for patients being considered for surgical or percutaneous (angioplasty and stenting) revascularization procedures; such procedures are undertaken to relieve limiting claudication, nonhealing ulcers, and severe ischemia [*see Figure 5*]. Magnetic resonance angiography is potentially useful in the initial evaluation of patients with renal insufficiency.

A normal ABI excludes PVD as the cause of claudication and prompts investigation of alternative conditions as the underlying disorder [*see Figure 6*].

For patients with an abnormal ABI and mild symptoms, medical therapy can be initiated and risk factors modified.[48] Patients with moderate to severe symptoms should undergo additional noninvasive testing using arterial Duplex ultrasound. Patients with limiting symptoms or threatened limb loss should undergo angiography in anticipation of surgical or percutaneous revascularization.

Cardiac Murmurs

BACKGROUND

The increased access to health care and the widespread use and availability of echocardiography have resulted in a large number of patients being diagnosed and evaluated for various cardiac murmurs. A cardiac murmur may indicate underlying valvular, congenital, or myocardial disease, but it may also be caused by systemic illnesses and occur in the setting of a structurally normal heart.

Cardiac murmurs result from disturbed or turbulent blood flow, often through diseased cardiac valves or intracardiac structures. The presence of a cardiac murmur, however, does not always indicate underlying cardiac pathology. Hyperthyroidism, anemia, and a febrile illness may all result in increased blood flow through the aortic valve and produce a soft, crescendo-decrescendo, systolic murmur over the aortic area. In this setting, the aortic valve is structurally normal, and the murmur is the result of augmented blood flow (i.e., a flow murmur) caused by the systemic illness. Another common cause of a systolic murmur is calcification of the aortic valve, which is referred

Figure 5 **Abdominal aortogram showing peripheral runoff. (*a*) Mild irregularities of the peripheral vessels are present, but there is no evidence of severe disease. The arrow indicates mild irregularities of the right superficial femoral artery. (*b*) Severe peripheral vascular disease with occlusion of proximal right superficial femoral artery (arrowhead) is evident. The midportion of the right superficial femoral artery is reconstituted from collateral vessels supplied by the right profunda femoralis artery (circle).**

to as aortic sclerosis when there is no obstruction to left ventricular outflow. Aortic sclerosis is a common finding in elderly patients; 25% of those older than 65 years are affected.[49] This condition is often diagnosed when a systolic murmur is detected in an otherwise asymptomatic patient during a routine physical examination. In addition to being caused by diseases of the cardiac valves, murmurs may result from intracardiac communications (atrial and ventricular septal defects), congenital abnormalities (patent ductus arteriosus), and disease of the myocardium (hypertrophic cardiomyopathy).

A thorough history and physical examination can often provide the etiology of a murmur. Additional diagnostic tests, such as the ECG, chest roentgenogram, and echocardiogram, are used to confirm the diagnosis and establish the severity of the abnormality.

HISTORY AND PHYSICAL EXAMINATION

A history of a childhood murmur may indicate a congenital abnormality of a cardiac valve, such as a bicuspid or unicuspid

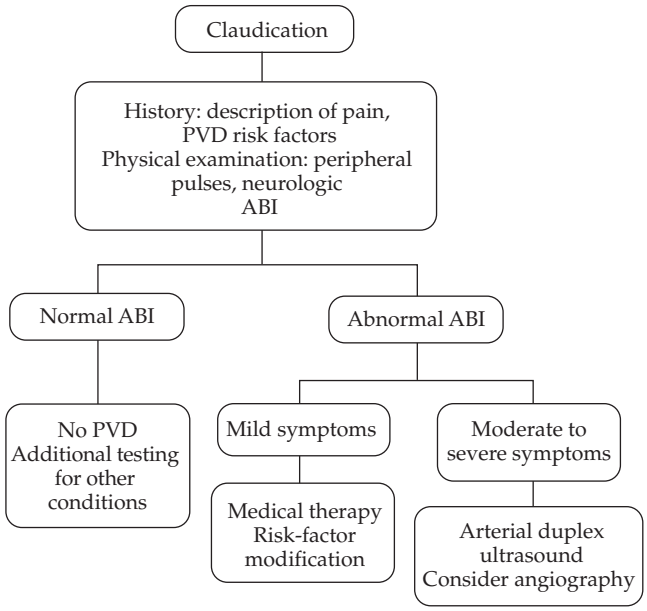

Figure 6 **Evaluation of patients with claudication.**

aortic valve. A febrile illness occurring in childhood should raise the suspicion of rheumatic fever, possibly resulting in rheumatic mitral stenosis. Although rheumatic fever is uncommon in the United States, it may still be seen in immigrants from Asia, Latin America, and the Caribbean.

Establishing the presence or absence of cardiovascular symptoms is essential in the evaluation of a cardiac murmur. Otherwise healthy young adults without cardiac symptoms, with a systolic flow murmur and no other cardiac findings on examina-

    - Austin Flint murmur associated with chronic aortic regurgitation
    - Severe mitral regurgitation (augmented antegrade mitral valve flow)
- Continuous
  - Patent ductus arteriosus

Table 13 Physical Findings Useful for Evaluating a Cardiac Murmur

Condition	*Timing*	*Location*	*Radiation*	*Characteristics*	*Effects of Maneuvers*	*Associated Findings*
Innocent flow murmur	Midsystolic	Base	Variable or none	Soft, ejection	No change	None
Aortic stenosis	Systolic	Base (right second ICS)	Carotid arteries	Crescendo-decrescendo	Decrease with handgrip or standing	Single S_2, delayed and decreased carotid upstroke, ES if mobile valve leaflets
Mitral regurgitation	Systolic	Apex	Axilla (sometimes back)	Holosystolic	Increase with handgrip	Hyperdynamic apical impulse
Ventricular septal defect	Systolic	Left sternal border	None	Holosystolic	No change	Palpable thrill
Atrial septal defect	Systolic	Left second ICS	None	Crescendo-decrescendo	Possible increase with inspiration	Fixed split S_2
Hypertrophic cardiomyopathy	Systolic	Base	Carotid arteries	Late-peaking crescendo	Increase with standing and strain phase of Valsalva maneuver	Brisk carotid upstroke
Tricuspid regurgitation	Systolic	Left lower sternal border	Right lower sternal border	Holosystolic	Increase with inspiration	Prominent v waves in JVP, pulsatile liver
Pulmonic stenosis	Systolic	Left second ICS	None	Crescendo-decrescendo	No change	ES if mobile valve leaflets
Aortic regurgitation	Diastolic	Left sternal border	None	Decrescendo, high-pitched	Increase with handgrip	Wide pulse pressure, displaced and enlarged apical impulse
Mitral stenosis	Diastolic	Apex	None	Low-pitched rumble, presystolic accentuation	Best heard in left lateral decubitus position	Loud S_1, opening snap
Pulmonic regurgitation	Diastolic	Left second ICS	Left sternal border	Decrescendo	May increase with inspiration	—
Tricuspid stenosis	Diastolic	Right lower sternal border	Right upper abdomen	Low-pitched rumble	Increase with inspiration	Right ventricular heave
Patent ductus arteriosus	Continuous	Left second ICS	Back	Machinery-like	None	Wide pulse pressure, bounding pulses

ES—ejection sound ICS—intercostal space JVP—jugular venous pulse S_1, S_2—first, second heart sounds

tion, often require no additional evaluation.[50] In contrast, the finding of a cardiac murmur in patients with cardiovascular symptoms must be further explored and a diagnosis established.

Aortic stenosis may result in the triad of angina, syncope, and impaired exercise tolerance or dyspnea on exertion. Patients with hypertrophic cardiomyopathy experience similar symptoms but may also complain of palpitations from associated atrial or ventricular arrhythmias. Hypertrophic cardiomyopathy is most commonly familial, with an autosomal dominant inheritance pattern; therefore, the patient should be questioned about a family history of sudden cardiac death, heart failure, and syncope. Symptoms of mitral stenosis include shortness of breath, impaired exercise tolerance, palpitations (from associated atrial fibrillation), and hemoptysis. These symptoms may occur during episodes of tachycardia, volume overload, or both as mitral valve flow is increased and the stenotic mitral valve impairs filling of the left ventricle. Asymptomatic women with mitral stenosis may develop symptoms during pregnancy. Mitral and aortic regurgitation cause a volume overload to the left atrium and left ventricle, respectively, and may result in shortness of breath, orthopnea, paroxysmal nocturnal dyspnea, lower extremity edema, and impaired exercise capacity. A ventricular septal defect is either congenital or ischemic (e.g., occurring after a myocardial infarction). The congenital form often becomes apparent during adolescence; the ischemic form presents several days after a myocardial infarction as a new holosystolic murmur associated with significant respiratory distress.

The physical examination begins with determining the timing of the murmur in the cardiac cycle—systolic, diastolic, or continuous [*see Table 12*]. The grade, quality, location, area of radiation, and change in intensity with maneuvers should then be described. Murmurs are graded on a scale of 1 to 6. Grade 1 is a soft intermittent murmur, grade 4 is a palpable murmur, and grade 6 is a murmur that can be appreciated without a stethoscope. Thus, most murmurs are classified as grade 2 or 3. Midsystolic murmurs are derived from the aortic or pulmonic valves or occur in association with hypertrophic cardiomyopathy. In contrast, holosystolic murmurs are the result of regurgitant blood flow through either the mitral or the tricuspid valves or a ventricular septal defect. The murmur of a ventricular septal

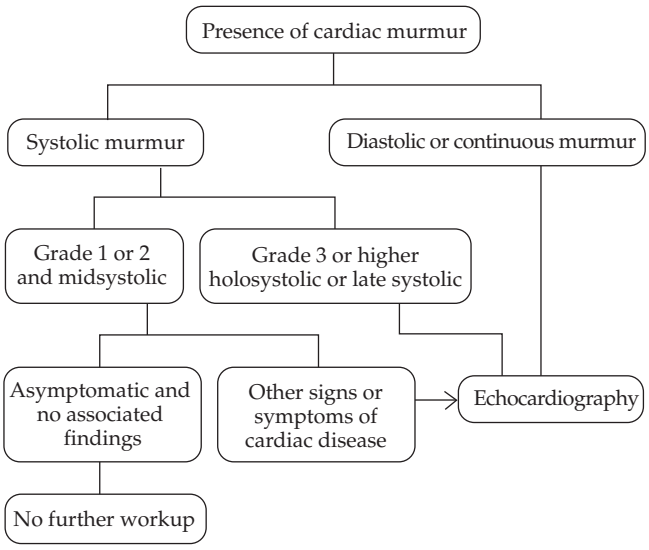

Figure 7 **Evaluation of patients with cardiac murmurs.**[45]

defect is usually well localized to the fourth left intercostal space, does not radiate significantly, and is often associated with a thrill (i.e., grade 4 or higher). Late systolic murmurs occur from mitral regurgitation that is secondary to (1) ischemia or infarction to the papillary muscles (ischemic mitral regurgitation), (2) left ventricular dilatation with functional mitral regurgitation, or (3) mitral valve prolapse. Additional findings on cardiac auscultation, such as a fixed, split second heart sound or an ejection sound, may be helpful in determining the etiology of a systolic murmur [*see Table 13*]. Electronic stethoscopes and handheld ultrasound devices have begun to supplement the bedside evaluation of cardiac murmurs.

Diastolic murmurs always indicate underlying cardiac pathology and commonly occur in either early diastole or middiastole. Early diastolic murmurs begin at the onset of diastole (i.e., with the second heart sound) and originate from regurgitant flow across the pulmonic and aortic valves. Aortic regurgitation occurs because of failure of the aortic valve leaflets to adequately coadapt during diastole and may be the result of disease processes affecting the aortic valve (e.g., endocarditis) or the aortic root (e.g., aortic dissection). Pulmonary regurgitation is most commonly seen in patients with pulmonary hypertension and is therefore associated with a loud second heart sound. Middiastolic murmurs occur from either mitral or tricuspid stenosis; the Austin Flint murmur associated with chronic aortic regurgitation or occurring in the setting of severe mitral regurgitation arises from augmented antegrade flow across the mitral valve in diastole.

In adults, continuous murmurs are usually from a previously undiagnosed patent ductus arteriosus. Occasionally, a patient with chronic aortic regurgitation may have a prominent systolic murmur in addition to the early diastolic murmur, thus simulating a continuous murmur. The systolic murmur in this case is the result of enhanced stroke volume from increased diastolic filling of the left ventricle. Whereas both conditions are associated with a widened pulse pressure and murmurs that occur during both systole and diastole, the murmur of a patent ductus arteriosus is continuous and peaks on the second heart sound; with chronic aortic regurgitation, there is a so-called silent period at the end of systole as the systolic murmur fades, before the beginning of the diastolic murmur.

Additional findings on physical examination can assist in determining the severity of the valve lesion and in excluding other conditions that result in similar murmurs. For patients with a midsystolic murmur presumed to be aortic stenosis, the carotid upstroke and splitting of the second heart sound should be carefully evaluated. A delayed carotid upstroke and single splitting of the second heart sound indicate hemodynamically severe aortic stenosis. However, physical examination has a low sensitivity for diagnosis of severe aortic stenosis, and overreliance on examination findings can lead to serious errors. The threshold for diagnostic imaging should be low in a patient with possible aortic valve stenosis. In contrast, hypertrophic cardiomyopathy results in a brisk carotid upstroke (the so-called spike-and-dome configuration) and normal splitting of the second heart sound. Severe mitral regurgitation can be identified by a holosystolic murmur associated with a third heart sound and a middiastolic murmur that results from the increased blood flow crossing antegrade across the mitral valve in diastole.

Several bedside maneuvers may also be useful in the evaluation of cardiac murmurs.[51] Right-sided murmurs (e.g., tricuspid regurgitation) increase in intensity during inspiration because of augmented right heart filling. The murmur of hypertrophic cardiomyopathy is extremely dependent on left ventricular filling, such that both the strain phase of the Valsalva maneuver and moving from squatting to the standing position augment the intensity of the murmur.

DIAGNOSTIC EVALUATION

An ECG should be obtained to evaluate for the presence of cardiac chamber enlargement and hypertrophy. Aortic stenosis imposes a pressure overload to the left ventricle, resulting in left ventricular hypertrophy by ECG in approximately 50% of patients. Hypertrophic cardiomyopathy is characterized by increased ventricular muscle mass, which is usually apparent on the ECG with extreme voltage amplitudes and small Q waves in leads I, aVL, and V4 through V6, referred to as septal Q waves. Mitral stenosis results in left atrial enlargement and occasionally right axis deviation and right ventricular hypertrophy.

A chest roentgenogram should be reviewed for chamber enlargement and the presence of calcification. Chronic aortic and mitral insufficiency cause a volume overload to the left ventricle and left atrium, respectively. Left atrial enlargement, without enlargement of the left ventricle, and mitral valve calcification suggest mitral stenosis. Calcification of the aortic valve frequently occurs with valvular aortic stenosis but is rarely apparent on the chest roentgenogram.

In the absence of cardiovascular symptoms and other physical findings, a grade 1 or grade 2 midsystolic murmur does not require additional evaluation [*see Figure 7*].[50] Midsystolic murmurs of grade 3 and higher, holosystolic murmurs, or late systolic murmurs should be further evaluated by echocardiography. All patients with a diastolic or continuous murmur should be referred for echocardiography because these murmurs always indicate underlying cardiac pathology. In addition to confirming the etiology of a cardiac murmur, echocardiography provides evaluation of left ventricular systolic and diastolic function, wall motion abnormalities (that may indicate associated CAD), and estimation of pulmonary arterial pressures. For patients with valvular, congenital, or myocardial diseases, echocardiography provides a baseline from which additional studies can be obtained and used to follow disease progression over time.

Cardiovascular Information on the Internet

There are numerous sources of cardiovascular information on the Internet. The most useful general information sites are listed [*see Sidebar* Pertinent Web Sites].

II HEART FAILURE

Shannon Winakur, m.d.
Mariell Jessup, m.d.

Definition

Heart failure is a clinical syndrome resulting from a structural or functional cardiac disorder that impairs the ability of the ventricle to fill with or eject blood to meet the needs of the body. This syndrome, which is a constellation of signs and symptoms, is primarily manifested by dyspnea, fatigue, fluid retention, and decreased exercise tolerance. Heart failure may result from disorders of the pericardium, the myocardium, the endocardium, valvular structures, or the great vessels of the heart or from rhythm disturbances. It is important to emphasize that not all patients with heart failure symptoms have similar cardiac structural abnormalities. Indeed, the major thrust of an initial evaluation of a patient with heart failure is to define the cardiac abnormalities responsible for the symptoms.

Classification

Heart failure has been classified in many ways. One useful framework involves describing the underlying cardiomyopathy, which frequently will suggest the etiology [*see Table 1 and Figure 1*].[1-4] Some examples of the World Health Organization (WHO) classification include ischemic cardiomyopathy, hypertrophic or restrictive cardiomyopathy, and idiopathic dilated cardiomyopathy. In the United States, the most common cause of heart failure is ischemic cardiomyopathy from coronary artery disease (CAD).[5,6]

Another practical approach for classification is to divide patients with heart failure into those with primarily systolic dysfunction and those with diastolic dysfunction. For the clinician, this usually means assessing the patient's left ventricular ejection fraction (LVEF), most commonly with echocardiography.[7,8] Patients with systolic heart failure typically have a low LVEF (usually less than 40% to 45%), a dilated left ventricular cavity, and a reduced cardiac output because of diminished contractility of the myocardium. In contrast, patients with diastolic heart failure have a normal LVEF and normal contractility, but there is impaired filling of the heart secondary to a variety of pathophysiologic abnormalities.[9-11]

Despite an increased understanding of the etiologies and pathophysiology of heart failure and advancements in treatment, morbidity and mortality remain unacceptably high for the majority of patients stricken with this disorder.[12,13] Most experts agree that earlier recognition of the syndrome or better identification of patients at risk for heart failure may be our best hope for the future reduction of heart failure's death toll. This is analogous to the concerted efforts to screen for cancer at its earliest stages, before the disease can defy therapy. Consequently, the committee charged with revising the American College of Cardiology/American Heart Association (ACC/AHA) Guidelines for the Evaluation and Management of Heart Failure took the bold step of developing a new classification for patients with heart failure.[14] These guidelines can be obtained from the ACC or AHA Web sites: http://www.acc.org/clinical/statements.htm and http://my.americanheart.org/portal/professional/guidelines.

The ACC/AHA classification emphasizes the evolution and progression of heart failure; it defines four stages of the disorder [*see Table 2 and Figure 2*]. Stage A identifies patients who are at high risk for developing heart failure but who have no apparent structural abnormality of the heart. This includes patients with hypertension, diabetes, or CAD; patients with a history of rheumatic fever, alcohol abuse, or exposure to cardiotoxic drugs; and patients with a family history of cardiomyopathy. Stage B denotes patients with a structural abnormality of the heart but in whom symptoms of heart failure have not yet developed. This includes patients found to have left ventricular hypertrophy or dilatation, a decreased LVEF, or valvular disease, as well as patients with prior myocardial infarction. Stage C refers to patients with a structural abnormality of the heart and symptoms of heart failure. This would include patients with dyspnea, fatigue, or fluid overload, as well as patients with a prior diagnosis of heart failure who are receiving treatment that has relieved their symptoms. Importantly, once patients have had symptoms of heart failure, they remain in stage C even if they subsequently experience clinical improvement. Stage D includes the patient with end-stage heart failure that is refractory to standard treatment. Typical patients include those who require frequent hospital admissions for heart failure, are awaiting a heart transplant, are being supported with intravenous agents or mechanical assist devices, or are receiving hospice care for end-stage heart failure.

The ACC/AHA classification is a departure from the traditional New York Heart Association (NYHA) classification, which characterizes patients by symptom severity.[15] Patients with heart failure may progress from stage A to stage D, but never the reverse. In contrast, many patients with NYHA class IV symptoms can be restored to class II with appropriate therapy. The ACC/AHA classification highlights the importance of known risk factors and structural abnormalities in the development of heart failure. Additionally, it reinforces the concept that heart failure is a progressive disease whose onset can be prevented, or its progression halted, by early identification and intervention.

Epidemiology

Heart failure is one of the major public health problems in the United States today, both in terms of the number of patients affected and health care dollars spent. Nearly five million patients have heart failure, and almost 500,000 patients are diagnosed with the disease each year. Estimated direct and indirect costs for heart failure came to $21 billion in 2001, more than 5% of that year's health care budget[16]; annual spending on drugs for heart failure treatment is about $500 million.[14] Hospitalizations for heart failure increased by 159% from 1979 to 1998,[16] and this trend will likely continue as the United States population ages.

Heart failure is primarily a disease of the elderly.[17] Approximately 6% to 10% of people older than 65 years have heart failure,[18] and roughly 80% of patients hospitalized with heart failure are older than 65 years.[19] More Medicare dollars are spent on heart failure than on any other disease, and heart failure is the most common Medicare diagnosis-related group.[5]

Table 1 Examples of Descriptive and Etiologic Classifications of Heart Failure

Classification Scheme	*Disorder or Disease Process*	*Comments*
By disorder	Dilated cardiomyopathy	Dilatation and impaired function of left ventricle or both ventricles; multiple etiologies: ischemia, valvular disease, infectious process, inflammatory process, toxins, familial/genetic cause, idiopathic
	Hypertrophic cardiomyopathy	Hypertrophy of left ventricle or both ventricles, often asymmetrical and involving the interventricular septum; often associated with mutations in sarcoplasmic proteins; associated with arrhythmias and sudden death
	Restrictive cardiomyopathy	Usually associated with normal systolic function and impaired diastolic function; can be idiopathic or associated with infiltrative diseases, such as amyloidosis, sarcoidosis, and endomyocardial fibrosis
	Arrhythmogenic right ventricular cardiomyopathy	Replacement of myocardium with fatty tissue; can involve left ventricle as well; associated with ventricular arrhythmias; may have a genetic component
By underlying disease process	Ischemic heart disease	Secondary to coronary artery disease
	Valvular disease	Caused by primary valvular disease
	Hypertension	Usually associated with left ventricular hypertrophy; can involve systolic and/or diastolic dysfunction
	Diabetes mellitus	Associated with systolic and/or diastolic dysfunction and left ventricular hypertrophy, even independent of coexisting hypertension or coronary artery disease
	Inflammatory/infectious disease	Systolic dysfunction from myocarditis; multiple infectious etiologies, both viral (e.g., coxsackievirus, echovirus, HIV) and bacterial (rheumatic fever)
	Metabolic disorders	Associated with endocrine abnormalities (e.g., hyperthyroidism, hypothyroidism), electrolyte deficiencies (potassium, magnesium), nutritional deficiencies (e.g., beriberi), and glycogen storage disease (e.g., Pompe disease, Gaucher disease)
	General systemic disease	Associated with connective tissue diseases (e.g., systemic lupus erythematosus, rheumatoid arthritis) and infiltrative diseases (e.g., sarcoidosis, amyloidosis)
	Muscular dystrophies	Includes Duchenne, Becker, and myotonic muscular dystrophies
	Neuromuscular disease	Includes Friedreich ataxia and Noonan syndrome
	Toxins	Associated with alcohol and cocaine abuse, treatment with cardiotoxic chemotherapeutic agents (e.g., anthracyclines), and radiation therapy
	Tachycardia	Associated with uncontrolled tachycardias (e.g., atrial fibrillation and other supraventricular tachycardias)
	Genetic/familial disorders	Associated with a family history of cardiomyopathy and/or sudden death; many cardiomyopathies previously designated as idiopathic may fall into this category
	Pregnancy	Manifests in peripartum period

It is important to recognize that heart failure has diverse causes and affects diverse populations. Until recently, this diversity was not reflected in the composition of heart failure trials in the United States, which typically enrolled middle-aged white men with ischemic cardiomyopathy. In fact, the heart failure population in the United States includes significant numbers of women, elderly persons, and members of racial minorities—and these patients tend to have different forms of heart failure. For example, in an estimated 20% to 50% of patients with heart failure, ventricular systolic function is preserved (i.e., the patients have diastolic heart failure), and these patients are more likely to be elderly women.[20-23]

Etiology

CAD is responsible for roughly two thirds of cases of heart failure in the United States.[24] Coronary ischemia or infarction can lead to heart failure through a variety of mechanisms: acute coronary syndromes or infarction can cause acute heart failure in an otherwise normal heart; likewise, repeated insults of ischemia or infarction can cause a chronic cardiomyopathy. Moreover, many patients with diastolic heart failure have underlying CAD.

Ventricular dysfunction can result from a multitude of nonischemic causes [*see Table 1*]. These include hypertension; diabetes; valvular disease; arrhythmias; myocardial toxins; myocarditis from a variety of infectious agents (including HIV); and hypothyroidism. Infiltrative causes of ventricular dysfunction, which are usually associated with restrictive cardiomyopathy, include amyloidosis, hemochromatosis, and sarcoidosis. Myocardial systolic dysfunction for which there is no apparent cause is labeled idiopathic cardiomyopathy. Over the past several years, there has been increased recognition that many of these so-called idiopathic dilated cardiomyopathies are familial; a number of centers are actively focusing on the identification of the genetic irregularities responsible for the abnormal phenotypes.[25]

Pathophysiology

There is no single, simple model that effectively explains the syndrome of heart failure; currently, the consensus view integrates multiple pathophysiologic models to explain the complex cascade of events leading to this clinical syndrome.[26] The different structural, functional, and biologic changes that culminate in heart failure have led to a variety of treatment

modalities to target this array of causative factors.[27,28] For example, for many years, beta blockers were contraindicated in patients with heart failure because the disorder was thought to be primarily a result of decreased myocardial contractility that would worsen with negative inotropic therapy. However, we have come to realize the central role of pathologic sympathetic activation in heart failure—the maladaptive mechanisms that lead to vasoconstriction, arrhythmias, and ventricular remodeling (see below). This model explains the therapeutic benefits of beta blockade.

The hemodynamic model of heart failure concentrated on the role of increased load on a failing ventricle; this conceptual approach led to the successful use of vasodilators and inotropes. Later, the neurohumoral model of heart failure identified the critical importance of the renin-angiotensin-aldosterone axis and the sympathetic nervous system in the progression of car-

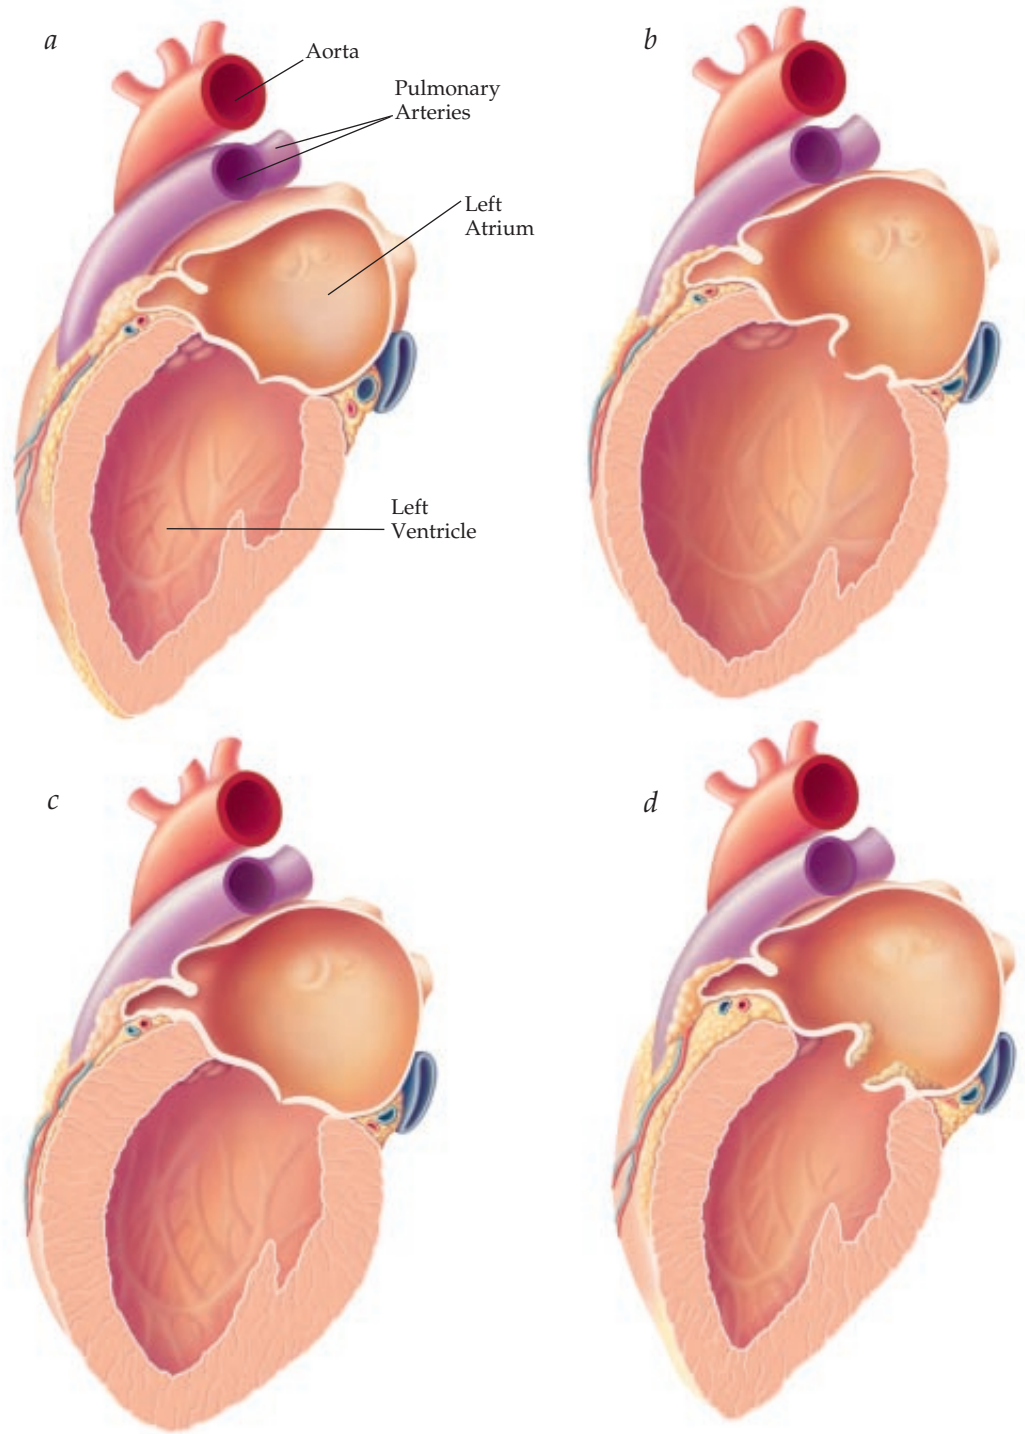

Figure 1 **The different cardiac morphologies in heart failure. The heart is viewed from the left side, with the mitral valve partially cut away; the aortic valve is visible in the upper portion of the left ventricle. Table 2 Stages of Heart Failure[14]

Stage	*Description*	*Examples*
A	Patients at high risk for heart failure because of the presence of conditions strongly associated with the development of heart failure; no identified structural or functional abnormalities of the pericardium, myocardium, or cardiac valves; no current or previous history of signs or symptoms of heart failure	Patients with systemic hypertension, coronary artery disease, diabetes mellitus, history of cardiotoxic drug therapy or alcohol abuse, history of rheumatic fever, family history of cardiomyopathy
B	Patients with structural heart disease that is strongly associated with the development of heart failure but who have no current or previous history of signs or symptoms of heart failure	Patients with left ventricular hypertrophy or fibrosis, left ventricular dilatation or hypocontractility, asymptomatic valvular heart disease, previous myocardial infarction
C	Patients who currently have or who in the past have had symptoms of heart failure associated with underlying structural heart disease	Patients with dyspnea or fatigue due to left ventricular systolic dysfunction; asymptomatic patients undergoing treatment for prior symptoms of heart failure
D	Patients with advanced structural heart disease and marked symptoms of heart failure at rest despite maximal medical therapy; need for specialized interventions	Patients who are frequently hospitalized for heart failure and cannot be safely discharged from the hospital; patients in hospital awaiting heart transplantation; patients at home receiving continuous intravenous support for symptom relief or support with a mechanical circulatory assist device; patients in a hospice setting for the management of heart failure

diac dysfunction, leading to widespread use of angiotensin-converting enzyme (ACE) inhibitors and beta blockers.

The recognition that progressive ventricular dilatation serves as a marker for disease progression has focused attention on the myocyte and on the role of the cardiac interstitium. Both medical and surgical therapies have been directed at this mechanism.

Left ventricular dysfunction begins with an injury to the myocardium. The unanswered question is why ventricular systolic dysfunction continues to worsen in the absence of recurrent insults. This pathologic process, which has been termed remodeling, is the structural response to the initial injury. Mechanical, neurohormonal, and possibly genetic factors alter ventricular size, shape, and function to decrease wall stress and compensate for the initial injury. Remodeling involves hypertrophy, loss of myocytes, and increased fibrosis and is secondary to both neurohormonal activation and other mechanical factors.[29,30] Ultimately, the changes in ventricular shape lead to a less efficient cardiac pump. Functional mitral regurgitation often occurs as the left ventricle dilates and becomes more globular, increasing volume overload. Remodeling seems to beget more remodeling.

Arrhythmias often contribute to myocardial dysfunction and are an unwelcome side effect of heart failure. Supraventricular arrhythmias, particularly atrial fibrillation, often unmask systolic or diastolic dysfunction in a previously asymptomatic patient.[31] In addition, intraventricular conduction delays and bundle branch block are often present in patients with heart failure. Abnormal ventricular conduction, particularly left bundle branch block, has significant detrimental hemodynamic effects.[32-35] In addition to contributing to worsening heart failure, ventricular arrhythmias are likely a direct cause of death in many of these patients; the rate of sudden cardiac death in persons with heart failure is six to nine times that seen in the general population.[36]

These pathophysiologic models do not easily explain diastolic heart failure.[37] In the 20% to 50% of patients who have heart failure despite normal systolic function, cardiac output is limited by abnormal filling and disordered relaxation of the ventricles, especially during exercise. Ventricular pressures are elevated for a given ventricular volume, leading to pulmonary congestion, dyspnea, and peripheral edema identical to that seen in patients with a dilated, poorly contracting heart.[9,11,38,39] CAD or ischemia frequently compounds the impairment of ventricular performance in patients with diastolic heart failure, who typically are elderly women[22] with hypertension, diabetes, and obesity.

Diagnosis

STAGE A

The first step in the diagnosis of heart failure is to identify patients who are at risk for developing the syndrome; this concept was part of the reasoning behind the new ACC/AHA staging system.[14] Patients in stage A are those with CAD, hypertension, diabetes, a history of alcohol abuse or exposure to cardiotoxic drugs (e.g., certain chemotherapeutic agents, cocaine), a history of rheumatic fever, or a family history of cardiomyopathy or sudden death. In these high-risk patients, reversible risk factors should be aggressively treated to prevent heart failure from developing.[40,41]

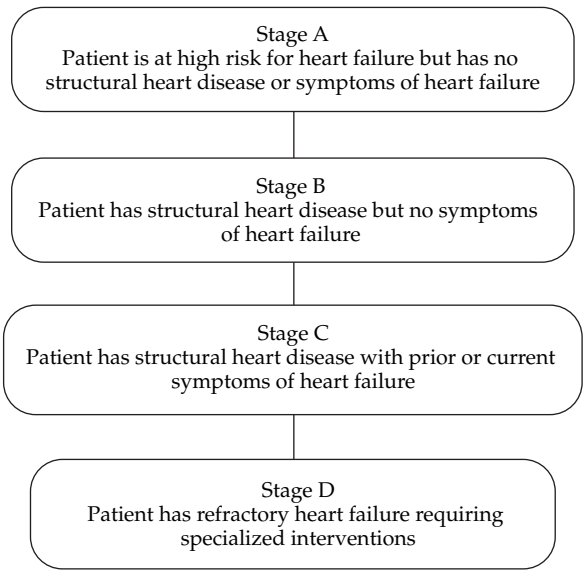

Figure 2 **The evolution of heart failure by stage.[14]**

STAGE B

Stage B patients have asymptomatic, structural heart disease. Echocardiography is easily the best diagnostic tool to uncover left ventricular hypertrophy or dilatation, valvular disease, or wall motion abnormalities indicative of previous myocardial infarction. Patients in stage B represent a significant portion of the heart failure population and constitute a key opportunity for intervention. In a community-based survey, less than half of patients with moderate or severe systolic or diastolic dysfunction, as defined by echocardiographic parameters, had recognized heart failure.[42] At this time, the ACC/AHA guidelines do not recommend routine screening echocardiography for the large number of patients at risk for the development of heart failure. Nonetheless, a class IIa indication is given for noninvasive evaluation of left ventricular function in patients with a strong family history of cardiomyopathy or in those exposed to cardiotoxic therapies.[14]

STAGES C AND D

Stages C and D fit the traditional definition of heart failure. Patients in stage C or D usually present with decreased exercise tolerance, fluid retention, or both. Initial assessment of these patients should focus on the structural abnormality leading to heart failure, as well as evaluation of its etiology. Initial testing should include a 2-D echocardiogram with Doppler flow studies, a chest x-ray, electrocardiography, and laboratory studies, including urinalysis, complete blood count, serum chemistries, liver function studies, and thyroid-stimulating hormone measurement. These tests serve primarily to exclude other potential causes of dyspnea or fatigue.[14] In patients with dyspnea, measurement of serum brain natriuretic peptide (BNP) may aid in the diagnosis; marked elevation of BNP levels suggests that the dyspnea is cardiac rather than pulmonary in origin.[43] Strong consideration should be given to excluding significant CAD, because CAD is the leading cause of left ventricular dysfunction.[24] The ACC/AHA guidelines strongly encourage that patients with heart failure be evaluated with coronary angiography rather than noninvasive testing, even if they do not have a known history of CAD; the guidelines cite the fact that noninvasive testing can often lead to inaccurate results in patients with cardiomyopathies (e.g., perfusion defects or wall motion abnormalities in patients with a nonischemic cardiomyopathy).[14] Nonetheless, some argue that there is little evidence that revascularization changes outcome or prognosis in patients with left ventricular dysfunction and that it should therefore be used only to relieve angina.[44]

Several clinical parameters are useful for the subsequent evaluation and management of heart failure. Patients' weights should be measured in the office, and patients should be taught to follow their weights at home to assess for fluid retention. Office evaluation of jugular venous pressure, hepatojugular reflux, the presence of a gallop rhythm, and peripheral edema can aid in initial diagnosis and can guide the need for diuresis. In addition, these signs of heart failure may be prognostically important.[45]

DIASTOLIC HEART FAILURE

There is no precise definition of diastolic heart failure[11]; the diagnosis is usually made by a clinician who recognizes the typical signs and symptoms of heart failure despite the finding of normal systolic function (i.e., a normal LVEF) on an echocardiogram. Doppler echocardiographic techniques can also aid in establishing the diagnosis of diastolic dysfunction.[46,47]

Table 3 Treatment of Heart Failure[14]

Stage A	Treat hypertension Encourage smoking cessation Treat lipid disorders Encourage regular exercise Discourage alcohol intake, illicit drug use Prescribe ACE inhibitors if appropriate
Stage B	All measures used for stage A ACE inhibitors if appropriate (see text) Beta blockers if appropriate
Stage C	All measures used for stage A Drugs for routine use: ACE inhibitors Beta blockers Digitalis Dietary salt restriction
Stage D	All measures used for stages A, B, and C Mechanical assist devices Heart transplantation Continuous (not intermittent) I.V. inotropic infusions for palliation Hospice care

ACE—angiotensin-converting enzyme

Treatment

Treatment for heart failure is keyed to the stage of the syndrome as defined by the recent ACC/AHA guidelines [*see Table 3*]. Treatment in all stages is aimed at preventing or palliating the remodeling process [*see* Pathophysiology, *above*]. In addition, therapy in stages C and D is intended to relieve the disabling symptoms of heart failure.

STAGE A

The goal of treatment in stage A is to prevent structural heart disease. This is achieved by controlling risk factors (e.g., hypertension, CAD, diabetes mellitus, hyperlipidemia, smoking, alcohol ingestion, and use of cardiotoxic drugs), which lowers the incidence of later cardiovascular events. For example, effective treatment of hypertension decreases left ventricular hypertrophy and cardiovascular mortality; it can also reduce the incidence of heart failure by 30% to 50%.[40,41]

Diabetes deserves particular attention because diabetes patients have a high incidence both of CAD and of heart failure in the absence of CAD; diabetes causes many detrimental biochemical and functional cardiac changes independent of ischemia.[48] ACE inhibitors and angiotensin receptor blockers (ARBs) have assumed a major role in risk reduction for diabetic patients (see below). Studies have shown that in asymptomatic high-risk patients with diabetes or vascular disease who have no history of heart failure or left ventricular dysfunction, treatment with these agents yields significant reductions in death, myocardial infarction, and stroke[49-51] or delays the first hospitalization for heart failure.[52]

STAGES B, C, AND D

The goals of therapy for patients with heart failure and a low LVEF are to decrease the progression of disease and the number of hospitalizations, improve symptoms and survival, and

Table 4 Pharmacotherapy of Heart Failure

Category	*Drug (Trade Name)*	*Dosage*		*Comment*
		Initial Daily Dose	*Maximum Daily Dose*	
Loop diuretics	Bumetanide (Bumex) Furosemide (Lasix) Torsemide (Demadex)	0.5–1 mg q.d. or b.i.d. 20–40 mg q.d. or b.i.d. 10–20 mg q.d. or b.i.d.	Up to 10 mg Up to 400 mg Up to 200 mg	Titrate to achieve dry weight; carefully monitor serum potassium and creatinine levels
ACE inhibitors	Captopril (Capoten) Enalapril (Vasotec) Fosinopril (Monopril) Lisinopril (Prinivil, Zestril) Quinapril (Accupril) Ramipril (Altace)	6.25 mg t.i.d. 2.5 mg b.i.d. 5–10 mg 2.5–5 mg 10 mg b.i.d. 1.25–2.5 mg	50 mg t.i.d. 10–20 mg b.i.d. 40 mg 20–40 mg 40 mg b.i.d. 10 mg	Carefully monitor serum potassium and creatinine levels
Beta blockers	Bisoprolol (Zebeta) Carvedilol (Coreg) Metoprolol tartrate (Lopressor) Metoprolol succinate extended release (Toprol-XL)	1.25 mg 3.125 mg b.i.d. 6.25 mg b.i.d. 12.5–25 mg	10 mg 25 mg b.i.d. (50 mg b.i.d. for patients > 85 kg) 75 mg b.i.d. 200 mg	Titrate dosage up over 2- to 4-week intervals, carefully monitoring for signs and symptoms of fluid overload
Digitalis glycosides	Digoxin (Lanoxin)	0.125–0.25 mg	0.125–0.25 mg	Narrow therapeutic window; monitor levels carefully in older patients and those with renal insufficiency
Aldosterone inhibitors	Spironolactone (Aldactone)	25 mg	50 mg	50 mg q.d. was maximum dosage used in RALES trial[78]; use carefully with concurrent ACE inhibitor or ARB; carefully monitor serum potassium and creatinine levels; use if potassium < 5.0 mmol/L, creatinine < 2.5 mg/dl
Angiotensin receptor blockers	Candesartan (Atacand) Irbesartan (Avapro) Losartan (Cozaar) Valsartan (Diovan)	8 mg 75 mg 25 mg 80 mg	32 mg 300 mg 100 mg 320 mg	Use if patients have cough or angioedema on ACE inhibitor

ACE—angiotensin-converting enzyme ARB—angiotensin receptor blocker RALES—Randomized Aldosterone Evaluation Study

minimize risk factors. Simple interventions can help patients control their disease. For example, basic habits of moderate sodium restriction, weight monitoring, and adherence to medication schedules serve to prevent hospitalizations for rapid fluid overload. Other frequent causes of decompensation in heart failure include anemia, arrhythmias (especially atrial fibrillation), noncompliance with medications and diet, or the use of nonsteroidal anti-inflammatory drugs (NSAIDs).[52-55]

Medical Therapy

Pharmacologic treatment of heart failure routinely includes diuretics, angiotensin antagonists, beta blockers, and digoxin; spironolactone or inotropes may be beneficial in some cases [*see Table 4*].

Diuretics In symptomatic patients in stage C and stage D, diuretics are often the first drugs prescribed to decrease fluid overload and congestive symptoms. Loop diuretics are most often given to these patients, either as maintenance therapy or on an as-needed basis. Loop diuretics can be combined with thiazides to optimize diuresis.[56,57]

ACE inhibitors ACE inhibitors are recommended for all patients in stages B, C, and D. By decreasing the conversion of angiotensin I to angiotensin II, ACE inhibitors minimize the multiple pathophysiologic effects of angiotensin II, such as vasoconstriction and fibrosis. ACE inhibitors (but not ARBs) also decrease the degradation of bradykinin, a substance that causes vasodilation and natriuresis. In patients with heart failure, ACE inhibitors have been shown to improve survival and cardiac performance, to decrease symptoms and hospitalizations, and to decrease or slow the remodeling process.[58-60]

Currently, it is not clear whether all ACE inhibitors are equally effective in all forms of heart failure. There are few data from controlled trials, for example, about the efficacy of ACE inhibitors in diastolic heart failure. Moreover, although several guidelines have emphasized the need to maximize the dose of ACE inhibitor to target levels (rather than using blood pressure alone to guide dose titration), current recommendations underscore the need to add beta blockers to the regimen of patients in stage C early in the course of treatment, even if target ACE inhibitor doses have not been achieved.

Angiotensin receptor blockers What is the role of ARBs in heart failure? These agents block the effects of angiotensin II at the angiotensin II type 1 receptor site. ACC/AHA guidelines recommend the use of ARBs only in patients who cannot tolerate ACE inhibitors because of cough or angioedema[14]; the guidelines stress that ARBs are comparable to ACE inhibitors but are not superior.[61-63] Since publication of the guidelines,

however, several key trials have reported successful intervention with ARBs in stage B and C patients.[64,65] The role of ARBs in patients already on beta blockers, with or without an ACE inhibitor, remains to be elucidated. Symptomatic patients who cannot tolerate ACE inhibitors or ARBs, usually because of renal insufficiency, may benefit from a combination of hydralazine and isosorbide dinitrate for afterload reduction.[66]

Beta blockers Although it was once taught that beta blockers were contraindicated in heart failure secondary to systolic dysfunction, multiple studies have now shown an impressive effect of these drugs on many aspects of heart failure and at all stages of the syndrome. The primary action of these agents is to counteract the harmful effects of the increased sympathetic nervous system activity in heart failure. Beta blockers improve survival, ejection fraction, and quality of life; they also decrease morbidity, hospitalizations, sudden death, and the maladaptive effects of remodeling.[67,68] Long-term placebo-controlled trials have shown improvement in systolic function and reversal of remodeling after 3 to 4 months of treatment with beta blockers.[69-71] A recent analysis showed that even in the sickest of heart failure patients, beta-blocker therapy was well tolerated and led to a decrease in mortality and hospitalizations as early as 14 to 21 days after initiation of therapy.[72] However, clinicians should be extremely cautious about starting beta blockers in patients with significant reactive airway disease, in diabetic patients with frequent episodes of hypoglycemia, or in patients with bradyarrhythmias or heart block who do not have a pacemaker implanted.

In the United States, two beta blockers are specifically approved for treatment of heart failure: carvedilol and long-acting metoprolol. Beta blockers should be started at the lowest possible dose and titrated up slowly at 2- to 4-week intervals. Patients should be closely monitored for worsening of symptoms or fluid retention, which can sometimes occur early in therapy with these agents. If patients do have exacerbations during initiation of beta blockade, diuretic therapy can be increased, and titration of the beta blocker can proceed more slowly.

Digoxin Digoxin has long been a mainstay in the treatment of symptomatic patients with left ventricular dysfunction, despite a lack of data from clinical trials showing benefit. A large randomized study demonstrated that digoxin was successful in decreasing hospitalization for heart failure—an important clinical end point—but did not decrease mortality.[73] Recent post hoc analysis of data from this trial showed that in the patients randomized to receive digoxin therapy, mortality may have been higher in women than in men.[74] It is hypothesized that the therapeutic window for digoxin may be different in men and women, with women perhaps needing a lower dose of the drug.[75] Indeed, data suggest that digoxin improves morbidity as effectively at low serum concentrations (< 0.09 ng/ml) as at higher levels, and with less toxicity.[76] Clinicians should carefully monitor all patients for signs and symptoms of digoxin toxicity, especially those patients who are elderly or have renal dysfunction. Physicians and patients should also keep in mind that digoxin interacts with numerous other drugs.

Spironolactone Another relatively old drug with new data to support its use in heart failure is the aldosterone antagonist spironolactone. Because of the activation of the renin-angiotensin-aldosterone axis, which is incompletely suppressed by ACE inhibitors, patients with heart failure have increased circulating levels of aldosterone. This leads to sodium retention and potassium loss. Aldosterone also works locally within the myocardium, contributing to hypertrophy and fibrosis in the failing heart.[77] A large randomized trial has shown that the addition of low-dose spironolactone (25 mg daily) to standard treatment reduces morbidity and mortality in patients with NYHA class III and IV heart failure (stage C and D patients).[78]

Intravenous inotropes Patients with refractory heart failure (stage D patients) often require intermittent intravenous inotropic therapy to aid in diuresis and to improve symptoms. No survival benefit has been demonstrated with inotropic treatment. These agents have received a class IIb indication in the ACC/AHA guidelines[14]—that is, they are regarded as palliative.

DIASTOLIC HEART FAILURE

Despite the large number of patients with primarily diastolic heart failure, few clinical trials have addressed the management of these cases. Physiologic principles used to guide treatment in these patients include control of blood pressure, heart rate, myocardial ischemia, and blood volume.[14]

REVASCULARIZATION AND SURGICAL THERAPY

Patients in all stages of heart failure must be evaluated for CAD. Angioplasty and surgical revascularization improve ischemic symptoms and can lead to improved ejection fraction and decreased incidence of sudden death.[79]

Clinical trials to investigate the role of surgical interventions in halting or reversing the remodeling process are now under way. Such interventions include mitral valve repair or replacement, mechanical devices to reduce wall stress, and surgical excision of infarcted tissue.[80-83]

Cardiac transplantation remains the only definitive treatment for stage D patients, but it is available only to roughly 2,500 patients a year in the United States.[84] Left ventricular assist devices are available to support patients waiting for heart transplant. There is growing evidence supporting the use of these devices as destination therapy for stage D patients, many of whom are not eligible for cardiac transplantation.[85]

IMPLANTED DEVICES

Biventricular Pacing Systems

Many heart failure patients have intraventricular conduction delays that may contribute to altered myocardial contractility or dyssynchrony. Biventricular pacing is a novel therapy for patients with left ventricular systolic dysfunction, particularly those with a left bundle branch block. The goal of this therapy is to restore the usual pattern of electrical activation of the left ventricle and thereby restore ventricular synchrony. Pacing leads are placed in the right atrium and the right ventricle and into a cardiac vein in the lateral wall of the left ventricle via the coronary sinus. There is evidence that with restored ventricular synchrony from a biventricular pacing system, the remodeling process is halted and reversed. Trials have shown that implantation of a biventricular pacer results in decreased ventricular size and volumes, improved ventricular function, and less mitral regurgitation. This has led to improved exercise tolerance, decreased hospitalizations, and improved quality of life.[86-88] Although individual randomized trials have not shown a mortality benefit for biventricular pacing, a recent meta-analysis of four of the largest trials to date showed a 51% decrease in death

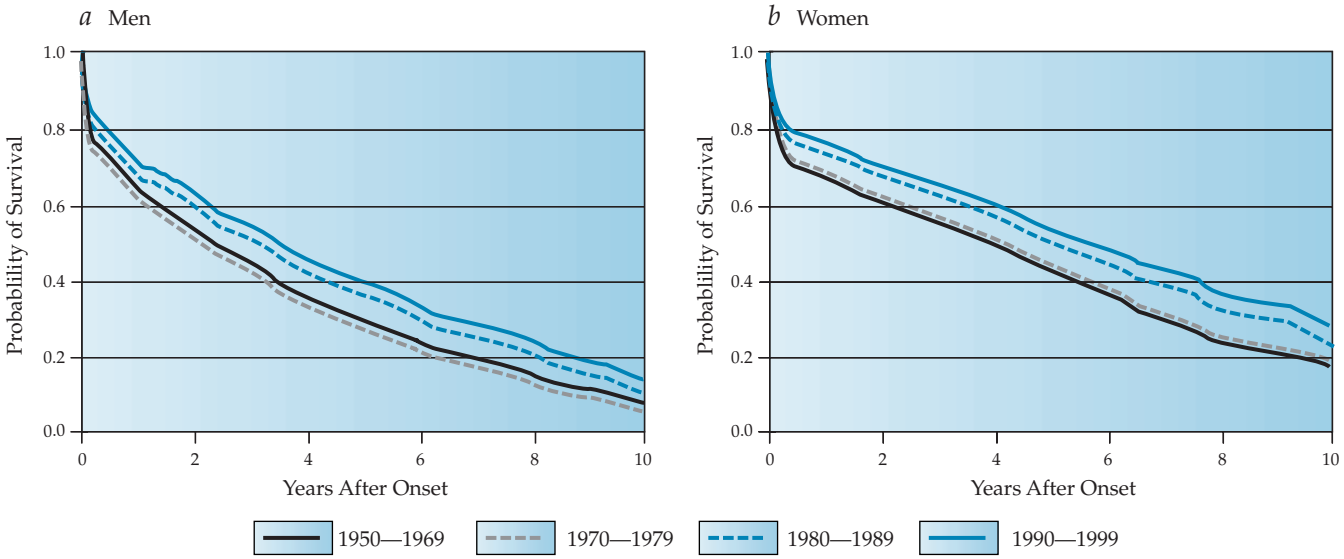

Figure 3 **Data from the Framingham Heart Study indicate a steady upward trend since the 1950s in age-adjusted survival after the onset of heart failure.[96] Estimates shown are for patients 65 to 74 years of age.**

from progressive heart failure.[89] In addition, a large clinical trial of biventricular pacing in patients with heart failure was stopped early because resynchronization therapy was found to confer a statistically significant benefit regarding the combined end point of mortality and hospitalization.[90]

Cardioverter-Defibrillators

The use of implantable cardioverter-defibrillators (ICDs) for the primary prevention of sudden death in patients with left ventricular dysfunction has grown enormously in recent years. There is increasing evidence that ICD placement reduces mortality in patients with ischemic cardiomyopathy, regardless of whether they have nonsustained ventricular arrhythmias.[91] The role of these devices in patients with heart failure of a nonischemic cause has yet to be elucidated and is the subject of several ongoing trials.

Prognosis

Despite many advances in the management of heart failure, this disorder remains life-threatening. Symptomatic heart failure continues to confer a worse prognosis than the majority of cancers in the United States, with 1-year mortality averaging 45%.[12,13] Nonetheless, it is difficult to discuss the prognosis of heart failure as a whole, because an individual patient's likelihood of survival is related to the cause of the heart failure, as well as multiple other clinical factors. For example, given the same severity of heart failure symptoms, an 85-year-old woman with ischemic cardiomyopathy would have a lower likelihood of survival than a 45-year-old man with idiopathic cardiomyopathy. One study of 1,230 patients with cardiomyopathy found that survival was significantly worse in patients with cardiomyopathy from ischemia, infiltrative disease, cardiotoxic chemotherapy, HIV infection, or connective tissue disease than in patients with idiopathic cardiomyopathy.[92]

There are conflicting data about the prognosis of diastolic heart failure. However, recent studies have shown that mortality in these cases may be as high as in systolic heart failure, and hospitalization rates are equal.[42,93]

It is also important for clinicians to remember that a low LVEF is not universally predictive of poor outcome. In patients referred for transplantation, survival has correlated more closely with other variables—notably, peak exercise oxygen consumption.[94] One prospectively validated model for predicting survival in patients with severe heart failure incorporates LVEF with six other clinical factors: presence of coronary disease, resting heart rate, mean arterial blood pressure, presence of intraventricular conduction delays, serum sodium concentration, and peak exercise oxygen consumption.[95] These tools can be used to stratify patients according to risk and to make the most appropriate use of modern therapies and treatment modalities.

How can we improve the prognosis of patients with heart failure? A recent report from the Framingham Heart Study has shown promising evidence of increasing survival after the diagnosis of heart failure [*see Figure 3*].[96] To further this trend, we must work toward widespread implementation of the therapies known to decrease morbidity and mortality in heart failure. We must also investigate more completely the impact of medical therapy on the survival of patients with diastolic heart failure. There should be continued efforts to increase the number of traditionally underrepresented patients (e.g., women and minorities) enrolled in heart failure trials. Finally, in keeping with the emphasis of the ACC/AHA guidelines, we must concentrate on identifying and treating those patients at greatest risk for heart failure to prevent it from occurring.

III HYPERTENSION

Gary L. Schwartz, m.d.
Sheldon G. Sheps, m.d.

Hypertension is the most common chronic disorder in the United States, affecting 29% of the adult population.[1] It is the most common reason adults visit the doctor's office. In the year 2000, hypertension accounted for more than 1 million office visits to health care providers. The prevalence increases with age: for a normotensive middle-aged person in the United States, the lifetime risk of developing hypertension approaches 90%.[2] With the increasing age of the population in most developed and developing societies, it seems safe to assume that hypertension will become steadily more widespread in the coming years.

Hypertension is a major risk factor for stroke, myocardial infarction, heart failure, chronic kidney disease, progressive atherosclerosis, and dementia.[3-5] The treatment of hypertension is highly effective in reducing cardiovascular (CV) morbidity and mortality.[6,7] However, despite widespread public and professional education regarding the risks of hypertension and the benefits of treatment and despite the ready availability of effective therapies, only 58% of adults with hypertension are receiving treatment, and in only 31% is hypertension controlled.[1,8]

Improving control rates for hypertension depends on setting appropriate, patient-specific, evidence-based therapeutic goals, understanding and using available treatment options in an efficient and cost-effective manner, involving the patient in goal setting and the care process in an empathetic manner, and employing timely follow-up to monitor and adjust therapy as necessary. It is important to recognize that multiple classes of drugs are often needed for control; that patient education, communication, and involvement in the process is vital to long-term compliance; and that systematic approaches to therapy are required to achieve and maintain control over time.

Definition

Blood pressure (BP) is a quantitative trait that is continuously distributed in the population. Essential hypertension represents the upper end of the distribution of this trait and is defined by the BP level associated with a threshold value of increased CV risk. Any definition of hypertension is arbitrary because the risk of CV disease related to BP level increases steadily across the spectrum of BP values. Based on a meta-analysis of studies relating BP level to vascular mortality, optimum BP is defined as less than 115/75 mm Hg.[9] According to the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7), normal BP (the level associated with minimal risk) for adults 18 years of age or older is a systolic BP of less than 120 mm Hg and a diastolic BP of less than 80 mm Hg [*see Table 1*].[8] Blood pressures ranging from 120 to 139 mm Hg systolic or 80 to 89 mm Hg diastolic are considered prehypertensive. Patients with BP in this range are at increased risk for the development of target organ injury and for progression to definite hypertension over time.[9,10] Therefore, these patients should have annual BP checks and be educated in strategies to lower BP and CV risk and to prevent the development of hypertension [*see* Prevention of Hypertension, *below*]. For patients with diabetes or renal disease, BP in the prehypertensive range poses a significantly higher risk than for healthy persons, and a lower threshold for intervention is indicated for these patients: above 130 mm Hg systolic or 80 mm Hg diastolic.

For the general population, hypertension is defined as a systolic BP of 140 mm Hg or higher or a diastolic BP of 90 mm Hg or higher. Hypertension is further divided into two stages, based on the highest level of either the systolic or diastolic BP. Prospective drug intervention trials have demonstrated the benefit of treatment for patients with a diastolic BP of 90 mm Hg or higher. Isolated systolic hypertension (ISH), which occurs mainly in persons older than 55 years, is defined as a systolic BP of 140 mm Hg or higher and a diastolic BP of less than 90 mm Hg. ISH is the most common hypertension subtype in older adults, who are the most rapidly growing segment of the population.[11] Epidemiologic data clearly demonstrate elevated and graded risk associated with systolic BP higher than 115 mm Hg.[9] However, those drug intervention trials that showed a benefit enrolled only subjects whose systolic BP was 160 mm Hg or higher[7]; the benefits of drug intervention for patients with ISH whose pretreatment systolic BP is below 160 mm Hg is inferred.

Epidemiology

Currently, it is estimated that 58 million adults in the United States have hypertension or are taking antihypertensive medications.[1] In addition to definitive hypertension, an additional 45 million adults in the United States have prehypertension.

In developed societies, BP increases with age. Diastolic BP plateaus in the fifth decade and may decline thereafter, but systolic BP continues to rise through the seventh decade. In persons younger than 50 years, diastolic BP level is the major predictor of CV risk, whereas systolic BP is the major predictor in those older than 60 years.[12] Individual risk is related to the level and duration of BP, as well as to the presence of other CV risk factors and of injury to so-called target organs—brain, heart, kidneys, peripheral arteries, and retina.[3]

The relationship between BP and CV morbidity and mortality begins in patients whose BP is higher than optimal levels (115/75 mm Hg) and is strong, continuous, graded, consistent, and independent. The relationship between BP and CV risk has largely been determined in middle-aged and older people, but above-normal BP in young adulthood is also related to increased long-term CV and all-cause mortality.[13] In young adult-

Table 1 Classification of Blood Pressure for Adults 18 Years of Age and Older[8]

Category	*Blood Pressure Level (mm Hg)*
Normal	Systolic < 120 and diastolic < 80
Prehypertension	Systolic 120–139 or diastolic 80–89
Hypertension	
Stage 1	Systolic 140–159 or diastolic 90–99
Stage 2	Systolic ≥ 160 or diastolic ≥ 100

Note: These categories apply to patients who are not taking antihypertensive drugs and are not acutely ill. When systolic and diastolic blood pressures fall into different categories, the higher category should be selected to classify the person's blood pressure status.

hood and early middle age, hypertension is more common in men than in women, but the opposite is the case in persons 60 years of age and older.[1] At all ages, hypertension is more common in African Americans than in whites; in all ethnic and racial groups, it is more common in the economically disadvantaged. At any given level of BP, CV risk is greater in men than women, in African Americans than whites or members of other racial or ethnic groups, in older persons than younger ones, and in patients with target organ disease and longer duration of hypertension.[3]

Etiology and Genetics

Essential hypertension develops as the consequence of a complex interplay over time between susceptibility genes and environmental factors. Numerous family and population studies suggest a significant role for genetic factors. Hypertension in persons younger than 55 years is four times more common in individuals with a family history of hypertension than in those with no family history of it. Estimates of the genetic contribution to BP variation range from 30% to 50%. However, the genetic contribution to essential hypertension is complex. Multiple genes are likely involved, and although the effects of some genes may affect BP independently, most genetic effects involve both gene-gene interaction (epistasis) and gene-environment interaction. Important interactions between the effects of specific genes and environments may occur at a particular time (perinatal life) or over the lifetime of an individual. Thus, sorting out the genetic contribution to essential hypertension is complex and challenging.

Some insight into the genetic contribution to essential hypertension has been gained from the identification of rare monogenic forms of hypertension.[14] Interestingly, most of these forms of hypertension arise from gene mutations that result in impairment of renal sodium excretion; renal impairment occurs either through the disruption of the renal sodium transport systems or through interference with mineralocorticoid receptor activity. Additional insight has come from studies that employ a candidate gene approach, in which genes are chosen on the basis of animal studies or previous knowledge of genes that encode proteins involved in BP regulatory pathways. Polymorphisms of candidate genes have been studied in association and linkage studies to assess their potential role in essential hypertension in humans. Most extensively studied have been genes encoding components of the renin-angiotensin-aldosterone system. Results of this line of investigation have implicated polymorphisms of the angiotensinogen *(AGT)* gene and the angiotensin-converting enzyme *(ACE)* gene in human essential hypertension.[15,16] The M235T variant of the *AGT* gene has been associated with higher circulating levels of AGT and is found more often in hypertensive than in normotensive persons.[16] An insertion/deletion polymorphism of the *ACE* gene has been associated with differences in ACE activity, with higher levels associated with the deletion allele.[17] The deletion allele has also been associated with several cardiovascular phenotypes, including higher BP levels and greater risk of target organ complications in hypertensive individuals.[15,18] In large samples, the observed associations have frequently been gender specific, suggesting interaction between the effects of the insertion/deletion polymorphism and gender.[15,19]

Variants of other genes have been implicated in essential hypertension. Adducin is a membrane skeleton protein consisting of α and β subunits that may influence ion transport across membranes. A variant of the α-adducin gene (Gly 460 Trp) has been associated with essential hypertension in case-control studies and may play a role in salt-sensitive hypertension.[20] Linkage studies have also found evidence indicating a role for variants of adrenergic and dopamine receptor genes.[21]

Experts expect that the number of gene polymorphisms associated with essential hypertension will continue to grow. However, because of the limitations of candidate gene studies, as well as linkage and association studies, there is a need for new approaches that can assess the effects of multiple genes and environments. These types of studies will be difficult to perform but will be necessary if we are to someday be able to determine the specific genotypes and environments present in the majority of persons destined to develop hypertension.[22]

Regarding the role of genetics in hypertension, it is important to note that hypertension is virtually nonexistent in primitive peoples who follow a preagricultural hunter-gatherer lifestyle. This lifestyle involves significant daily physical activity and a diet rich in potassium and low in fat and sodium. Obesity is uncommon. Dietary patterns involve periods of feasting interspersed with long periods with minimal food. Given that the human gene pool has changed little over the past 30,000 years, some suggest that hypertension is the consequence of a human genome selected for a hunter-gatherer lifestyle but now interacting with a modern one. In contrast to primitive societies, modern societies are characterized by a low level of physical activity and constant availability of abundant food that is rich in sodium and fat and low in potassium; the result is an increase in body weight with aging and a high incidence of obesity. Genetic adaptation to the hunter-gatherer lifestyle provided survival advantages in that environment but may now be contributing to many modern diseases such as obesity and hypertension.

Pathophysiology and Pathogenesis

Simplistically, BP is the product of cardiac output and peripheral vascular resistance (BP = cardiac output × peripheral vascular resistance). Thus, variation in extracellular fluid volume, the contractile state of the heart, and vascular tone determine variation in BP level. The hemodynamic hallmark of established essential hypertension is elevated peripheral vascular resistance. An increase in cardiac output is occasionally noted early but is not a persistent finding. Hypertension can be viewed as the final outcome of a complex interaction between genetic and environmental factors that act on intermediate physiologic systems involved in BP regulation (i.e., those that influence fluid volume, heart contractility, and vascular tone).

A central hypothesis for the pathogenesis of essential hypertension involves an interaction between the high dietary sodium intake typical of industrial society and defects in renal sodium excretion. Evidence of a role for dietary sodium comes from animal studies and from epidemiologic and experimental studies in humans.[23,24] Guyton hypothesized that hypertension develops when the kidneys require a higher BP to maintain extracellular volume within normal limits.[25] This would occur in persons with impaired renal sodium excretion. Studies support the possibility of an inherited defect in renal sodium excretion as the basis of human essential hypertension. Most monogenic forms of hypertension discovered so far involve mutations that impair renal sodium excretion by increasing mineralocorticoid activity or by influencing tubular sodium transport systems.[14]

Moreover, renal sodium excretion can be influenced by variation in activity of both the renin-angiotensin-aldosterone system and the sympathetic nervous system. Angiotensin II enhances renal tubular sodium reabsorption directly and indirectly through stimulation of aldosterone release and the sympathetic nervous system. Additional mechanisms that may explain defective renal sodium excretion include an inherited reduction in the number of nephrons, as well as the presence of a subpopulation of so-called ischemic nephrons, which occur as a result of increased afferent renal artery tone and that lead to increased renin activity.[26,27] Extracellular volume expansion could lead to chronic increases in vascular resistance through mechanisms of organ autoregulation of blood flow (i.e., variation in the tone of vessels that occurs so as to regulate organ blood flow to meet metabolic needs). Some studies have suggested that volume expansion stimulates the release of a sodium-potassium-adenosine triphosphatase (Na^+,K^+-ATPase) inhibitor (i.e., an ouabain-like substance) that facilitates renal sodium excretion but increases vascular tone by interfering with sodium-calcium exchange in vascular smooth muscle cells.[28]

Other evidence suggests that increased sympathetic nervous system activity has a role in causing hypertension in some persons.[29] These cases could be the result of a genetic tendency toward increased sympathetic activity interacting with repetitive psychogenic stress, obesity, or high sodium intake. Hypertension could also arise or be sustained by defects in baroreceptor function.[30]

Weight gain and obesity (especially abdominal fat accumulation) are associated with an increased risk of hypertension. A number of humoral factors may be responsible, including increased activity of the sympathetic nervous system and the renin-angiotensin system.[31] In addition, obesity is associated with insulin resistance and hyperinsulinemia. Hyperinsulinemia may directly stimulate sympathetic activity, in addition to promoting vascular hypertrophy (increased vascular tone) and renal sodium retention.[32] In addition, leptin levels are increased in obese individuals. Leptin may also increase BP by stimulation of the sympathetic nervous system.[33]

More general abnormalities of cell membranes or multiple ion transport systems acting across cell membranes could contribute to the development of hypertension. In addition to impairing sodium excretion in the kidneys, these defects could act in a variety of ways to influence vascular structure and tone.[34] Vascular tone could also be influenced by variation in vascular endothelial function through an imbalance in the production of substances that cause vasodilation (e.g., nitric oxide) and those that cause vasoconstriction (e.g., endothelin).[35]

Table 2 Proper Blood Pressure Measurement Technique

Patient should refrain from smoking or caffeine ingestion for 30 min before measurement
Patient should be at rest, seated in a chair with back and feet supported, for at least 5 min before measurement is taken
Patient should not speak while blood pressure is being measured
Patient's arm should be bare, with no tight clothing constricting the upper arm
Select a proper cuff size for the arm: bladder should encircle at least 80% of arm (many adults will require a large cuff)
Position patient's arm so cuff is at the level of the heart
Place stethoscope bell over brachial artery
Inflate cuff to occlude the pulse
Deflate at rate of 2–3 mm/sec
Measure systolic (first sound) and diastolic (last sound) to nearest 2 mm Hg
Repeat measurement after 2 min
Under special circumstances, measure blood pressure with patient in standing position

Diagnosis

The diagnosis of hypertension relies on multiple office measurements of BP performed in a rigorous manner with a validated and well-maintained mercury or aneroid sphygmomanometer and a cuff of appropriate size. Several expert groups have published guidelines for proper BP measurement; unfortunately, these guidelines are rarely complied with in most clinics [*see Table 2*].[36] The diagnosis of hypertension requires findings of an elevated average BP on at least two office visits, with at least two standardized measures of BP made at each visit. For most patients, confirmation can occur over a 1- to 2-month period. If an initial BP is severely elevated, confirmation should occur over a shorter period of time. Self-measurements of BP outside the office setting can be used to distinguish sustained hypertension from isolated clinic hypertension; self-measurement has the further advantages of involving patients in the process of care (which often improves compliance) and aiding in the assessment of response to therapy. On average, home readings are lower than office readings; therefore, values above 135 mm Hg systolic or 85 mm Hg diastolic are considered elevated.[8] BP devices for home use (aneroid or oscillometric) need to be validated twice yearly by the health care provider, and patients need to be educated in the technique of proper BP measurement [*see Table 2*].

AMBULATORY BP MONITORING

Cross-sectional studies show that BP averages from ambulatory BP monitoring (ABPM) correlate better with the presence of target organ injury (especially left ventricular hypertrophy [LVH]) than office BP measurements.[37] Also, prospective studies and population-based observational studies have shown that average BP derived from ABMP predicts additional risk for CV events after adjustment for clinic or office BP.[38] This is true for both untreated as well as treated patients.[39] ABPM is the best method to establish the presence of isolated clinic hypertension (so-called white-coat hypertension), which is defined as an elevation in BP that occurs only in the clinic setting, with normal BP in all other settings, in the absence of evidence of target organ injury.[8] Screening for white-coat hypertension is currently a reimbursable indication for ABPM by Medicare.[40] The possibility of a white-coat effect should be considered in selected patients with resistant hypertension, in elderly patients with significant office systolic hypertension, and in some pregnant women. Other uses for ABPM include assessment of hypotensive symptoms, episodic hypertension, and suspected autonomic dysfunction in patients with postural hypotension.[8] ABPM is also useful in the evaluation of the occasional patient with hypertensive target organ injury (LVH, stroke) whose office BP is normal. In addition, it is now recognized that some patients have so-called white-coat normotension, or masked hypertension; for these patients, BP is normal in the office but is elevated outside the office setting.[41] This important group is often missed in routine practice.

Table 3 Classic Features of Essential Hypertension

- Onset of hypertension in the fourth or fifth decade of life
- Family history of hypertension
- BP < 180/< 110 mm Hg at diagnosis
- Asymptomatic
- History, physical examination, and routine laboratory studies are normal (no target-organ damage at time of diagnosis)
- BP control achieved with lifestyle changes and one or two drugs
- BP control is maintained once achieved

INITIAL EVALUATION

The initial evaluation of patients with elevated BP has four major objectives: (1) to identify lifestyle factors contributing to elevated BP and higher CV disease risk, (2) to identify associated modifiable CV risk factors, (3) to assess for target organ injury or clinical CV disease, and (4) to identify any secondary causes of hypertension.[8] The second and third objectives are important for risk stratification, which defines the BP threshold for initiation of drug therapy and establishes the BP goal to achieve with therapy.[42,43]

The overall frequency of secondary hypertension is 5% to 10% in primary care practices. The classic picture of essential hypertension should be compared to the individual patient's presentation [*see Table 3*]. Secondary hypertension should be suspected on finding features that are not consistent with essential hypertension. Such features include age at onset younger than 30 or older than 50 years; BP higher than 180/110 mm Hg at diagnosis; significant target organ injury at diagnosis; hemorrhages and exudates on fundus examination; renal insufficiency; LVH; poor response to appropriate three-drug therapy; and accelerated or malignant hypertension. Specific features that suggest secondary causes of hypertension vary with the individual condition [*see Table 4*].

HISTORY

The clinician should inquire about a family history of hypertension, premature CV disease, and disorders that would increase the possibility of secondary hypertension (e.g., polycystic kidney disease or other renal disease, medullary cancer of the thyroid, hyperparathyroidism, or pheochromocytoma). The patient should be questioned about lifestyle habits that influence BP (e.g., level of physical activity, sodium intake, use of caffeine and alcohol, history of weight gain), and CV risk (tobacco use); in addition, the patient should be asked about symptoms suggesting target organ disease (angina, symptoms of heart failure, transient cerebral ischemia, or renal disease) or secondary hypertension (spells suggesting pheochromocytoma). A known history of dyslipidemia, diabetes, or cerebrovascular, heart, or renal disease also should be documented. In addition, a thorough medication review (including prescription and over-the-counter drugs, herbs and herbal compounds, and street drugs) is important to identify drugs that can raise BP or interfere with the antihypertensive effect of planned drug therapy [*see Table 5*].[44] In patients with a history of hypertension, the duration of hypertension, the previous BP levels, and the specific drugs used for treatment, together with the efficacy of those drugs and the reasons for discontinuation, should be ascertained. Other comorbid conditions and their treatments need to be documented, because they may influence antihypertensive drug selection.

PHYSICAL EXAMINATION

The examination should include at least two standardized measurements of BP with the subject in the seated position. Initially, BP should also be measured in the opposite arm (to identify arterial narrowing, which can cause an inaccurately low reading in one arm) and in the standing position, especially in diabetic patients and older patients (to identify orthostatic declines). Height and weight should be determined, to permit calculation of body mass index, and waist circumference (a potential CV risk factor) should be recorded.

The physical examination is directed toward identifying target organ injury or features suggesting secondary hypertension [*see Table 4*]. Retinal examination should be performed, primarily to identify retinal changes of diabetes or severe hypertension (i.e., hemorrhages, exudates, papilledema). Arteriolar narrowing, focal constrictions, and arteriovenous nicking on retinal examination are more closely associated with atherosclerosis and are of limited value for predicting the severity of hypertension or assessing overall CV risk.[43,45]

Table 4 Features Suggesting Specific Causes of Secondary Hypertension

Condition	*Features*
Primary aldosteronism	Unprovoked hypokalemia
Pheochromocytoma	Labile BP with episodic headache, sweats, tachycardia, pallor, abdominal pain, weight loss Neurofibromas, café-au-lait spots Orofacial neuromas (multiple endocrine neoplasia type II) Retinal angiomas (von Hippel–Lindau syndrome)
Renovascular hypertension	Abdominal or flank bruits Peripheral bruits/diminished pulses from atherosclerosis Elevated serum creatinine level, hypokalemia Flash pulmonary edema Hypertension in a patient younger than 30 yr (fibromuscular dysplasia) Sudden onset or worsening of systolic-diastolic hypertension after age 50 yr (atheromatous disease) Accelerated-malignant hypertension Treatment-resistant hypertension Unexplained subacute decline in renal function
Cushing syndrome	Truncal obesity, proximal muscle weakness and atrophy Stria, acne, thin skin, bruises, hyperpigmentation Elevated plasma glucose, hypokalemia
Coarctation of the aorta	Headaches Cold feet, claudication Delay of femoral pulse compared to radial pulse Weak or absent femoral pulses High BP in arms/low BP in legs Murmurs front/back chest
Polycystic renal disease	Abdominal/flank masses, family history of renal disease

Table 5 Drugs That Can Increase Blood Pressure or Interfere with Antihypertensive Drug Efficacy

Drug	*Mechanism*
Oral contraceptives	Sodium retention, increase level of angiotensinogen, facilitate action of catecholamines
Alcohol (moderate or heavy intake)	Activate sympathetic nervous system, increase cortisol secretion and intracellular calcium levels
Sympathomimetics and amphetamine-like substances (over-the-counter cold or allergy formulas, diet pills)	Increase peripheral vascular resistance
Nonsteroidal anti-inflammatory drugs	Sodium retention, renal vasoconstriction; interfere with efficacy of all antihypertensive drugs, especially diuretics, beta blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers
Corticosteroids	Iatrogenic Cushing disease
Tricyclic antidepressants	Inhibit action of centrally acting sympatholytics (clonidine, guanfacine)
Serotoninergics (antidepressants)	Systemic vasoconstriction (increase peripheral vascular resistance)
Cyclosporine	Renal and systemic vasoconstriction (sodium retention, increased peripheral vascular resistance)
Erythropoietin	Systemic vasoconstriction (increased peripheral vascular resistance)
Monoamine oxidase inhibitors + tyramine-containing foods (aged cheeses, red wine)	Prevents degradation of norepinephrine released by tyramine-containing foods; increase in BP with reserpine
Cocaine	Systemic vasoconstriction (increased peripheral vascular resistance)
Marijuana	Increases systolic blood pressure
Glycyrrhizinic acid (chewing tobacco, imported licorice, health food products)	Inhibits renal metabolism of cortisol to cortisone (increased mineralocorticoid activity causing sodium retention, loss of potassium)
Grapefruit products	Inhibit cytochrome P-450 metabolism of some drugs
Herbs	
Bloodroot	CNS stimulant
Blue cohosh	Action of methylcytisine
Broad bean	Unknown
Scotch broom	Sympathomimetic
Cola nut	Sympathomimetic
Ephedra	Sympathomimetic, CNS stimulant
Foxglove	Cardiac inotrope
Gentian	Unknown
Ginseng	CNS stimulant, glucocorticoid effect
Goldenseal	Systemic vasoconstriction
Grindelia	CNS stimulant
Jimson weed	Anticholinergic effect
Juniper	Aquaretic
Kava	Unknown
Yohimbe	Central alpha blocker

Table 6 Laboratory Evaluation of Newly Diagnosed Hypertensive Patients

Purpose	*Tests*
Identify cardiovascular risk factors	Cholesterol (total, HDL), triglycerides, fasting blood glucose
Identify target-organ injury	Chest x-ray, ECG, urinalysis, serum creatinine or BUN, uric acid
Screen for secondary hypertension	Serum creatinine, potassium, calcium; urinalysis
Calculate kidney function	Cockcroft and Gault equation: GFR = (140 – age in yr) × (weight in kg) × 0.85 (if patient is female)/72 × S_{Cr} Modification of Diet in Renal Disease (MDRD) equation: GFR = 170 × $(S_{Cr})^{-0.999}$ × (age in yr)$^{-0.176}$ × 0.762 (if patient is female) × 1.18 (if patient is black) × (BUN)$^{-0.17}$ × (alb)$^{0.318}$

alb—serum albumin concentration (g/dl) BUN—blood urea nitrogen (mg/dl)
ECG—electrocardiogram GFR—glomerular filtration rate (ml/min)
HDL—high-density lipoprotein S_{Cr}—serum creatinine (mg/dl)

LABORATORY TESTS

Laboratory studies are performed to support the general goals of the initial evaluation [*see Table 6*]. In addition, they provide baseline information for monitoring in patients who are subsequently treated with antihypertensive drugs that can influence laboratory values (i.e., diuretics, beta blockers, ACE inhibitors, and angiotensin receptor blockers [ARBs]). Additional studies are not advised unless the history, physical examination, or initial laboratory studies are inconsistent with essential hypertension or suggest a specific secondary etiology.

If the initial assessment suggests renal dysfunction, the patient should be evaluated for chronic kidney disease by measuring 24-hour urinary protein excretion and estimating glomerular filtration rate (GFR). Equations are available to estimate GFR [*see Table 6*].[46,47] The Modification of Diet in Renal Disease (MDRD) equation requires measurement of blood urea nitrogen and serum albumin concentrations in addition to serum creatinine concentration. The estimate of GFR can also be calculated with an online tool (available at www.hdcn.com/calcf/gfr.htm).

RISK STRATIFICATION

At any given level of BP, specific factors in an individual patient may result in deviations above or below the average CV risk observed in population studies. These factors are used to determine the BP threshold and timing of drug therapy and the BP goal for the individual patient. Individual specific factors that determine risk include the presence of other CV risk factors and the presence of injury to the target organs of hypertension or clinical CV disease.[3] A simple and clinically useful scheme modified from the JNC VI report separates patients into three levels of risk [*see Table 7*].[42] This scheme suggests aggressive treatment and lower BP goals for patients at the highest level of risk and more conservative treatment and BP goals for patients at the lowest level of risk. For example, in a patient with diabetes, drug therapy is indicated initially (along with lifestyle changes) when BP exceeds 130/80 mm Hg. In contrast, in a young patient who has no other CV risk factors or evidence of target organ injury or CV disease, a 6- to 12-month trial of lifestyle changes rather than drugs is indicated as initial therapy

Table 7 Risk Stratification and Treatment in Hypertensive Patients[8,42,43]

Blood Pressure Stage (mm Hg)	*Risk Group A (no risk factors, no TOD/CCD*)*	*Risk Group B (≥ 1 risk factor, not including diabetes; no TOD/CCD)*	*Risk Group C (TOD/CCD and/or diabetes ± other risk factors)*
Prehypertension 120–139/80–89)	Lifestyle modification	Lifestyle modification	Lifestyle modification, drug therapy‡
Stage 1 (140–159/90–99)	Lifestyle modification (up to 12 mo)	Lifestyle modification (up to 6 mo)†	Lifestyle modification, drug therapy
Stage 2 (≥ 160/≥ 100)	Lifestyle modification, drug therapy	Lifestyle modification, drug therapy	Lifestyle modification, drug therapy

*Risk factors are cigarette smoking, dyslipidemia, diabetes, age > 55 yr in men and > 65 yr in women, male sex, postmenopausal status in women, family history of premature cardiovascular disease (women < 65 yr, men < 55 yr), nephropathy (microalbuminuria or glomerular filtration rate < 60 ml/min), obesity (body mass index ≥ 30 kg/m^2; waist circumference ≥ 102 cm in men and ≥ 88 cm in women), C-reactive protein level ≥ 1 mg/dl, physical inactivity. TOD/CCD includes left ventricular hypertrophy, angina, prior myocardial infarction, heart failure, previous coronary revascularization procedure, stroke, transient ischemic attack, nephropathy, peripheral arterial disease, retinopathy.
†For patients with multiple risk factors, consider drugs initially in addition to lifestyle modifications.
‡Use drugs if BP > 130 mm Hg systolic or > 80 mm Hg diastolic and patient has heart failure, chronic kidney disease, or diabetes.
TOD/CCD—target-organ disease/clinical cardiovascular disease

unless BP is of stage 2 (≥ 160 mm Hg systolic or ≥ 100 mm Hg diastolic). In these low-risk cases, the goal BP is less than 140/90 mm Hg. Guidelines from Europe provide an even more detailed approach to risk stratification.[43]

Prevention of Hypertension

In many cases, the assessment will show BP in the prehypertensive range (i.e., 120 to 139/80 to 89 mm Hg); in the United States, 22% of adults, or approximately 45 million persons, fit this category. Preventive care is indicated in these patients.

Multiple studies support the effectiveness of environmental manipulation in preventing or delaying the onset of hypertension.[48-51] Prevention of hypertension is important, given that treatment of established hypertension is only partly effective in reducing the associated morbidity and mortality.[52] Furthermore, the relationship between BP level and CV morbidity and mortality is continuous and extends into nonhypertensive levels; approximately one third of the coronary artery disease deaths attributable to BP occur in persons whose BP is in the prehypertensive range. Prevention strategies that lower BP in prehypertensive patients extend the benefits of BP reduction to this large group.

The risk of developing hypertension is increased in African Americans and in all persons with prehypertension or a family history of hypertension. Reversible patient characteristics associated with an increased risk of developing hypertension include being overweight or obese; having a sedentary lifestyle; ingesting a high-sodium, low-potassium diet; using excessive amounts of alcohol; and manifesting the so-called metabolic syndrome. The metabolic syndrome is defined as three or more of the following conditions: abdominal obesity (waist circumference > 40 inches in men or > 35 inches in women), glucose intolerance (fasting blood glucose ≥ 110 mg/dl), BP of 130/85 mm Hg or higher, elevated triglycerides (≥ 150 mg/dl) or low high-density lipoprotein (HDL) cholesterol (< 40 mg/dl in men or < 50 mg/dl in women).[53] Clinical trials support the efficacy of six interventions in such people for the primary prevention of hypertension [*see Table 8*].[48,49,51] Combining interventions is beneficial.[54,55] For patients with the metabolic syndrome, in addition to intensive lifestyle modifications, drug therapy is recommended for management of each of its components when appropriate.

Treatment

The overall goal of treatment in hypertensive patients is to reduce the risk of CV morbidity and mortality by lowering BP and treating other modifiable risk factors. In general, the goal is to lower BP to below 140/90 mm Hg. In patients with heart failure, diabetes, or renal disease, the goal is to lower BP to below 130/80 mm Hg. In older patients with ISH, the goal is to lower systolic BP to below 140 mm Hg.

These goals are achieved through lifestyle modification and, in most cases, drug therapy. In addition, comorbid conditions such as dyslipidemia or diabetes should be addressed.[53] Low-dose aspirin should be considered once BP is controlled.[56] Self-measurement of BP should be encouraged.

LIFESTYLE FACTORS

Observational studies have identified several environmental factors associated with hypertension, and prospective studies have demonstrated BP lowering with manipulation of these factors [*see Table 8*].[48,49,51,54,55,57-60] In addition to lowering BP, lifestyle recommendations are designed to reduce overall CV risk. These measures should be advised for all patients with BP above the normal level. Tobacco use should be discouraged because, in addition to being a powerful CV risk factor, each cigarette smoked elevates BP for 15 to 30 minutes, and multiple cigarettes can raise BP for most of the day. A new device that facilitates deep-breathing exercises (RESPeRATE) has been shown to low-

Table 8 Lifestyle Modifications for Hypertension Prevention and Management

- Lose weight if overweight
- Reduce sodium intake to ≤ 100 mmol/day (2.4 g sodium, 6 g salt)
- Increase aerobic exercise (30–45 min/day)
- Limit alcohol intake to no more than 1 oz (30 ml; e.g., 24 oz of beer, 10 oz of wine, 2 oz of 100-proof whiskey) or to 0.5 oz for women and lighter-weight people
- Maintain adequate intake of potassium (90 mmol/day)
- Ingest a diet rich in fruits and vegetables and low-fat dairy products but reduced in saturated and total fat (e.g., Dietary Approaches to Stop Hypertension [DASH] diet)
- Discontinue tobacco use

er BP and can be considered as an adjunct to lifestyle and drug treatments.[61]

PHARMACOLOGIC TREATMENT

The JNC 7 report recommends thiazide diuretics as initial drugs of choice for most patients; this recommendation is based on the totality of data from randomized trials, including the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT).[8,62-64] Critics of diuretics have cited evidence suggesting that diuretic-based treatment does not provide protection from coronary artery disease events to the degree predicted from epidemiologic studies. The ALLHAT was designed to determine whether treatment with a diuretic would be inferior to treatment with an alpha blocker, a calcium antagonist, or an ACE inhibitor in preventing fatal and nonfatal coronary artery disease events in a high-risk group of adults with essential hypertension. The study showed no difference among the drugs for the outcome of fatal and nonfatal coronary artery disease or total mortality. Moreover, diuretic treatment was superior to alpha blocker, calcium antagonist, or ACE inhibitor treatment with some CV disease outcomes. The alpha-blocker arm of the trial was terminated early because of an almost twofold increase in the risk of heart failure compared with the diuretic group. On the basis of these results, alpha blockers are no longer considered an appropriate initial therapy for hypertension. Compared with the diuretic group, the calcium antagonist group also had a higher risk of heart failure. Compared with the diuretic group, the ACE inhibitor group had an increased risk of stroke and combined CV disease, but much of the increased risk occurred in blacks, in whom BP control with the ACE inhibitor was inferior to the control achieved with the diuretic.

Alternative medications should be considered if diuretics are contraindicated or are poorly tolerated or there is a compelling indication for a drug from a different class. Alternative drug choices are beta blockers, ACE inhibitors, ARBs, and calcium antagonists.

A subsequent study contradicted the results of ALLHAT and suggested that ACE inhibitors are superior to diuretics in older men.[65] In truth, differences in outcomes by drug choice likely reflect differences in achieved BP rather than unique effects of specific agents.[66] Therefore, achieving the BP goal is more important than the specific agents used to achieve it.

Randomized clinical trials suggest that the presence of certain comorbid conditions constitutes a so-called compelling indication for selection of specific drugs [*see Table 9*]. Other considerations that should influence drug selection include concomitant conditions for which some agents may be beneficial and others contraindicated [*see Tables 9 and 10*], potential drug-drug interactions, concerns about quality of life, cost (generic formulations are available for diuretics, beta blockers, calcium antagonists, and ACE inhibitors), and, finally, demographics (in general, older patients and blacks respond better to diuretics and calcium antagonists, whereas younger patients and whites respond better to beta blockers, ACE inhibitors, and ARBs). In general, the drug chosen should have a long half-life (once-daily dosing is preferable). It should be continued only if the patient tolerates it and is comfortable with its cost, because these are important factors in long-term compliance. To achieve currently recommended goal BP levels, many patients will require more than one drug; this possibility should be discussed at the outset with the patient. Regardless of the agent chosen, BP should be reassessed after 2 to 4 weeks of treatment [*see Figure I*].

Combination Therapy

The JNC 7 report suggests initiation of therapy with two drugs (combination therapy) rather than a single agent if BP is more than 20 mm Hg systolic or 10 mm Hg diastolic above the treatment goal.[8] Generally, a two-drug regimen should include a diuretic appropriate for the level of renal function. An increasing number of antihypertensive combination products are available in a number of dosing options.[8] Although combination products may be more convenient, it is often less expensive to use individual agents, because generic drugs are frequently available. In addition, titration of doses of the two agents may be easier when the two drugs are prescribed separately. Once BP control is achieved with given doses of two agents, switching to the same therapy in combination form can be considered.

The advantages and disadvantages of using combination products have been reviewed.[67] Caution is advised when using combination therapy in older persons and diabetic patients, because of the increased risk of precipitous declines in BP or aggravation of orthostatic hypotension.

Improving Control Rates

In general, significant progress has been made in lowering BP in patients with hypertension. Although the proportion of patients with BP lower than 160/95 mm Hg has increased significantly since the 1970s, the percentage of patients with controlled hypertension (defined as systolic BP maintained below 140 mm Hg and diastolic BP, below 90 mm Hg) remains low. It is estimated that control of hypertension was accomplished in 31% of patients for the period from 1999 to 2000.[1] This is well below the Healthy People 2010 goal of at least 50% of patients achieving control. It is commonly believed that the major factors responsible for lower control rates are lack of access to health care and patient noncompliance and believed that the population of patients with uncontrolled hypertension comprises disproportionately large numbers of ethnic and racial minorities. However, studies suggest that other factors are also important. Analyses of the Third National Health and Nutrition Examination Survey (NHANES III) identified factors associated with the likelihood both of attaining control of hypertension and of failing to attain control.[68] Factors associated with an increased likelihood of controlling hypertension included being married (greater social support), having private health insurance, visiting the same health care facility or having the same provider over time, having had BP measured within the previous 6 to 11 months, and using lifestyle modifications in the treatment program. On the other hand, factors associated with an increased likelihood of uncontrolled hypertension included being 65 years or age or older, being male, being black, and failing to see a physician in the preceding year. Interestingly, not having health insurance or not having a source of health care was not predictive of uncontrolled hypertension.

Most cases of uncontrolled hypertension occur in older persons and represent mild ISH (systolic BP, 140 to 160 mm Hg).[69] In a study of self-reported treatment practices among primary care physicians, 43% of physicians would neither start drug therapy for a patient whose systolic BP is between 140 and 160 mm Hg nor intensify treatment for a patient whose systolic BP is 158 mm Hg.[70] In this same study, 41% of the care givers were unfamiliar with national hypertension guidelines. In a further analysis, familiarity with the guidelines lowered the provider's BP treatment threshold. Other studies of physician practices

Table 9 Patient Condition and Choice of Antihypertensive Drugs

Conditions	*Drug Choice*
No comorbid conditions	Diuretics
Isolated systolic hypertension (elderly patients)	Diuretics (preferred), calcium antagonists (DHP)*
Angina	Beta blockers,* calcium antagonists (non–short-acting DHP)
Angina (with diabetes or LV dysfunction)	ACE inhibitors† (in addition to beta blockers and calcium antagonists)
Atrial fibrillation	Beta blockers,* calcium antagonists (rate limiting)*†
Cough with ACE inhibitors	ARBs*
Diabetes mellitus type 1 with proteinuria	ACE inhibitors*; calcium antagonists (non-DHP); diuretics, beta blockers†
Diabetes mellitus type 2 with proteinuria	ARBs*†; calcium antagonists (non-DHP)†; diuretics, beta blockers†
High risk of type 2 diabetes	ACE inhibitors†
Essential tremor	Beta blockers (noncardioselective)†
Heart failure, LV dysfunction	ACE inhibitors, beta blockers, diuretics, aldosterone antagonists*; ARBs†; generally, an ACE inhibitor is first choice, ± a beta blocker in asymptomatic patients; diuretic used to treat congestion; aldosterone antagonist used only in advanced disease in combination with other agents; ARB should not be used in patients on an ACE inhibitor and beta blocker [*see 1:II Heart Failure*]
High risk of cardiovascular disease or type 2 diabetes	ACE inhibitor†
Hyperlipidemia	Alpha blockers (not considered first-line therapy)†
Intolerance to other antihypertensive drugs	ARBs†
Left ventricular hypertrophy (by ECG)	ARBs†
Migraine	Beta blockers (noncardioselective), calcium antagonists (non-DHP)†
Myocardial infarction	Beta blocker (non-ISA) most often drug of choice, with ACE inhibitor added if LV function impaired*; aldosterone antagonist can be added to standard therapy in patients with LV dysfunction*; diltiazem (non–Q wave infarction)†; verapamil†
Osteoporosis	Thiazide diuretics†
Peripheral vascular disease	Calcium antagonists†
Preoperative hypertension if at increased cardiovascular risk	Beta blockers†
Previous stroke	Diuretic + ACE inhibitor*; ACE inhibitor as monotherapy had no effect on BP or outcome; benefit noted only with combination that lowered BP
Prostatism	Alpha blockers (not considered first-line therapy)†
Renal insufficiency with proteinuria from any cause	ACE inhibitors, ARBs, calcium antagonists (non-DHP)†

*Compelling indication.
†Specific indication.
ACE—angiotensin-converting enzyme ARB—angiotension II receptor blocker DHP—dihydropyridine ISA—intrinsic sympathomimetic activity LV—left ventricle

have shown similar results. Emerging from these studies is the realization that a major factor in continued poor control rates for hypertension is a tolerance by the health care provider of elevated systolic BP, especially in older patients. On the basis of these study results, health care providers should consider steps to improve control rates in their practice [*see Table 11*].

REFRACTORY/RESISTANT HYPERTENSION

Studies conducted to determine what causes resistant hypertension have used different definitions of the term. In most studies, hypertension was considered resistant or refractory if control was not achieved with a combination of lifestyle modifications and the rational use of full therapeutic doses of two or three antihypertensive medications, one of which was a diuretic appropriate for the level of renal function. Studies suggest five issues to consider when evaluating patients with resistant hypertension[42]: noncompliance with therapy, interfering substances, an inappropriate drug regimen, office hypertension or pseudohypertension, and secondary hypertension. In most cases, causative factors will be identified if these five issues are given careful attention.

Noncompliance

Lack of BP control often results from noncompliance with the drug regimen or diet. Common reasons for noncompliance with drug therapy include drug costs, side effects, complex dosing schedules, and inadequate follow-up. Patients are reluctant to admit noncompliance with drug treatment, so a high degree of vigilance is required. Asking an open-ended question

Table 10 Contraindications to Antihypertensive Drugs

Class of Drug	*Possible Contraindications*	*Compelling Contraindications*
Diuretics	Dyslipidemia (high doses), allergy to sulfa-based antibiotics, patient is sexually active man, diabetes mellitus (high doses)	Gout, allergy to sulfa-based diuretics
Beta blockers	Bronchospastic disease (asthma, COPD, noncardioselective agents), dyslipidemia (non-ISA agents), severe peripheral vascular disease, athletes	Bronchospastic disease (noncardioselective agents) second- or third-degree heart block
ACE inhibitors, ARBs	Renovascular disease (bilateral renal artery stenosis), renal insufficiency	Pregnancy, hyperkalemia
Calcium antagonists	—	Second- or third-degree heart block (non-DHP agents); heart failure (except amlodipine, felodipine)
Alpha blockers	Postural hypotension	Urinary incontinence
Reserpine	Peptic ulcer, nasal allergy	Depression
Methlydopa	Liver disease	—
Labetalol	Liver disease	—
Central alpha agonists	Depression, sleep disorders	—

ACE—angiotensin-converting enzyme ARBs—angiotensin receptor blockers COPD—chronic obstructive pulmonary disease DHP—dihydropyridine ISA—intrinsic sympathomimetic activity

such as, "Many people have problems remembering their drug schedule; do you?" is occasionally effective. Clues to noncompliance include failure to keep follow-up appointments or renew prescriptions, or complaints about the cost of drugs or side effects. Certain drugs are expected to cause findings on the physical examination or laboratory evaluation. An absence of these findings may indicate noncompliance. Examples are slowing of the heart rate with beta blockers, electrolyte changes with diuretics, or dry mouth with clonidine. Noncompliance with a low-salt diet can also be important. A high-salt diet can interfere with the effectiveness of almost all of the currently used antihypertensive drugs.

Interfering Substances

Certain prescription drugs, over-the-counter medications, herbals, and street drugs can raise BP or interfere with the BP-lowering effect of antihypertensive drugs [*see Table 5*]. Taking a complete medication history and asking patients to bring in all their medication bottles is essential for identifying interfering substances. Alcohol abuse should also be considered, because in addition to its physiologic effects, alcohol abuse is often associated with poor compliance and lack of BP control.

Inappropriate Drug Regimens

The drug regimen should be carefully reviewed. Full therapeutic doses of drugs should be employed. In general, it is preferable to use drugs that have complementary actions and that work by interfering with different BP regulatory pathways. In compliant patients, inadequate control of extracellular volume is the most common cause of resistant hypertension.[71] Extracellular volume expansion tends to occur as BP is lowered and is a secondary effect of some drugs (e.g., centrally acting sympatholytics in modest doses and some direct vasodilators). In patients with renal dysfunction, impaired renal excretion of sodium often is an important factor in raising BP. Thiazide diuretics are often ineffective when serum creatinine is higher than 2.0 mg/dl or creatinine clearance is less than 30 ml/min. In

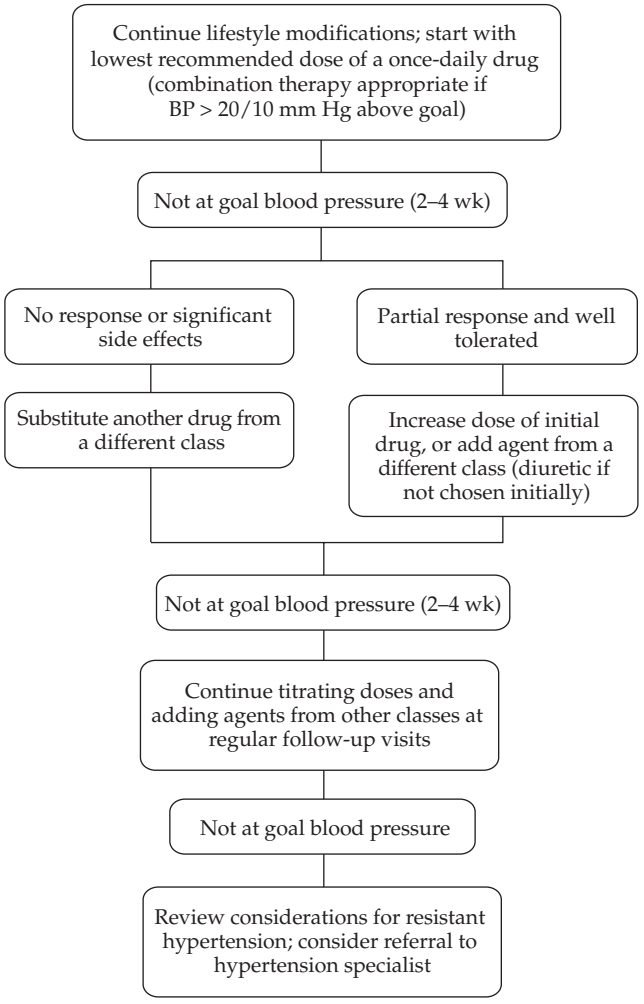

Figure 1 **Overview of drug treatment for hypertension.**

Table 11 Considerations for Improving Blood Pressure Control Rates

Become familiar with national guidelines (set a BP goal with the patient)
Schedule regular follow-up visits
Recommend self-monitoring of BP (involve patients in the treatment process)
Measure BP at every follow-up office visit and articulate a treatment recommendation if BP is above goal (be more aggressive, especially with systolic hypertension in older patients)
Emphasize lifestyle factors as part of the treatment program (involve patients in the treatment process); review progress and barriers at each visit
Use adequate doses of antihypertensive drugs; be willing to use multiple drugs
Encourage communication regarding medication costs and side effects
Be aware of poor control rates in men and African Americans

such patients, loop diuretics are required. For patients on multidrug regimens, the lack of a diuretic or the use of low doses of short-acting loop diuretics given only once daily may explain the resistant state. In some patients with renal disease, combinations of loop agents and thiazide diuretics are required to control volume.

Office Hypertension/Pseudohypertension

Office measures of BP may overestimate the usual or average level [*see* Ambulatory BP Monitoring, *above*]. Before embarking on further evaluation, the clinician should consider using out-of-office BP readings or ABPM to exclude a white-coat effect. Patients with white-coat hypertension are more likely to be younger (although cases of white-coat ISH do occur in elderly patients), female, and of normal weight. They often have no target organ injury and complain of fatigue and weakness (which are symptoms of hypotension) when drug doses are increased. One study suggested that up to 50% of hypertensive patients deemed resistant by office determinations of BP in fact had controlled hypertension.[72]

Some elderly patients may have pseudohypertension—falsely elevated systolic and diastolic BP as determined by cuff measurement that results from atherosclerosis of the brachial artery. Because of the excessive stiffness of the vessel wall, higher cuff pressure must be applied to produce vascular occlusion. In addition, the accuracy of oscillometric devices is impaired under these circumstances. Such patients often have evidence of severe generalized atherosclerosis and remarkable elevations of systolic BP without concomitant symptoms. They may complain of weakness and fatigue with increases in drug doses. The ability to palpate the pulseless radial artery after cuff inflation (i.e., a positive Osler sign) increases the likelihood of pseudohypertension, but this is not a sensitive test.[73] Confirmation of pseudohypertension requires intra-arterial measures of BP.

Secondary Hypertension

Secondary forms of hypertension are relatively uncommon in the general hypertensive population but may account for a significant proportion of cases of resistant hypertension. Once the other considerations have been eliminated, patients with resistant hypertension should be considered for further evaluation of secondary causes [*see* Secondary Hypertension, *below*].

HYPERTENSIVE CRISIS

An acute and severe rise in BP is a serious medical concern. Prompt therapy may be lifesaving. Clinically, acute and severe increases in BP can be classified as either hypertensive urgencies or emergencies (crises).[42]

The term hypertensive emergency or hypertensive crisis is defined as severely elevated BP associated with acute injury to target organs (i.e., brain, heart, kidneys, vasculature, and retina). Prompt hospitalization and reduction of BP with parenteral therapy is required. Examples of hypertensive emergencies include malignant hypertension, hypertensive encephalopathy, aortic dissection, eclampsia, unstable angina or acute myocardial infarction, pulmonary edema, and acute renal failure.

Malignant hypertension is an old term that describes a clinical syndrome associated with acute severe elevation of BP that may be fatal if not promptly treated. It is associated with a marked increase in peripheral vascular resistance caused by systemic (angiotensin II) or locally generated (endothelin) vasoconstrictors. Any form of hypertension can progress to the malignant phase. Clinical characteristics include severe hypertension (diastolic BP > 130 mm Hg); hemorrhages, exudates, and papilledema on retinal examination; encephalopathy (i.e., headache, confusion, somnolence, stupor, visual loss, focal neurologic deficits, seizure, or coma); oliguria and azotemia; nausea, vomiting, and dyspnea; and physical findings of heart failure (rales, an S_3 heart sound). Encephalopathy arises from the failure of cerebral autoregulation of blood flow at critically high pressures, which results in cerebral vasodilation, hyperperfusion, vascular leakage, and cerebral edema. The hallmark vascular lesion of malignant hypertension is fibrinoid necrosis of arterioles that, in turn, increases both ischemic injury and further vasoactive substance release, setting up a vicious cycle. Microangiopathic hemolytic anemia with fragmentation of red cells and intravascular coagulation may occur in the setting of fibrinoid necrosis.

Hypertensive urgency is defined as severe hypertension without evidence of acute target organ injury that requires BP reduction over 24 to 48 hours. Oral therapy in the outpatient setting is often adequate. Examples include severe hypertension in a patient with known coronary artery disease, an aortic aneurysm (or aneurysm at another site), or a history of heart failure. The term accelerated hypertension is often used to describe a state of acute, severe hypertension with hemorrhages and exudates on retinal examination (but not papilledema) but without other findings of acute organ injury. This condition can be managed with oral therapy but may progress to malignant hypertension if left untreated.

The causes of hypertensive urgencies and emergencies include neglected essential hypertension (approximately 7% of untreated hypertension can progress to the malignant phase), sudden discontinuance of drug therapy (especially multiple drug regimens or regimens containing clonidine or beta blockers), renovascular disease, collagen vascular disease (especially scleroderma), eclampsia, acute glomerulonephritis, and pheochromocytoma. Approximately 50% of hypertensive crises occur in patients with preexisting hypertension.

The goals of the initial evaluation are to assess for target organ injury and to define potential causes. The evaluation begins with a focused medical history and physical examination. In taking the history, the clinician must ask about compliance with prescribed antihypertensive medications and the use of drugs that can raise BP [*see Table 5*]. Retinal examination is a mandatory aspect of the physical examination. Immediate laboratory

Table 12 Parenteral Therapy for Hypertensive Crisis

Drug	*Dosage*	*Comments*
Sodium nitroprusside	0.25–10.0 μg/kg/min I.V. infusion	General drug of choice; produces direct arteriolar and venous dilation; immediate onset and offset; side effects include metabolic acidosis, nausea, vomiting, agitation, psychosis, tremor (monitor thiocyanate levels)
Labetalol	Repetitive I.V. boluses of 20–80 mg q. 10 min or constant infusion of 0.5–2.0 mg/min	Combination alpha/beta blocker; onset 5–10 min, offset 3–6 hr; useful in most settings, especially postoperative state, hypertensive crisis of pregnancy; avoid in acute heart failure; take beta-blocker precautions; side effects include scalp tingling, vomiting, heart block, orthostatic hypotension
Glyceryl trinitrate	5–100 μg/min I.V. infusion	Produces direct arteriolar and venous dilation; onset 5–10 min, offset 3–5 min; especially useful in acute coronary ischemia, CHF; tolerance with prolonged infusion; side effects include headache, flushing, nausea, methemoglobinemia
Esmolol	50–300 μg/kg/min I.V.	Cardioselective beta blocker, onset 1–2 min, offset 10–20 min; especially useful in postoperative state, aortic dissection, ischemic heart disease; take beta-blocker precautions; side effects include bradycardia, nausea
Hydralazine	10–20 mg I.V. bolus	Causes direct arteriolar vasodilation; onset 10–20 min, offset 3–8 hr; used primarily for hypertensive crisis of pregnancy; avoid in acute MI, angina, aortic dissection; side effects include headache, flushing, nausea, vomiting, tachycardia, angina
Enalapril	1.25–5 mg I.V. bolus, q. 6 hr	ACE inhibitor; onset 15 min, offset 6 hr; especially useful in acute heart failure in postoperative state; lower doses in renal disease; side effects include precipitous decline in BP (high-renin states), acute renal failure (presence of renal vascular disease)
Nicardipine	5–15 mg/hr I.V. infusion	Dihydropyridine calcium antagonist; onset 5–10 min, offset 1–4 hr; especially useful in postoperative state; avoid in acute heart failure; side effects include headache, nausea, flushing, phlebitis
Fenoldopam	0.1–1.6 μg/kg/min I.V. infusion	Dopamine (DA1) agonist; onset 5 min, offset 30–60 min; especially useful in patients with impaired renal function because it increases renal blood flow and sodium excretion; side effects include nausea, vomiting, headache, flushing
Phentolamine	5–15 mg I.V. bolus	Alpha blocker; onset instantaneous, offset 3–10 min; drug of choice for pheochromocytoma crisis; side effects include flushing, tachycardia
Trimethaphan	0.5–15 mg/min I.V. infusion	Ganglionic blocker; onset 1–5 min, offset 10 min; tachyphylaxis common with prolonged infusion; side effects include urinary retention, paralytic ileus, dry mouth, blurred vision, orthostatic hypotension
Diazoxide	1–150 mg/kg I.V. bolus over 10 min; repeat at 10–15 min intervals if needed	Considered obsolete; direct arteriolar dilator; onset 1 min, offset 3–18 hr; avoid in acute MI, aortic dissection; side effects include hyperglycemia, hyperuricemia, fluid retention

ACE—angiotensin-converting enzyme CHF—chronic heart failure MI—myocardial infarction

studies include a complete blood count (to check for anemia); blood smear (to look for fragmented red blood cells); serum creatinine and blood urea nitrogen assays; urinalysis; serum sodium, potassium, and glucose assays; a chest x-ray; and an electrocardiogram. In hypertensive crisis, evaluation for secondary hypertension should be deferred until the patient is stable. If a cause of the crisis is not apparent, such patients should eventually have an evaluation to exclude renal vascular disease, pheochromocytoma, scleroderma, and primary aldosteronism.

Patients with hypertensive crisis should be hospitalized in an intensive care unit. The challenge of treatment is to lower BP without aggravating ischemia to vital organs. Parenteral therapy should be used [*see Table 12*]. Sodium nitroprusside is generally the drug of choice. Diazoxide is considered obsolete, because of the availability of newer and safer drugs. Mean BP should be lowered by 20% in the first hour (diastolic BP should be reduced to 100 to 110 mm Hg). As BP is lowered, the patient should be monitored for evidence of worsening cerebral, renal, or cardiac function. If the patient is stable, BP should be further lowered over the next 24 hours. Oral therapy can be started, and parenteral therapy gradually discontinued.

TREATMENT FOR SPECIFIC PATIENT GROUPS

The Elderly

Approximately 60% to 70% of persons 60 years of age or older have hypertension.[1] In this age group, systolic BP is the dominant predictor of adverse events, and ISH is the most common type of blood pressure disturbance.[11,12] Treatment of hypertension in the elderly reduces CV disease event rates and lessens the risk of development and progression of cognitive dysfunction and dementia.[7,74] The benefits of treatment have been shown for persons with either systolic-diastolic hypertension or ISH and for those older than 80 years. Although most elderly persons have primary hypertension, secondary forms of hypertension should be considered if the onset is recent or the hypertension is resistant.

There are special concerns regarding BP measurement in the elderly. Systolic BP is often quite variable, and the phenomenon of white-coat hypertension may be common in the elderly, especially in older women. Thus, readings of BP outside the office should be encouraged, as should selective use of ambulatory monitoring, especially if the patient has no target organ changes

related to hypertension or complains of side effects that suggest hypotension with treatment. As noted, white-coat hypertension is an indication for ambulatory monitoring that is covered under Medicare.[40] Orthostatic hypotension and postprandial hypotension are more common in the elderly, in most cases because of dysautonomia of aging. Systolic hypertension is a predictor of orthostatic hypotension, and diabetic patients are at greater risk because of autonomic neuropathy. Thus, BP measurement in the standing position is required in all elderly patients at all office visits. Pseudohypertension should be considered in elderly patients who have palpably stiff vessels, who lack significant target organ changes despite very high BP readings, and who complain of hypotensive symptoms with treatment. Such patients may require a direct intra-arterial measure of BP for clarification.

In general, treatment of hypertension in the elderly follows the same principles as treatment in younger patients. The BP goals are the same as for the general hypertensive population. However, because the benefit of treatment on longevity is less in most elderly patients, the costs of drugs, side effects, and quality of life are important considerations. Goal BP may be difficult to achieve in some patients with systolic hypertension, but any reduction is beneficial. Thus, in some patients, a higher systolic goal may be reasonable.

Modification of adverse lifestyle factors is beneficial in the elderly and should be encouraged.[75] Salt sensitivity increases with age and with the reduction in renal function that is common in the elderly.[76] In patients who require drugs, lower initial doses should be considered, especially in the presence of orthostatism or comorbid vascular diseases. However, many elderly patients ultimately require multiple drugs for BP control.

In the elderly with systolic-diastolic hypertension, placebo-controlled studies have shown that initial therapy with a diuretic or a beta blocker is beneficial. In one trial, treatment using newer drugs (calcium antagonists or ACE inhibitors) was not superior to treatment using diuretics and beta blockers.[77] In another study, however, starting treatment with an ACE inhibitor rather than a diuretic was associated with better outcomes, particularly in men.[65] Studies in patients with ISH have shown efficacy of thiazide diuretics and long-acting dihydropyridine calcium antagonists.[7] In elderly patients with LVH, the LIFE (Losartan Intervention For Endpoint reduction in hypertension) trial demonstrated that, compared with therapy using a beta blocker (atenolol), use of an ARB (losartan) was associated with fewer CV events, including strokes.[78] This observation was noted overall and in the subset of elderly patients with ISH. In elderly patients with a history of stroke or transient ischemic attack, the combination of indapamide and perindopril reduced the risk for subsequent stroke and progression to dementia.[79] In many elderly patients, comorbid conditions will determine the use of specific drugs. Because of the problem of polypharmacy in the elderly, a goal should always be to keep the program as simple as possible.

Diabetic Patients

Patients who have both hypertension and diabetes have twice the risk of CV disease as nondiabetic hypertensive patients. In addition, hypertension increases the risk of diabetic retinopathy and nephropathy.[80] Epidemiologic and observational studies have shown that the risk of BP-related CV disease and mortality in diabetic patients begins to rise when BP exceeds 120/70 mm Hg.[80,81] There does not appear to be a threshold value for risk associated with systolic BP in diabetic patients. In the Hypertension Optimal Treatment Trial (HOT), diabetic patients randomized to the lowest diastolic BP goal (≤ 80 mm Hg; the achieved diastolic BP was 82.6 mm Hg) had the best outcomes.[56] In the United Kingdom Prospective Diabetes Study (UKPDS), a mean achieved diastolic BP of 82 mm Hg was beneficial, as compared with less aggressive BP reduction.[82] On the basis of these data, the American Diabetes Association, the National Kidney Foundation, and the JNC 7 report recommend a goal BP of less than 130/80 mm Hg in hypertensive diabetic patients.[8,81,83]

All patients with diabetes should be encouraged to adopt lifestyle modifications [*see Table 8*]. Weight loss (if the patient is overweight or obese) and moderate exercise are especially beneficial in diabetic patients because in addition to lowering BP, these interventions improve insulin sensitivity and blood lipid levels. Many patients will require lifestyle modifications and three or more drugs to achieve the BP goals. Meeting these goals may be difficult in some patients. The clinician must balance benefit from lower BP with cost of medication, side effects, and risks associated with the lower goals in some patients. The American Diabetes Association recommends a trial of lifestyle modifications alone for up to 3 months if the initial systolic BP is 130 to 139 mm Hg or the diastolic BP is 80 to 89 mm Hg. Drug monotherapy should be considered initially along with lifestyle modifications if the initial systolic BP is 140 mm Hg or higher or if the diastolic BP is 90 mm Hg or higher.[81] The JNC 7 report suggests that if the initial systolic BP is 150 mm Hg or higher or the initial diastolic BP is 90 mm Hg or higher, consideration should be given to starting therapy with a combination of two drugs, one of them a thiazide diuretic.[8] Before initiating drug therapy, it is important to measure BP in the standing position to detect orthostatism, the presence of which may be a clue to autonomic neuropathy and would necessitate a modification to the treatment approach.

Placebo-controlled trials in diabetic patients have shown the efficacy of ACE inhibitors, ARBs, diuretics, and beta blockers as initial therapy. Numerous studies have shown the effectiveness of ACE inhibitors and ARBs in retarding progression of diabetic nephropathy.[84,85] For diabetic patients with nephropathy, the American Diabetes Association guidelines recommend ACE inhibitors as initial drugs of choice in type 1 diabetes but ARBs in type 2 diabetes.[81] It is unclear whether ARBs are as cardioprotective in diabetic patients as ACE inhibitors have been shown to be. In some studies, the incidence of cardiac events has been higher in diabetic patients treated with dihydropyridine calcium antagonists, as compared with ACE inhibitors.[86] Beta blockers should be considered in the setting of coronary artery disease, a common comorbidity in patients with diabetes. On balance, treatment data suggest that reaching the goal BP in diabetic patients is probably more important than the choice of drugs used to achieve it.

Patients with Heart Disease

Ischemic heart disease is the most common cause of death in patients with hypertension. Poorly controlled hypertension also results in the development of LVH. Both LVH and ischemic injury lead to the development of heart failure from either systolic or diastolic dysfunction.[87] Hypertension is the most common antecedent of heart failure.[88] Hypertensive effects on the heart also increase the risk for atrial fibrillation.

For asymptomatic patients with known coronary artery dis-

ease, an ACE inhibitor should be considered initially because some studies (but not all) suggest that their use may be associated with a reduced risk of cardiovascular events.[89] An ACE inhibitor would also be the initial drug of choice for patients with concomitant reduced systolic function or concomitant diabetes with renal involvement.[81,84,90] If there is a history of myocardial infarction, the first drug should be a beta blocker.[91] For hypertensive patients with previous myocardial infarction and reduced left ventricular function, combination therapy with a beta blocker and an ACE inhibitor should be considered.[92] In addition, the aldosterone antagonist eplerenone has been shown to be effective.[93] If eplerenone is used, serum potassium levels should be monitored carefully, especially in patients with renal dysfunction or if ACE inhibitors or ARBs are used.

The drug of choice in hypertensive patients with stable angina, both to lower BP and to relieve symptoms and ischemia, is a beta blocker. Long-acting dihydropyridine or nondihydropyridine calcium antagonists have been shown to relieve symptoms and are alternative agents if beta blockers are contraindicated; these alternative agents are also suitable as additional therapy for BP or symptom control. Newer vasoselective, long-acting dihydropyridine calcium antagonists such as amlodipine or felodipine can be used safely to lower BP in patients with impaired left ventricular function. Nitrates can be used in combination with either beta blockers or calcium antagonists for symptomatic relief and may lower systolic BP. Beta blockers should be avoided in pure vasospastic angina, a disorder best managed with long-acting calcium antagonists or nitrates. Diuretics are safe antihypertensives for patients with coronary artery disease; they work well with other agents to lower BP. Hypokalemia should be avoided.

LVH is associated with a doubling of the risk of myocardial infarction and death in hypertensive patients.[94] Effective BP control causes regression of LVH and improves prognosis. Weight loss and the use of antihypertensive drugs of all major classes have been shown to induce regression of LVH; however, increasing evidence suggests that ACE inhibitors and ARBs may be more effective than other agents.[95]

The goal of treating hypertensive patients with heart failure is a BP of less than 130/80 mm Hg. The American College of Cardiology/American Heart Association have developed guidelines for the evaluation and management of heart failure in adults that encompass a staging system and evidence-based treatment recommendations for patients with heart failure [*see I:II Heart Failure*].

Patients with Chronic Kidney Disease

Kidney disease is both a cause and a consequence of hypertension. Hypertension is the second most common cause of the development of end-stage kidney disease, and most people with kidney disease have hypertension. Aggressive control of elevated BP can slow progression of renal damage and delay or prevent the development of end-stage disease.[83-85,96] The currently recommended goal BP for patients with kidney disease is a level below 130/80 mm Hg. Also, patients with chronic kidney disease are at high risk for CV morbidity and mortality. Therefore, in addition to elevated BP, other modifiable CV risk factors require management.

Chronic kidney disease is defined as either a GFR of less than 60 ml/min/1.73 m^2 or the presence of albuminuria (> 300 mg/day or > 200 mg albumin per gram of creatinine).[83] The GFR can be estimated using the Cockcroft-Gault or MDRD equation [*see Table 6*]. Determination of creatinine clearance using timed urine collections generally does not improve upon the estimates of GFR obtained using these equations.

ACE inhibitors and ARBs may be more effective than other drugs in slowing progression of proteinuric kidney disease. Whether these agents provide a specific advantage in the absence of proteinuria is less certain.[83] Serum creatinine concentrations often increase acutely when these drugs are used, so serum creatinine and potassium should be measured within several days of initiating treatment. An increase in creatinine is not a reason to stop the drug unless it is excessive or associated with severe hyperkalemia. Concomitant use of potassium-sparing diuretics, potassium supplements, or nonsteroidal anti-inflammatory drugs should be avoided. A persistent increase in creatinine with treatment raises the possibility of renal artery stenosis. Most patients with kidney disease will require a diuretic as part of the treatment regimen. If GFR is estimated to be less than 30 ml/min, thiazide diuretics are usually ineffective, and loop diuretics are required. Often, three or more drugs are required to control BP.

Patients with Acute Stroke

The majority of patients presenting with either acute ischemic or hemorrhagic stroke have hypertension.[97] The temporal profile is that of an initial acute rise in BP in the first 24 hours, followed by a slow decline over the next several days. On the whole, observational studies show that high BP at stroke onset is associated with an increased risk of death or dependency.[98] However, this association is not evident in some studies, especially studies in patients with ischemic stroke.[99]

Unfortunately, at present there is little evidence from clinical trials to provide clear recommendations for the appropriate management of BP during acute stroke. Currently, there is consensus that in patients with acute intracranial hemorrhage, BP should be lowered if it exceeds 200/120 mm Hg, to prevent growth of the hematoma or rebleeding. Lowering of BP by less than 20% is suggested in this setting.[100] Guidelines for BP management in acute ischemic stroke from the Stroke Council of the American Heart Association suggest that in patients who are not candidates for thrombolytic therapy, hypertension should be managed with observation alone if BP is less than 220 mm Hg systolic and 120 mm Hg diastolic, unless there is evidence of other acute target-organ injury (e.g., aortic dissection, acute myocardial infarction, pulmonary edema, hypertensive encephalopathy).[101] For patients with systolic BP higher than 220 mm Hg or diastolic BP of 121 to 140 mm Hg, treatment with intravenous labetalol or nicardipine is recommended. Labetalol is given in a dosage of 10 to 20 mg over 1 to 2 minutes; the dose is repeated or doubled as needed every 10 minutes to a maximum dose of 300 mg. Nicardipine is given in an initial 5 mg/hr infusion and titrated to desired effect by increasing the dosage by 2.5 mg/hr every 5 minutes, to a maximum rate of 15 mg/hr. It is suggested that BP be lowered by 10% to 15%. Nitroprusside is recommended if diastolic BP is higher than 140 mm Hg; the dose should be titrated to lower BP by 10% to 15%.

In patients who are eligible for thrombolytic therapy, the Stroke Council suggests lowering BP before initiating thrombolysis if the BP is higher than 185 mm Hg systolic or 110 mm Hg diastolic. Treatment with labetalol, 10 to 20 mg intravenously over 1 to 2 minutes, is advised. If needed, this dose can be repeated once; or nitroglycerin paste, 1 to 3 inches, can be applied.

Table 13 Screening Options for Secondary Hypertension

Disorder	*Screening Tests (Sensitivity/specificity)*	*Comments*
Renovascular hypertension[112-114]	Captopril radionuclide renal scan (75%/85%)	Advantage: no contrast allergy Disadvantages: renal dysfunction impairs interpretation, may miss accessory- or branch-vessel disease
	Duplex ultrasound (80%–90%/90%)	Advantages: no contrast allergy, can be used in patients with renal dysfunction; calculation of resistive index identifies patients with renal dysfunction likely to benefit from intervention Disadvantages: failure to visualize both renal arteries; may miss accessory- or branch-vessel disease
	Spiral CT angiography	Advantages: excellent images of renal arteries; can identify dissection, accessory vessels, and fibromuscular disease Disadvantage: considerable contrast load precludes use in presence of renal dysfunction
	Magnetic resonance angiography (85%–100%/79%–98%)	Advantages: contrast allergy and renal dysfunction; no radiation exposure Disadvantages: cost, may overstate degree of stenosis, claustrophobic patients may not tolerate test
	Renal angiography	Gold standard Advantages: identifies accessory- and branch-vessel disease; percutaneous interventions can be performed as part of study Disadvantages: cost, contrast exposure, invasive (atheroemboli)
Primary aldosteronism[105,115]	Measurement of serum sodium, potassium, PRA, and PAC; 24-hr urinary aldosterone, sodium, and PRA after 3 days of 200 mEq sodium diet	Diagnosis confirmed if U_{Na} > 200 mEq, U_{aldo} > 12, and PRA < 1.0; 30% of patients with primary aldosteronism will be normokalemic at presentation Ratio of PAC/PRA > 20 (PAC >15 ng/dl and PRA < 2.0 ng/ml) Advantage: simple Disadvantages: many antihypertensive drugs can influence values of PRA and PAC; sensitive screen but not specific
Pheochromocytoma[107]	Plasma free metanephrine (highly sensitive); 24-hr fractionated urinary metanephrines	—
Cushing syndrome	24-hr urinary free cortisol (95%–100%/97%–100%)	Diagnosis certain if 24-hr urinary free cortisol level > 3× normal; diagnosis excluded if level normal; use low-dose dexamethasone suppression test if elevation < 3× normal
Coarctation of the aorta	Chest x-ray; transesophageal echocardiogram; CT or MRI of the aorta	Diagnostic findings on chest x-ray: "3" sign from dilation of aorta above and below the coarctation, rib notching from collateral vessels

PAC— plasma aldosterone concentration PRA—plasma renin activity

If antihypertensive treatment does not reduce BP to below 185/110 mm Hg, thrombolytic therapy is not advised. During and after thrombolytic treatment, BP should be monitored frequently (every 15 minutes for 2 hours, then every 30 minutes for 6 hours, and then every hour for 16 hours). During this period, treatment with nitroprusside is advised for diastolic BP higher than 140 mm Hg. For systolic BP higher than 180 mm Hg or diastolic BP of 105 to 140 mm Hg, intravenous labetalol in a dosage of 10 mg administered over 1 to 2 minutes is recommended; the dosage should be repeated or doubled every 10 minutes to a maximum of 300 mg, or a drip at a rate of 2 to 8 mg/min should be started.

Secondary Hypertension

Detection of secondary hypertension is important because, depending on the cause, it may be possible to cure the underlying condition or tailor therapy to achieve optimal BP control. Certain features suggest the presence of specific secondary forms of hypertension [*see Table 4*], which should then direct further testing [*see Table 13*].

Common reversible causes of hypertension include obesity, the use of drugs that raise BP [*see Table 5*], obstructive sleep apnea, and renal disease. Obstructive sleep apnea is prevalent in the population and is often associated with hypertension. Renal insufficiency from any etiology causes BP to rise. Elevated BP in turn accelerates loss of renal function, and a vicious cycle ensues. Traditional secondary causes of hypertension include renal vascular disease, coarctation of the aorta, the adrenal causes of primary aldosteronism, pheochromocytoma, and Cushing syndrome.

RENOVASCULAR HYPERTENSION

Renovascular hypertension is the most common form of potentially curable secondary hypertension. It probably occurs in 1% to 2% of the overall hypertensive population. The prevalence may be as high as 10% in patients with resistant hypertension, and even higher in patients with accelerated or malignant hypertension.

Stenosing lesions of the renal circulation cause hypertension through ischemia-mediated stimulation of the renin-angiotensin-aldosterone axis. Correcting renal ischemia eliminates excess renin production and improves or cures the hypertension. In unilateral disease, prolonged hypertension can cause nephrosclerosis in the nonischemic kidney; nephrosclerosis lessens the likelihood of benefit from correction of the renal vascular lesion.

Fibromuscular disease is the most common cause of renovascular hypertension in younger patients, especially women between 15 and 50 years of age; it accounts for approximately 10% of cases of renovascular hypertension.[102] Vascular lesions typically affect the middle and distal portions of the renal artery and often extend into branches. Three subtypes are defined on the basis of the layer of the vascular wall affected: (1) intimal hyperplasia (1% to 2% of cases), (2) medial fibromuscular dysplasia (95% of cases), and (3) periadventitial fibrosis (1% to 2% of cases). The most common subtype, medial fibromuscular dysplasia, presents as a classic string-of-beads (aneurysmal dilatations) on angiography; it progresses in 30% of cases. It is rarely associated with dissection or thrombosis. In contrast, the rarer forms can progress rapidly, and dissection and thrombosis are common. Fibromuscular dysplasia is a rare cause of renal artery occlusion.

Atheromatous disease is the most common cause of renovascular hypertension in middle-aged and older patients and accounts for approximately 90% of renovascular hypertension.[102] Vascular lesions are usually in the proximal third of the renal arteries, often near or at the orifice. The prevalence of atheromatous renal artery disease increases with age and is common in older hypertensive patients, especially in those with diabetes or with atherosclerosis in other vascular beds. Most patients with atheromatous renal vascular disease and hypertension have essential hypertension. The disease is frequently bilateral (30%) and is often progressive. The likelihood of progression can be decreased by aggressive control of risk factors (e.g., dyslipidemia, cigarette smoking, and hypertension).

The presentations of hemodynamically significant bilateral renal artery disease (ischemic nephropathy) include the following: an acute decline in renal function with use of an ACE inhibitor or ARB or with a sudden decrease in blood pressure; acute hypertension and pulmonary edema (flash pulmonary edema); or an unexplained subacute decline in renal function with or without worsening of hypertension.[103] Bilateral atherosclerotic renal artery disease accounts for a small but increasing number of cases of end-stage renal disease in older persons.[104]

Atheroembolic renal disease can mimic renovascular hypertension and ischemic nephropathy, in that it may present as hypertension of acute onset or as a worsening of hypertension in conjunction with a subacute decline in renal function. Atheroembolic renal disease often occurs after angiography or vascular surgery. Physical findings include the presence of distal livido reticularis and peripheral emboli. Laboratory findings include an elevated erythrocyte sedimentation rate, anemia, hematuria, eosinophilia, and eosinophiluria.

PRIMARY ALDOSTERONISM

The classic syndrome of primary aldosteronism consists of hypertension, hypokalemia from excessive renal excretion, alkalosis, suppressed plasma renin activity, and increased aldosterone secretion.[105] Hypokalemia is the abnormality that most often raises suspicion of this disorder, but approximately 30% of patients with primary aldosteronism present with normal serum potassium levels.

Although several subtypes of primary aldosteronism have been identified, the most common are unilateral aldosterone-producing adenoma, which comprises 30% to 40% of cases; and bilateral adrenal zona glomerulosa hyperplasia (also known as idiopathic hyperaldosteronism [IHA]), which comprises 60% to 70% of cases. Rare subtypes include glucocorticoid-suppressible hyperplasia, unilateral hyperplasia, and aldosterone-producing cortical carcinoma. The prevalence of primary aldosteronism is probably around 2%, but studies have suggested the prevalence to be as high as 15% of the hypertensive population. The higher prevalence estimates reflect an increase in the number of patients being diagnosed with IHA, a condition that may be part of the spectrum of essential hypertension.

Patients for whom the diagnosis of primary aldosteronism should be considered include the following: all hypertensive patients with spontaneous hypokalemia of renal origin (for a hypokalemic patient, a 24-hour urinary potassium level higher than 30 mEq/L is consistent with renal potassium wasting); most patients with excessive hypokalemia who are receiving usual doses of diuretics (serum potassium < 3.0 mEq/L); most patients with resistant hypertension, even if normokalemic; and all patients with hypertension and an adrenal mass.

PHEOCHROMOCYTOMA

Pheochromocytomas are rare tumors of chromaffin cell origin that produce excess amounts of catecholamines, which leads to paroxysmal or sustained hypertension. The incidence in the general population is 2 to 8 cases per million persons per year. The prevalence is about 0.5% in patients with hypertension who have suggestive symptoms, and approximately 4% in patients with adrenal incidentalomas. Most tumors are benign, but approximately 10% are malignant. Symptomatic paroxysms occur in less than 50% of patients. Episodes are characterized by symptoms of headache, diaphoresis, palpitations, and pallor associated with increases in blood pressure.[106] Such paroxysms are usually rapid in onset, and offset and can be precipitated by a variety of activities (e.g., exercise, bending over, urination, defecation, induction of anesthesia, infusion of intravenous contrast media, smoking). A history of unintended weight loss is not uncommon. The hypertension may be associated with marked BP lability and orthostatic hypotension. Rarely, patients may present with catecholamine-induced cardiomyopathy, fever, or peripheral vasospasm. The hypertension can be severe and resistant to control.

Most pheochromocytomas are sporadic, but 10% are familial. Familial syndromes include a simple autosomal dominant form not associated with other abnormalities, the multiple endocrine neoplasias (type IIA [medullary thyroid carcinoma, hyperparathyroidism] and type IIB [medullary thyroid carcinoma, mucosal neuromas, marfanoid habitus, thickened corneal nerves, intestinal gangliomatosis]), neurofibromatosis, and the von Hippel-Lindau syndrome (retinal hemangiomatosis, cerebellar hemangioblastomas, renal cell carcinoma). Familial pheochromocytomas can be bilateral.

Most pheochromocytomas (90%) are located in one or both adrenal glands. Extra-adrenal pheochromocytomas can occur anywhere along the sympathetic chain and, rarely, in other sites (i.e., the superior para-aortic region, the glomus jugulare, the inferior para-aortic region, the bladder, or the thorax). About 98% of pheochromocytomas are located in the abdomen.

Screening for pheochromocytoma should be selective and based on suggestive clinical features. Screening tests include measurement of catecholamines (i.e., epinephrine, norepinephrine, dopamine) and their metabolites (i.e., metanephrine, normetanephrine, and vanillylmandelic acid [VMA]) in the plasma and urine. Traditionally, most experts have considered measurement of 24-hour urinary catecholamines or catecholamine metabolites to be the screening tests of choice.[106] However, stud-

Table 14 Causes for False Positive Screening Results for Plasma Free Metanephrines and 24-Hour Urinary Metanephrines

Category	*Sources*	*Tests Affected*
Diet	Coffee (including decaffeinated)	Plasma metanephrines/urinary HPLC electrophoresis
	Acetaminophen (direct effect)	Plasma metanephrines/urinary HPLC electrophoresis
	Caffeine (increases plasma catecholamines)	All
	Unknown diet sources	Plasma metanephrines/urinary HPLC electrophoresis
Drugs	Nicotine (increases plasma catecholamines)	All
	Tricyclic antidepressants (norepinephrine and its metabolites)	All
	Dibenzyline (norepinephrine and its metabolites)	All
	Drugs containing catecholamines (decongestants)	All
	Labetalol	Urinary HPLC electrophoresis
	Withdrawal from clonidine	All
	Withdrawal from alcohol	All
	Withdrawal from benzodiazepines	All
	Levodopa	All
	Cyclobenzaprine	All
	Amphetamines	All
	Phenothiazines	Unknown
	Benzodiazepines	Unknown
Physiologic stress	Obstructive sleep apnea, heart failure	All

HPLC—high-pressure liquid chromatography

ies now suggest that measurement of plasma free metanephrines is a much more sensitive screening test (for hereditary tumors, sensitivity is 97%, versus 60% for urinary metanephrines; for sporadic tumors, sensitivity is 99%, versus 88% for urinary metanephrines).[107] Also, this screening test obviates the concerns associated with obtaining an adequate 24-hour urine collection. Although the sensitivity of the plasma screen is higher than that of urinary tests, its specificity is lower with regard to screening for sporadic tumors (for sporadic tumors, specificity is 82% with the plasma test versus 89% with the urinary test; in hereditary tumors, specificity is 96% with the plasma test versus 97% with the urinary test). Plasma metanephrine assay should be strongly considered as the screening test of choice if a hereditary form of pheochromocytoma is suspected; it should also be considered the test of choice for patients with a history of pheochromocytoma and for patients in whom the clinical suspicion is high. A negative result on either a plasma or urinary metanephrine test excludes the diagnosis in most cases.

Because of the low prevalence of pheochromocytomas in patients screened for this disorder, false positive results outnumber true positive results. This is of major concern because positive results from screening tests often lead to additional tests and anxiety on the part of the both the physician and the patient. There are three main factors associated with false positive results: diet, drugs, and physiologic stressors [*see Table 14*]. Specific dietary factors and drugs affect plasma screens and urinary metanephrine screens differently. Moreover, for urinary metanephrine screens, different drugs affect the results differently depending on the method of analysis used (i.e., high-pressure liquid chromatography [HPLC] versus mass spectrophotometry). Anticipation of these potential problems and proper preparation of the patient can prevent many false positive results.

A positive screening test should prompt a search for the tumor if sources of a false positive result have been excluded. Abdominal imaging with computed tomography or magnetic resonance imaging is the initial test of choice, given that 90% of pheochromocytomas are on the adrenal glands and 98% are in the abdomen. Additional studies may be required if a tumor is not found with initial imaging.[108] Medical treatment is required before surgical intervention. The mainstay of treatment is alpha blockade with phenoxybenzamine. Beta blockers can be used to control the tachycardia that occasionally follows adequate alpha blockade. Because pheochromocytomas can recur in 10% of patients, long-term biochemical follow-up is required.

CUSHING SYNDROME

Cushing syndrome arises from excess production of glucocorticoids. It is rare: the incidence of the ectopic adrenocorticotropic hormone (ACTH) syndrome is about 660 cases per million population; in 50% of these cases, the underlying cause is small cell lung cancer. The incidence of adrenal tumors is one to five cases per million population per year. The incidence of pituitary ACTH-dependent disease is estimated to be five to 25 cases per million population per year. The signs and symptoms of Cushing syndrome arise from long-term exposure to excess glucocorticoids. They include central obesity, skin atrophy, striae, acne, slow wound healing, proximal muscle wasting and weakness, osteoporosis, menstrual irregularity, hyperpigmentation (ACTH dependent), glucose intolerance, hypokalemia, and hypertension. Clinical manifestations vary on the basis of degree and duration of glucocorticoid excess, the presence or absence of androgen excess (in women, androgen excess produces hirsutism, decreased libido, virilization, and oily skin), and the cause of hypercortisolism (hyperpigmentation results from excessive ACTH; androgen excess is more common in adrenal carcinomas). States of pseudo–Cushing syndrome can result from significant stress, severe obesity, depression, and chronic alcoholism.[109]

Patients suspected of having Cushing syndrome should undergo measurement of 24-hour urinary free cortisol. Normal levels exclude the diagnosis, and levels higher than threefold normal confirm it. In patients with equivocal results, a low-dose

dexamethasone suppression test can be used. For this test, the patient is given a 1 mg tablet at 11 P.M. Serum cortisol is measured on a specimen drawn the next morning at 8 A.M. A normal response is a serum cortisol level of less than 5 μg/dl. An alternative method is to give a 0.5 mg tablet every 6 hours for eight doses and to measure 24-hour urinary cortisol excretion on the second day. A normal response is a urinary cortisol excretion of less than 10 μg/24 hr and a serum cortisol level of less than 5 μg/dl.

COARCTATION OF THE AORTA

Congenital constriction of the aorta accounts for approximately 7% of congenital cardiovascular diseases. Coarctation can occur anywhere along the aorta but most often occurs just distal to the takeoff of the left subclavian artery. The disorder is usually detected in childhood, but occasionally it escapes detection until adulthood. Symptoms include headache, cold feet, and claudication. The classic feature of coarctation is elevated blood pressure in the arms and low or unobtainable blood pressure in the legs. This finding can be identified by direct measurement. The presence of weak femoral pulses or a delay in sensing the femoral pulse when simultaneously palpating the radial pulse is cause to suspect coarctation. Other findings include visible pulsations in the neck or chest wall and murmurs in the front and back of the chest from collateral vessels. Physical findings may be subtle. If the diagnosis is suspected, screening tests include transesophageal echocardiography or MRI or CT imaging of the aorta. Treatment is surgical in most cases [*see 1:XII Diseases of the Aorta*].

Complications

Left untreated, hypertension leads to premature death or disability from complications of CV diseases, especially atherosclerosis.[3-5] Hypertension affects blood vessels directly, inducing endothelial dysfunction, and acts in concert with other factors (e.g., smoking, hyperlipidemia, and diabetes) to promote the atherosclerotic process. Although the effect of hypertension on blood vessels is systemic, it expresses itself by characteristic effects on target organs—the heart, brain, kidneys, and eyes.

Hypertension increases the risk of myocardial infarction and sudden cardiac death twofold.[3] It contributes to the risk of atrial fibrillation and is the single most important antecedent to the development of heart failure.[87,88] These adverse effects of hypertension reflect both acceleration of atherosclerosis and the development of structural adaptation of the heart (LVH and left atrial enlargement) to increased afterload. The structural changes limit coronary reserve.

Heart failure can be the result of either systolic or diastolic dysfunction. Hypertension is commonly associated with abnormal diastolic relaxation, which can be demonstrated by echocardiography. Progression of these effects on the heart can lead to symptoms of heart failure with preserved systolic function, a condition known as diastolic heart failure [*see 1:II Heart Failure*]. In addition, long-standing hypertension leads to LVH and ventricular remodeling, which progresses to systolic dysfunction. This process is aggravated by myocardial infarction.

Hypertension is the single most important cause of stroke, which itself is the third leading cause of death in the United States.[110] Hypertension increases the risk of stroke by aggravating atherosclerosis in the aortic arch and carotid and cerebral arteries (causing thrombotic or embolic ischemic strokes) and by inducing arteriosclerosis in small, penetrating subcortical cerebral vessels, leading to leukoaraiosis (periventricular leukoenceophalopathy) and lacunar strokes. Severe hypertension is also associated with intraparenchymal and subarachnoid hemorrhage.

Hypertension in midlife is associated with an increased risk of cognitive dysfunction and dementia in later life.[5] This may be a complication of multiple cerebral infarctions (multi-infarct dementia), but it also occurs in the absence of previous strokes. In some persons, cognitive dysfunction may arise from the effects of elevated BP on the small penetrating subcortical arterioles, leading to ischemic injury to white matter (visible as leukoaraiosis on brain imaging studies). Although vascular dementia in the elderly is strongly related to hypertension, the relationship between BP and cognition is less clear in persons older than 75 years. In some cases, an inverse relationship has been noted. This may reflect a shift in cerebral autoregulation to a higher range in patients with hypertension-induced small vessel disease, making these patients more vulnerable to further ischemic brain injury when BP is lowered.

Hypertension is a risk factor for abdominal aortic aneurysm. In addition, the majority of patients with aortic dissection have hypertension. Aortic dissection arises from the combined effects of accelerated aortic atherosclerosis and increased pulsatile stress on the aortic wall. Hypertension increases the risk of peripheral vascular disease, especially in cigarette smokers and diabetic patients.

Hypertension is the second leading cause of end-stage renal disease.[104] Arteriosclerotic changes lead to ischemic injury and loss of glomeruli and tubular elements, ultimately leading to the shrunken kidney of nephrosclerosis. End-stage kidney disease from hypertension is much more common in blacks. Malignant hypertension induces fibrinoid necrosis of renal arterioles and can lead to acute renal failure.

Hypertension-related vascular disease causes loss of vision through a variety of mechanisms.[111] Chronic hypertension causes arteriosclerosis of retinal vessels. These changes at the site of arterial-venous crossings can lead to branch retinal vein occlusion. Central retinal vein occlusion can also occur. Ischemic optic neuropathy can be a complication of chronic hypertension or acute severe hypertension. Acute, severe elevations in BP can also cause retinal hemorrhages, exudates, and papilledema. Hypertension accelerates atherosclerosis. Atherosclerotic emboli can occlude central or branch retinal arteries, with sudden and irreversible visual loss. Reduced blood flow in the carotid or ophthalmic artery because of severe atherosclerosis can cause venous stasis retinopathy. Occlusive disease of retinal vessels can lead to cystoid macular edema, epiretinal membrane formation, and collateral vessel formation.

Prognosis

Effective treatment has a dramatic effect on the prognosis of patients with hypertension. Prospective treatment trials have established that BP reduction with drug therapy markedly reduces CV morbidity and mortality. Active treatment of hypertension lessens the tendency for BP to increase over time. For patients whose diastolic BP is 90 mm Hg more or whose systolic BP is 160 mm Hg or more, drug intervention has been shown to reduce the risk of stroke by 35% to 40%; the risk of myocardial infarction is reduced by 20% to 25%; and the risk of heart failure is reduced by over 50%. In hypertensive patients with chronic

kidney disease, drug intervention reduces the risk of progression to dialysis, transplantation, and death. However, even when BP is brought down to current recommended levels, hypertensive individuals remain at higher risk for CV disease events compared with normotensive individuals. Patients with target-organ disease remain at even higher risk, despite good BP control. These observations argue for application of public health and individual patient strategies to prevent the development of hypertension and for early detection and effective treatment of high BP.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

IV ATRIAL FIBRILLATION

Anthony Aizer, m.d.
Valentin Fuster, m.d., ph.d.

Atrial fibrillation (AF) is a supraventricular tachyarrhythmia defined by rapid, irregular atrial activation. This disordered atrial activation results in loss of coordinated atrial contraction; irregular electrical input to the atrioventricular (AV) node typically leads to sporadic ventricular contractions. On an electrocardiogram, AF is characterized by the absence of visible discrete P waves, the presence of irregular fibrillatory waves, or both, and an irregularly irregular ventricular response [*see Figure 1*].

AF may occur by itself or with other arrhythmias, notably, atrial flutter. Atrial flutter is more organized than AF, involving regular atrial activation that often produces a characteristic sawtooth pattern on ECG. Cardiac rhythm may alternate between AF and atrial flutter, AF may trigger atrial flutter, or atrial flutter may degenerate into AF.

Classification

Numerous classification schemes have been used to characterize AF patients, and the lack of a consistent classification scheme across studies has led to difficulties in comparison of analyses and an inability to extrapolate results to all patients. Consequently, the American College of Cardiology (ACC), the American Heart Association (AHA), and the European Society of Cardiology (ESC), in collaboration with the North American Society of Pacing and Electrophysiology, have established guidelines for the classification of AF.[1] The ACC/AHA/ESC guidelines include the following categories:

- Recurrent—AF occurring in a patient who has experienced an episode of AF in the past.
- Lone—AF occurring in a patient younger than 60 years who has no clinical or echocardiographic evidence of cardiopulmonary disease.
- Valvular or nonvalvular—Valvular AF is AF that occurs in a patient who has evidence or history of rheumatic mitral valve disease or who has a prosthetic heart valve; all other forms of AF are classified as nonvalvular.
- Paroxysmal—AF that typically lasts 7 days or less and that converts spontaneously to sinus rhythm.
- Persistent—AF that typically lasts longer than 7 days or requires pharmacologic or direct current (DC) cardioversion.
- Permanent—AF that is refractory to cardioversion or that has persisted for longer than 1 year.

Paroxysmal, persistent, and permanent AF categories do not apply to episodes of AF lasting 30 seconds or less or to episodes precipitated by a reversible medical condition. Reversible conditions include acute myocardial infarction, cardiac surgery, pericarditis, myocarditis, hyperthyroidism, pulmonary embolism, and acute pulmonary disease.

Epidemiology

AF is the most common sustained arrhythmia, currently affecting more than 2.2 million persons in the United States.[2] The incidence is approximately 0.1% per year for the entire population; however, the incidence of AF increases steadily with age. As a result, one out of 11 Americans older than 80 years has AF.[3-5]

AF is associated with significant morbidity and mortality. The annual incidence of ischemic stroke in patients with AF is 5%, which is two to seven times higher than the incidence in the general population. In addition, the mortality in patients with AF is approximately twice that of patients without AF.[3,6,7] AF frequently leads to reduced functional capacity, dyspnea, palpitations, fatigue, tachycardia-induced cardiomyopathy, heart failure, and angina, significantly impairing quality of life.[8]

Finally, AF results in tremendous health care expenditures. There are more than 370,000 hospital admissions for AF annually.[9] After the first diagnosis of AF, hospitalization costs are typically 35% higher for patients with AF than for age-matched control subjects.[10]

Pathophysiology

Central to the pathophysiology of AF are two factors: the electrical trigger that initiates the arrhythmia and the abnormal myocardial substrate that allows AF to be maintained. A spectrum of triggers is thought to initiate AF, ranging from premature atrial contractions to atrial tachycardias; ultimately, AF may be self triggering.[11-13] Ectopic atrial foci, frequently located in the pulmonary veins, have been shown to trigger AF.

For AF to persist, the atrial tissue must be primed to allow the propagation of multiple wavelets of electrical depolarization throughout the atria.[14] If a wavelet encounters refractory tissue, the wavelet can extinguish, divide into additional wavelets, or change direction. If the underlying atrial substrate leads to the extinction of the wavelets, then AF will not persist. In contrast, if the underlying atrial substrate promotes the generation of additional wavelets or the maintenance of the existing wavelets, then AF will continue. Fibrosis, hypertrophy, and fatty infiltration of atrial tissue likely allow for abnormal atrial electrical conduction and the maintenance of AF wavelets.

Diagnosis

clinical manifestations

AF can result in a wide variety of signs and symptoms. Some patients are asymptomatic, although they may have an irregularly irregular pulse. Other patients experience strokes, palpitations, fatigue, dyspnea, reduced exercise capacity, heart failure, angina, presyncope, or syncope. Additional complications include

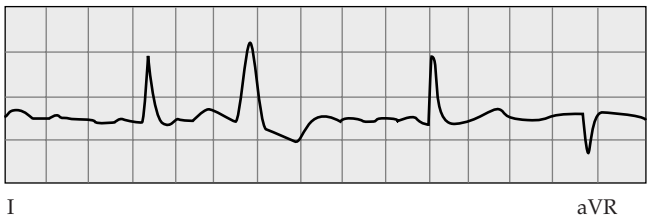

Figure 1 **An electrocardiographic tracing shows characteristic features of atrial fibrillation, with absent P waves, irregular fibrillatory waves, and an irregularly irregular ventricular response.**

Table 1 Initial Clinical Evaluation of Atrial Fibrillation[10]

Evaluation	*Features to Assess*
History and physical examination	Presence, frequency, onset, duration, termination, exacerbating and alleviating factors of AF; date of AF onset; AF classification; associated symptoms; reversible and irreversible contributing conditions; thromboembolic and hemorrhagic risk factors; response to pharmacologic or mechanical interventions
Laboratory studies	Thyroid function,* serum electrolytes, hemoglobin or hematocrit
Chest radiography	Lung parenchyma for intrinsic lung disease; abnormal pulmonary vasculature for pulmonary hypertension; cardiac size and shape for heart failure and pericardial disease
ECG	AF verification; P wave morphology for atrial flutter; preexcitation; atrial arrhythmias besides AF, as possible AF triggers; LVH, for hypertension and hypertrophic cardiomyopathy; bundle branch block and previous MI as markers for CAD, left ventricular dysfunction, and conduction system disease; RR, QRS, and QT intervals to guide antiarrhythmic drug therapy
Transthoracic echocardiography	Left and right atrial size and function; left ventricular size, function, and hypertrophy; valvular heart disease, including rheumatic heart disease; right ventricular systolic pressure for pulmonary hypertension; left atrial thrombus; spontaneous echocardiographic contrast (low sensitivity); pericardial disease; aortic plaque (low sensitivity)

*Reassessment of thyroid function should be considered if ventricular rate becomes difficult to control or atrial fibrillation recurs unexpectedly after conversion to sinus rhythm.
AF—atrial fibrillation CAD—coronary artery disease ECG—electrocardiogram LVH—left ventricular hypertrophy MI—myocardial infarction

thromboembolism and tachycardia-induced cardiomyopathy.[15] The effect of AF on the patient's quality of life is often a critical component that guides decisions regarding AF management.

CLINICAL EVALUATION

The initial evaluation of a patient with AF focuses on the following tasks: (1) confirming the diagnosis of AF, (2) classifying the type of AF, (3) identifying factors (both reversible and irreversible) that contribute to or cause AF, (4) establishing the risk of thromboembolism and additional adverse outcomes, and (5) defining the most effective treatment strategy. In taking the history, the clinician should try to determine whether this is the first episode of AF. If more than one episode of AF has occurred, the AF is defined as recurrent. If no reversible condition is detected in recurrent AF, the clinician may be able to classify the AF as paroxysmal, persistent, or permanent [*see* Classification, *above*].

LABORATORY STUDIES

The standard blood tests that are recommended by the ACC/AHA/ESC are thyroid function tests and measurement of serum electrolytes and hemoglobin or hematocrit. Other recommended laboratory studies include chest radiography, ECG, and transthoracic echocardiography [*see Table 1*]. Additional tests that may be indicated in specific situations are event and Holter monitoring, exercise testing, transesophageal echocardiography (TEE), and electrophysiologic study (EPS).

Event and Holter Monitors

Event monitors are of particular use for documenting infrequent symptomatic episodes in patients in whom AF has not been confirmed previously. In addition to their diagnostic utility for documenting AF, Holter monitors may be used for therapeutic follow-up to evaluate rate control.[16]

Exercise Testing

Exercise testing can confirm the presence of ischemic heart disease and may unmask exercise-mediated AF. In addition, exercise testing can be used to explore the safety of using specific antiarrhythmic medications and to assess rate control.

Transesophageal Echocardiography

TEE is of greatest use in establishing the risk for embolic stroke, most notably in association with cardioversion to sinus rhythm. Risk factors for cardiogenic embolism that are best identified with TEE include the following: left atrial and left atrial appendage thrombus, left atrial and left atrial appendage spontaneous echo contrast (smoke), left atrial appendage flow velocity, and aortic plaque.[17]

Electrophysiologic Study

EPS can define specific forms of AF that are amenable to catheter-based intervention (i.e., radiofrequency ablation). In addition, EPS allows for assessment of the underlying conduction system to determine the etiology of wide-complex tachycardias, whether supraventricular or ventricular in origin.

Management

Treatment of AF includes either restoration and maintenance of sinus rhythm or control of ventricular rate if AF is persistent or if future paroxysmal events are likely to occur. In ad-

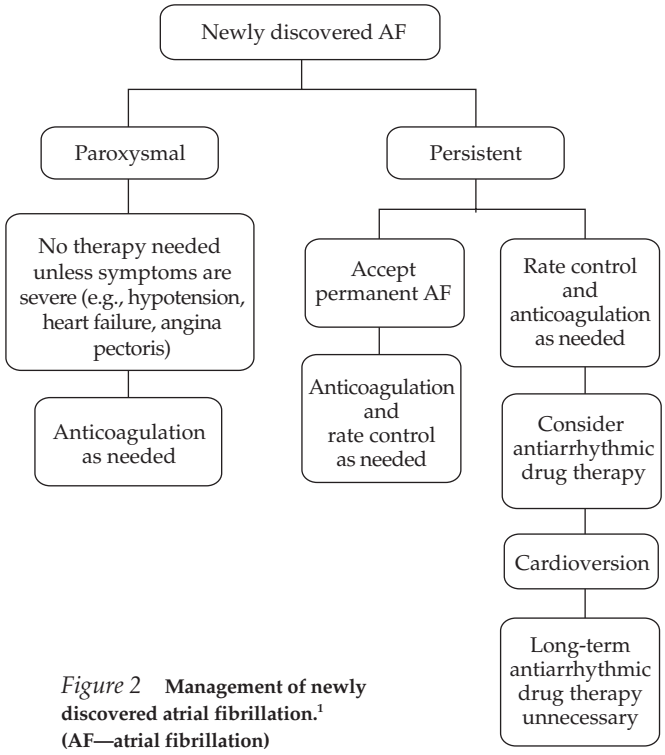

Figure 2 **Management of newly discovered atrial fibrillation.[1] (AF—atrial fibrillation)**

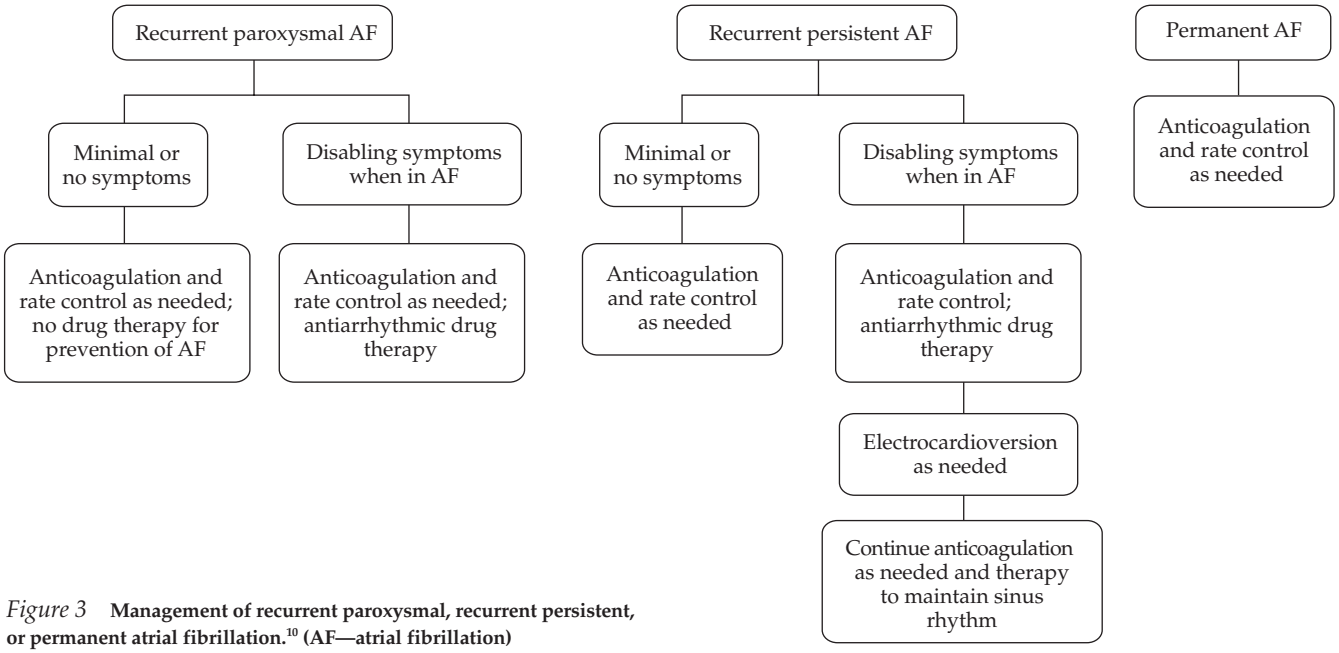

Figure 3 **Management of recurrent paroxysmal, recurrent persistent, or permanent atrial fibrillation.[10] (AF—atrial fibrillation)**

dition, antithrombotics are used to reduce embolic risk [*see Figures 2 through 4*].[10] Treatment decisions involve a synthesis of research results with the characteristics of the individual patient.

Several trials have compared restoration of sinus rhythm with control of ventricular rate in patients with AF. Outcomes evaluated have included overall mortality, stroke, symptoms, and quality of life. Contrary to the expectations of many experts, maintenance of sinus rhythm provided no survival advantage and possibly a higher mortality when compared with ventricular rate control.[18,19] Maintenance of sinus rhythm frequently requires the use of antiarrhythmic medications that may precipitate ventricular arrhythmias, bradycardia, and depression of left ventricular function. It was theorized that maintenance of sinus rhythm would reduce rates of thromboembolism and the need for anticoagulation; however, trial results demonstrated no significant reduction in thromboembolic risk. Peak exercise capacity may improve with maintenance of sinus rhythm, but both treatment strategies result in a similar degree of perceived symptomatic impairment.[8,20,21]

Nevertheless, ventricular rate control frequently is not feasible because of the complications that patients experience while in AF. Clinical scenarios in which AF often is not tolerated include unstable angina, acute myocardial infarction, heart failure, and pulmonary edema. In addition, patients in whom atrial contraction provides a significant proportion of ventricular filling because of impaired ventricular relaxation often need to be maintained in sinus rhythm.

RESTORATION AND MAINTENANCE OF SINUS RHYTHM

Sinus rhythm can be restored with medication, electrical shocks, or a combination of both. Electrical shocks typically are more effective than medication for cardioversion and pose a lower risk of life-threatening ventricular arrhythmias. However, shocks require conscious sedation. In a proportion of patients refractory to medication or electrical shocks, the combination of both therapies results in return of sinus rhythm.

Pharmacologic Cardioversion

Antiarrhythmic medications typically alter the conduction properties of both diseased and normal atrial tissue, suppressing AF triggers or inhibiting the propagation of AF electrical wavelets. Although pharmacologic cardioversion might seem simpler than electrical cardioversion, it has a lower success rate and it poses a risk of life-threatening arrhythmias; the latter risk often precludes use of this strategy. The efficacy of medications for cardioversion of AF typically declines as the duration of AF increases.[22]

A number of medications can be used for cardioversion or for maintenance of sinus rhythm [*see Tables 2 and 3*]. Some medications can be used for both purposes, but others should be used for cardioversion only or for maintenance of sinus rhythm only.

Medication selection for pharmacologic cardioversion must be based on individual patient characteristics. Amiodarone, dofetilide, and ibutilide (agents with potassium channel blocking effects) can be given safely to patients with heart failure or reduced left ventricular systolic function. In contrast, flecainide and propafenone may exacerbate heart failure and should be avoided in such patients. Dofetilide and ibutilide have higher success rates for conversion of atrial flutter than of AF, whereas flecainide and propafenone have higher success rates with conversion of AF than of atrial flutter. Flecainide, propafenone, disopyramide, procainamide, and quinidine also may increase ventricular rate response, especially if patients convert from AF to atrial flutter. Before receiving one of these medications, the patient should be pretreated with an AV nodal blocking agent (typically, diltiazem or verapamil, or possibly digoxin).

Disopyramide, procainamide, and quinidine have either limited efficacy for cardioversion of AF or are associated with significant adverse effects that preclude their use except in rare circumstances. Sotalol effectively maintains sinus rhythm and controls ventricular rate in patients who have undergone cardioconversion from AF, but it has not been shown to effectively convert AF to sinus rhythm. Similarly, beta blockers, verapamil, diltiazem, and digoxin are effective for control of ven-

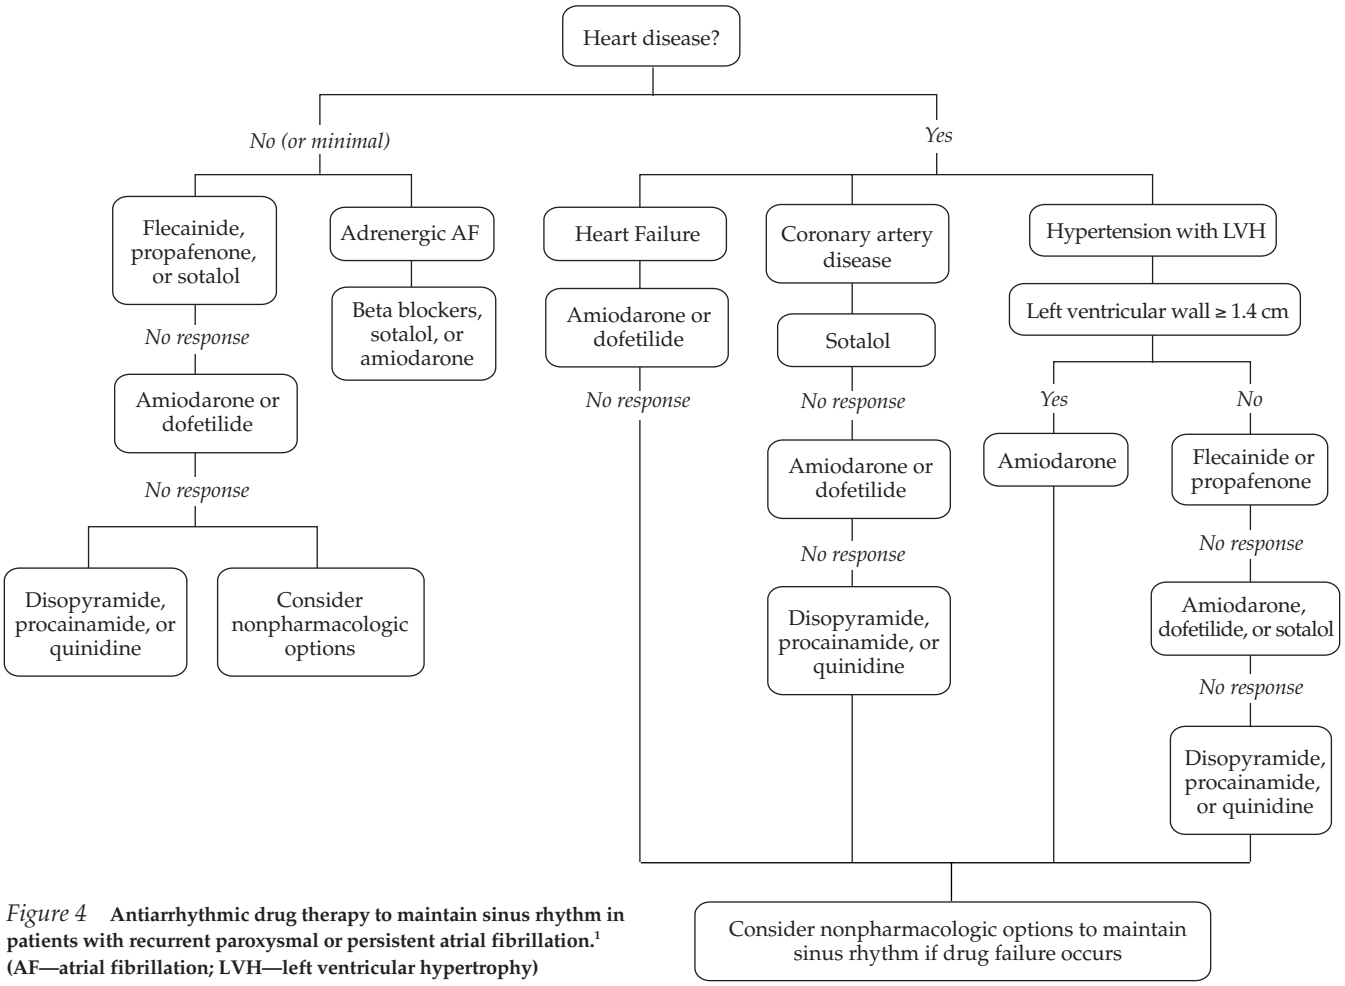

Figure 4 **Antiarrhythmic drug therapy to maintain sinus rhythm in patients with recurrent paroxysmal or persistent atrial fibrillation.[1] (AF—atrial fibrillation; LVH—left ventricular hypertrophy)**

tricular rate in patients with AF, but these medications have little role in AF cardioversion.

Electrical Cardioversion

DC cardioversion is the most effective mechanism for achieving sinus rhythm, with success rates of approximately 70% to 90%.[23,24] DC cardioversion has an even greater rate of success with atrial flutter, approximating 95%.[25] The efficacy of DC cardioversion can be optimized by enhancing delivery of energy to the atrial myocardium. This is achieved through a number of maneuvers:

- Electrode paddle positioning. Anteroposterior positioning is more effective than anterolateral positioning.[26] In addition, applying pressure to the paddles during conversion reduces transthoracic impedance, improving energy conduction.
- Timing of cardioversion. Application of the energy when the patient has fully exhaled reduces pulmonary resistance to the current.[27]
- Use of rectilinear biphasic energy. Traditional energy sources supply monophasic energy. Biphasic energy transfers more efficiently to atrial tissue, leading to higher cardioversion success rates and lower cumulative energy discharge.[28]

Although numerous protocols have been validated, a reasonable protocol that uses monophasic energy to convert AF is to start at 200 joules (J), followed by 300 J, then by 360 J or 400 J.[29] For patients with atrial flutter, cardioversion is frequently achieved with 50 J of monophasic energy; therefore, the monophasic AF protocol can be modified for AF by starting with 50 J, followed by 100 J. If biphasic energy is utilized for AF, a protocol of 70 J or 100 J followed by 150 J and then by 200 J may be utilized.[28,30]

Although success rates are high with DC cardioversion, a number of risk factors for cardioversion failure have been identified. These include longer duration of AF (notably, greater than 1 year), older age, left atrial enlargement, cardiomegaly, rheumatic heart disease, and transthoracic impedance.[25,28] Pretreatment with amiodarone, ibutilide, sotalol, flecainide, propafenone, disopyramide, and quinidine have been shown to increase DC cardioversion success rates.[1] Transvenous cardioversion also may be successfully used for cardioversion for patients in whom transthoracic cardioversion fails.[31,32]

DC cardioversion of AF is extremely safe, typically resulting in no significant myocardial damage if cardioversion attempts are separated by at least 1 minute. Nevertheless, clinicians must give consideration to two types of adverse events[33,34]:

- Reprogramming or malfunction of permanent pacemakers or implantable cardioverter-defibrillators (ICDs). Electricity transmitted from endocardial wires to myocardium can lead to tissue scarring and an increased threshold for tissue capture.[35] In addition, cardioversion energy can erase or alter the programming of permanent pacemakers or ICDs. For that

Table 2 Drugs for Cardioversion of Atrial Fibrillation and Maintenance of Sinus Rhythm[10]

Medication	*Route*	*Time to Conversion*	*Precautions*	*Drug Interactions*	*Side Effects*	*Comments*
Amiodarone	Oral/ I.V.	Hours to weeks	—	Increases digoxin, procainamide, quinidine, and warfarin levels	Bradycardia, visual disturbances, nausea, constipation, phlebitis (I.V. form); hepatic, ocular, pulmonary, thyroid, neurologic toxicity	Safe for use in patients with left ventricular dysfunction; TdP/VT less common than with dofetilide, ibutilide, or sotalol
Dofetilide	Oral	Days to weeks	—	Levels increased by cimetidine and verapamil	—	Safe for use in patients with left ventricular dysfunction; associated with TdP
Ibutilide	I.V.	< 1 hr	Check serum potassium, magnesium levels; requires 4 hr of monitoring for TdP	—	—	Safe for use in patients with left ventricular dysfunction; associated with TdP; not used for maintenance of sinus rhythm
Sotalol	Oral	Incompletely studied; reduced efficacy or no proven efficacy for cardioversion of AF	May exacerbate CHF and/or COPD	—	Bradycardia	Use with caution in patients with reduced left ventricular function; associated with TdP
Flecainide	Oral	3 hr	Pretreat with AV nodal blocking agents* to avoid accelerated ventricular response; avoid in patients with heart failure, left ventricular dysfunction, or CAD	Levels increased by amiodarone	—	
Propafenone	Oral/I.V.	< 6 hr	Pretreat with AV nodal blocking agents* to avoid accelerated ventricular response; avoid in patients with heart failure, left ventricular dysfunction, or CAD; may exacerbate COPD	Increases digoxin and warfarin levels	Blurred vision, hypotension	Efficacy reduced in patients with structural heart disease
Quinidine	Oral/I.V.	2–6 hr	Pretreat with AV nodal blocking agents* to avoid accelerated ventricular response; avoid in patients with heart failure or left ventricular dysfunction	Increases digoxin levels; levels increased by verapamil	Hypotension, nausea, diarrhea, fever, hepatic dysfunction, thrombocytopenia, hemolytic anemia	Safety limits use in cardioversion; side effects limit use; associated with TdP
Disopyramide	Oral/I.V.	< 12 hr	Incompletely studied, reduced efficacy or no proven efficacy for cardioversion of AF; pretreat with AV nodal blocking agents* to avoid accelerated ventricular response; avoid in patients with heart failure or left ventricular dysfunction	—	Dry mucous membranes, constipation, urinary retention; significant reduction of left ventricular function	Side effects limit use; associated with TdP
Procainamide	I.V.	< 24 hr	Incompletely studied, reduced efficacy or no proven efficacy for cardioversion of AF; pretreat with AV nodal blocking agents* to avoid accelerated ventricular response; avoid in patients with heart failure or left ventricular dysfunction	—	Drug-induced lupus, vasculitides, blood dyscrasias, central nervous system disturbances	Reduced efficacy, side effects limit use; associated with TdP

*AV nodal blocking agents typically used are verapamil or diltiazem, and possibly digoxin.
AF—atrial fibrillation CAD—coronary artery disease CHF—chronic heart failure COPD—chronic obstructive pulmonary disease TdP—torsade de pointes VT—ventricular tachycardia

Table 3 Dosages of Drugs for Pharmacologic Cardioversion of Atrial Fibrillation and Maintenance of Sinus Rhythm[10,80]

Drug	*Dosage for Cardioversion*	*Daily Dosage for Maintenance of Sinus Rhythm*
Amiodarone	Oral, inpatient 1.2–1.8 g/day in divided doses until 10 g total, then 200–400 mg/day maintenance; or 30 mg/kg as single dose Oral, outpatient 600–800 mg/day in divided doses until 10 g total Intravenous/oral 5–7 mg/kg over 30–60 min, then 1.2–1.8 g/day continuous I.V. or in divided oral doses until 10 g total	100–400 mg
Dofetilide	Oral dosages for specified C_{Cr} values 500 μg b.i.d. for C_{Cr} > 60 ml/min 250 μg b.i.d. for C_{Cr} 40 to 60 ml/min 125 μg b.i.d. for C_{Cr} 20 to 40 ml/min Contraindicated for C_{Cr} < 20 ml/min	500–1,000 μg; dosage adjustment based on QTc
Ibutilide	I.V.: 1 mg over 10 min; repeat once, if necessary	Not available
Sotalol	Not effective for cardioversion	240–320 mg; dosage adjustment based on QTc; reduced dosing with renal insufficiency
Flecainide	Oral: 200–300 mg	200–300 mg; reduced dosing with renal insufficiency
Propafenone	Oral: 450–600 mg I.V.: 1.5–2.0 mg/kg over 10–20 min; reduced dosing with renal insufficiency	450–900 mg; reduced dosing with hepatic dysfunction
Quinidine	Oral: 0.75–1.5 g in divided doses over 6–12 hr I.V.: 1.5–2.0 mg/kg over 10–20 min	600–1,500 mg
Disopyramide	Oral: 200 mg q. 4 hr, up to 800 mg	400–750 mg; reduced dosing with renal insufficiency
Procainamide	I.V.: 100 mg q. 5 min, up to 1,000 mg	1,000–4,000 mg; reduced dosing with renal insufficiency or hepatic dysfunction

Note: Dosages given may differ from those recommended by the manufacturer; see Table 2 for guidance regarding medication selection and dosing adjustments.
C_{Cr}—creatinine clearance QTc—corrected QT interval

reason, all such devices should be interrogated before and after DC cardioversion. Distancing of paddles from implanted devices may limit these adverse events.

- Arrhythmias. Life-threatening arrhythmias are more common with pharmacologic conversion but can occur with DC cardioversion. Ventricular tachycardia and ventricular fibrillation can result from cardioversion in patients with hypokalemia or digoxin toxicity. Failure to synchronize DC energy with ventricular rhythm can lead to ventricular fibrillation if energy is applied during ventricular repolarization.

Finally, many patients with AF have underlying sinus node dysfunction that may require permanent pacing once cardioversion is completed.[36]

Pharmacologic Approaches to Maintaining Sinus Rhythm

Except for patients in whom the cause of AF is reversible, pharmacologic therapy likely will be required to maintain sinus rhythm after cardioversion. In approximately 50% of AF patients who undergo cardioversion to sinus rhythm, AF will return within 1 year if prophylactic drug therapy is not employed; AF will recur in approximately 75% of patients within 4 years.[24] Before prescribing medication to maintain sinus rhythm, the clinician must assess the patient for underlying cardiovascular disease [*see Table 1*]. The presence of heart failure, coronary artery disease (CAD), or hypertension with left ventricular hypertrophy has a critical impact on the selection of antiarrhythmic medications [*see Figure 4*].

Class I antiarrhythmics frequently suppress left ventricular function. Randomized clinical trials have demonstrated that amiodarone and dofetilide maintain sinus rhythm without reducing survival in AF patients with heart failure.[37-39] As a result, these two drugs have become first-line therapy in this patient subgroup. In patients with ICDs, sotalol may be used safely.[40,41]

Agents with beta-blocking properties are preferred for patients with CAD. Sotalol has the advantage of blocking both beta-adrenergic receptors and potassium channels. In addition, sotalol has been shown to reduce reinfarction rates after a myocardial infarction, and its use has been associated with a trend toward reduced mortality.[42] However, in patients with concomitant heart failure or reduced ventricular function, amiodarone or dofetilide is preferable.

Hypertension and left ventricular hypertrophy may affect drug selection. If the left ventricular wall thickness is 14 mm or greater, amiodarone is recommended.

Although these recommendations can be applied to the majority of patients with AF, a number of distinct clinical scenarios require a tailored approach. In patients who do not have structural heart disease but who experience AF during exercise or under adrenergic stimulation, beta blockers are the treatment of choice, followed by sotalol or amiodarone. Vagally mediated AF that is not associated with structural heart disease often re-

sponds to disopyramide, a vagolytic medication. Second-line therapy includes flecainide and amiodarone.

Combination therapy may be used when a single medication fails to maintain sinus rhythm. With the combination of medications comes the increased risk of drug-induced side effects, notably, torsade de pointes and heart failure. Monitoring of symptoms and the width of the QTc and QRS intervals is critical.

Monitoring of antiarrhythmic therapy ECG monitoring is necessary in all patients receiving antiarrhythmic medications for maintenance of sinus rhythm. If flecainide or propafenone is used, QRS widening should not exceed 150% of pretreatment QRS width. QRS width should be assessed during exercise ECG testing, typically within 3 days after starting the medication. With all antiarrhythmics except amiodarone, QTc width should not exceed 520 msec. In addition, renal function and levels of serum potassium and serum magnesium should be monitored periodically, because abnormalities in these levels may predispose to arrhythmias.

Outpatient Initiation of Antiarrhythmic Drugs

In a subset of patients with AF, drugs for restoration and maintenance of sinus rhythm can be started safely in the outpatient setting. Advantages of this approach are elimination of the need for DC cardioversion, reduction of hospitalization time, and a decrease in early recurrences of AF after conversion to sinus rhythm. Although outpatient pharmacologic therapy to restore sinus rhythm is appealing, the concern for induction of life-threatening arrhythmias often precludes use of this approach.

Flecainide and propafenone may be initiated on an outpatient basis if the patient has no history of heart failure; if there is no left ventricular dysfunction; if the QRS width is normal; and if the QTc interval is not prolonged. Patients should have both a normal ECG (without any evidence of bradycardia, sinus node disease, or AV nodal disease) and a documented history of at least one episode of inpatient cardioversion with these medications during which no conduction abnormality was unmasked. Amiodarone and sotalol may be started in the ambulatory setting, provided there is no history of structural heart disease, left ventricular hypertrophy, reduced left ventricular function, bradycardia, sinus node or AV nodal conduction disease, hypokalemia, hypomagnesemia, or previous arrhythmias other than AF or atrial flutter. Flecainide, propafenone, amiodarone, or sotalol should not be started if the patient is also taking other medications that may prolong the QTc interval or predispose to electrolyte abnormalities. Dofetilide, disopyramide, procainamide, and quinidine typically should not be started in the ambulatory setting.[1]

Nonpharmacologic Approaches to Maintaining Sinus Rhythm

Several mechanical techniques offer the benefit of reducing the use of antiarrhythmics. The need for anticoagulation with these techniques remains uncertain, however.

Catheter-based ablation Radiofrequency energy emitted from intravascular catheters promotes the generation of endocardial scars to eliminate AF. These procedures focus primarily on elimination or isolation of ectopic foci, many of which are located in the pulmonary veins. Although these procedures have the potential to cure AF, many patients experience recurrence of AF. The risks of catheter-based ablation include thromboembolism, pulmonary vein stenosis, and cardiac perforation.[43]

Endovascular radiofrequency ablation is less suited to AF than to atrial flutter, which it can cure with minimal risks and a high rate of success. Ablation of atrial flutter typically involves creating a scar within the right atrium and therefore has a lower risk of complications than AF ablation of the pulmonary veins. Radiofrequency ablation for atrial flutter is curative in more than 90% of cases and should be considered primary therapy for these patients.[44]

Surgical ablation Surgical ablation of AF is similar in concept to catheter-based ablation. During open thoracotomy, linear lesions are created across atrial tissue to generate scars that will act as electromechanical obstacles, extinguishing the reentrant circuits needed for the maintenance of AF. There is a greater than 90% rate of success in eliminating AF with this procedure; however, approximately 25% of patients require a permanent pacemaker for sinus node dysfunction postoperatively.[45-47] This approach has an operative mortality of less than 1% but involves the morbidity of an invasive surgical procedure. The procedure is most often utilized when patients are undergoing cardiac surgery for other indications. The techniques utilized to generate the scars, as well as the location and number of scars created, continue to be modified to reduce surgical time while maintaining efficacy.

Atrial pacing In patients requiring ventricular pacing, the addition of atrial pacing reduces the risk of AF. However, the use of atrial pacing as the primary treatment to prevent AF has not been validated.[48-50]

Atrial defibrillators Implantable devices to detect and provide DC cardioversion for AF have been shown to successfully terminate AF in more than 95% of episodes.[51] Although promising, the use of atrial defibrillators is limited by the generation of pain associated with the release of the electrical shock, as well as the risks associated with device implantation (typically, bleeding and infection). As a result, atrial defibrillators have been used in patients who are unable to tolerate a strategy of ventricular rate control and whose condition is refractory to pharmacologic and ablative therapies.

CONTROL OF VENTRICULAR RATE

Ventricular rate control must be addressed both in the acute and the chronic setting. Medication selection in these scenarios is influenced by the rate of onset of the medication, its potential side effects, and its convenience of use.

Hemodynamically unstable patients with angina, myocardial infarction, heart failure, or symptomatic hypotension should be considered for acute conversion to sinus rhythm rather than rate control. In contrast, acute rate control can often be achieved rapidly in hemodynamically stable patients through the use of intravenous beta blockers, diltiazem, verapamil, or digoxin. Oral formulations of these medications are utilized for transition to long-term rate control [*see Table 4*]. More than one medication is often required to achieve ventricular rate control. Although digoxin is available orally and intravenously, its onset of action is at least 1 hour after infusion, so it is rarely sufficient for stand-alone therapy in the acute clinical setting.

Depending on the clinical scenario, specific agents may be more or less preferable for rate control. This is true of patients with reduced ventricular function, CAD, high sympathetic tone, pulmonary disease, and atrial flutter.

Table 4 Drugs for Ventricular Rate Control in Atrial Fibrillation[10]

Drug	*I.V. Loading Dose*	*I.V. Onset*	*I.V. Maintenance Dose*	*Oral Loading Dose*	*Oral Onset*	*Oral Maintenance Dose*	*Drug Interactions and Precautions*
Esmolol*	0.5 mg/kg over 1 min	5 min	5–20 μg/kg/min	Available in I.V. form only	—	—	—
Metoprolol*	2.5–5 mg over 2 min, up to 15 mg	5 min	Bolus every 4–6 hr	Not applicable	4–6 hr	50–200 mg daily in divided doses	—
Propranolol*	0.15 mg/kg over 1 min, repeat once	5 min	Bolus every 4 hr	Not applicable	1–1.5 hr	80–240 mg daily in divided doses	—
Diltiazem	0.25 mg/kg over 2 min	2–7 min	5–15 mg/hr	Not applicable	2–4 hr	120–360 mg daily in divided doses	Increases levels of digoxin, quinidine, simvastatin
Verapamil	75–150 μg/kg over 2 min	3–5 min	Bolus q. 3–6 hr	Not applicable	1–2 hr	120–360 mg daily in divided doses	Increases levels of digoxin, dofetilide, quinidine, simvastatin
Digoxin	0.25 mg q. 2 hr, up to 1.5 mg	2 hr	0.125–0.25 mg daily	0.25 mg q. 2 hr, up to 1.5 mg	2 hr	0.125–0.250 mg/day	Reduce dosing with renal insufficiency; levels increased by amiodarone, propafenone, quinidine, diltiazem, verapamil, spironolactone
Amiodarone	1.2–1.8 g/day until 10 g total	1–3 wk	720 mg/day up to 3 wk; limited data on continuous infusion beyond 3 wk	800 mg/day × 1 wk, 600 mg/day × 1 wk, 400 mg/day × 4–6 wk	1–3 wk	200 mg/day	Increases levels of digoxin, procainamide, quinidine, and warfarin

Note: Typical dosing regimens are provided; however, adjustments are necessary based on individual patient characteristics.
*Other beta-blocking medications may also be used.

Reduced Ventricular Function

Diltiazem and verapamil can significantly exacerbate left ventricular dysfunction and associated heart failure and so should be avoided in the acute setting. Beta blockers can also have this effect but are preferable for acute rate control. Intravenous esmolol has the advantage of rapid onset and clearance and so may be used to determine whether a patient with left ventricular dysfunction tolerates intravenous beta blockade. However, the large infusion of saline given with esmolol makes long-term intravenous use unattractive for patients with heart failure. If the patient tolerates intravenous esmolol, the clinician should consider changing to another intravenous beta blocker or to oral beta blockade. In addition, digoxin can be utilized in patients with left ventricular dysfunction without concern for exacerbating heart failure. Intravenous amiodarone may also be used in the subacute setting for rate control of patients with AF and reduced ventricular function.

Chronic rate control can be achieved through the oral administration of beta blockers. Bisoprolol, extended-release metoprolol, and carvedilol improve symptoms and survival in patients with systolic dysfunction and heart failure independent of atrial rhythm.[52-54] These medications should be first-line therapy for long-term rate control in these patients. If these medications are not tolerated, oral amiodarone should be considered. In addition, digoxin is effective and well tolerated in heart failure patients with AF.

Coronary Artery Disease

Beta blockers have been shown to reduce mortality in patients with CAD. Because of this additive benefit, beta blockers typically should be selected for CAD patients.

High Sympathetic Tone

The effects of digoxin are attenuated in patients with high sympathetic tone, so this agent rarely provides significant control of heart rate in acute, high sympathetic tone states.

Pulmonary Disease

Patients with asthma can experience significant exacerbation of their lung disease with the use of beta blockers. In these patients, diltiazem and verapamil should be used. Patients with chronic obstructive pulmonary disease without reactive airway disease may or may not tolerate beta blockers. Use of beta blockers in this population should be carefully monitored.

Atrial Flutter

It is often more difficult to achieve ventricular rate control in patients with atrial flutter than in those with AF. If rate control cannot be achieved easily in patients with atrial flutter, radiofrequency ablation should be reconsidered.

Monitoring Rate Control

Adequacy of rate control should be assessed both with the patient at rest and under stress. The history, physical examination, and ECG provide significant data for this assessment, but Holter monitoring and exercise stress testing also can be used. The ventricular rate should be maintained between 60 and 80 beats/min during rest and 90 to 115 beats/min during moderate exercise.[55,56] If rate control cannot be achieved with pharmacologic therapy, AV nodal ablation, combined with permanent pacemaker insertion, should be considered. In addition, permanent pacemaker insertion may be necessary for patients with AF who have labile responses to pharmacologic therapy to avoid episodes of symptomatic bradycardia.

Table 5 Data Collection for Assessment of Thromboembolic Risks and Need for Antithrombotic Therapy in Atrial Fibrillation

Characteristic	*Comments*
Age	
Sex	
History of hypertension	Patients with medically treated hypertension are considered hypertensive for risk-stratification guidelines
Diabetes mellitus	Irrespective of control with insulin or oral medications
Coronary artery disease	
Heart failure	Past or current
Hyperthyroidism	Treatment varies depending on whether currently euthyroid
Rheumatic heart disease	Defined as involving the mitral valve
Previous thromboembolism	Includes strokes, transient ischemic attacks, and other emboli
Prosthetic heart valves	
LVEF less than 35%	

LVEF–left ventricular ejection fraction

ANTITHROMBOTIC THERAPY

AF (including paroxysmal, permanent, and chronic forms) is associated with an increased risk of stroke and other embolic phenomena. The risk of stroke for an individual AF patient varies according to the presence or absence of a number of thromboembolic risk factors. These factors can be garnered from the baseline history, physical examination, laboratory evaluation, ECG, and transthoracic echocardiogram; assessment of these thromboembolic risk factors can serve to guide antithrombotic therapy [*see Table 5*].

Current ACC/AHA/ESC guidelines for anticoagulation recommend the use of aspirin or warfarin [*see Table 6*]. Clinical trials have shown that both aspirin and warfarin significantly reduce AF-related strokes in high-risk patients.[57-59] Warfarin reduces the risk of stroke by greater than 60%, whereas aspirin reduces stroke risk by 19%. However, the increased benefits of warfarin must be counterbalanced by the increased risk of hemorrhage.[60] Use of lower-intensity warfarin in combination with aspirin provides no additional stroke prevention over aspirin alone, and the combination of full-dose warfarin with aspirin further increases the risk of intracranial hemorrhage.[61,62] After warfarin therapy is started, the international normalized ratio (INR) of prothrombin time should be measured at least weekly until stable dosing is reached, and monthly thereafter [*see 1:XVIII Venous Thromboembolism*].

Atrial Flutter

Although clinical trial data are limited, epidemiologic studies demonstrate that the risk of stroke with atrial flutter, although less than that with AF, remains elevated.[63] As a result, use of warfarin and aspirin in atrial flutter should be based on the current AF guidelines.

Elderly Patients

Patients who are 75 years of age or older are at increased risk for both stroke with AF and bleeding with AF anticoagulation.[64] As a result of these increased risks, anticoagulation must be tightly monitored in elderly patients, with a goal of maintaining the INR at 2.

Surgical Procedures

Anticoagulation may need to be discontinued in patients scheduled for elective surgical procedures. AF anticoagulation can be discontinued for up to 1 week for surgical procedures in patients without mechanical heart valves. In patients with mechanical valves, the practice has been to discontinue warfarin 1 week before surgery but to maintain anticoagulation with either unfractionated or low-molecular-weight heparin (LMWH). However, current case reports suggest that LMWH may not provide sufficient anticoagulation for patients with mechanical valves, irrespective of concomitant AF.[65] Until further data become available, intravenous unfractionated heparin should be utilized.[66]

Anticoagulation and Cardioversion

Cardioversion from AF or atrial flutter to sinus rhythm—whether it occurs spontaneously or is accomplished with drugs or electricity—is associated with a 1% to 5% risk of thromboembolism. Therefore, strategies for cardioversion of AF should include consideration of anticoagulation; the anticoagulation may start before cardioversion, extend after it, or both [*see Figure 5*].

If warfarin anticoagulation (to an INR of 2 to 3) is used for 3 to 4 weeks before and after cardioversion, the risk of stroke is reduced to 0.5% in the immediate follow-up period.[36,67,68] For that reason, anticoagulation before cardioversion has been strongly advocated.

TEE has been validated as an alternative mechanism to gauge the risk of thromboembolism at the time of cardioversion and immediately afterward. If TEE reveals no evidence of thrombus in the left atrium or left atrial appendage, cardioversion can be performed immediately, with a risk of thromboembolism comparable to that in patients pretreated with 3 to 4

Table 6 ACC/AHA/ESC Recommendations for Antithrombotic Therapy in Atrial Fibrillation Based on Underlying Risk Factors[10]

Patient Characteristics	*Antithrombotic Therapy*
Age < 60 yr, no heart disease (lone atrial fibrillation)	Aspirin, 325 mg daily, or no therapy
Age < 60 yr, heart disease but no risk factors	Aspirin, 325 mg daily
Age ≥ 60 yr but no risk factors	Aspirin, 325 mg daily
Age ≥ 60 yr with DM or CAD	Warfarin (INR, 2.0–3.0); consider addition of aspirin, 81–162 mg daily
Age ≥ 75 yr, especially in women	Warfarin (INR, 2.0)
Heart failure	Warfarin (INR, 2.0)
LVEF ≤ 0.35	Warfarin (INR, 2.0–3.0)
Thyrotoxicosis	Warfarin (INR, 2.0–3.0)
Hypertension	Warfarin (INR, 2.0–3.0)
Rheumatic heart disease (mitral stenosis)	Warfarin (INR, 2.5–3.5 or possibly higher)
Prosthetic heart valves	Warfarin (INR, 2.5–3.5 or possibly higher)
Prior thromboembolism	Warfarin (INR, 2.5–3.5 or possibly higher)
Persistent atrial thrombus on TEE	Warfarin (INR, 2.5–3.5 or possibly higher)

ACC/AHA/ESC—American College of Cardiology/American Heart Association/European Society of Cardiology CAD–coronary artery disease DM—diabetes mellitus INR—international normalized ratio LVEF–left ventricular ejection fraction TEE–transesophageal echocardiography

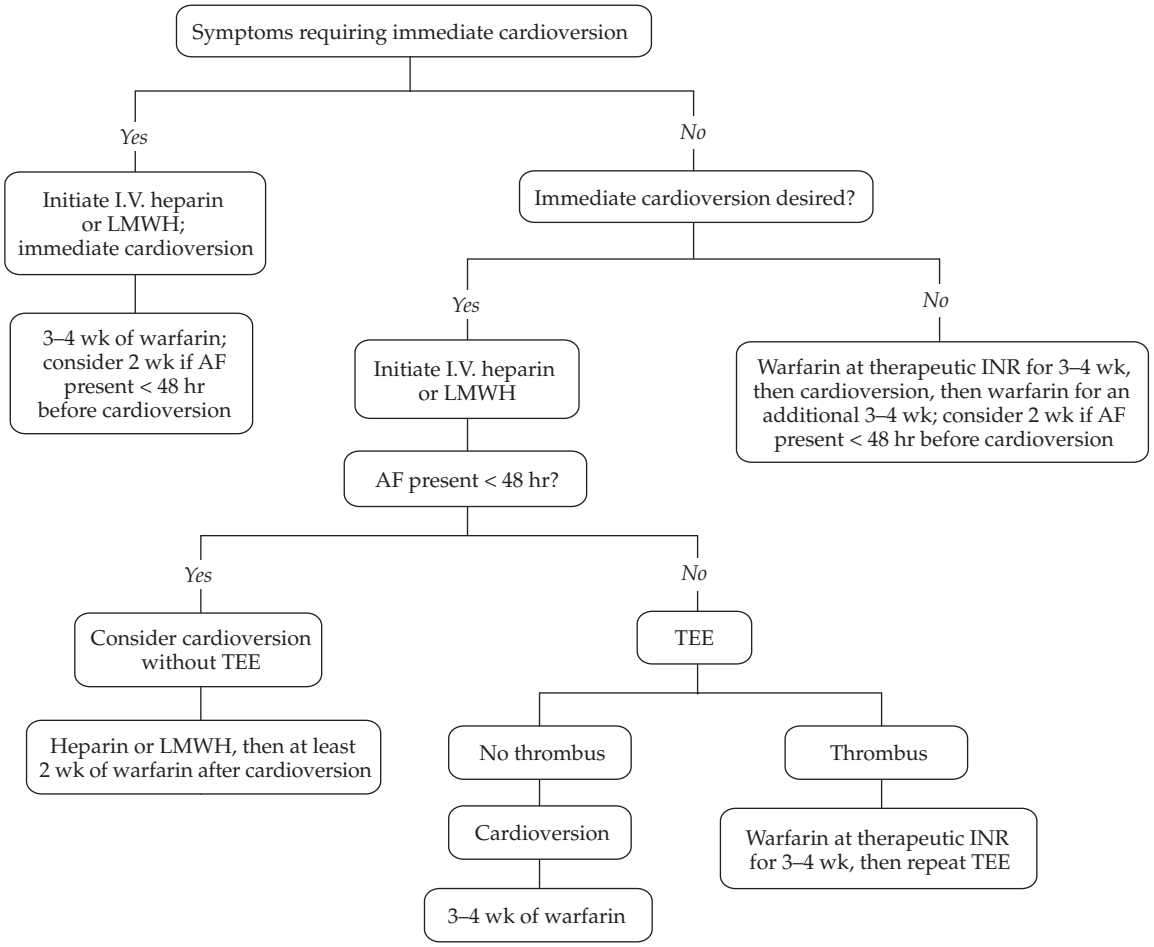

Figure 5 **Cardioversion and anticoagulation strategy for atrial fibrillation. Symptoms that frequently require cardioversion include hypotension, altered mental status, heart failure, pulmonary edema, angina, and myocardial infarction. Adjustment of warfarin intensity and therapy duration is based on individual patient characteristics; the anticoagulation goal is typically an INR of 2–3. (AF—atrial fibrillation; INR—international normalized ratio; LMWH—low-molecular-weight heparin; TEE—transesophageal echocardiography)**

weeks of warfarin therapy.[69] This approach allows for immediate cardioversion; however, because cardioversion frequently results in so-called stunning of left atrial and left atrial appendage tissue (a condition that may predispose to thrombus formation), warfarin anticoagulation is required for 3 to 4 weeks after cardioversion, even when TEE performed before cardioversion showed no thrombus. If TEE does identify thrombus, cardioversion should be postponed for 3 to 4 weeks of anticoagulation therapy with warfarin, after which TEE should be repeated.

Cardioversion without 3 to 4 weeks of warfarin pretreatment and without TEE assessment can be considered if the cardioversion can be done within 48 hours of the onset of AF or if the patient is started on heparin within 48 hours of AF initiation. Limited data suggest that LMWH may be used instead of intravenous unfractionated heparin, allowing both simplified dosing and transition to warfarin therapy on an outpatient basis.[70] This strategy should be most strongly considered in AF patients with significant symptoms of cardiac compromise, including hemodynamic instability, angina, myocardial infarction, heart failure, and shock. The need for anticoagulation after cardioversion in this scenario is unclear, but considering that more than 95% of postcardioversion thromboemboli occur within 10 days after cardioversion, at least 2 weeks of warfarin therapy should be strongly considered if the patient has no contraindications.[71]

Even if heparin was not started until more than 48 hours after the onset of AF, immediate cardioversion also may be necessary if the patient has symptoms of cardiac compromise. Unlike patients who present less than 48 hours after onset of AF, patients with AF of longer duration should receive 3 to 4 weeks of warfarin therapy after cardioversion.

Prolonged anticoagulation after cardioversion should be considered in patients at high risk for both AF recurrence and thromboembolic complications. Atrial flutter is associated with a risk of thromboembolism in the setting of elective cardioversion and should be treated in the same manner as AF.[67]

Ximelagatran

Ximelagatran is a direct thrombin inhibitor that can be administered orally. In the Sport Prevention Using Oral Thrombin Inhibitor in Atrial Fibrillation–III (SPORTIF III) trial, which was an open-label comparison of adjusted-dose warfarin and fixed-dose ximelagatran, there were no significant differences in rates of stroke, systemic thromboembolism, bleeding, or death with

the two drugs.[72] The SPORTIF V trial will compare the two drugs in a double-blinded format. Ximelagatran offers a wider therapeutic window than warfarin and requires no monitoring with coagulation studies. If the equivalence of ximelagatran with warfarin is confirmed, the ease of use of this medication will likely lead to its replacing warfarin for many patients with AF. Future studies will be required to determine whether ximelagatran can be applied to specific settings in which warfarin therapy has been validated.

TREATMENT IN SPECIFIC CLINICAL SCENARIOS

Cardiac Surgery

AF occurs after 25% of all coronary artery bypass surgeries and after more than 60% of combined coronary artery bypass and mitral valve surgeries.[73] Additional risk factors in these cases included advanced age, male sex, preoperative atrial arrhythmias, left atrial enlargement, chronic lung disease, and previous cardiac surgery.[74] AF after cardiac surgery leads to a significant increase in length of hospital stay and cost.[75] A number of prophylactic therapies to prevent postoperative AF have been examined and validated, including use of beta blockers, sotalol, amiodarone, and postoperative temporary atrial pacing.[76] The incremental cost of prophylactic therapy must be balanced against the potential savings achieved by reducing length of stay if AF is prevented. Unless contraindicated, beta blockers should be given to all patients scheduled for cardiac surgery. Sotalol, amiodarone, and biatrial pacing should be considered if patients are at high risk for postoperative AF because of additional risk factors.

Anticoagulation should be given if AF occurs after cardiac surgery and lasts longer than 48 hours. Although sinus rhythm returns spontaneously within 6 weeks in 95% of patients with postoperative AF, pharmacologic or DC cardioversion is often performed, particularly in patients who are symptomatic or hemodynamically unstable.[77] Medications to maintain sinus rhythm or to achieve ventricular rate control can be selected on the basis of patient characteristics.

Acute Myocardial Infarction

In patients with acute myocardial infarction, AF is an independent predictor of mortality and stroke. Immediate DC cardioversion should be performed in patients with severe hemodynamic compromise or persistent ischemia. If rate control is possible, digoxin can be combined with a beta blocker if left ventricular function is preserved. Because of the thromboembolic risk, heparin should be given acutely and followed with warfarin if AF persists or significant left ventricular dysfunction develops.

Wolff-Parkinson-White Syndrome

Wolff-Parkinson-White syndrome (WPW) in association with AF can be a life-threatening condition. The bypass tract of WPW may allow rapid conduction of atrial activity to the ventricles, precipitating hemodynamic compromise or ventricular fibrillation. In the acute setting, DC cardioversion should be pursued if hemodynamic compromise is present. If the patient is hemodynamically stable, the clinician may consider pharmacologic cardioversion to sinus rhythm with intravenous procainamide or ibutilide.[78] Agents that slow AV conduction are contraindicated, including digoxin, diltiazem, and verapamil. Beta blockers should be used rarely and with extreme caution. Once stabilization is achieved, catheter ablation of the WPW bypass tract should be pursued in all symptomatic WPW patients with AF.

Hyperthyroidism

Hyperthyroidism may cause AF and is associated with an increased risk of stroke. Hence, these patients require anticoagulation. Rate control should be attempted with beta blockers, supplemented with diltiazem, verapamil, or digoxin as needed. Warfarin should be given while the patient is thyrotoxic. Once the euthyroid state has returned, use of aspirin or warfarin should be based on underlying risk factors.

Hypertrophic Cardiomyopathy

AF in patients with hypertrophic cardiomyopathy is associated with a high risk of death and stroke.[79] Warfarin therapy is recommended (INR, 2 to 3).

Pulmonary Disease

In patients with pulmonary disease, hypoxia and other metabolic disturbances frequently initiate AF. Initial therapy focuses on treating the underlying lung disease. Beta blockers, propafenone, sotalol, and adenosine are contraindicated in patients with reactive airway disease. Diltiazem or verapamil, with or without digoxin, should be utilized for rate control in these patients.

V SUPRAVENTRICULAR TACHYCARDIA

Melvin M. Scheinman, m.d.

Over the past decade, enormous strides have been made in the treatment of patients with supraventricular tachycardia (SVT). Although acute therapy for SVT continues to require drugs or cardioversion, advances in the understanding of the mechanisms of SVT have led to the development of catheter ablation procedures for most forms of SVT.[1] These procedures often cure the condition, freeing the patient from the need for lifelong drug therapy. This chapter focuses on the most common forms of SVT—excluding atrial fibrillation, which is discussed in detail elsewhere [*see 1:IV Atrial Fibrillation*].

Classification

SVT is often paroxysmal (PSVT). Clinically, PSVT is marked by palpitations, occurring in episodes that start and end abruptly. During these episodes, the 12-lead ECG shows a heart rate greater than 100 beats/min and, typically, narrow QRS complexes. For almost all patients with PSVT, the underlying mechanism of the tachycardia is atrioventricular node reentry (AVNRT), reentry involving an accessory pathway (AVRT), or atrial tachycardia. AVNRT and AVRT are the most common and the second most common causes of PSVT, respectively. Atrial flutter also presents as a rapid regular tachycardia, but this arrhythmia usually does not begin and end abruptly.

The clinician has a variety of tools to distinguish the various mechanisms of SVT [*see Figure 1*]. The use of carotid massage[2] or intravenous adenosine[3] [*see Figure 2*] may be diagnostic, therapeutic, or both. If vagal maneuvers terminate the arrhythmia acutely or produce no effect, the patient probably has AVNRT or AVRT. In patients with atrial tachycardia, these maneuvers will frequently result in transient AV block. Perpetuation of the arrhythmia in the face of AV block strongly suggests atrial tachycardia or atrial flutter.[3] Intravenous adenosine will almost always terminate tachycardia from AVNRT or AVRT, but focal atrial tachycardia may also terminate abruptly after adenosine. Hence, the use of adenosine does not reliably distinguish those disorders from atrial tachycardia unless it produces AV block.[3]

Paying careful attention to the relationship between the P wave and the QRS complex during tachycardia is also very helpful in distinguishing tachycardia mechanisms[4] [*see Figure 1*]. If the retrograde P wave falls within or just after the QRS, the most likely diagnosis is AVNRT [*see Figure 3*]. If the tachycardia shows a retrograde P wave in the ST segment [*see Figure 4*], AVRT is

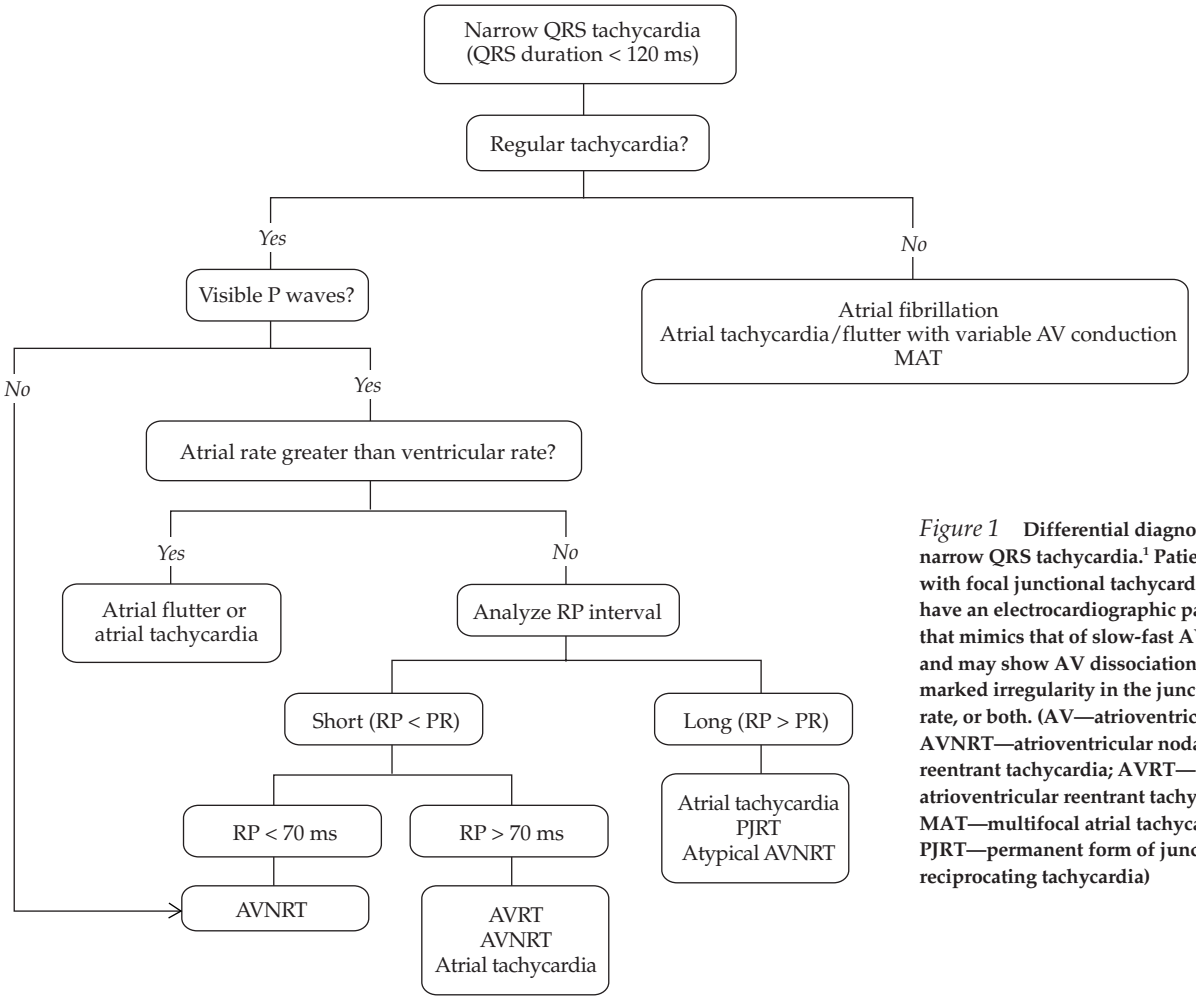

Figure 1 **Differential diagnosis for narrow QRS tachycardia.[1] Patients with focal junctional tachycardia may have an electrocardiographic pattern that mimics that of slow-fast AVNRT and may show AV dissociation, marked irregularity in the junctional rate, or both. (AV—atrioventricular; AVNRT—atrioventricular nodal reentrant tachycardia; AVRT—atrioventricular reentrant tachycardia; MAT—multifocal atrial tachycardia; PJRT—permanent form of junctional reciprocating tachycardia)**

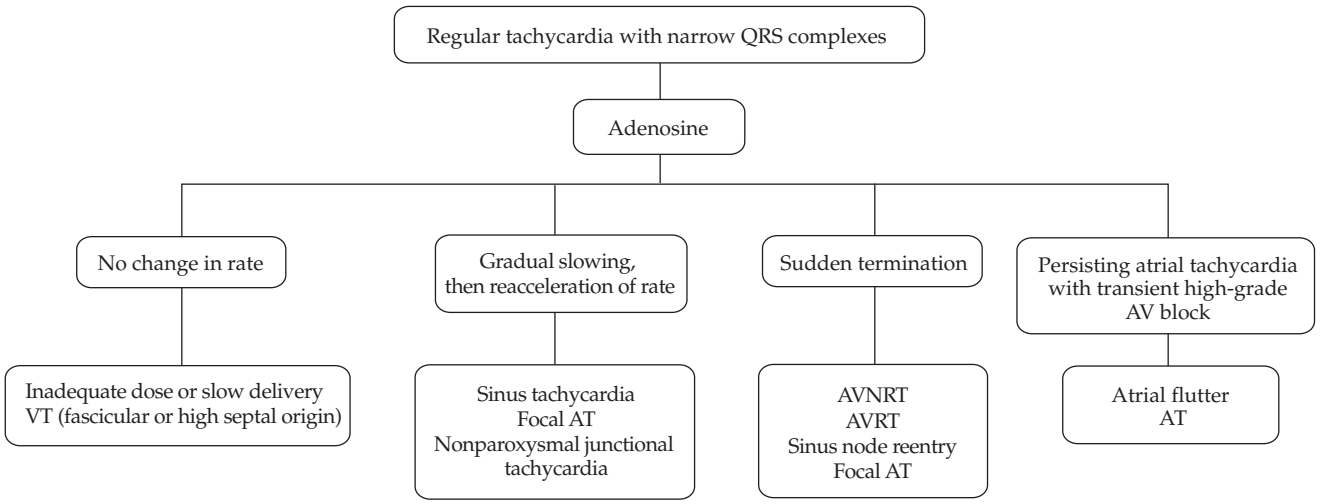

Figure 2 **The response to intravenous adenosine can be useful in determining the cause of tachycardia.[1] (AT—atrial tachycardia; AV—atrioventricular; AVNRT—atrioventricular nodal reentrant tachycardia; AVRT—atrioventricular reentrant tachycardia; VT—ventricular tachycardia)**

most likely. Finally, atrial tachycardia is characterized by the presence of P waves immediately in front of the QRS (long RP tachycardia) [*see Figure 5*].

Although the QRS complex is usually narrow in SVT, it may be broad (> 120 ms) in patients who have either bundle branch block or aberrant conduction. A number of ECG findings have been found very helpful in distinguishing SVT with a broad QRS complex from ventricular tachycardia (VT).[5,6] For example, AV dissociation (i.e., independent atrial activity during tachycardia), fusion beats, or capture beats prove the presence of VT. Unfortunately, AV dissociation is not apparent in 80% to 85% of patients with rapid VT, because the P wave is obscured by the QRS complex and T waves.[6] In this setting, morphologic criteria may be very helpful in distinguishing SVT from VT.

Use of morphologic criteria begins with careful attention to the precordial leads [*see Figure 6*]. Any of the following features in the precordial tracings will favor the diagnosis of VT: (1) Concordance of all the precordial leads (i.e., all are positive or all are negative); (2) absence of an initial positive deflection (r wave) followed by a negative deflection (s wave; recall that in ECG nomenclature, upper-case letters denote dominance; small waves are designated by lowercase letters); (3) an r/s pattern is present but the time from the initial r to the nadir of the s wave is greater than 60 ms; (4) presence of a right bundle branch pattern in lead V1, with an r greater than s or a qr pattern, where q indicates the initial negative deflection; (5) presence of a left bundle branch pattern in V1, with a broad r wave (> 30 ms) or an interval of greater than 60 ms from the onset of the r wave to the nadir of the s wave; (6) extreme left axis deviation; or (7) very broad QRS complexes (> 160 ms).

Atrioventricular Nodal Reentry Tachycardia

PATHOGENESIS

Normally, sinus impulses are discharged into the surrounding atria and directed to the region of the node that resides in the atrial septum. The AV nodal impulses then propagate through the ventricles over the His-Purkinje system. The normal AV node has a single transmission pathway. In two to three persons

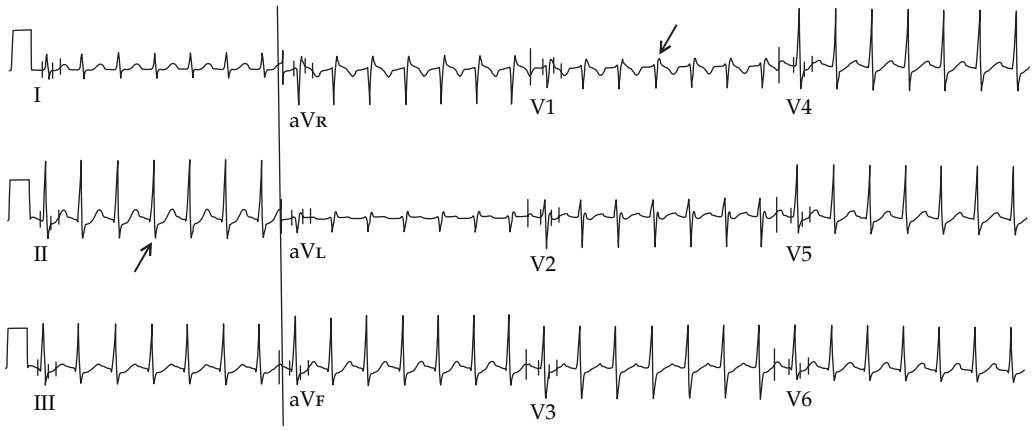

Figure 3 **A 12-lead ECG shows paroxysmal supraventricular tachycardia from AV nodal reentry (AVNRT). The arrows point to a pseudo r[1] in lead V1 and S waves in the inferior leads (II, III, and aVF), which disappeared with conversion to sinus rhythm.**

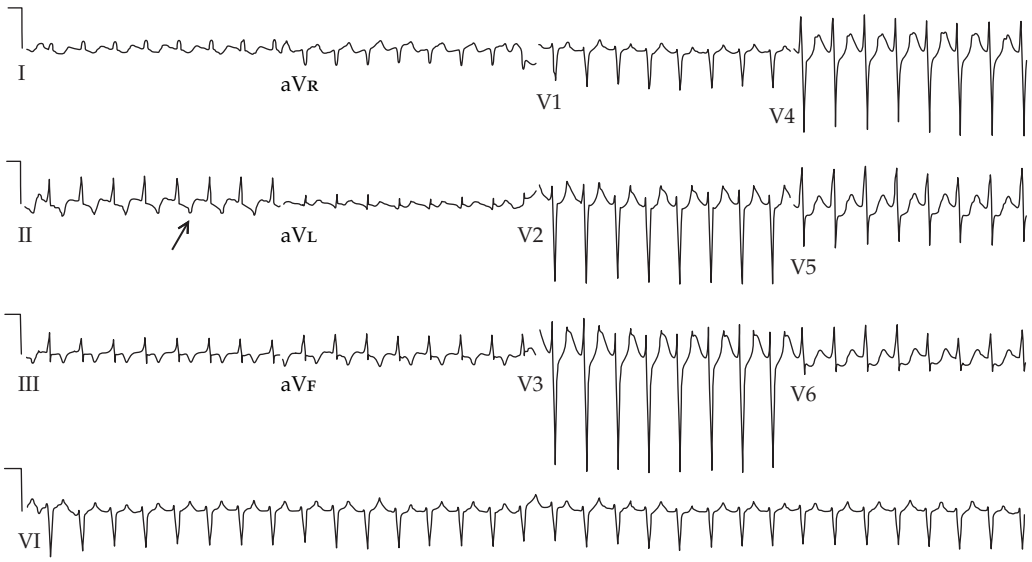

Figure 4 **A 12-lead ECG showing narrow complex tachycardia with P waves (arrow) inscribed well after the QRS, taken from a patient who had paroxysmal supraventricular tachycardia supported by an accessory pathway.**

per 1,000 population, however, the AV node has both a normal (fast) pathway and a second, slow pathway.[7,8] In such persons, the sinus impulse is ordinarily transmitted over the fast pathway to the ventricle, and slow pathway conduction is preempted. However, if an atrial premature complex (APC) occurs at a critical point in the conduction cycle, the impulse can block in the fast pathway, thus allowing for anterograde (forward) conduction over the slow pathway and retrograde (backward) conduction over the fast pathway [*see Figure 7*]. The latter situation may produce a single echo beat (a beat that returns to the chamber of origin) or stabilize into a circus-movement tachycardia.

DIAGNOSIS

The diagnosis of AVNRT can usually be made by careful analysis of the 12-lead ECG.[4] Because retrograde conduction over the AV node is occurring more or less simultaneously with anterograde conduction to the ventricles, the P wave is either buried within the QRS complex or inscribed just after the QRS. The P wave inscribed by retroconduction over the AV node will be negative in the inferior leads and positive in lead V1; therefore, PSVT from AVNRT may manifest as small negative deflections in the inferior leads and a small positive deflection in V1—the so-called pseudo r[1] pattern[5] [*see Figure 3*].

MANAGEMENT

Acute Therapy

AVNRT may respond to carotid sinus massage[2] but is highly responsive to intravenous adenosine,[3] beta blockers,[9] or calcium channel blockers[10] [*see Table 1*].

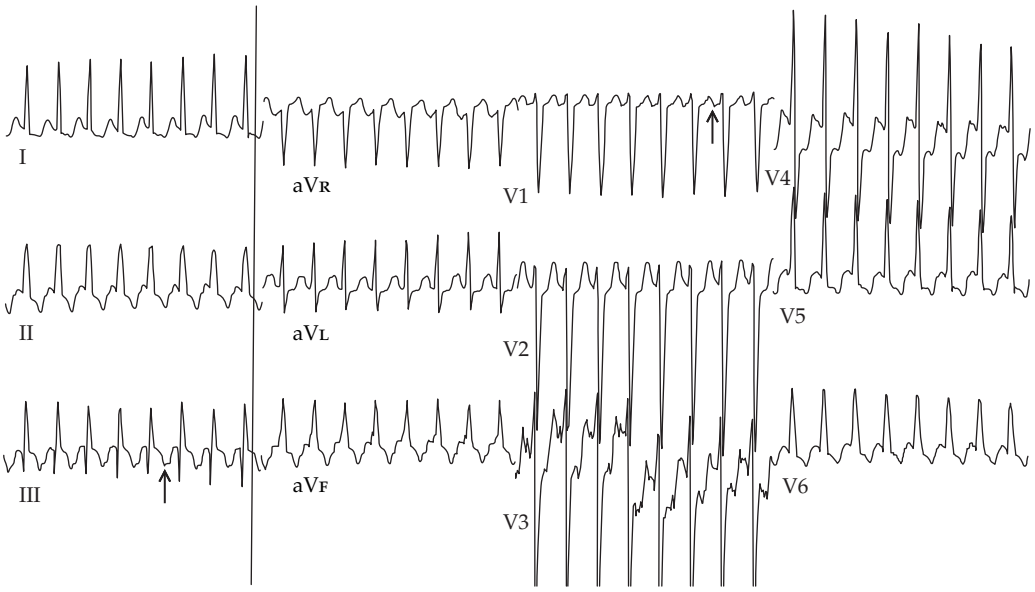

Figure 5 **A 12-lead ECG shows tachycardia with P waves (arrows) just preceding the QRS complex. The patient in this case had a focal atrial tachycardia emanating from the lateral tricuspid annulus.**

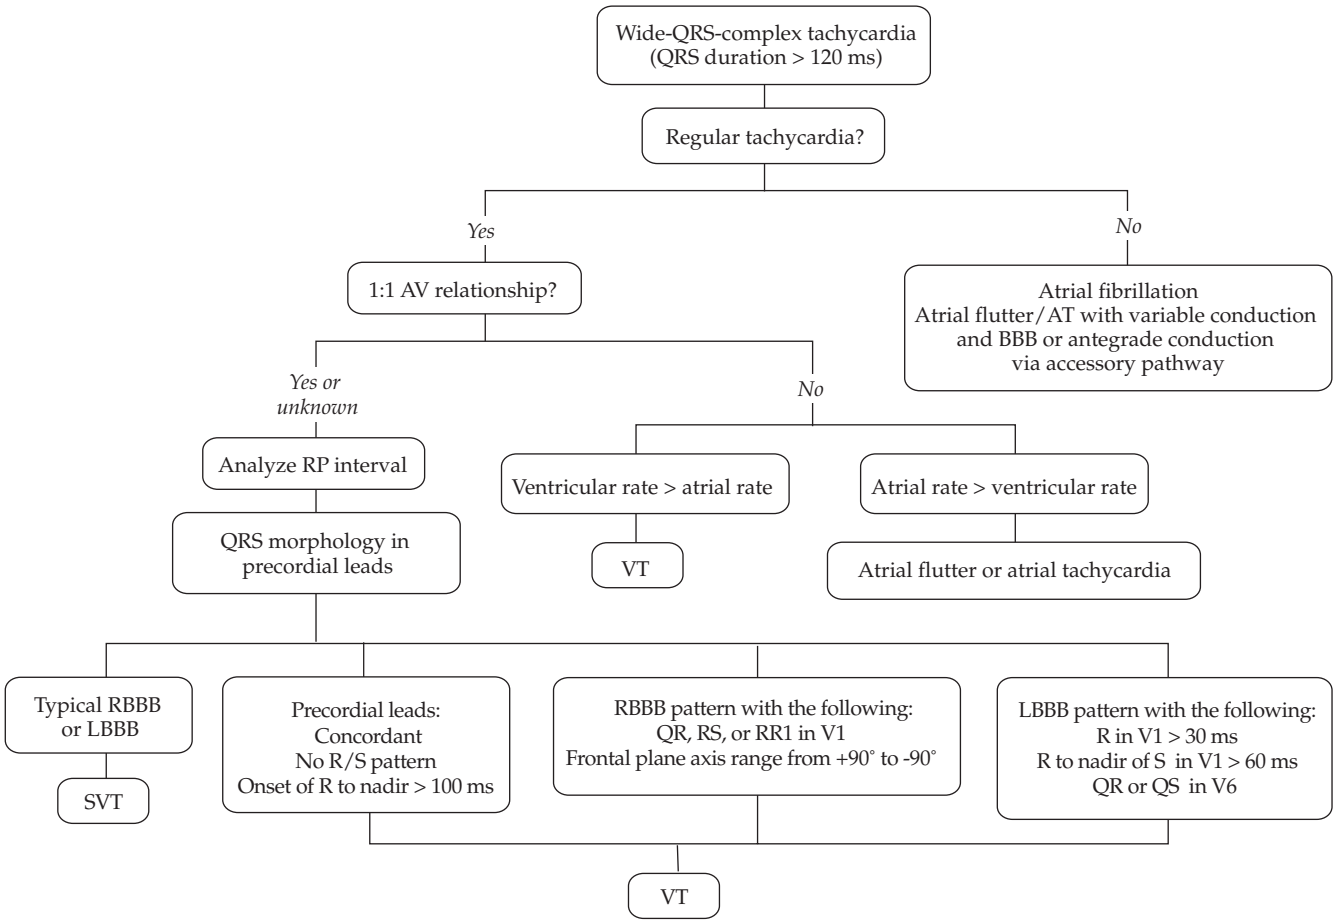

Figure 6 **Differential diagnosis for wide (> 120 ms) QRS complex tachycardia.[1] If the tachycardia is regular and comparison with a baseline electrocardiogram shows that the QRS complex is identical to that during sinus rhythm, the patient may have supraventricular tachycardia (SVT) with bundle branch block (BBB) or antidromic atrioventricular reentrant tachycardia (AVRT). If the patient has a history of myocardial infarction or has structural heart disease, ventricular tachycardia (VT) is likely. Vagal maneuvers or adenosine may convert regular tachycardia, although adenosine should be used with caution when the diagnosis is unclear, because this drug may produce ventricular fibrillation (VF) in patients with coronary artery disease and patients with alternative pathways who have atrial fibrillation with a rapid ventricular rate. Precordial leads are concordant when all show either positive or negative deflections. Fusion complexes are diagnostic of VT. In preexcited tachycardias, the QRS is generally wider (i.e., more preexcited) than during sinus rhythm. (AT—atrial tachycardia; AV—atrioventricular; LBBB—left bundle branch block; RBBB—right bundle branch block)**

Adenosine If carotid massage fails to convert SVT, the drug of choice is intravenous adenosine, which is effective in 95% of cases.[10,11] The initial dose is given as a rapid bolus infusion of 6 mg, followed by 12 mg and finally 18 mg if necessary. The bolus must be given rapidly and then followed by a saline flush. If administration is too slow, the adenosine may be metabolized before it reaches the AV node. Possible adverse effects include headache, wheezing, and flushing. These effects disappear within 45 to 60 seconds. It is important to note that atrial, ventricular, and junctional premature beats are commonly observed after adenosine. In 3% to 5% of cases, the APCs trigger atrial fibrillation,[3] which may result in serious problems for patients with accessory pathways (see below). If possible, an external defibrillator should be readily available when adenosine is administered.

The most common reason for failure to respond to adenosine is that multiple premature beats are retriggering the tachycardia. In this setting, a longer-acting intravenous preparation (i.e., 5 mg of metoprolol or 0.1 mg/kg of verapamil) is indicated. Agents that more selectively block purogenic receptors have been

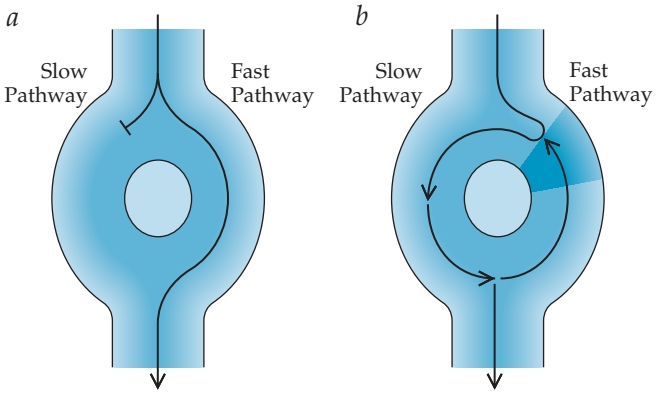

Figure 7 **In persons with dual pathways in the AV node, the sinus impulse is normally transmitted over the fast pathway to the ventricle and slow pathway conduction is preempted (*a*). However, if an atrial premature complex occurs during the fast pathway's refractory period, the impulse can block in the fast pathway. This may allow for anterograde (forward) conduction over the slow pathway and retrograde (backward) conduction over the fast pathway (*b*).**

Table 1 Drugs Used to Maintain Sinus Rhythm in Patients with Supraventricular Tachycardia[55]

Drug	*Typical Daily Dose*	*Potential Adverse Effects*
Amiodarone	100–400 mg*	Photosensitivity, pulmonary toxicity, polyneuropathy, GI upset, bradycardia, torsade de pointes (rare), hepatic toxicity, thyroid dysfunction
Disopyramide	400–750 mg	Torsade de pointes, heart failure, glaucoma, urinary retention, dry mouth
Dofetilide	500–1,000 μg	Torsade de pointes
Flecainide	200–300 mg	Ventricular tachycardia, heart failure, enchanced AV nodal conduction (conversion to atrial flutter)
Procainamide	1,000–4,000 mg	Torsade de pointes, lupuslike syndrome, GI symptoms
Propafenone	450–900 mg	Ventricular tachycardia, heart failure, enhanced AV nodal conduction (conversion to atrial flutter)
Quinidine	600–1,500 mg	Torsade de pointes, GI upset, enhanced AV nodal conduction
Sotalol	240–320 mg†	Torsade de pointes, heart failure, bradycardia, exacerbation of chronic obstructive or bronchospastic lung disease

*A loading dose of 600 mg/day is usually given for 1 month, or a dose of 1,000 mg/day is given for 1 week.
†Adjust dose for renal function and QT-interval response during in-hospital initiation phase
AV—atrioventricular GI—gastrointestinal

shown to be very effective and associated with fewer side effects than older agents. Selective purogenic blockers are currently under investigation.

Long-term Therapy

A wide variety of drugs have proved effective for controlling episodes of AVNRT, including beta blockers,[9] calcium channel blockers,[12] and digoxin[13] [*see Table 1*]. Long-term drug therapy is associated with frequent recurrences and adverse effects, however. In patients without structural cardiac disease, class IC antiarrhythmic agents (e.g., flecainide, propafenone) are more effective than drugs that act by blocking AV nodal conduction, but recurrence rates nevertheless range from 25% to 35%.[14-16] For patients who have episodes infrequently and tolerate them well, some cardiologists will prescribe medication for use as needed—the "pill in the pocket" approach. For example, single-dose diltiazem (120 mg) and propranolol (80 mg) have been shown to be more effective than placebo or flecainide in patients with PSVT.[17]

Catheter Ablation

Current catheter ablative techniques involve placement of an electrode catheter between the tricuspid annulus and coronary sinus in the so-called slow pathway region.[18] One or more applications of radiofrequency energy are delivered through the catheter to destroy or attenuate the slow pathway. The success rate of ablation is over 96%, and the only significant complication is AV block, which occurs in approximately 1% of patients.[19]

Catheter ablation for AVNRT has proved so safe and effective that it is clearly the procedure of choice for patients in whom drug therapy fails. Moreover, it can be offered to those with milder symptoms who prefer to avoid long-term drug therapy. Precise recommendations for drug therapy versus ablative therapy are provided in the American College of Cardiology/American Heart Association/European Society of Cardiology guidelines.[1]

Atrioventricular Reentry Tachycardia

PATHOGENESIS

The normal conduction system of the heart limits the propagation of electrical impulses from the atria to a single pathway through the AV node and the His-Purkinje system. This limitation delays ventricular activation and thus optimizes mechanical function. The presence of an alternative pathway of atrioventricular conduction creates the potential for reentrant tachycardia.

The most prominent manifestation of accessory atrioventricular pathways is the Wolff-Parkinson-White (WPW) syndrome. In this syndrome, the accessory pathway can be located at various regions around the tricuspid and the mitral atrioventricular rings, but it is most commonly sited at the left free wall of the mitral annulus. The next most common pathway sites are the posteroseptal and right free wall areas. Pathways in the anteroseptal and the midseptal regions are relatively rare. Occasionally, posteroseptal pathways can be associated with a branching vein from the coronary sinus. On occasion, a patient will have more than one accessory pathway.

The basic mechanism of tachycardia in AVRT is similar to that of AVNRT. Electrical impulses can travel down both the AV node and the accessory pathway to activate the ventricles, with ventricular activation occurring earlier at sites near the accessory pathway than at sites activated normally (i.e., ventricular preexcitation). An APC may block in the accessory pathway but conduct over the normal pathway to activate the ventricle. After ventricular depolarization, the impulse may return to the atrium via retrograde conduction over the accessory pathway, leading to a sustained tachycardia.[20]

The most feared arrhythmia in the WPW syndrome involves atrial fibrillation with dominant conduction over an accessory pathway that has rapid conduction properties[21,22] [*see Figure 8*]. These patients may experience extraordinarily rapid ventricular rates and are at risk for sudden cardiac death from ventricular fibrillation.[23] In one large series, atrial fibrillation developed in 30% of patients with the WPW syndrome.[24]

DIAGNOSIS

Clinical Presentation

Symptomatic tachyarrhythmias associated with the WPW syndrome generally begin in the teenage years or during early adulthood. Pregnancy may produce an initial attack in some women. Pregnancy can also be associated with an increasing frequency of attacks and more symptomatic episodes. Symptoms are generally paroxysmal palpitations with or without dizziness, syncope, shortness of breath, weakness, or chest pain. Diuresis is another frequently described symptom; it occurs 30 minutes to an hour after onset of tachycardia and may be related to production of atrial natriuretic factor during the arrhythmia.

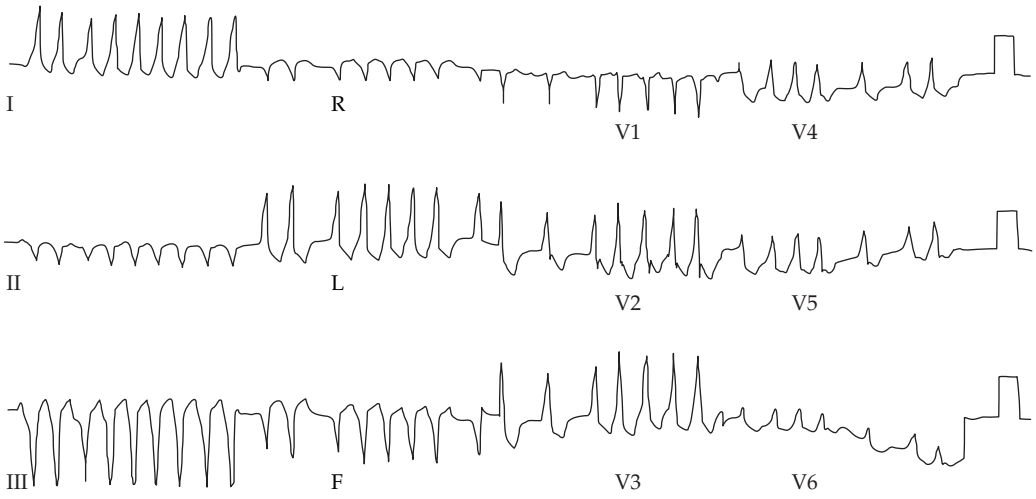

Figure 8 **A 12-lead ECG in a patient with Wolff-Parkinson-White syndrome shows the rapid, irregularly irregular ventricular rate and wide QRS complexes of atrial fibrillation with a very short refractory period. This is an especially dangerous arrhythmia.**

Electrocardiographic Findings

Ventricular preexcitation may be evident on a baseline ECG as fusion complexes (WPW pattern). The WPW pattern comprises a short PR interval and an earlier than normal deflection on the QRS complex (delta wave).[25] The ECG during AVRT will usually show a narrow complex with the retrograde P wave falling in the ST segment because atrial activation occurs well after ventricular depolarization[4] [*see Figure 4*]. Of interest is that a subset of patients with AVRT never show manifest anterograde conduction over the accessory pathway yet still have this form of tachycardia.[20] The only evidence that the tachycardia is supported by an accessory pathway is that the retrograde P wave clearly occurs after the QRS during tachycardia. On rare occasions, patients may have slowly conducting retrograde pathways[26]; their ECG will show a long RP–short PR relationship. These patients tend to have persistent tachycardias that have been referred to as the permanent form of junctional tachycardia (PJRT). In addition, approximately 5% of patients with the WPW syndrome (WPW pattern and arrhythmias) will show anterograde conduction over the accessory pathway with retrograde conduction through the AV node or over a separate accessory pathway. The ECG in these patients will show a wide-complex tachycardia with retrograde P waves preceding the QRS complex.

MANAGEMENT

Acute Therapy

Acute management of AVRT is similar to that for AVNRT: adenosine is the drug of choice,[11] but calcium channel blockers[13] or beta blockers[9] are also effective. Again, because adenosine usually provokes APCs and thus may in rare instances precipitate atrial fibrillation,[3] it is advisable to have ready access to an external defibrillator when using this agent.

Long-term Therapy

Long-term therapy for AVRT may be directed at interfering with conduction either through the AV node (i.e., with beta blockers or calcium channel blockers[27]) or through the accessory pathway (i.e., with class IC or class III antiarrhythmic agents[28-32]). Oral digitalis therapy is contraindicated because very rapid ventricular rates may occur if atrial fibrillation develops. Class IC agents appear to be more effective than AV nodal blockers, but their use is restricted to patients who do not have significant cardiac disease. Class III agents (particularly amiodarone) are limited by long-term systemic toxicity and modest efficacy for patients with WPW and atrial fibrillation.[30] In general, drug therapy is attended by a significant risk of arrhythmic recurrence and adverse drug effects.

Treatment of WPW and Atrial Fibrillation

The treatment of WPW and atrial fibrillation is different from the treatment of AVRT. Because atrial fibrillation may precipitate a life-threatening arrhythmia, urgent therapy is required. If the patient presents with hemodynamic collapse, emergency direct current (DC) cardioversion is the first step. If the patient is less ill, trials of intravenous drug therapy are in order.[33] The drug of choice is procainamide, 50 mg/min to a total of 1 g, or ibutilide, 2 mg infused over 15 minutes. Ibutilide is very effective but should be used only in patients without significant structural cardiac disease. Intravenous digoxin or calcium channel blockers may result in an inordinate increase in heart rate and so should be avoided. Beta blockers, lidocaine, and adenosine are not likely to be effective, and their use will tend only to delay effective therapy.

Catheter Ablation

Reports from both single centers[34,35] and multicenter prospective registries[36,37] have documented the efficacy and possible adverse effects of ablative therapy in AVRT. Current techniques allow for successful ablation of accessory pathways that traverse the AV annulus or the anterior or posteroseptal spaces. For pathways over the left AV groove, current ablation techniques involve use of either transseptal or retrograde aortic approaches.[38] The overall success rate for ablation is approximately 95%.

Complications of ablation are primarily related to the site of the accessory pathway. For example, patients with an anteroseptal accessory pathway are at risk for injury to the AV node (5%), whereas ablations of left-sided accessory pathways carry a risk of cerebrovascular accident, myocardial perforation, or coronary artery occlusion.[36,37] The overall incidence of significant adverse

effects varies from 2% to 4%. Death associated with ablative procedures is quite rare, occurring in 0.13% to 0.2% of cases.[36,37,39]

Treatment Selection

The remarkable efficacy and safety of ablation make this mode of therapy more attractive than long-term drug therapy for symptomatic patients. Drug therapy carries the possibility of recurrent arrhythmias, including atrial fibrillation. Hence, ablation is currently recommended for all patients with symptomatic WPW. Patients with mild symptoms and without manifest preexcitation can be managed with drug therapy, but even in these cases ablation would appear to be a favored approach. Some of these patients decline long-term drug therapy, leaving ablation as the only alternative.

Asymptomatic preexcitation The management of asymptomatic preexcitation remains controversial. The vast majority of these patients have an overall good prognosis; sudden cardiac death is a rare initial manifestation. Leitch and colleagues followed asymptomatic WPW subjects in whom atrial fibrillation was induced during invasive electrophysiologic study; although approximately 20% demonstrated the capacity for rapid ventricular conduction, on follow-up few became symptomatic and none died suddenly.[39] A later study, however, emphasized findings on electrophysiologic testing (e.g., inducible AVRT, atrial fibrillation, and multiple pathways) that indicated increased risk for subsequent spontaneous development of atrial fibrillation or even sudden death.[40] Whether to treat an asymptomatic patient can also be decided on an individual basis[1]; for example, patients judged to be in high-risk occupations (e.g., airplane pilots, bus drivers) might well be considered for ablative therapy.

Focal Atrial Tachycardia

Regular tachycardias emanating in an atrial area and showing a centripetal pattern of spread are designated as focal atrial tachycardias (FATs). These arrhythmias are the least common cause of PSVT but nevertheless can cause significant morbidity. This is particularly true if the arrhythmia is incessant, which can result in the development of so-called tachycardia myopathy.

Atrial tachycardia may arise from sites in either the right or left atrium. The most common site of FAT is in the right atrium, with predilection for sites over the crista terminalis, tricuspid annulus, or coronary sinus.[41,42] In the left atrium, FAT is more apt to develop at the ostium of the pulmonary veins or over the mitral annulus.[42]

ELECTROCARDIOGRAPHIC DIAGNOSIS

In patients with FAT, the P wave may appear anywhere in the diastolic cycle but most often appears in front of the QRS (long RP tachycardia) [*see Figure 5*]. The ectopic P wave has a different shape than the sinus P wave unless the tachycardia originates from the high cristal or right pulmonary vein area. The P wave morphology gives excellent clues to tachycardia localization.[43,44] For example, P waves from left atrial foci will show negative deflection in leads I or aVL and positive deflections in the precordial leads. Right atrial foci tend to show negative P waves in lead V1 but positive or biphasic deflection in aVL. As a rule, foci from superior atrial sites generally produce strongly positive P waves in the inferior leads, whereas those arising from the inferior atrium produce negative P waves.

MANAGEMENT

Acute Therapy

Acute treatment of FAT attempts either to convert the arrhythmia or to slow the heart rate. Drugs used to slow the rate are the AV nodal blockers (i.e., digoxin, beta blockers, or calcium channel blockers). In contrast, class IC antiarrhythmic agents (e.g., flecainide, propafenone) or class III agents (e.g., amiodarone or sotalol) may terminate the tachycardia. Intravenous adenosine may be effective in terminating FAT and should be tried early. DC cardioversion may not be effective, particularly if the tachycardia results from an automatic mechanism.

Long-term Therapy

Long-term oral therapy for FAT is not well defined.[1] The general approach is empirical, with initial use of AV nodal blockers followed by class IC or III antiarrhythmic agents if the AV nodal blockers are ineffective.

Catheter Ablation

Catheter ablative procedures have been successfully applied to patients with FAT. Ablation has proved more effective for patients with right atrial foci (in whom the success rate is approximately 90%) than for those with left atrial foci (in whom the success rate is approximately 70%). A study of pooled data that included 514 patients showed an overall success rate of 86%, with an incidence of significant complications from 1% to 2%.[45]

Multifocal Atrial Tachycardia

Multifocal atrial tachycardia, generally regarded as automatic in origin, is characterized by atrial rates of 100 to 130 beats/min, three or more morphologically distinct (nonsinus) P waves, and variable AV conduction. It is commonly associated with respiratory disease and heart failure. Hypoxemia is a frequent finding. The arrhythmia may be exacerbated by digitalis excess, theophylline toxicity, or hypokalemia.

Treatment of multifocal atrial tachycardia is usually directed at the underlying precipitants. Metoprolol (used cautiously in patients with bronchospasm) or verapamil may slow atrial and ventricular rates and, occasionally, may restore sinus rhythm. Potassium and magnesium supplements may help suppress the arrhythmia. Amiodarone has also been useful in restoring sinus rhythm.

Atrial Flutter

Rapid reentrant atrial arrhythmias are referred to as atrial flutter. The most common circuit involves reentry around the tricuspid annulus. The reentrant circuit is usually counterclockwise (in the left anterior oblique projection) but may be clockwise.[46] Other circuits may involve the upper portion of the right atrium.[47] Less commonly, left atrial (LA) circuits are operative. LA circuits may involve the mitral annulus or scars around the posterior LA wall, pulmonary veins, or the foramen ovale.[47]

DIAGNOSIS

Clinical Presentation

Atrial flutter generally occurs in older patients who have associated cardiopulmonary disease. Atrial flutter may appear acutely during acute myocardial infarction, after cardiac surgery, or

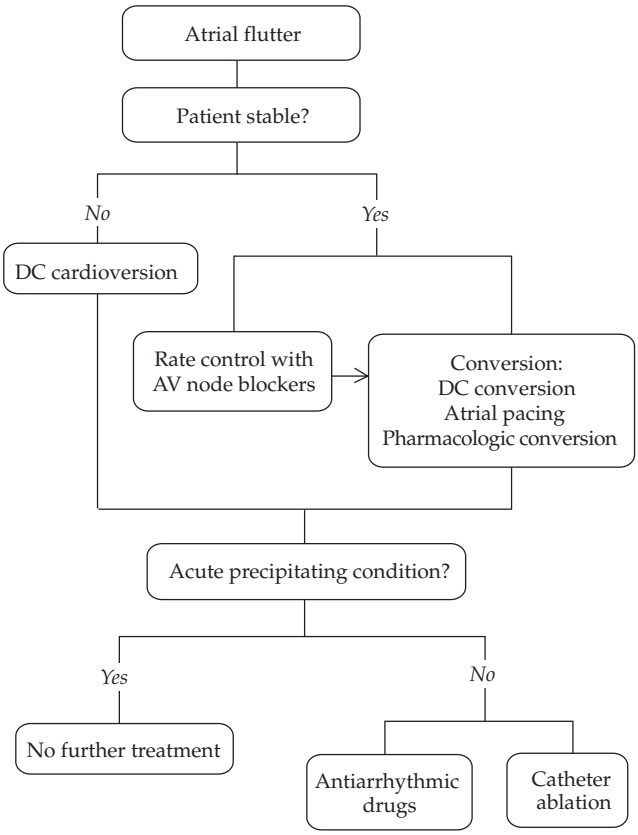

Figure 9 **Management of atrial flutter. With patients whose condition is unstable (e.g., because of heart failure, shock, or acute myocardial infarction), atrial flutter typically does not recur once the underlying disorder is resolved. Anticoagulant precautions, as per atrial fibrillation, should be taken in patients undergoing elective attempts to convert atrial flutter to sinus rhythm. (AV—atrioventricular; DC—direct current)**

with acute pulmonary insufficiency; in such cases, the arrhythmia usually does not recur once the inciting event has resolved. In contrast, atrial flutter in patients without concomitant acute illness tends to recur; like atrial fibrillation, it is usually a relapsing and remitting disease.

Electrocardiographic Findings

The ECG in patients with atrial flutter usually shows a flutter rate of 300 beats/min with 2:1 AV block. The most common atrial flutter pattern—a counterclockwise loop around the annulus—manifests as negative flutter waves in the inferior leads and positive waves in V1.[48] The ECG shows a continuous or so-called picket-fence appearance. In contrast, patients with a clockwise pattern will have positive flutter waves in the inferior leads and negative waves in V1. The ECG is much more variable for nonannular types of flutter circuits.[47]

MANAGEMENT

Acute Therapy

Treatment of atrial flutter is directed at attempts to convert the arrhythmia or use of AV nodal blockers to slow the ventricular response [*see Figure 9*]. Acute conversion of atrial flutter can be accomplished electrically by use of external DC shocks[49] or by pacing.[50,51] Atrial flutter is usually exquisitely responsive to a small "dose" of DC shock (i.e., 25 to 50 joules).[49] Atrial overdrive pacing is also quite effective for terminating flutter, especially when the patient has been pretreated with drugs (i.e., ibutilide or procainamide).[51] Overdrive pacing is particularly appropriate for atrial flutter that occurs after cardiac surgery, because atrial wires are routinely left in place postoperatively in such patients. Transesophageal pacing has also been used to terminate flutter,[52] but its popularity has been limited by the need for analgesics to alleviate the associated chest pain.

Ibutilide (a class III antiarrhythmic agent) may be used to convert atrial flutter to sinus rhythm. Randomized prospective studies have shown that ibutilide is approximately 70% effective for this purpose.[53] In addition, ibutilide has been shown to be far more effective than intravenous procainamide.[54] Ibutilide is given in 1 mg aliquots over 10 minutes separated by a 10-minute rest period. A total of 2 mg of the drug is used, and the patient must remain under telemetry monitoring for approximately 4 hours after drug delivery. Ibutilide should not be given to patients with severe structural cardiac disease (i.e., those with a left ventricular ejection fraction less than 30%) because the risk of torsade de pointes becomes significant in this setting.

Patients with atrial flutter are at risk for thromboembolism. The current recommendations for anticoagulant therapy are the same as those for patients with atrial fibrillation.[55] For example, if the flutter duration is less than 48 hours, the risk of left atrial clot is small, and one may proceed with chemical or electrical cardioversion without full anticoagulation. Anticoagulant therapy is still required for 4 to 6 weeks after conversion because of the increased risk of thromboembolism secondary to decreased left atrial flow velocity after conversion. If the flutter duration is greater than 48 hours, a transesophageal echocardiogram to exclude clot is recommended before cardioversion. Complete guidelines for antithrombotic therapy in patients with atrial flutter are described elsewhere [*see 1:IV Atrial Fibrillation*].

As an alternative to cardioversion, AV nodal blocking agents can be used to decrease the ventricular response in patients with flutter. Controlled trials have demonstrated the efficacy of intravenous calcium channel blockers (verapamil or diltiazem) in producing prompt decreases in heart rate.[56] Calcium channel blockers have been shown to reduce the heart rate below 100 beats/min more promptly than digoxin or amiodarone.

Long-term Therapy

Drug therapy for chronic atrial flutter is notoriously unreliable, and long-term rate control alone usually requires large doses of AV nodal blocking agents. A more effective intervention involves an ablative procedure in which radiofrequency lesions are applied in a line from the tricuspid annulus to the inferior vena cava.[57] This area is the critical isthmus for the usual type of atrial flutter circuit. Ablation of this area resulting in total conduction block of the isthmus is associated with a 90% to 100% cure rate in flutter.[58] Non–isthmus-dependent flutter circuits may involve either the right or the left atrium and usually require sophisticated mapping tools to determine the tachycardia circuit and the critical isthmus needed for curative ablation. These patients should be referred to experienced centers for evaluation.

Many patients have both atrial flutter and atrial fibrillation. For example, atrial flutter may deteriorate into atrial fibrillation, or bursts of atrial fibrillation may trigger atrial flutter. In addition, approximately 15% to 30% of patients treated with

class IC antiarrhythmics or amiodarone for atrial fibrillation will develop stable atrial flutter.[59] In these patients, radiofrequency ablation of the flutter circuit together with continuance of drug therapy is usually quite effective in controlling both atrial fibrillation and flutter. Ablation of the flutter usually does not cure the atrial fibrillation.[60]

Sinus Tachycardia

Sinus tachycardia is usually a normal reflex response to changes in physiologic, pharmacologic, or pathophysiologic stimuli, such as exercise, emotion (e.g., anxiety, anger), fever, hemodynamic or respiratory compromise, anemia, thyrotoxicosis, poor physical condition, sympathomimetic or vagolytic agents, and abnormal hemoglobins. Heart rate during sinus tachycardia generally does not exceed 180 beats/min, except perhaps in young persons, who may achieve sinus rates greater than 200 beats/min during vigorous exercise.

When sinus tachycardia is a reflex response to altered physiology, the resulting increase in cardiac output is usually beneficial. Tachycardia resolves when conditions return to normal.

Inappropriate Sinus Tachycardia

An infrequent but troublesome problem, inappropriate sinus tachycardia (IST) appears to be a true syndrome with cardiac, neurologic, and psychiatric components. It affects women more often than men. Structural heart disease is generally absent. In one series of 475 patients, IST was the indication for catheter ablation in 2.3%.[61]

DIAGNOSIS

Clinical Presentation

IST may be persistent or episodic. It is often precipitated by arising from a reclining or sitting position (postural orthostatic tachycardia).[62] Very rapid rates (> 170 beats/min) may be triggered by minimal exertion.

The tachycardia is frequently accompanied by symptoms of dizziness, near-syncope, or syncope. Fatigue and atypical chest pain may also accompany IST. Peculiar but inconsistent autonomic and hemodynamic findings may be seen in these patients. This suggests that the syndrome is not uniform in etiology.

Electrocardiographic Findings

Because tachycardia rates may arise from higher foci, the P waves seen during IST may differ slightly from those seen at rest.

MANAGEMENT

Drug Therapy

Beta blockers and calcium channel blockers (i.e., verapamil or diltiazem) may be used to alleviate tachycardia in IST. Unfortunately, these drugs are often not effective and tend to exacerbate the nonspecific symptoms that accompany this syndrome. Agents that alter sinus node automaticity, autonomic tone, or both, such as flecainide, propafenone, and amiodarone, may be tried in selected patients.[63]

Catheter Ablation

Radiofrequency ablation has been employed to ablate or modify the sinus node in IST. Large-tipped (8 to 10 mm) catheters are often required to create more sizable lesions. Successful modification or ablation has been achieved in 70% to 100% of patients.[64] Sinus nodal modification is associated with a 10% to 27% risk of sinus node damage necessitating permanent pacing.

Both intracardiac electrograms and intracardiac ultrasonography have been used to target lesion delivery. Intracardiac ultrasonography targets the fastest portions of the sinus node by ablating the uppermost portion of the crista terminalis. This approach seems to require fewer radiofrequency applications than do electrogram-guided approaches. It may also reduce the need for permanent pacing.

Long-term follow-up after radiofrequency modification has been less encouraging. Recurrence rates are high. Ablation to the extent that permanent pacing is required may be necessary for sustained success. Thus, patients require careful follow-up for recurrent tachycardia or progressive sinus node dysfunction. Surgical isolation of the sinus node for IST has also been followed by recurrent tachycardia at new foci.

VI VENTRICULAR ARRHYTHMIAS

Jonathan J. Langberg, m.d.
David B. DeLurgio, m.d.

Ventricular tachyarrhythmias characteristically are sudden in onset, unpredictable, and transitory. Consequently, their assessment and treatment present extraordinary challenges to the clinician. Moreover, the prognosis for patients with these arrhythmias is quite variable. In some patients, ventricular ectopic activity may be benign and without sequelae, but in other patients, comparable ectopy is a harbinger of ventricular fibrillation and sudden cardiac death.[1] This chapter summarizes the practical aspects of evaluation and treatment of patients with ventricular arrhythmias.

Pathophysiology

Ventricular tachyarrhythmias are mediated by one of three basic mechanisms: reentry, abnormal automaticity, and triggering. Although causation cannot be directly determined in individual patients, experimental and clinical observations make it possible to infer the mechanism underlying many of the ventricular arrhythmia syndromes encountered in practice.

Ventricular tachycardia caused by reentry

Reentrant arrhythmias (also called circus-movement tachycardias) are produced by a continuous circular or looping pattern of myocardial activation. Reentry can occur around lines of anatomic or functional block or occur as spinning wavefronts or rotors that lack a fixed anatomic path. When reentry occurs around lines of block, two features must be present for reentry to occur: (1) a barrier around which the wavefront circulates, either a fixed region of inexcitability caused by scarring or a dysfunctional region resulting from local refractoriness, and (2) unidirectional block at the entrance of the circuit. If activation spreads down both sides of the barrier, the impulses will collide distally and reentry will not occur; however, if propagation is blocked in one limb and proceeds in an anterograde direction over the other, the activation wavefront may be capable of retrograde invasion of the initially blocked pathway, thereby initiating sustained reentry.

In patients with structural heart disease, most symptomatic ventricular arrhythmias are mediated by reentry.[2,3] Sustained monomorphic ventricular tachycardia often occurs after transmural myocardial infarction (MI). The arrhythmia usually arises in the border zone of the scar [*see Figure 1*]. The larger the extent of this heterogeneous border zone, the greater the probability of a circuit capable of mediating reentrant ventricular tachycardia. This is consistent with the observation that the risk of malignant ventricular arrhythmias is proportional to the volume of the scar and the severity of left ventricular dysfunction after MI.[4]

Ventricular fibrillation is also a reentrant phenomenon.[5] Unlike ventricular tachycardia, during which a single activation wavefront circulates around a fixed barrier, ventricular fibrilla-

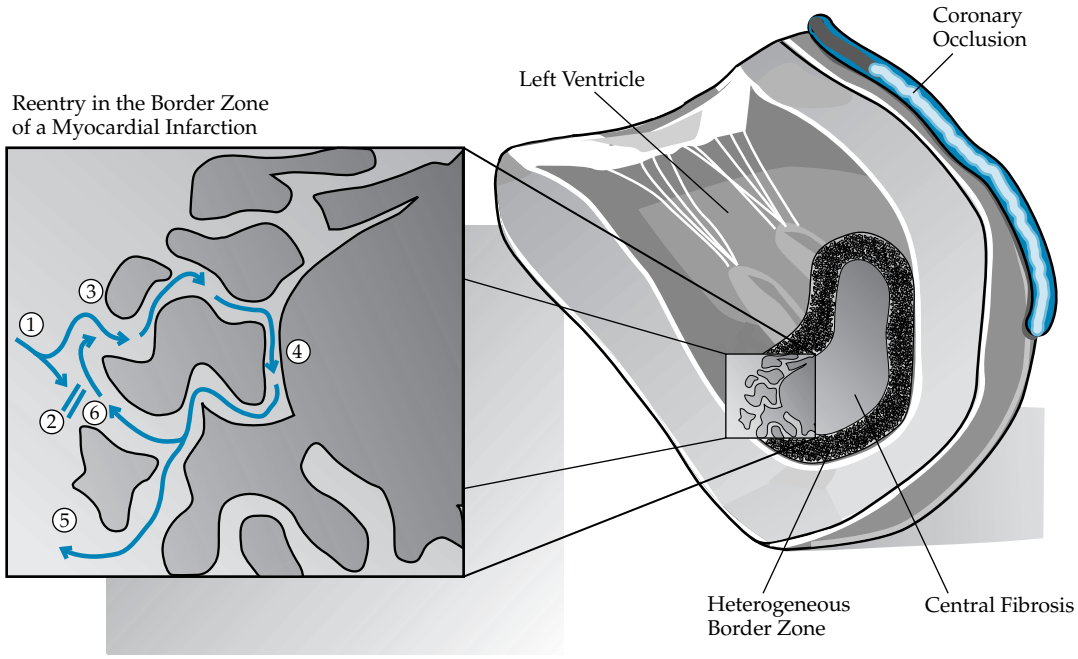

Figure 1 **Reentrant ventricular tachycardia usually arises as the result of reentry within the border zone of a myocardial infarction. This region consists of strands of viable myocytes interspersed with inexcitable fibrous tissue. Reentry begins when a wavefront of activation (1) encounters a bifurcation and blocks in one of the two pathways around an obstacle (2). The activation wavefront then conducts exclusively through the orthodromic pathway (3) and encounters a region of relatively slow conduction within the tachycardia circuit (4). The activation wavefront may exit from the tachycardia circuit at a site quite different from the entrance point (5). Although the anterograde limb of the circuit is initially refractory, it recovers excitability by the time it is depolarized by the reentrant wavefront (6). The activation wavefront reenters the orthodromic limb of the circuit, and the circus movement is established.**

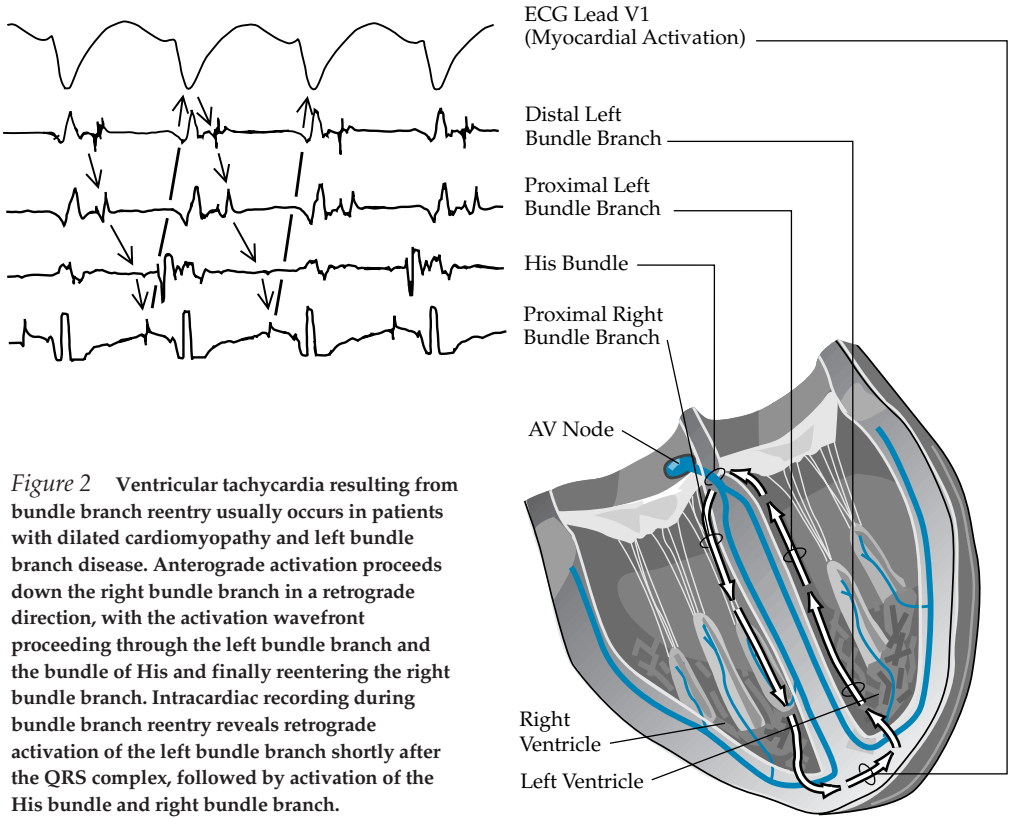

Figure 2 **Ventricular tachycardia resulting from bundle branch reentry usually occurs in patients with dilated cardiomyopathy and left bundle branch disease. Anterograde activation proceeds down the right bundle branch in a retrograde direction, with the activation wavefront proceeding through the left bundle branch and the bundle of His and finally reentering the right bundle branch. Intracardiac recording during bundle branch reentry reveals retrograde activation of the left bundle branch shortly after the QRS complex, followed by activation of the His bundle and right bundle branch.**

tion is caused by multiple simultaneous impulses that travel around functional barriers of refractory tissue, moving continuously throughout the myocardium to create very rapid, irregular, and ineffective activation. Alternatively, in some patients, ventricular fibrillation may be initiated by very early ectopic beats in the specialized conduction system.[6]

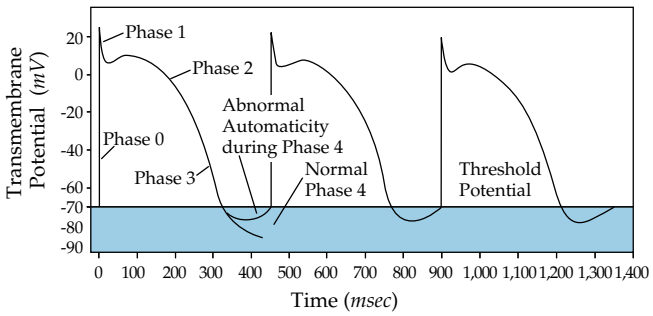

Figure 3 **The resting transmembrane potential of the myocardial cell is created by active maintenance of sodium and potassium gradients. The cell is depolarized (phase 0) by an electrical stimulus that allows a sudden influx of sodium (Na^+). Repolarization, phases 1 through 3, requires an early rapid chloride influx, a plateau phase mediated by calcium currents, and reestablishment of the resting transmembrane potential via potassium (K^+) efflux. Between action potentials, the resting potential is designated as phase 4. In cells with automaticity, depolarization mediated by calcium (Ca^{2+}) and Na^+ currents may occur during phase 4, resulting in spontaneous generation of the next action potential. In normal ventricular myocytes, the resting potential during electrical diastole (phase 4) remains in the region of –80 to –90 mV. The rate of automatic firing is determined by the resting potential, the slope of phase 4, and the threshold potential.**

Like postinfarction arrhythmias, the ventricular tachycardia in patients with nonischemic cardiomyopathy is often the result of reentry in a zone of patchy fibrosis. However, in patients with left ventricular dilatation and slowed conduction in the specialized conduction system, the tachycardia may be mediated by bundle branch reentry: anterograde conduction over the right bundle branch, activation of the septum, and retrograde conduction over the left bundle branch [*see Figure 2*].[7] Although an infrequent cause of ventricular tachycardia, bundle branch reentry is of interest to cardiac electrophysiologists because it can be cured by selective destruction of either the right or the left bundle branch by use of radiofrequency catheter ablation [*see 1:VII Pacemaker Therapy*].

VENTRICULAR TACHYCARDIA MEDIATED BY ABNORMAL AUTOMATICITY

Normal ventricular myocytes maintain a steady transmembrane resting potential of –80 to –90 mV, depolarizing only when stimulated by an activation wavefront. Extrinsic factors, such as electrolyte imbalance and ischemia, or intrinsic disease may reduce the resting potential and produce simultaneous diastolic (phase 4) depolarization [*see Figure 3*].

Unlike reentry, which can usually be induced and terminated by premature beats, automatic rhythms tend not to be influenced by pacing. Changes in heart rate at the onset of ventricular tachycardia may also provide insight into the arrhythmia mechanism. Reentrant tachycardias are usually stable because of a fixed conduction time around the circuit. In contrast, automaticity often shows warm-up, with progressive acceleration during the first few seconds of the tachycardia.

Abnormal automaticity may play a role in a number of clinical arrhythmia syndromes. An accelerated idioventricular rhythm

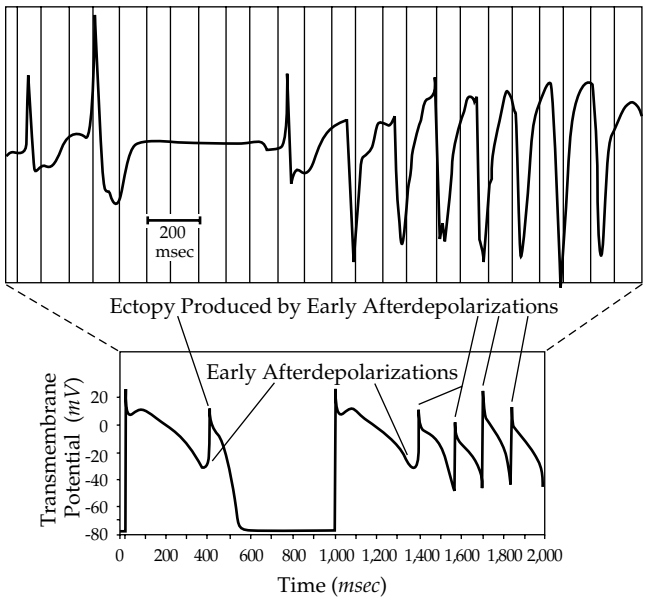

Figure 4 **In ventricular tachycardia caused by triggering, prolongation of the action potential (and the QT interval) results in depolarization during phase 3. Such early afterdepolarizations are manifested as positive deflections at the end of the phase 2 plateau or during the phase 3 rapid repolarization of the action potential. If this deflection exceeds the threshold potential, one or more triggered beats will occur. Bradycardia-dependent torsade de pointes is an example of an arrhythmia caused by early afterdepolarizations. The electrocardiogram of a patient with quinidine intoxication reveals an extrasystole and polymorphic ventricular tachycardia.**

(60 to 100 beats/min) or episodes of slow ventricular tachycardia (100 to 140 beats/min) occur in approximately 20% of patients who are monitored after transmural MI.[8] These slow-fast rhythms are probably the result of abnormal automaticity in ischemic Purkinje fibers.

More rapid ventricular tachycardia is also a frequent complication of acute ischemia, reperfusion, or both. These arrhythmias are often polymorphic, characterized by QRS complexes that change in amplitude and cycle length, with heart rates that may approach 300 beats/min. Abnormal automaticity in ischemic myocardium probably causes many of these episodes.

Ventricular tachycardia occasionally occurs in patients without apparent structural heart disease.[9] This idiopathic arrhythmia generally originates in the right ventricular outflow tract, just beneath the pulmonary valve. A number of observations suggest that it, too, is sometimes mediated by abnormal automaticity. It can develop spontaneously in response to increased adrenergic tone and, as a rule, cannot be induced or terminated by pacing. It may occur as a pattern of recurrent short bursts of tachycardia interspersed with equally short interludes of sinus rhythm, a pattern more consistent with automaticity than reentry.[10]

VENTRICULAR TACHYCARDIA CAUSED BY TRIGGERING

Early Afterdepolarization

Triggered activity, defined as premature activation caused by one or more preceding impulses, is the result of afterdepolarizations that occur either during (early afterdepolarization) or just after (delayed afterdepolarization) completion of the repolarization process [*see Figure 4*]. Factors that slow the heart rate tend to prolong the duration of depolarization, which is identified by a lengthened QT interval on the electrocardiogram, often sufficiently to bring early afterdepolarizations to threshold. Thus, triggered ventricular tachycardia that results from early afterdepolarizations is characteristically bradycardia dependent or pause dependent.

Early afterdepolarizations have been produced experimentally under a variety of conditions, including ischemia, hypokalemia, and antiarrhythmic drug toxicity. The arrhythmias seen in these studies are bradycardia dependent and, typically, are both rapid and polymorphic. Slowing of the tachycardia rate just before spontaneous termination is another characteristic feature of early afterdepolarization–mediated ventricular tachycardia.

Although it is difficult to prove, it seems likely that early afterdepolarizations mediate a variety of clinical arrhythmias. Prolongation of the QT interval—whether congenital or acquired as a result of drugs (class IA antiarrhythmic agents or, more commonly, other drugs such as haloperidol or erythromycin) or electrolyte depletion—increases the risk of a polymorphic ventricular tachycardia. As in the experimental situation, patients with QT prolongation tend to develop polymorphic ventricular tachycardia as a result of slowing of the heart rate, heart rate pauses, or sudden surges in adrenergic tone. Unlike rhythms mediated by automaticity or reentry, ventricular tachycardia in the setting of QT prolongation is almost always polymorphic, sometimes with the twisting pattern that characterizes torsade de pointes.

Delayed Afterdepolarization

Arrhythmias mediated by delayed afterdepolarization are distinctly different from those associated with early afterdepolarization and appear to be caused by abnormal accumulation and oscillation of cytosolic calcium concentration. The amplitude of these arrhythmias is augmented by acceleration rather than slowing of the heart rate. Delayed afterdepolarizations have been implicated in the genesis of ventricular tachycardia in patients with digitalis toxicity, and in some patients with ventricular tachycardia who have no apparent structural heart disease. Verapamil may be therapeutic in this subset of patients.[11] Although these arrhythmias have been recorded from surviving Purkinje fibers and infarcted canine myocardium, their role in clinical arrhythmias during and after MI is less well established.

Delayed afterdepolarizations are induced at a critical heart rate range, which is patient specific, either spontaneously or during atrial or ventricular pacing. As with reentrant arrhythmias, tachycardia resulting from delayed afterdepolarizations is often terminated by overdrive pacing, although it will frequently persist for several cycles after cessation of pacing.

Asymptomatic Ventricular Ectopy

Ventricular ectopy is recorded in more than half of normal persons undergoing ambulatory electrocardiographic monitoring. Complex ectopy (multifocal premature ventricular complexes and nonsustained ventricular tachycardia) is less frequent but is still observed in 5% to 10% of healthy persons with no apparent heart disease.[12]

The prognostic significance of ventricular ectopy depends on the severity of left ventricular dysfunction. In the absence of structural heart disease, asymptomatic ventricular ectopic activity is benign, with no demonstrable risk of sudden death, even in the presence of ventricular tachycardia. In patients with structural heart disease, however, ventricular ectopic activity is associat-

ed with an increased risk of sudden cardiac death. This risk is markedly increased with progressive left ventricular dysfunction.[13] For example, post-MI patients with a left ventricular ejection fraction (LVEF) greater than 40% who experience fewer than 10 ventricular premature complexes (VPCs) an hour after MI have a mortality of 5% to 7% a year. Those patients who experience more than 10 VPCs an hour, however, have a mortality of 12% to 18%. The combination of an LVEF of less than 40% and more than 10 VPCs an hour raises the annual mortality to between 27% and 40%.

The presence of frequent ventricular premature beats 7 to 10 days after MI is associated with a fivefold increase in the risk of symptomatic or fatal arrhythmias during follow-up.[4] Because many patients with frequent ectopy do not develop malignant ventricular arrhythmias, the positive predictive accuracy of this finding is only 16%. Conversely, because the majority of patients without frequent ectopy remain free of fatal arrhythmias, its absence is associated with a negative predictive accuracy of 82%. The occurrence of nonsustained ventricular tachycardia (fewer than three consecutive rapid beats over a period of less than 30 seconds) during monitoring appears to confer an even greater risk than does the presence of frequent isolated ventricular premature beats.[4,12,13]

The association between ambient ventricular ectopy and the risk of arrhythmic death is less well established in patients with nonischemic (i.e., valvular, hypertensive, or idiopathic) cardiomyopathy. However, most reports in the literature do suggest that the presence of high-grade ventricular arrhythmias, defined as multifocal VPCs or nonsustained ventricular tachycardia, confers an increased risk of sudden death that is independent of the severity of left ventricular dysfunction.[14,15]

Because the significance of ventricular ectopy depends on the degree of ventricular function impairment, cardiac imaging should be part of the initial evaluation. Echocardiography is the most versatile test; it provides information regarding regional wall motion abnormalities and valvular lesions as well as the LVEF. Radionuclide ventriculography also gives precise information regarding ejection fraction and may be of value in patients whose heart disease is already well characterized. If ventricular function is normal or close to normal, reassurance or treatment with beta blockers or calcium channel blockers to suppress bothersome symptoms is appropriate. In contrast, if patients have evidence of significant ventricular dysfunction or other significant structural heart disease such as hypertrophic cardiomyopathy, further evaluation and therapy may be appropriate. This evaluation may include additional tests that can help define the risk of a sustained arrhythmic event and the need for a prophylactic implantable cardioverter-defibrillator (ICD).

SIGNAL-AVERAGED ELECTROCARDIOGRAPHY

Signal-averaged electrocardiography may be useful for estimating risk in patients with heart disease and ventricular ectopy. This noninvasive test detects signals from areas of slow conduction in the arrhythmogenic regions on the periphery of an MI. The surface ECG is recorded for approximately 250 beats, and the signal is averaged by a computer and filtered, resulting in dramatic reduction of the signal-to-noise ratio. This allows detection of low-amplitude, high-frequency late potentials that result from the activation of zones of slow conduction just after the offset of the QRS complex.

Low-amplitude, high-frequency late potentials are recorded in about one third of patients after MI. These patients have a 20% incidence of life-threatening ventricular arrhythmias during the first year after infarction, compared with a 3% incidence in patients without late potentials.[16] Signal-averaged ECG findings are independently predictive of adverse events after MI and provide additional information regarding risks in patients with frequent ventricular premature contractions and impaired left ventricular function. A limitation of signal-averaged ECG is that it cannot be used in patients with bundle branch block or atrial fibrillation.

MICROVOLT T WAVE ALTERNANS

Another screening test that may be useful for assessing risk of sudden cardiac death in patients with left ventricular dysfunction is microvolt T wave alternans.[17] In this technique, signal processing is used to detect minute beat-to-beat variation in T wave amplitude that takes place during low-level exercise. Like signal-averaged ECG, microvolt T wave alternans has been approved by the Food and Drug Administration,[18] although currently it has little role in the selection of patients for ICDs. Unlike signal-averaged ECG, microvolt T wave alternans appears to have prognostic value in nonischemic as well as ischemic cardiomyopathy. A limitation of the test is that patients must be able to exercise for 5 minutes to a heart rate of at least 110 beats a minute.

ELECTROPHYSIOLOGIC TESTING

Electrophysiologic study can be used to assess the inducibility of sustained ventricular arrhythmias in patients with structural heart disease.[4] Electrode catheters are introduced percutaneously into the venous system, usually via the femoral vein, and advanced under fluoroscopic guidance into the right ventricle. Programmed electrical stimulation is performed in an attempt to elicit ventricular tachycardia or fibrillation. This usually consists of a drive train at a constant paced cycle length followed by one, two, or three extra stimuli (premature beats). The stimuli are introduced at progressively more premature coupling intervals until tachycardia is induced or the stimuli fail to capture as the result of local refractoriness [*see 1:VII Pacemaker Therapy*].

Programmed stimulation can induce sustained monomorphic ventricular tachycardia in about 20% of patients with reduced left ventricular function after MI and can induce ventricular fibrillation in an additional 10% to 15% of such patients. During follow-up, arrhythmic events occur in 5% of the noninducible patients, in 10% of patients with inducible ventricular fibrillation, and in 50% of patients with inducible ventricular tachycardia.

Although electrophysiologic study has reasonable sensitivity for prediction of subsequent arrhythmic events, the positive predictive value of the test is probably no better than that of the signal-averaged ECG, T wave alternans testing, or both, especially when such tests are combined with measurements of left ventricular systolic function and quantification of ambient ectopy. Electrophysiologic study is invasive and relatively expensive. Moreover, there is no evidence to suggest that treatment of this group of patients with antiarrhythmic drugs improves survival. Thus, it is difficult to justify routine electrophysiologic testing in asymptomatic patients after MI. The role of invasive electrophysiologic study for risk stratification in asymptomatic patients after MI has diminished with the increasing use of ICDs for primary prevention of sudden cardiac death.

Electrophysiologic testing is of uncertain value for stratification of risk in patients with nonischemic cardiomyopathy and asymptomatic ventricular ectopy. In this population, induction of sustained monomorphic ventricular tachycardia is infrequent

and does not appear to be predictive of subsequent sudden cardiac death.

Currently, electrophysiologic studies are perhaps most useful in patients who have an LVEF of 30% to 40% and evidence of nonsustained ventricular tachycardia. In this select group, electrophysiologic testing can help determine whether the risk of sudden cardiac death is sufficiently high to merit prophylactic implantation of an ICD [*see* The Implantable Cardioverter-Defibrillator, *below*].

Syncope and Ventricular Arrhythmias

Syncope, defined as transient loss of consciousness, is a common phenomenon, accounting for about 3% of all emergency room visits.[19] Because the spells usually resolve by the time the patient is initially evaluated, determination of the cause of loss of consciousness is difficult but extremely important, because prognosis depends on the nature of the episode. If ventricular arrhythmias are detected during subsequent monitoring, additional evaluation should be undertaken to determine whether the syncope was produced by a paroxysm of ventricular tachycardia.

HISTORY AND PHYSICAL EXAMINATION

A thorough history may provide important clues to the diagnosis of ventricular tachycardia. The onset of syncope mediated by ventricular tachycardia is usually abrupt, with only a brief prodrome of light-headedness or no premonitory symptoms at all. The absence of rapid heartbeat does not exclude the diagnosis, because only about one half of patients with documented sustained ventricular tachycardia experience this symptom. The duration of unconsciousness is brief, rarely lasting longer than several minutes. Because of the abrupt onset, traumatic injury is common.

Spontaneous movements during syncope often cause confusion and misdiagnosis. Cerebral hypoperfusion from any cause, including ventricular tachycardia, may produce one or more clonic jerks of the extremities. However, syncopal episodes differ from seizure activity in three respects: (1) the movements in syncopal episodes are not reciprocating (tonic-clonic), (2) they are much briefer in duration, and (3) bladder or bowel incontinence rarely occurs.

Historical information regarding the patient's condition after awakening is frequently overlooked but may be very helpful. Patients typically recover quickly from ventricular tachycardia–mediated syncope. Postictal confusion lasting longer than 5 minutes suggests a grand mal event rather than an arrhythmic one. Similarly, persistent residual malaise, nausea, and weakness are characteristic of a faint produced by the vasodepressor syndrome rather than arrhythmic syncope.

Ventricular tachycardia of sufficient rate or duration to produce loss of consciousness is rare in patients with normal ventricular function. Thus, patients in whom ventricular arrhythmias are identified after a syncopal episode must be thoroughly evaluated for structural heart disease. The presence of severe left ventricular dysfunction in these patients is associated with an ominous prognosis.

Patients with coronary artery disease, syncope, or ventricular arrhythmias require evaluation of myocardial ischemia with a functional study (e.g., thallium scintigraphy), coronary angiography, or both, in addition to quantification of ventricular function. Acute ischemia may precipitate rapid ventricular tachycardia that is sufficient to cause loss of consciousness. In such cases, exercise treadmill testing may induce ventricular ectopy, thereby suggesting the diagnosis, especially if premonitory symptoms are reproduced.

ELECTROCARDIOGRAPHY

On occasion, findings on a 12-lead ECG will suggest the cause of the loss of consciousness in a patient with unexplained syncope. A prolonged QT interval can indicate congenital long QT syndrome; ST segment elevation in lead V1 can indicate the Brugada syndrome; and a short QT interval may indicate short QT syndrome [*see* Heritable Ventricular Arrhythmias, *below*].

Signal-averaged electrocardiography plays a limited but important role in the evaluation of patients with syncope and ventricular arrhythmias. The positive predictive accuracy of this test is inadequate to confirm the diagnosis of an arrhythmic event. However, a negative result makes the possibility of sustained ventricular tachycardia unlikely enough that additional, more invasive studies are probably not justified.

Ambulatory electrocardiography is useful in selected patients with a history of syncope and ventricular arrhythmias. The yield of 24-hour or 48-hour Holter monitoring is low in patients with infrequent arrhythmic episodes, however. In such patients, a transtelephonic loop recorder is more likely to provide diagnostic information. This device is worn by the patient for 4 to 6 weeks, continuously recording and storing several minutes of the ECG in an endless loop. Immediately after presyncope or a syncopal spell, the patient presses the event button on the device to stop the recording and store the preceding ECG in memory. The output of the device is then transmitted over the telephone to a receiving station. This system has been shown to be more cost-effective than Holter monitoring and is preferable unless symptoms are present on a daily basis.

ELECTROPHYSIOLOGIC TESTS

Electrophysiologic testing can be useful in determining whether an episode of loss of consciousness was produced by ventricular tachycardia.[20] Assessment of sinus node function and atrioventricular conduction should be performed during electrophysiologic testing even when ventricular tachycardia is suspected, because episodic bradyarrhythmias may produce spells with very similar symptoms.

The induction of sustained monomorphic ventricular tachycardia during programmed stimulation increases the probability that the patient's spontaneous episode was mediated by ventricular tachycardia and increases the likelihood that therapy will be effective. Several studies have shown a lower rate of recurrent syncope in patients whose therapy is based on results of electrophysiologic testing, compared with those in whom the study was unrevealing or for whom no effective treatment could be found.[20,21]

Evaluation of the Patient Rescued from Cardiac Arrest

In 80% to 90% of patients who develop out-of-hospital cardiac arrest, the precipitating event is either primary ventricular fibrillation or a rapid ventricular tachycardia that degenerates into ventricular fibrillation. Bradyarrhythmic events occur occasionally, but when asystole is recorded as the initial rhythm, it is usually indicative of a prolonged downtime interval and is associated with a very poor prognosis.

The majority of patients who sustain cardiac arrest have structural heart disease. In industrialized societies, this is most often the result of coronary atherosclerosis. Studies of both victims

and survivors of cardiac arrest show significant coronary obstruction in 75% to 80% of patients. Unfortunately, sudden cardiac death is the initial manifestation of coronary artery disease in 10% to 20% of patients, making it the most common cause of mortality in adults younger than 65 years.[22]

Despite the close association between coronary artery disease and sudden cardiac death, acute MI is an infrequent cause of cardiac arrest. Only about 20% of patients rescued from an episode of ventricular fibrillation have evidence of an evolving MI during their subsequent hospitalization.[23] The prognosis is favorable for cardiac arrest survivors in whom the event can be clearly linked to acute myocardial ischemia, with a recurrence rate of only 2% during the subsequent year. In contrast, patients with ventricular fibrillation not related to an ischemic event have an annual recurrence rate of greater than 20%, presumably because they have a chronic substrate capable of mediating malignant ventricular arrhythmias.[22,23]

All patients rescued from cardiac arrest require serial ECGs and enzyme measurements to determine whether the event was a consequence of acute MI. Coronary angiography should be performed in all patients as well, except those in whom the precipitating factor has already been unequivocally identified.

ELECTROCARDIOGRAPHY

Laboratory evaluation of patients rescued from cardiac arrest should be directed at the identification of specific reversible causative factors. As in patients who have experienced syncope, the postresuscitation ECG may provide important information. A prolonged QT interval suggests the possibility of drug-induced torsade de pointes or the congenital long QT syndrome. A short PR interval and slurring of the QRS onset (a delta wave) are manifestations of the Wolff-Parkinson-White (WPW) syndrome [*see 1:V Supraventricular Tachycardia*]. Patients with WPW syndrome have an accessory connection linking the atrium and ventricle across either the mitral or the tricuspid annulus. A subset of patients with the WPW syndrome are capable of very rapid anterograde conduction over the accessory connection. If these patients develop atrial fibrillation, the ventricular response may be in excess of 300 beats/min and can degenerate into ventricular fibrillation.

LABORATORY TESTS

The initial evaluation of serum electrolytes is sometimes revealing, because severe depletion of serum potassium, serum magnesium, or both may precipitate ventricular arrhythmias. Such depletions are characteristic of patients with chronic heart failure who are maintained on long-term diuretic therapy with inadequate electrolyte supplementation.

ELECTROPHYSIOLOGIC TESTS

Electrophysiologic study was once an important part of the evaluation of cardiac arrest survivors in whom a reversible cause cannot be identified. With ICD therapy becoming commonplace for such patients, however, the usefulness of electrophysiologic testing has become limited to patients in whom the exact nature of the arrhythmia that precipitated the arrest remains uncertain. In a study of electrophysiology testing in 572 patients with ventricular fibrillation, ventricular tachycardia with syncope, or sustained ventricular tachycardia in the setting of left ventricular dysfunction, 67% of patients had inducible sustained ventricular tachycardia or ventricular fibrillation, but inducibility of these arrhythmias did not predict death or arrhythmia recurrence. These investigators concluded that electrophysiologic testing may not be worth the risks and costs of the procedure in this patient population, particularly in those patients likely to receive an ICD.[24]

Heritable Ventricular Arrhythmias

Alterations in the duration of the QT interval are most often acquired, typically from drugs.[25] In rare cases, however, ventricular arrhythmias result from genetic disorders that alter ventricular repolarization. These disorders include long QT syndrome, Brugada syndrome, and short QT syndrome.

LONG QT SYNDROME

A familial disorder with distinct clinical features, the congenital long QT syndrome usually presents as syncope (or, in rare instances, as cardiac arrest) during childhood or the teenage years, mediated by recurrent bouts of rapid, polymorphic ventricular tachycardia. Many patients are incorrectly diagnosed with a grand mal seizure disorder. Loss of consciousness characteristically occurs with a sudden surge in adrenergic tone caused by abrupt physical, emotional, or auditory stimulation. There is often a family history of unexplained syncope or premature sudden cardiac death.

The hallmark of this disorder is abnormal prolongation of the QT interval on the ECG. Prolongation is present if the heart rate–corrected QT interval (QT/RR interval) exceeds 0.47 in children, 0.46 in men, or 0.48 in women. Other depolarization abnormalities are often present in the long QT syndrome. The T wave is flattened and may have a bifid, or double-hump, appearance. In addition, a prominent U wave may be seen. About one third of patients will have a resting heart rate of less than 60 beats/min.

Congenital long QT syndrome has two principal phenotypes. The originally described Jervell and Lange-Nielsen syndrome, an autosomal recessive disorder with associated deafness, has proved to be quite rare.[26] The more common Romano-Ward syndrome is an autosomal dominant disorder and is not associated with hearing loss. Genomic studies in families with congenital long QT syndrome have shown that the disorder is produced by mutations of membrane ion channel proteins. To date, more than 300 of these mutations have been identified in seven genes, accounting for approximately 70% of affected patients.[27] Interestingly, the different mutations seem to produce slightly different ECG appearances.

Evaluation of a patient for the long QT syndrome should include screening of all first-degree relatives. A careful history regarding unexplained syncope and a 12-lead ECG should be obtained. A point system has been developed that combines ECG findings, clinical history, and family history (e.g., unexplained sudden death at a young age in an immediate family member) into a score that indicates the likelihood of disease.[28] Genetic testing for long QT syndrome is now commercially available and includes analysis of five major cardiac ion channel genes. The sensitivity of this test is approximately 70%, and its role in the management of affected patients and their families has not been established. Treatment of long QT syndrome is with beta blockers, ICD placement in high-risk patients, and left thoracic sympathectomy in selected cases.[29] Treatment of asymptomatic family members should be considered if screening uncovers a prolonged QT interval.

BRUGADA SYNDROME

Brugada syndrome is an inherited disorder that is manifested by syncope or sudden cardiac death. It is characterized by an

ECG that shows an incomplete right bundle branch block and ST segment elevation in leads V1 through V3.[30] However, these ECG findings also occur in many patients who do not have Brugada syndrome. Because of the low specificity of the ECG characteristics, the diagnosis should not be made on the basis of the ECG alone.[31] A set of diagnostic criteria that includes history, ECG and electrophysiologic test results, and family history has been proposed.[32] As with the long QT syndrome, genetic testing for Brugada syndrome is commercially available, but it is of uncertain utility. ICD placement is recommended for patients with Brugada syndrome who have experienced symptoms; recommendations for ICD placement are less well established for patients with Brugada syndrome who are asymptomatic or have inducible arrhythmias.

SHORT QT SYNDROME

Short QT syndrome is an inherited disorder characterized by a family history of sudden death (perhaps including sudden infant death syndrome), an abnormally short QT (QTc < 300 msec), and inducible ventricular fibrillation.[33,34] The syndrome has been traced to mutations in the cardiac ion channel genes.[35] Because short QT syndrome has only recently been recognized, its incidence remains uncertain. It is important to remember that electrolyte and drug effects that cause QT shortening (e.g., hypercalcemia and digitalis) need to be excluded before this diagnosis is entertained.

Pharmacologic Therapy

As a result of changes in the medical care system, more primary care practitioners bear direct responsibility for treatment decisions in patients with cardiac arrhythmias. The use of antiarrhythmic drugs in patients with ventricular arrhythmias presents a growing challenge, especially given that the medical literature contains reports of real and potential harm associated with the use of antiarrhythmic drugs.

CLASSIFICATION AND MECHANISMS OF ANTIARRHYTHMIC DRUGS

Antiarrhythmic drugs directly alter the electrophysiologic properties of myocardial cells. Therefore, an understanding of basic cellular electrophysiology is critical for an informed use of these compounds [*see Figure 5*].[36]

The most widely accepted classification of antiarrhythmic drugs, originally proposed by Vaughan Williams in 1970, involves four main classes of drugs, with the first class further divided into three subgroups [*see Table 1*].[37] This classification is based primarily on the ability of the drug to control arrhythmias by blocking ionic channels and currents. Few drugs demonstrate pure class effects, however, and other characteristics, such as influence of the drug on autonomic tone, contractility, and adverse effects, may be more important clinically and will be discussed as they pertain to individual drugs.

Class I agents inhibit the fast Na^+ channel during depolarization (phase 0) of the action potential, with resultant decreases in depolarization rate and conduction velocity [*see Figure 5*]. Agents in class IA (quinidine, procainamide, disopyramide, and moricizine) significantly lengthen both the action potential duration and the effective refractory period (and therefore the QT interval) through a combination of the class I effect of Na^+ channel inhibition and the lengthening of repolarization by K^+ channel blockade, a class III effect.

Class IB drugs (lidocaine, mexiletine, and phenytoin) are less powerful Na^+ channel blockers and, unlike class IA agents, shorten the action potential duration and refractory period in normal ventricular tissue, probably by inhibition of a background Na^+ current during phase 3 of the action potential.[38,39] In ischemic tissue, lidocaine may also block an adenosine triphosphate (ATP)–dependent K^+ channel, thus preventing ischemically mediated shortening of depolarization.[40]

Class IC drugs (flecainide and propafenone), the most potent Na^+ channel blockers, markedly decrease phase 0 depolarization rate and conduction velocity. Unlike other class I agents, they have little effect on the action potential duration and the effective refractory period in ventricular myocardial cells, but they do shorten the action potential of the Purkinje fibers.[41,42] This inhomogeneity of depolarization combined with marked slowing of conduction may contribute to the proarrhythmic effects of this class of drugs.

Class II agents are the beta-adrenergic antagonists. The efficacy of these drugs in the reduction of arrhythmia-related morbidity and mortality has become more evident in recent years, but the precise ionic bases for their salutary effects have not been fully elucidated. Beta-adrenergic antagonism has been shown to decrease spontaneous phase 4 depolarization and, therefore, to decrease adrenergically mediated automaticity, an effect that may be of particular importance in the prevention of ventricular arrhythmias during ischemia and reperfusion. Beta blockade also results in the slowing of heart rate and decreased oxygen consumption, effects long recognized as desirable in MI patients.[43] Effects on the cardiac action potential differ in atrial, ventricular, and specialized conduction tissues. For example, conduction velocity is slowed most profoundly in specialized conduction tissue, resulting in prolongation of the PR interval, whereas action potential duration in ventricular myocardium is generally not affected.

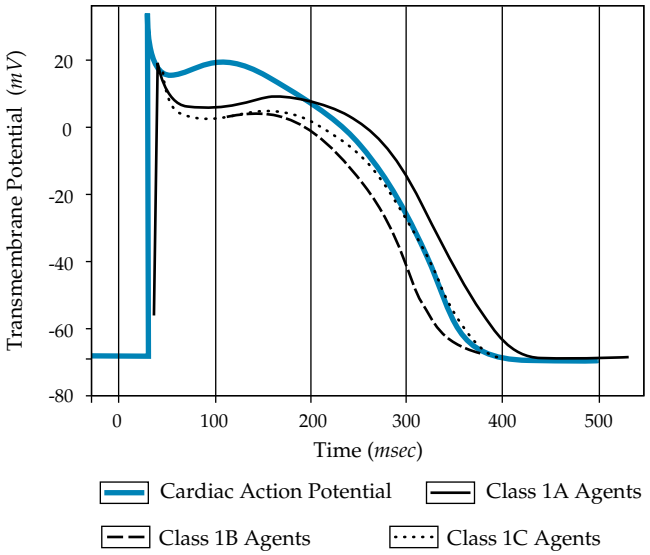

Figure 5 **The electrophysiologic hallmark of class I antiarrhythmic drugs is inhibition of the fast Na^+ channel, which results in a decrease in the slope and amplitude of phase 0 of the cardiac action potential. Class IA agents (quinidine, procainamide, and disopyramide) also prolong the action potential duration, whereas class IB agents (lidocaine and mexiletine) may shorten the action potential duration, particularly in ischemic tissue. Class IC agents (flecainide and propafenone) have little effect on action potential duration.**

Table 1 Classification of Antiarrhythmic Drugs

Class (Agents)	*Action*	*I.V. Dosage*	*Oral Dosage*	*Route of Elimination*	*Side Effects*
I	Inhibit membrane sodium channels; affect Purkinje fiber action potential during depolarization (phase 0)				
IA					
Quinidine	Slow the rate of rise of the action potential and prolong its duration; slow conduction; increase refractoriness	6–10 mg/kg (I.M. or I.V.) over 20 min	200–400 mg every 4–6 hr or every 8 hr (long-acting)	Hepatic	GI, ↓LVF, ↑Dig, torsade de pointes
Procainamide		100 mg every 1–3 min to 500–1,000 mg; maintain at 2–6 mg/min	50 mg/kg/day in divided doses every 3–4 hr or every 6 hr (long-acting)	Renal	SLE, hypersensitivity, ↓LVF, torsade de pointes
Disopyramide			100–200 mg every 6–8 hr	Renal	Urinary retention, dry mouth, markedly ↓LVF
Moricizine			200–300 mg every 8 hr	Hepatic	Dizziness, nausea, headache, ↓theophylline level, ↓LVF
IB					
Lidocaine	Shorten action potential duration; do not affect conduction or refractoriness	1–2 mg/kg at 50 mg/min; maintain at 1–4 mg/min		Hepatic	CNS, GI
Mexiletine			100–300 mg every 6–12 hr; maximum, 1,200 mg/day	Hepatic	CNS, GI, leukopenia
IC					
Flecainide	Slow the rate of rise of the action potential and slow repolarization (phase 4); slow conduction; increase refractoriness		100–200 mg twice daily	Hepatic	CNS, GI, ↓↓LVF, incessant VT, sudden death
Propafenone			150–300 mg every 8–12 hr	Hepatic	CNS, GI, ↓↓LVF, ↑Dig
II					
Beta blockers					
Esmolol	Inhibit sympathetic activity; decrease automaticity; prolong atrioventricular conduction and refractoriness	500 μg/kg over 1–2 min; maintain at 25–200 μg/kg/min	Other beta blockers may be used	Hepatic	↓LVF, bronchospasm
Propranolol		1–5 mg at 1 mg/min	40–320 mg in 1–4 doses (depending on preparation)	Hepatic	↓LVF, bradycardia, AV block, bronchospasm
Acebutolol			200–600 mg twice daily	Hepatic	↓LVF, bradycardia, positive ANA, lupuslike syndrome
III					
Amiodarone	Block potassium channels; predominantly prolong action potential duration, prolong repolarization, widen QRS complex, prolong QT interval, decrease automaticity and conduction, and prolong refractoriness	150 mg I.V. over 10 min, then 1 mg/min for 6 hr; maintain at 0.5 mg/min; overlap with initiation of oral treatment	800–1,600 mg/day for 7–21 days; maintain at 100–400 mg/day (higher doses may be needed)	Hepatic	Pulmonary fibrosis, hypothyroidism, hyperthyroidism, corneal and skin deposits, hepatitis, ↑Dig, neurotoxicity, GI
Sotalol			80–160 mg every 12 hr (higher doses may be used for life-threatening arrhythmias)	Renal (dosing interval should be extended if creatinine clearance < 60 ml/min)	↓LVF, bradycardia, fatigue and other side effects associated with beta blockers
Dofetilide			125–500 μg b.i.d.	Renal (dosing based on creatinine clearance)	Infrequent (rare CNS)
IV					
Verapamil	Slow calcium channel blockers; block the slow inward current; decrease automaticity and atrioventricular conduction	10–20 mg over 2–20 min; maintain at 5 μg/kg/min	80–120 mg every 6–8 hr; 240–360 mg once daily with sustained-release preparation (not approved for arrhythmia)	Hepatic	↓LVF, constipation, ↑Dig
Diltiazem		0.25 mg/kg over 2 min; second 0.35 mg/kg bolus after 15 min if response is inadequate; infusion rate, 5–15 mg/hr	180–360 mg daily in 1–3 doses, depending on preparation (oral forms not approved for arrhythmias)	Hepatic metabolism, renal excretion	Hypotension, ↓LVF

ANA—antinuclear antibodies AV—atrioventricular CNS—central nervous system ↑Dig—elevation of serum digoxin level GI—gastrointestinal (nausea, vomiting, diarrhea) ↓LVF—reduced left ventricular function SLE—systemic lupus erythematosus VT—ventricular tachycardia

The primary actions of class III agents (amiodarone, sotalol, and dofetilide) are prolongation of depolarization, the action potential duration, and the effective refractory period by K^+ channel blockade. These effects may prevent arrhythmias by decreasing the relative proportion of the cardiac cycle during which the myocardial cell is excitable and therefore susceptible to a triggering event. Reentrant tachycardias may be suppressed if the action potential duration becomes longer than the cycle length of the tachycardia circuit and if the leading edge of the wavefront suddenly impinges on inexcitable tissue. Class III agents have proven efficacy and an incidence of proarrhythmia lower than that seen with class IA agents.

Class IV agents act by inhibiting the inward slow Ca^{2+} current, which may contribute to late afterdepolarizations and therefore to ventricular tachycardia. These Ca^{2+} channel blockers reduce afterdepolarizations and are useful in the treatment of idiopathic ventricular tachycardia.[11,44,45] They have no appreciable effect on conduction velocity or repolarization and tend to evoke sympathetic activation. Thus, their role in the treatment of ventricular tachycardia in the setting of structural heart disease is limited.

Antiarrhythmic drugs in clinical use today have activity in multiple classes. For example, in addition to its class III effects, amiodarone also exhibits prominent Na^+ channel blockade (class I), beta blockade (class II), and Ca^{2+} channel blockade (class IV). Sotalol is a racemic mixture of d and l isomers, which have similar class III effects, whereas the l-isomer is essentially a beta blocker. d-Sotalol has been shown to increase mortality in patients with left ventricular dysfunction and recent MI.[46] The lower incidence of proarrhythmia seen with amiodarone or racemic sotalol therapy may be related to beneficial class II effects.

PROARRHYTHMIA

Proarrhythmia refers to the worsening of an existing arrhythmia or the induction of a new one by an antiarrhythmic drug. Three types of proarrhythmia have been described: torsade de pointes (the most common), incessant ventricular tachycardia, and extremely wide complex ventricular rhythm.

Torsade de Pointes

Torsade de pointes is triggered by early afterdepolarizations in a setting of delayed repolarization and increased dispersion of refractoriness. Class IA and class III drugs, which prolong refractoriness (and thus the QT interval) by K^+ channel blockade, provide the milieu for torsade de pointes. Drug-induced torsade de pointes is often pause dependent or bradycardia dependent, because the QT interval is longer at slower heart rates and after pauses. Exacerbating factors, such as hypokalemia, hypomagnesemia, and the concomitant use of other QT-prolonging drugs, are particularly important in this type of proarrhythmia.

Incessant Ventricular Tachycardia

Incessant ventricular tachycardia may be induced by drugs that markedly slow conduction (class IA and class IC) sufficiently to make the patient's own ventricular tachycardia continuous.[47,48] The arrhythmia is generally slower because of the drug effect, but it may become resistant to drugs or cardioversion, with potentially disastrous consequences in the presence of hemodynamic instability. This proarrhythmia is rarely associated with class IB drugs, which affect weaker Na^+ channel blockades.

Extremely Wide Complex Ventricular Rhythm

Extremely wide complex ventricular rhythm is usually associated with class IC agents, also in the setting of structural heart disease, and has been linked to excessive plasma drug levels or a sudden change in dose. The arrhythmia is not thought to represent a preexisting reentrant tachycardia and easily degenerates to ventricular fibrillation.

EFFICACY AND OUTCOMES OF ANTIARRHYTHMIC DRUG USE

Suppression of ambient ventricular ectopy by an antiarrhythmic agent does not prevent future life-threatening arrhythmias. In fact, patients effectively treated with class IC agents in the Cardiac Arrhythmia Suppression Trial (CAST) had a greater risk of sudden cardiac death than those who received placebo, a finding that underlines the proarrhythmic potential of these agents.[49] Conversely, beta blockers, which typically do not suppress ambient ectopy, appear to reduce the risk of malignant ventricular arrhythmias. A retrospective analysis of the CAST data showed that mortality related to arrhythmias, as well as from all causes, was reduced in patients who received beta blockers. The Electrophysiologic Study versus Electrocardiographic Monitoring (ESVEM) trial compared seven antiarrhythmic drugs and found that the risk of arrhythmia recurrence and cardiac mortality was greater with the class I agents than with sotalol.

As mentioned, patients with a history of MI and ventricular arrhythmias have an increased risk of fatal arrhythmias during follow-up. Meta-analysis of 138 trials involving 98,000 patients showed increased mortality with class I drugs.[50] Beta blockers have been conclusively associated with short-term and long-term survival in this population.[51] Therefore, all such patients should receive a beta blocker unless it is specifically contraindicated. In contrast, evidence that class IA and class IC agents increase mortality suggests that these drugs should be avoided in MI patients. Class IV agents have shown neither benefit nor harm.

Amiodarone is not associated with a significant survival benefit in MI patients, nor does it seem to be associated with an increased risk of sudden death. For example, the randomized, double-blind, placebo-controlled Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT) was conducted in 1,202 MI patients with frequent or repetitive ventricular premature depolarizations. Resuscitated ventricular fibrillation or arrhythmic death occurred in 6.9% of patients in the placebo group and in 4.5% of those in the amiodarone group.[52]

Treatment of ventricular arrhythmias in patients with chronic heart failure is particularly challenging. The presence of a reduced ejection fraction and ventricular ectopy significantly increases the risk of sudden death. No antiarrhythmic drug has been shown to produce a significant survival benefit in this population. The proarrhythmic and negative inotropic effects of class IA and class IC drugs preclude their use in these patients. Amiodarone, overall, appears to be neutral in its effects. The Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure did not show significantly greater improvement in survival in patients treated with amiodarone than in those who received placebo, despite an antiarrhythmic effect.[15] Similarly, in the European Myocardial Infarct Amiodarone Trial (EMIAT), a randomized, double-blind, placebo-controlled trial conducted in 1,486 MI survivors with an LVEF of 40% or less, neither all-cause mortality nor cardiac mortality differed between the amiodarone and the placebo groups. The investigators noted, however, that the 35% risk reduction in arrhythmic deaths in the amiodarone group support the use of amiodarone in patients for whom antiarrhythmic therapy is indicated.[53] Therefore, the only indication for the use of amiodarone in patients with chronic heart failure appears

to be to suppress symptoms from frequent ectopy and nonsustained ventricular tachycardia. Improvement in survival requires ICD therapy.

Nonpharmacologic Therapy

SURGERY AND CATHETER ABLATION OF VENTRICULAR TACHYCARDIA

Surgical techniques for the treatment of ventricular tachycardia after MI were introduced in the late 1970s. However, these procedures are associated with relatively high perioperative mortality and require ventriculotomy, which can further compromise an already damaged ventricle. For these reasons, along with the increased simplicity of ICD implantation, surgical treatment is now rarely performed.

Radiofrequency catheter ablation has a role in selected patients with idiopathic ventricular tachycardia. Ablation is also useful for palliation in patients who have had an ICD implanted and are experiencing frequent shocks.

THE IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR

The ICD automatically detects ventricular tachycardia or fibrillation and terminates the arrhythmia by overdrive pacing, high-energy shocks, or both. Since the first implantation of an ICD in a human, in 1980, the device has been utilized in hundreds of thousands of patients worldwide, and its use is growing exponentially.

All ICD systems contain three elements: the generator, rate-sensing leads, and electrodes to deliver high-energy shocks. In the early ICDs, defibrillating shocks were delivered via wire-mesh patch electrodes applied directly to the epicardial surface, and the generator was implanted subcutaneously in the abdomen. The implantation procedure required a thoracotomy and was associated with considerable morbidity and a perioperative mortality of 3% to 5%.[54] Current ICD models use transvenous leads, and the generator is implanted in a subcutaneous pocket in the anterior chest wall [*see Figure 6*].[55] ICD implantation is simple and safe, with a median duration of less than an hour and a median postoperative stay of 24 hours or less. The incidence of surgical complications is less than 2%—similar to that with routine pacemaker implantation.[55] As with modern pacemakers, the current generation of ICDs are multiprogrammable, microprocessor-based devices capable of automatically detecting ventricular tachycardia or fibrillation on the basis of timing information. The heart rate and duration of a tachycardia episode that will trigger overdrive pacing or shock therapy can be programmed. Additional detection enhancements can be used to reduce the probability that inappropriate pacing or shock will be delivered during episodes of sinus tachycardia or atrial fibrillation that exceed the programmed rate cutoff. The device can also be programmed to initiate therapy only if the heart rate increases abruptly during one cycle and only if the rate variability during the episode is less than a specified amount.

The ICD's output can also be tailored to suit patients' individual needs. For patients with a history of primary ventricular fibrillation, the ICD is programmed to deliver high-energy shocks when it detects tachycardia. Patients with a history of stable monomorphic ventricular tachycardia may benefit from overdrive pace termination. Cardioverting shocks will be delivered only if the specified number of pacing trains fails to terminate or if pacing accelerates the arrhythmia. Because overdrive pacing is associated with little or no discomfort, the device may be considered in patients with recurrent episodes of tolerated ventricular tachycardia.

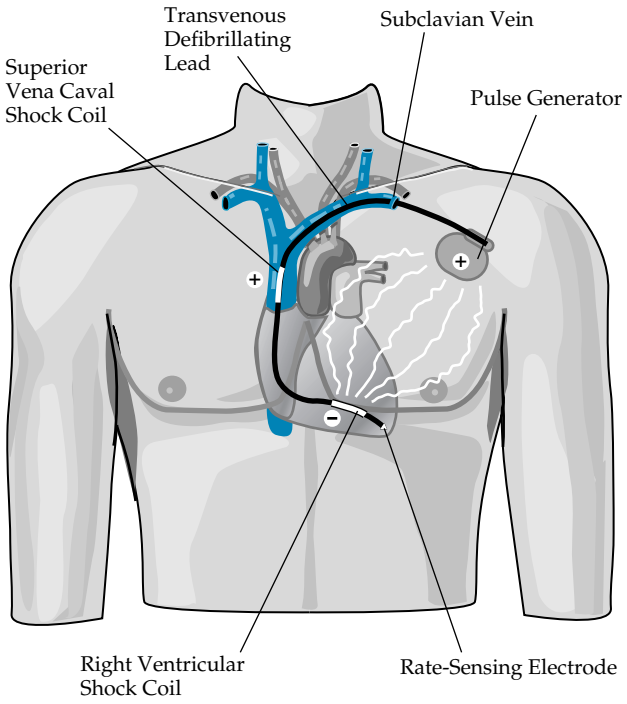

Figure 6 **An implantable cardioverter-defibrillator (ICD) consists of a pulse generator and one or more leads for cardioversion and defibrillation. The pulse generator is usually installed in a subcutaneous pocket in the pectoral region. It comprises a battery, capacitors, memory chips, integrated circuits and microprocessors, and a telemetry module, which are sealed within a titanium casing. A transvenous defibrillating lead from the pulse generator is inserted into the subclavian vein and advanced into the apex of the right ventricle. When a persistent ventricular tachyarrhythmia with a rate faster than the programmed rate cutoff is detected by the rate-sensing electrode in the lead's tip, the device charges and delivers a high-voltage defibrillating shock. For this purpose, the shock coil in the right ventricle serves as the cathode, whereas the proximal shock coil in the superior vena cava portion of the lead, plus the metal casing of the generator, serve as the anode. In older ICD models, the metal casing alone serves as the anode.**

The ICD also functions as a ventricular demand pacemaker, obviating a second device in patients with symptomatic bradyarrhythmias. This feature is also useful for prevention of the transitory bradycardia that sometimes occurs after delivery of a defibrillating shock.

The ICD has the capability of recording individual arrhythmia episodes. When tachycardia is detected, the device stores the electrograms in memory that can then be played back through the programmer at the time of a follow-up visit. This Holter function provides valuable diagnostic information regarding arrhythmia frequency, duration, rate, and response to therapy.

ICD Trials

ICDs were initially used for secondary prevention in survivors of cardiac arrest and in patients with documented life-threatening ventricular arrhythmias. Three large randomized trials have compared ICD therapy with pharmacologic treatment for the prevention of death in survivors of ventricular fibrillation or sustained ventricular tachycardia: the Antiarrhythmics vs Implantable Defibrillator (AVID) study,[56] the Cardiac Arrest Study

Table 2 Recommendations for Implantable Cardioverter-Defibrillator Therapy[66]

Recommendation Class	*Indication*	*Level of Evidence*
I	Cardiac arrest due to VF or VT not due to a transient or reversible cause	A
	Spontaneous sustained VT in association with structural heart disease	B
	Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiologic study when drug therapy is ineffective, not tolerated, or not preferred	B
	Nonsustained VT in patients with coronary disease, prior MI, LV dysfunction, and inducible VF or sustained VT at electrophysiologic study that is not suppressible by a class I antiarrhythmic drug	BA
	Spontaneous sustained VT in patients without structural heart disease not amenable to other treatments	C
IIa	LVEF ≤ 30% at least 1 mo after MI and 3 mo after coronary artery revascularization surgery	B
IIb	Cardiac arrest presumed to be due to VF when electrophysiologic testing is precluded by other medical conditions	C
	Severe symptoms (e.g., syncope) attributable to ventricular tachyarrhythmias in patients awaiting cardiac transplantation	C
	Familial or inherited conditions with a high risk for life-threatening ventricular tachyarrhythmias such as long QT syndrome or hypertrophic cardiomyopathy	B
	Nonsustained VT with coronary artery disease, prior MI, LV dysfunction, and inducible sustained VT or VF at electrophysiologic study	B
	Recurrent syncope of undetermined origin in the presence of ventricular dysfunction and inducible ventricular arrhythmias at electrophysiologic study when other causes of syncope have been excluded	C
	Syncope of unexplained origin or family history of unexplained sudden cardiac death in association with typical or atypical right bundle branch block and ST segment elevations (Brugada syndrome)	C
	Syncope in patients with advanced structural heart disease in whom thorough invasive and noninvasive investigations have failed to define a cause	C
III	Syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease	C
	Incessant VT or VF	C
	VF or VT resulting from arrhythmias amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, right ventricular outflow tract VT, idiopathic left ventricular tachycardia, or fascicular VT)	C
	Ventricular tachyarrhythmias due to a transient or reversible disorder (e.g., acute MI, electrolyte imbalance, drugs, or trauma) when correction of the disorder is considered feasible and likely to substantially reduce the risk of recurrent arrhythmia	CB
	Significant psychiatric illnesses that may be aggravated by device implantation or may preclude systematic follow-up	C
	Terminal illness with projected life expectancy less than 6 mo	C
	Patients with coronary artery disease with LV dysfunction and prolonged QRS duration in the absence of spontaneous or inducible sustained or nonsustained VT who are undergoing coronary bypass surgery	B
	NYHA class IV drug-refractory congestive heart failure in patients who are not candidates for cardiac transplantation	C

LV—left ventricular LVEF—left ventricular ejection fraction MI—myocardial infarction NYHA—New York Heart Association VF—ventricular fibrillation VT—ventricular tachycardia

Hamburg (CASH),[57] and the Canadian Implantable Defibrillator Study (CIDS).[58] A meta-analysis of the three trials showed consistent benefit from ICDs: patients who received ICDs had a significant reduction in death from any cause, with a summary hazard ratio (ICD:amiodarone) of 0.72; for arrhythmic death, the hazard ratio was 0.50.[59] Furthermore, 11-year follow-up of a subset of CIDS patients found that the benefit of the ICD over amiodarone increases with time; eventually, most amiodarone-treated patients develop side effects, experience recurrences of arrhythmia, or die.[60]

More recently, ICDs have been used for the primary prevention of sudden death. The first Multicenter Automatic Defibrillator Implantation Trial (MADIT I) compared ICD therapy with conventional medical therapy in MI patients with reduced ejection fraction, nonsustained ventricular tachycardia, and inducible nonsuppressible ventricular tachycardia on electrophysiologic testing. MADIT I showed that compared with conventional therapy, ICD therapy saved lives, with an ICD to non-ICD hazard ratio of 0.46.[61] The magnitude of the survival benefit increased with the severity of cardiac dysfunction.[62]

To study the role of ICDs in primary prevention, MADIT II enrolled MI patients with advanced left ventricular dysfunction (LVEF, 30% or less) who did not necessarily have manifest or inducible ventricular tachycardia. ICD implantation also increased survival in this population: over 20 months of follow-up, the ICD to non-ICD hazard ratio for death from any cause was 0.69.[63]

Additional trials have been performed to determine whether prophylactic ICD implantation is beneficial in all patients with chronic heart failure of any cause, ischemic or nonischemic. In the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), patients were evenly divided between those with ischemic and those with nonischemic cardiomyopathy. Patients who were receiving conventional treatment for heart failure were randomly assigned to supplemental therapy with amiodarone, placebo, or an ICD. Amiodarone did not increase survival, but simple, shock-only ICDs decreased mortality by 23%. The protective effect of the device was independent of the cause of the heart failure.[64] The Comparison of Medical Therapy, Pacing and Defibrillation in Heart Failure (COMPANION) trial was designed to compare medical therapy with a biventricular pacemaker and with a ventricular ICD in patients with advanced chronic heart failure and a wide QRS. Cardiac resynchronization with a biventricular pacemaker improved outcome, compared with medical therapy. Compared with biventricular pacing, biventricular ICD had an additional 21% survival benefit.[65]

Indications for ICD Implantation

Guidelines for the selection of patients for ICD implantation have been developed by the American College of Cardiology, the American Heart Association, and the National Association for Sport & Physical Education [*see Table 2*].[66] Since the 2002 revision of these guidelines, the indications for ICD implantation have expanded to include patients with nonischemic cardiomyopathy and an LVEF of less than 30%, even in the absence of symptomatic arrhythmias.[64]

AUTOMATED EXTERNAL DEFIBRILLATORS

An automated external defibrillator (AED) is a compact, easily portable device that can automatically analyze a patient's cardiac rhythm and, if it detects ventricular fibrillation, direct the rescuer to apply a shock. AEDs require minimal training to operate and are achieving widespread distribution.

Public-Access AEDs

AEDs can now be found in many public places, such as airports, stadiums, casinos, and large office buildings. Preliminary data suggest that these devices may confer a survival benefit,[67] although cost-effectiveness is difficult to calculate. It seems safe to say that the availability of public-access AEDs will result in increased numbers of patients successfully resuscitated from cardiac arrest, who will then require follow-up treatment.

Home AEDs

The FDA has approved several AED models for consumer use in the home, without a prescription, and these devices are now being marketed directly to the public for this purpose. The utility of home AEDs is uncertain, but the patients for whom these devices should be considered are those who meet the criteria for prophylactic ICD therapy but either have declined the implantation procedure or have comorbidities that make the implantation procedure inadvisable. The cost-effectiveness of these devices will be difficult to measure, and the potential medicolegal liability issues involved may be complex.

Wearable Automatic Defibrillators

An automatic defibrillator that is worn as a vest has been approved by the FDA.[68] This device is typically worn by patients who are awaiting heart transplants or who recently experienced an MI or underwent coronary revascularization. At our institution, we have used the device to provide temporary prophylaxis for a patient who required removal of an ICD because of site infection.

The authors serve as clinical investigators for Medtronic, Inc, Guidant Corporation, and St. Jude Medical, Inc.

VII PACEMAKER THERAPY

Jonathan Lowy, m.d.
Roger A. Freedman, m.d.

Worldwide, more than 250,000 permanent cardiac pacemakers are implanted each year. As the population ages and as indications for pacemakers expand, the number of implants continues to increase. Advances in technology have played an important role in the evolution of pacemaker therapy: currently available pacemakers are smaller and more reliable than older models and contain a multitude of sophisticated programmable features.

Normal Cardiac Electrical System

The primary role of cardiac pacing is to augment or replace the heart's intrinsic electrical system. This specialized system consists of structures capable of automaticity and conduction and provides the timing and synchrony needed to maintain appropriate cardiac output.

SINOATRIAL NODE

In normal circumstances, the sinoatrial (SA) node (also referred to as the sinus node) is the origin of impulse generation and dictates the intrinsic heart rate. The SA node is located in the superior aspect of the right atrium. It is composed of specialized tissue that demonstrates the fastest rate of spontaneous depolarization (automaticity) of any of the cardiac tissues.

ATRIOVENTRICULAR NODE

The atrioventricular (AV) node is the junction between the atria and the ventricular conduction system. This node is a dense and complex structure that plays three important roles. First, it demonstrates spontaneous depolarization and is capable of acting as an auxiliary pacemaker. Second, it delays propagation of the impulse between the atria and the ventricles, thereby allowing normal atrioventricular synchrony. Third, it acts as a filter, limiting the number of impulses that can be propagated from the atria to the ventricles and protecting the heart from rapid ventricular rates.

HIS-PURKINJE SYSTEM

The His-Purkinje system originates at the inferior border of the AV node. From this point, the bundle of His courses down the interventricular septum, where it diverges into the left and right bundle branches and terminates in the Purkinje fiber network. The bundle of His and the bundle branches provide rapid and synchronous depolarization of the ventricles. The Purkinje fibers serve as the interface between the specialized conduction system and the local ventricular myocardium.

MODULATION OF HEART RATE

The basal heart rate is maintained by the balance between sympathetic and parasympathetic tone. Changes in the heart rate are mediated by the autonomic nervous system and circulating catecholamines. There is a normal physiologic acceleration of the heart rate that results from increased demand for cardiac output. This acceleration is mediated by both increased sympathetic tone and reduced parasympathetic tone. Inability to increase the heart rate in response to increased demand for cardiac output can result in a number of symptoms, including fatigue, poor exercise tolerance, and exertional dyspnea.

Disruption or imbalance of sympathetic and parasympathetic inputs to the SA node or the AV node can cause profound abnormalities in the heart rate, resulting in inappropriate increases or decreases that give rise to significant symptoms. SA node dysfunction may be caused by intrinsic abnormalities of the conduction system or by imbalances in autonomic tone.

Indications for Permanent Pacing

GENERAL CONSIDERATIONS

The cardiac conduction system can be affected by any of a wide variety of pathologic states, ranging from benign abnormalities to conditions that can lead to severe symptoms and substantial morbidity and mortality.

Guidelines for permanent pacemaker implantation were established by a joint task force of the American College of Cardiology and the American Heart Association and were first published in 1984.[1] These guidelines were subsequently revised in 1991,[2] 1998,[3] and 2002.[4] The North American Society of Pacing and Electrophysiology (NASPE) was also involved in the 2002 revision [*see Table 1*]. Current recommendations are divided into the following three broad categories on the basis of (1) the strength of the available data and (2) the consensus of experts in the field:

- Class I: conditions for which there is evidence or general agreement that a given procedure or treatment is beneficial, useful, and effective.
- Class II: conditions for which there is conflicting evidence or a divergence of opinion about the usefulness or efficacy of a procedure or treatment.
  IIa: conditions for which the weight of the evidence or expert opinion is in favor of usefulness/efficacy.
  IIb: conditions for which usefulness or efficacy is less well established by evidence or opinion.
- Class III: conditions for which there is evidence or general agreement that a procedure or treatment is not useful or effective and, in some cases, may be harmful.

GUIDELINES FOR SPECIFIC PACEMAKER INDICATIONS

Acquired Atrioventricular Block

AV block is defined as delayed or failed conduction from the atria to the ventricles.[5-9] It is usually categorized as occurring either at or below the level of the AV node. First-degree AV block describes conduction delay from the sinus impulse to the ventricles and is defined as prolongation of the PR interval without a dropped QRS complex. Usually, first-degree AV block occurs at the level of the AV node, though it may also occur in the His-Purkinje system.

Second-degree AV block is present when some, but not all, P waves are conducted to the ventricles. It can be further subdivided into Mobitz type I (Wenckebach) and Mobitz type II. In type I second-degree AV block, there is a progressive prolongation of the PR interval preceding a nonconducted P wave. The anatom-

Table 1 Guidelines for Permanent Pacemaker Implantation

Condition	*Indications for Pacing*			
	Class I	*Class IIa*	*Class IIb*	*Class III*
Acquired AV block	Third-degree AV block or advanced second-degree AV block associated with any of the following: Symptomatic bradycardia Medical conditions requiring medications that result in symptomatic bradycardia (e.g., beta blockers, calcium channel blockers, antiarrhythmic agents) Asymptomatic asystole ≥ 3 sec or escape rate < 40 beats/min in awake patient Ablation of AV junction Postoperative AV block not expected to resolve after cardiac surgery Neuromuscular disease, including myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy, and peroneal muscular atrophy, with or without symptoms of bradycardia Second-degree AV block, regardless of type, with documented associated bradycardia	Asymptomatic third-degree AV block with average ventricular rate ≥ 40 beats/min when awake Asymptomatic type II second-degree AV block with narrow QRS complex Asymptomatic type I second-degree AV block found during electrophysiologic study performed for another reason First- or second-degree AV block with symptoms similar to those of pacemaker syndrome	Marked first-degree AV delay > 30 msec in patients with left ventricular dysfunction and congestive symptoms of heart failure Neuromuscular disease, including myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy, and peroneal muscular atrophy, with or without symptoms of bradycardia, with any degree of AV block, with or without symptoms	Asymptomatic first-degree AV block Asymptomatic type I (Wenckebach) second-degree AV block Any AV block that is expected to resolve and does not
Chronic bifascicular and trifascicular block	Intermittent third-degree AV block Type II second-degree AV block Alternating bundle-branch block	Syncope in which other causes (specifically, ventricular tachycardia) have been excluded but that has not been demonstrated to be due to AV block Asymptomatic patients in whom electrophysiologic study reveals prolonged HV interval Electrophysiologic study finding of nonphysiologic block below His bundle	Neuromuscular diseases with any degree of fascicular block, with or without symptoms, in which there is unpredictable progression	Fascicular block without AV block or symptoms Fascicular block with first-degree AV block without symptoms
Myocardial infarction	Persistent second-degree AV block in His-Purkinje system with bifascicular block or third-degree AV block within or below His-Purkinje system after acute MI Persistent and symptomatic second- or third-degree AV block Transient advanced second- or third-degree infranodal AV block and associated bundle-branch block; electrophysiologic study may be indicated to identify level of block	None	Persistent second- or third-degree block at level of AV node	Transient AV block in absence of intraventricular conduction delay Transient AV block in presence of isolated left anterior fascicular block Acquired left anterior hemiblock in absence of AV block Persistent first-degree AV block in presence of old bundle-branch block
SA node dysfunction	SA node dysfunction with documented symptomatic bradycardia Symptomatic SA node dysfunction resulting in bradycardia that occurs as consequence of essential drug therapy to which there is no acceptable alternative Symptomatic chronotropic incompetence	SA node dysfunction occurring either spontaneously or as a result of drug therapy with heart rates < 40 beats/min where there is clear association between symptoms but where actual presence of bradycardia during symptoms has not been documented Syncope of unexplained origin in which major abnormalities of SA node are elicited during electrophysiologic studies	Patients with minimal symptoms with resting heart rates < 40 beats/min while awake	Asymptomatic patients, including those on drug therapy with resting heart rates < 40 beats/min Patients with symptoms of bradycardia in which SA node dysfunction is clearly not associated with symptoms SA node dysfunction with symptomatic bradycardia caused by unnecessary drug therapy
Neurocardiogenic syncope and hypersensitive carotid sinus syndrome	Recurrent syncope caused by carotid sinus massage that results in ventricular asystole ≥ 3 sec (must occur in absence of any medication that depresses SA node or AV conduction)	Recurrent syncope without another cause and cardioinhibitory response to carotid sinus massage Symptomatic and recurrent neurocardiogenic syncope associated with documented bradycardia	None	Hyperactive cardioinhibitory response to carotid sinus massage in absence of symptoms or in presence of vague symptoms Recurrent symptoms in absence of documented cardioinhibitory response Situational vasovagal syncope in which avoiding behavior or environmental factors is effective

ic site of the block is usually the AV node, and the QRS complex is usually narrow. In type II second-degree AV block, there is a fixed PR interval preceding the dropped QRS complex. Type II block is often accompanied by bundle branch block, and its anatomic location is usually below the AV node in the His-Purkinje system.

When every other P wave is conducted, 2:1 AV block is present; 2:1 block cannot be classified as either type I or type II block, because there are not consecutive PR intervals preceding the nonconducted P wave. When 2:1 block is accompanied by bundle branch block, the site of the block is likely to be below the AV node in the His-Purkinje system. High-degree (or advanced) type II AV block is defined as blockage of two or more consecutive P waves. Complete heart block, or third-degree block, denotes a complete absence of conduction from the atria to the ventricles.

The anatomic location of AV block has important prognostic implications. Typically, a block occurring at the level of the AV node—such as first-degree block, type I second-degree block, and 2:1 block at the level of the AV node—does not typically lead to abrupt complete heart block, though gradual progression is common. A block occurring below the level of the AV node, on the other hand, can often progress quickly to complete heart block. In addition, high-degree or complete heart block at the level of the AV node is often ameliorated by junctional escape rhythms, whereas escape rhythms are much less reliable when the block is at the level of the His-Purkinje system.

Chronic Bifascicular and Trifascicular Block

The conduction system below the AV node is composed of three fascicles: the right bundle branch, the left anterior fascicle, and the left posterior fascicle. The left anterior and left posterior fascicles are divisions of the left bundle branch. Bifascicular block denotes blockage of the right bundle and either the left anterior or the left posterior fascicle; trifascicular block is present when alternating bundle branch block is seen or when right bundle branch block occurs in conjunction with alternating left anterior and left posterior hemiblock.[10] Trifascicular block may also be present when bifascicular block is accompanied by first-degree AV block. More commonly, however, this electrocardiogram pattern is the result of bifascicular block combined with conduction delay at the AV node.

Acute Myocardial Infarction

Conduction abnormalities are common in the setting of acute myocardial infarction.[11-15] Pathophysiologic mechanisms include ischemia, necrosis, autonomic influences, and the neurohumoral response to injury. Temporary transvenous pacing is often required during the acute phase of an infarction. The need for temporary pacing does not, however, predict the need for permanent pacing, given that many of the conduction abnormalities are transient and resolve after revascularization or upon recovery from the acute phase of the infarction.

Patients with acute inferior infarction can manifest a variety of abnormalities, including SA node dysfunction, first-degree AV block, type I second-degree block, and third-degree block at the level of the AV node. It is uncommon for any of these conduction disturbances to persist after the acute phase of the infarction. These patients often require temporary pacing if they manifest hemodynamic instability, but they rarely require permanent pacing.

Patients with anterior infarction can manifest bundle branch block, bifascicular block, trifascicular block, type II second-degree block, or complete heart block. These patients are much more likely to require permanent pacing than those with inferior infarction are. Although conduction abnormalities are associated with higher mortality in the setting of anterior infarction, the increased mortality is a consequence of the larger infarct size and is not directly related to the conduction abnormality.

SA Node Dysfunction

SA node dysfunction is a loose term that includes a number of different arrhythmias, including sinus bradycardia, sinus arrest, sinoatrial block, and the bradycardia-tachycardia syndrome.[16-20] The bradycardia-tachycardia syndrome is characterized by atrial tachyarrhythmias (usually atrial fibrillation) alternating with periods of bradycardia or sinus pauses. SA node dysfunction must be differentiated from the physiologic sinus bradycardia seen in trained athletes. During sleep, sinus rates as low as 30 beats/min and type I second-degree AV block are commonly seen in normal persons.

Pacing for Neurocardiogenic Syncope and Hypersensitive Carotid Syndrome

Neurocardiogenic syncope is syncope secondary to vasodilatation or bradyarrhythmias resulting from abrupt imbalance of autonomic input to the heart and the vascular system.[21-25] Classic neurocardiogenic syncope involves sinus tachycardia followed by bradycardia, vasodilatation, and syncope. Some patients have primarily a vasodepressive (vasodilatation) syndrome, whereas others have a syndrome with a significant cardioinhibitory component (bradycardia). Thus, bradycardia is not always a contributing component in neurocardiogenic syncope. Head-up tilt testing is often useful for diagnosing the presence and type of neurocardiogenic syncope.

The hypersensitive carotid syndrome is characterized by a similar abnormal response of the autonomic nervous system, in which baroreceptors in the carotid sinus trigger a vasodepressive or cardioinhibitory response. A hyperactive carotid sinus response is defined as a sinus pause longer than 3 seconds or a substantial symptomatic decrease in systolic blood pressure.

Other Pacemaker Indications

Besides those already mentioned, there are several indications for which pacemakers are implanted that warrant mention, including treatment of hypertrophic cardiomyopathy, prevention or suppression of tachyarrhythmias, and resynchronization therapy for congestive heart failure. Cardiac resynchronization therapy is an exciting new development in the treatment of heart failure but lies outside the scope of this chapter.

Pacemaker Systems

A basic pacemaker system is made up of three main components: the pulse generator, the pacemaker lead(s), and the programmer.

PULSE GENERATOR

Over the past 30 years, pulse generators have evolved from large, bulky devices into small, sophisticated systems [*see Figure 1*]. All pulse generators contain hardware, software, and a battery; however, the systems currently available can differ from one another with respect to a number of factors, including number of chambers, biventricular pacing capability, presence and type of activity sensor, size, battery life, and cost. All of these fac-

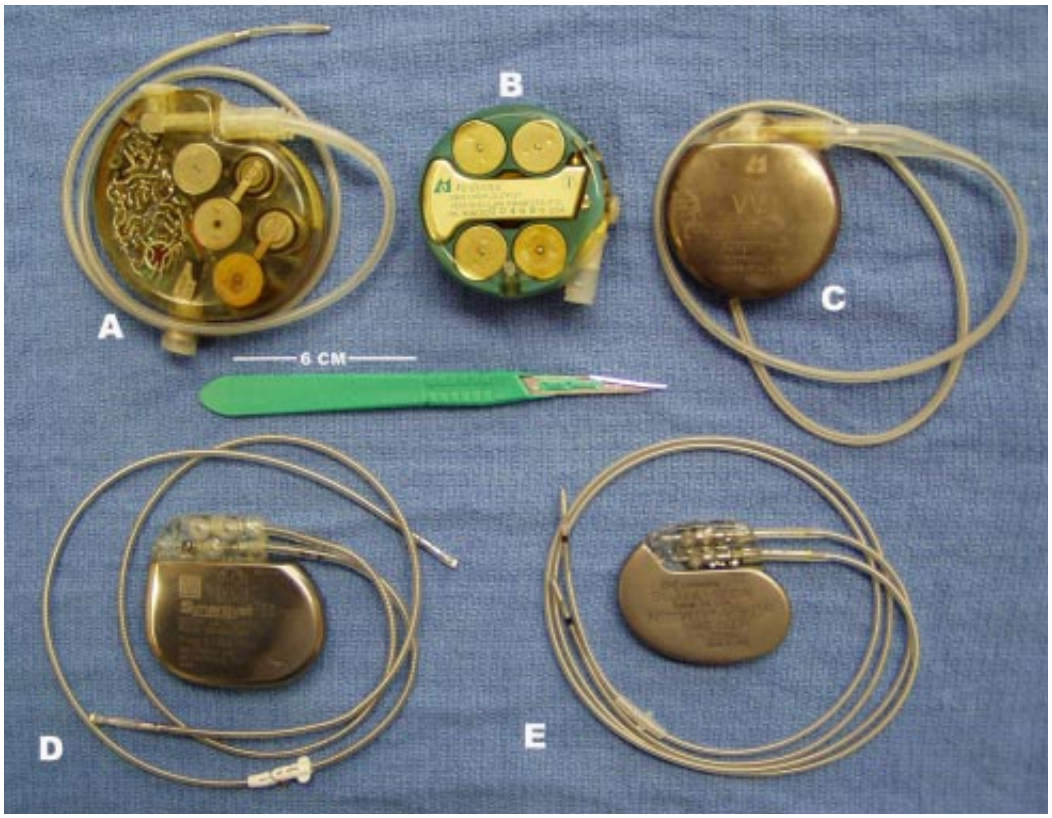

Figure 1 **Shown are five different pacemaker generators. The first three are older single-chamber devices from (*a*) 1972, (*b*) 1977, and (*c*) 1983. The last two are modern dual-chamber devices from (*d*) 1994 and (*e*) 2000.**

tors are taken into account in selecting a specific generator for a specific patient.

Generators are usually described as being either single-chamber or dual-chamber. Single-chamber systems have one lead, which is usually placed in the right ventricle (though it may, on occasion, be placed in the atrium). Dual-chamber systems have two leads, one of which is implanted in the right atrium and the other in the right ventricle. The biventricular pacemaker devices currently used in patients with heart failure have a third lead that is usually placed in a branch of the coronary sinus to provide left ventricular pacing. Dual-chamber systems can be programmed to single-chamber modes of operation.

At present, most generators currently use lithium iodine batteries that have a typical life span of 5 to 10 years. These batteries are not rechargeable or replaceable; accordingly, when the battery reaches the end of its life, a new generator must be implanted.

PACEMAKER LEADS

Pacemaker leads are the conduits from the generator to the myocardium. Most leads are implanted transvenously. There are still occasional applications for epicardial leads, but these are generally limited to patients with mechanical tricuspid valves, certain congenital heart abnormalities, or other conditions that preclude transvenous leads. Like pulse generators, leads have gone through a complex evolution since they were first developed. Various types are currently used [*see Figure 2*]; the major differences among them have to do with type of insulation, fixation mechanism, and polarity.

Most pacemaker leads are insulated with either silicone or polyurethane. In the past, there were significant differences between the two materials with respect to durability and handling. Today, however, the differences are minimal, and the choice of material is usually operator dependent.

Leads can be attached to the myocardium via either passive or active fixation. Passive-fixation leads usually have tines at the distal tip to help maintain stability. Active-fixation leads have a corkscrew helix mechanism at the distal end, which inserts into the myocardium. Both fixation mechanisms are reliable, and lead dislodgment is uncommon with either one.

Finally, leads can be either unipolar or bipolar. Unipolar leads have a single conductor and a single electrode; the unipolar pacing circuit involves the single electrode and the metal housing of the generator. Bipolar leads have two conductors and two electrodes; the pacing circuit is between the two electrodes. Advantages of unipolar leads include decreased diameter and reduced susceptibility to lead fracture. Advantages of bipolar leads include reduced risk of inappropriate sensing of myopotentials, greater resistance to electromagnetic interference (EMI), less likelihood of pectoral muscle stimulation, and better compatibility with implanted defibrillators. At present, bipolar leads are more commonly used, but unipolar leads are still employed on occasion.

Currently available lead systems are very reliable: failure rates at 5 years are typically 5% or lower.

PACEMAKER PROGRAMMER

The programming computer allows telemetric communication with the implanted pulse generator and serves as the interface between the health care provider and the pacemaker. Because there is no standardization among pacemaker manufacturers, each company's device requires its own programmer.

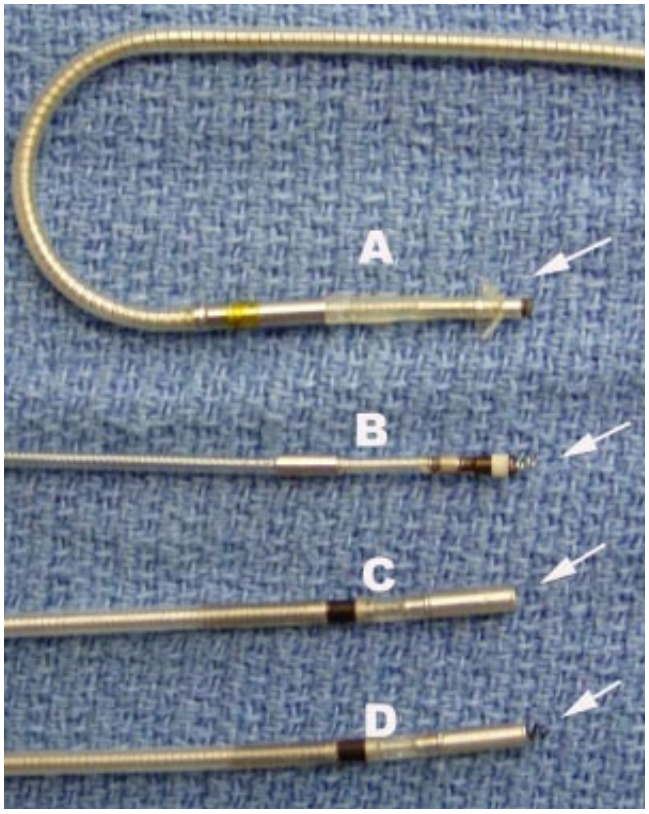

Figure 2 **Shown are four different pacemaker leads. The first (*a*) is a passive-fixation lead with soft tines at the tip (arrow); it is also a preformed J lead used for atrial pacing. The second (*b*) is an active-fixation lead with a fixed helix. The third (*c*) and fourth (*d*) are active-fixation leads with a retractable helix; the fourth has the helix mechanism exposed.**

Programmers are equipped with a wand that provides external telemetry through the skin, thus allowing direct communication with the pacemaker generator and access to the software contained within it. The pacemaker programmer is used to perform a multitude of functions, including assessing battery status, modifying pacemaker settings, and providing access to diagnostic information the pacemaker has stored (e.g., heart rate trends and tachyarrhythmia documentation).

PACEMAKER MAGNETS

Pacemaker generators are designed to respond to the placement of a strong magnet over the device. The response of most pacemakers is to pace at a set "magnet rate" in an asynchronous mode. Magnets also can be used to perform any of a number of functions designated by the manufacturer, including checking battery life, threshold testing, and obtaining event snapshots (in much the same way as an event monitor). Magnets should be available in the hospital and clinic, as well as on code carts for immediate access.

Although such use is beyond the scope of this chapter, it is worth mentioning that magnets can also temporarily turn off defibrillation therapy in implantable cardioverter-defibrillators.

Pacemaker Programming

Detailed description of specific programming techniques and indications is beyond the scope of this chapter; however, familiarity with the basic functions and nomenclature is critical for understanding how pacemakers function.

BASIC FUNCTIONS

A pacemaker has three basic functions: pacing, sensing, and action. Its other, more complicated functions are based on these three. Pacing is the delivery of an electrical impulse to the myocardium to elicit depolarization. Sensing is the ability to "see" intrinsic depolarization (i.e., the local intrinsic electrical signal that passes by the tip of the lead). Action is the response of the pacemaker to a sensed event—namely, either inhibition or triggering of a paced event.

CODES

The basic functions—pacing, sensing, and action—are determined by basic pacemaker programming. In 1974, the American Heart Association and the American College of Cardiology proposed a three-letter code for describing the basic functions of pacemakers. Under the guidance of NASPE and the British Pacing and Electrophysiology Group (BPEG), this code evolved into the five-position code currently in use [*see Table 2*].[26] The first position denotes the chamber or chambers paced; the second denotes the chamber or chambers sensed; the third denotes the action or actions performed; the fourth denotes rate response; and the fifth denotes multiple-site pacing. The simplest mode of pacing is VVI, otherwise known as ventricular demand pacing or ventricular inhibited pacing. The most commonly used mode in dual-chamber pacing is DDD.

TIMING CYCLES

A pacemaker is governed by timing cycles, which are a hierarchy of clocks that regulate how the pacemaker functions. The most basic timing cycle is the lower rate, which reflects how long the pacemaker will wait after a paced or sensed beat before initi-

Table 2 NASPE-BPEG Generic Five-Position Code for Antibradycardia Pacing

	Position				
	I	*II*	*III*	*IV*	*V*
Parameter measured	Chamber(s) paced	Chamber(s) sensed	Response or action	Rate modulation	Multisite pacing
Possible values	O = None A = Atrium V = Ventricle D = Dual (A + V)	O = None A = Atrium V = Ventricle D = Dual (A + V)	O = None I = Inhibited T = Triggered D = Dual (I + T)	O = None R = Rate response on	O = None A = Atrium V = Ventricle D = Dual (A + V)

NASPE—North American Society of Pacing and Electrophysiology BPEG—British Pacing and Electrophysiology Group

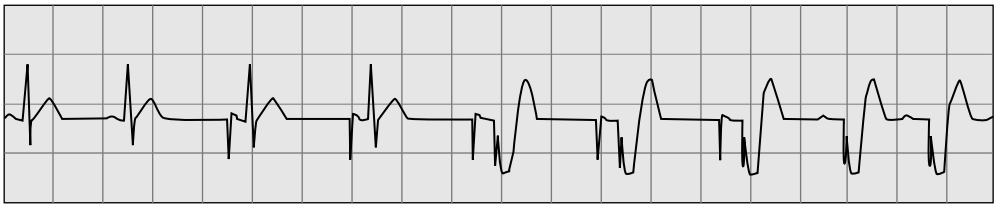

Figure 3 **Illustrated are different forms of DDD pacing. In the first two beats (labeled "Inhibited"), the pacemaker senses both the intrinsic P wave and the QRS complex; the result is inhibition of pacing. In the next two beats (labeled "Atrial"), there is a pacing spike preceding each P wave; the result is atrial pacing. The intrinsic QRS complex is then sensed, and ventricular pacing is inhibited. In the third set of beats (labeled "Sequential"), there are pacing spikes preceding both the P wave and the QRS complex. Both chambers are paced. The paced QRS morphology is noticeably different from the intrinsic complexes seen in the previous examples. In the final set of beats (labeled "Tracking"), an intrinsic P wave is followed by a paced QRS. The intrinsic atrial beat is sensed and triggers ventricular pacing.**

ating pacing. If the pacemaker is set to VVI mode at a lower rate of 60 beats/min, then as long as the interval between intrinsic beats is less then 1,000 msec, the pacemaker will reset the lower rate clock with each sensed QRS complex, and pacing will not occur. If, however, the intrinsic heart rate falls below 60 beats/min, the pacemaker's lower-rate clock will time out before an intrinsic beat is sensed, and pacing will occur. After a paced beat, the lower-rate clock is reset and the cycle repeats. In a modern dual-chamber pacemaker, there are a number of additional timing cycles that regulate how the pacemaker responds to these paced and sensed events [*see Figure 3*].

Patients with chronic atrial fibrillation and slow ventricular response are generally treated with single-chamber ventricular pacemakers. Such devices are also occasionally used in patients with isolated SA node dysfunction.

Pacemaker Implantation

Most pacemakers are implanted by cardiologists, and most implantation procedures are performed in the cardiac catheterization laboratory.[27]

PREPROCEDURAL CONSIDERATIONS

There are several issues that should be considered after the need to implant a pacemaker has been established. In particular, the patient's underlying health must be assessed and any comorbid conditions evaluated.

In select patients, the issue of reversal and reinitiation of oral anticoagulation must be addressed before implantation. In the past, all patients receiving warfarin had their international normalized ratios (INRs) normalized before the procedure. Furthermore, patients with a strong indication for anticoagulation (e.g., a mechanical heart valve) required prolonged hospitalization for reinitiation of oral anticoagulation after the procedure. In the past few years, however, favorable results have been reported with routine pacemaker implantation in patients undergoing therapeutic anticoagulation with warfarin. These results suggest that preprocedural reversal of anticoagulation may not be necessary.[28-29]

Pacemakers can interfere with or preclude certain imaging procedures, such as mammography and magnetic resonance imaging. In the case of elective pacemaker implants, a baseline mammogram should be performed beforehand.[30] Any MRI pro-

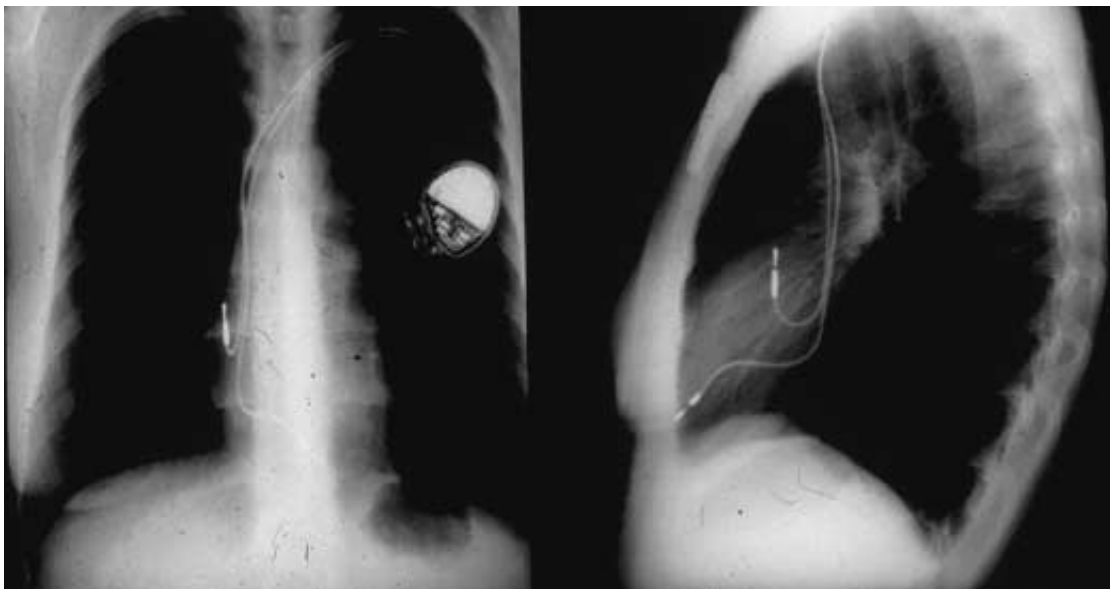

Figure 4 **Shown is the typical appearance of a dual-chamber pacemaker on posteroanterior (left) and lateral (right) chest x-rays. The RV lead is at the apex, and the RA lead is in the right atrial appendage.**

cedures that may be indicated should also be performed before implantation.

Local anesthesia is typically employed in conjunction with parenteral sedation. In certain circumstances (e.g., in pediatric patients or other patients who would tolerate the procedure poorly under local anesthesia), an anesthetist should be involved, but such circumstances are relatively uncommon. Antibiotic prophylaxis is commonly employed, but not in a uniform manner. There are no strict guidelines, and antibiotic regimens vary greatly.[31]

PACEMAKER POCKET PLACEMENT

The pulse generator pocket is usually placed on the upper left aspect of the chest, just medial to the angle of the deltopectoral grove and 2 to 3 cm below the clavicle. In the case of left-handed patients or in certain other specific situations (e.g., when left subclavian vein acclusion is present or the patient has undergone a left mastectomy), the pacemaker may be located on the right side. It is important to locate the generator medially enough that it does not interfere with normal shoulder function. The pocket is formed deep to the subcutaneous tissue and above the plane of the pectoral fascia. Occasionally, if the patient is extremely thin or if cosmetic considerations are a priority, the generator may be placed either below the pectoral muscle or via a retromammary approach.

VASCULAR ACCESS

Vascular access is most frequently gained by means of the Seldinger technique. The subclavian vein remains the most common venous access site; however, the axillary vein is becoming an increasingly popular site. Venous access may also be obtained via the cephalic vein or the internal jugular vein. In addition, leads may be tunneled subcutaneously from a remote entry site (e.g., the internal jugular vein) to the site of the generator pocket. Occasionally, thoracotomy and the use of epicardial lead systems are still necessary.

RISKS

Overall, transvenous pacemaker implantation is both safe and well tolerated. The risk of major adverse events (e.g., death, myocardial infarction, stroke, and the need for emergency thoracotomy) is approximately 0.1%. Other complications sometimes encountered include pneuomothorax, vascular injury, cardiac perforation, tamponade, local bleeding, pocket hematoma, infection, and venous thrombosis. There is also a small risk that one or more leads may become dislodged and have to be repositioned in a second procedure.

POSTPROCEDURAL CARE

At most institutions, it is standard practice to admit patients for overnight observation after routine pacemaker implantation. Routine exchange of the pacemaker generator because of battery depletion is often performed as a same-day outpatient procedure. Longer hospitalizations may be required in certain specific situations, as when anticoagulation must be reversed and reinitiated or when a major comorbid condition must be treated.

After implantation of new devices or leads, the ipsilateral arm is placed in a sling or a soft restraint for 12 to 24 hours. Nonnarcotic analgesics are usually sufficient for pain control, but occasionally, oral narcotics are indicated. Patients are monitored via continuous telemetry. We routinely obtain a portable chest x-ray and a 12-lead ECG immediately after implantation.

The day after the procedure, the pacemaker is interrogated and the final settings confirmed. Posteroanterior and lateral chest x-rays are obtained both to verify the positioning of the leads and to rule out the possibility of a slowly accumulating pneumothorax [*see Figure 4*].

Before discharge, the patient receives instruction about the pacemaker teaching and is given a temporary pacemaker card that lists the manufacturer, the specific generator and lead(s) used, and complete serial-number information. Later, the manufacturer mails the patient a permanent identification card, which the patient is asked to keep on hand at all times.

POSTDISCHARGE INSTRUCTIONS AND RESTRICTIONS

Postoperative care focuses on averting hematoma and preventing lead dislodgment. Patients are prohibited from showering for the first 48 to 72 hours. After this period, they may shower, but for the first week, they are advised to cover the implantation site with plastic wrap to protect it from contamination. When 24 hours have passed after implantation, minimal range-of-motion restrictions are placed on the ipsilateral arm and shoulder. Patients are asked to refrain from raising the arm above shoulder level and to perform only limited heavy lifting for the first few weeks. After this period, patients may return to normal activity levels without having to be concerned about displacing the leads or the generator system.

Usually, a follow-up visit is scheduled 7 to 10 days after implantation. During this visit, a wound check is performed to ensure proper healing and to remove the skin suture if it is nonresorbable. As a rule, the pacemaker pocket heals completely within 2 to 4 weeks.

LONG-TERM FOLLOW-UP

Pacemaker patients need routine follow-up care, including interrogation of the pacemaker. Follow-up care can be provided during office visits, via transtelephonic monitoring (TTM), or both. Guidelines for follow-up have been published by NASPE,[32] as well as by the Canadian Working Group in Cardiac Pacing.[33] We recommend that patients either be seen in the office or undergo TTM every 3 months. As the battery approaches the end of its life, more frequent visits may be required.

Complications

Pacemaker complications are infrequent but can lead to serious situations. To minimize adverse consequences, it is important to identify problems early in their course, initiate appropriate workup and treatment, and refer when necessary [*see Table 3*]. Generally, pacemaker complications can be classified according to whether they primarily affect the pocket, the generator, or the leads.

GENERATOR POCKET COMPLICATIONS

Pocket hematomas can occur in any patient but are especially likely to occur in those receiving anticoagulants. These hematomas are usually self-limited, and intervention is rarely necessary. Acute management includes direct manual compression, sandbag compression, pressure dressings, or a combination thereof. Needle aspiration and opening the pocket to drain the hematoma are discouraged because of the risk of introducing infection. Reoperation is generally limited to situations in which there is impending compromise of the incision, uncontrollable bleeding, uncontrollable pain, or suspected infection. Other possible pocket problems include erosion of the underlying hardware, infection, pocket pain, migration of the pulse generator,

Table 3 Common Findings Related to Pacemaker Problems

Findings	*Potential Causes*	*Treatment/Workup*	*When to Refer*
Ecchymoses Hematoma Oozing at incision site	Local bleeding Anticoagulation	External compression; avoid needle aspiration or surgical drainage if possible Withhold anticoagulation	Impending wound dehiscence, uncontrolled pain Signs of infection
Palpable hardware, including header or leads	Benign unless findings consistent with impending erosion	No treatment Cushion with gauze or dressing to avoid irritation from clothing Pocket revision	Signs of impending erosion Pain requiring consideration of pocket revision
Adhesion of skin Thinning or atrophy of skin Scaling of skin Erythema	Impending generator or lead erosion	Pocket revision	Early If hardware becomes exposed, extraction may be required
Exposed hardware	Erosion with infection	Blood cultures Blood count Antibiotics Hardware extraction	Immediately
Pocket erythema Pocket swelling Purulent discharge	Infection Local inflammatory reaction Local trauma	Blood cultures Chest x-ray Blood counts	Early
Pocket pain	Superficial implant Infection Generator migration Pacemaker allergy Superficial irritation from bra strap or clothing	Chest x-ray Examination of generator pocket for signs of migration or infection	Signs of infection Continued pain despite mild analgesics
Fever, chills, or other signs of systemic infection or bacteremia, even without signs of pocket infection	Systemic infection, including bacteremia, bloodstream infection, or endocarditis	Blood cultures Chest x-ray Blood counts Echocardiography	Immediately
Ipsilateral arm swelling Arm heaviness Superior vena cava syndrome	Venous thrombosis	Doppler ultrasonography Arm elevation Anticoagulation	Early
Pectoral muscle twitching Diaphragmatic stimulation	Lead fracture Unipolar pacing Autocapture feature Phrenic nerve stimulation	Chest x-ray Pacemaker interrogation	Early

and misplacement of the generator (so that it interferes with shoulder movement).

Erosion of the underlying hardware can be quite serious, in that it usually leads to infection of the system. In normal circumstances, the underlying hardware, including the leads, can be felt during palpation of the pacemaker pocket, especially if the patient is thin. In extreme cases, the outlines of the generator and the leads can be clearly seen through the skin. It is important to be able to distinguish between normal palpability or visibility and impending pacemaker pocket erosion. Normally, the skin overlying the pacemaker is freely mobile, without discoloration or tenderness to palpation. Fixation, erythema, thinning, atrophy, and scaling of the skin over the underlying hardware are signs of impending erosion. It is crucial to identify early signs of erosion before the hardware breaks the skin. If the skin is intact, surgical revision of the pocket is often all that is needed to protect the hardware from contamination and infection. Once the hardware has been exposed, however, the device must be assumed to be infected, and treatment usually involves a much more complex procedure that includes removal of all the hardware.[34]

Device migration is unusual but can cause significant discomfort. In some cases, surgical revision of the pocket is required to restore an appropriate position.

Chronic pacemaker pocket pain is also infrequent. There is normally some postoperative discomfort while the site heals and the capsule of scar tissue develops. Chronic pain may indicate that the device is not properly located in relation to the shoulder joint and the clavicle or may be an early sign of subacute infection.

GENERATOR COMPLICATIONS

On the whole, pacemaker generators are highly reliable: normal battery depletion aside, failure is unusual. True allergy to pacemaker materials does occur but is rare.

LEAD COMPLICATIONS

Pacemaker lead complications include dislodgment, fracture,

and infection. Fractures can occur throughout the body of the lead, but the most common location is the area where the lead passes between the first rib and the clavicle; fracture at this site leads to the so-called subclavian crush syndrome. Lead fractures may be asymptomatic or may give rise to symptoms related to failure to pace or sense appropriately. Extracardiac stimulation and changes in measured parameters of lead function may be noted. Some lead fractures may be evident on chest x-ray; however, only the conductors are radiopaque, and thus, simple disruption of the outer insulation will not be visible.

A common lead complication is the so-called twiddler's syndrome, which refers to patients who, whether intentionally or subconsciously, continually manipulate the generator within the pocket, eventually causing lead damage or dislodgment.

PACEMAKER INFECTIONS

Bacterial infections can affect any part of the pacemaker system, and the consequences can be devastating. The most com-

Table 4 Sources of Electromagnetic Interference That Can Affect Pacemakers

	Source	*Safe with Pacemaker*	*Specific Recommendations*
Medical sources	MRI	No	Rarely done; restricted to life-threatening situations with close monitoring
	CT scanning	Yes	Pacemaker may interfere with images of thorax
	Lithotripsy	Yes	Activity sensors should be disabled Pacemaker-dependent patients should be programmed to asynchronous mode Shocks should be synchronized to R wave Contraindicated in patients with abdominal implants
	External direct current cardioversion	Yes	Avoid placing patches or paddles directly over pacemaker Have transcutaneous pacing available Use lowest possible energy and biphasic waveform when possible Interrogate pacemaker after procedure
	Neurostimulation	Yes	Test at highest output for pacemaker inhibition before discharge
	Peripheral nerve stimulation	Yes	Nerve conduction studies below the elbow or knee are safe
	Transcutaneous electric nerve stimulation (TENS)	Yes	May require increasing sensing threshold Avoid placing TENS electrodes parallel to pacing vector
	Radiation therapy	Yes	Avoid direct irradiation; maximize shielding If total dose is expected to exceed 10 Gy, device may have to be relocated out of field Reprogram to asynchronous mode if patient is pacemaker dependent Initiate continuous monitoring if patient is pacemaker dependent Check device function after each session and for first few weeks after therapy
	Diagnostic ultrasonography, including echocardiography	Yes	No precautions needed
	Surgical electrocautery	Yes	[*See Figure 5*]
Household and industrial sources	Microwave ovens, TV remote-control devices, cordless telephones, other household appliances	Yes	All devices considered safe; controlled studies lacking
	Slot machines	Yes	May cause interaction and spurious shocks with ICDs
	Walk-through metal detectors	Yes	Do not dwell in scanner; device will probably set off alarm Patients should be advised to carry pacemaker ID card as proof
	Handheld security wand	Yes	Patient should instruct person conducting search not to put wand directly over pacemaker generator
	Cellular telephones	Yes	Keep phone at least 10 cm from pacemaker; do not keep phone in shirt pocket above pacemaker; try to use contralateral ear when using phone
	Electronic article surveillance devices	Yes	Do not dwell in scanner
	Industrial sources, including large electric motors, magnets, and high-voltage power	Yes/No	Depends on source and proximity of pacemaker; site visit may be needed to determine safety
	Arc-welding equipment	No	Cannot be used because of magnetic field of cable

ICD—implantable cardioverter-defibrillator

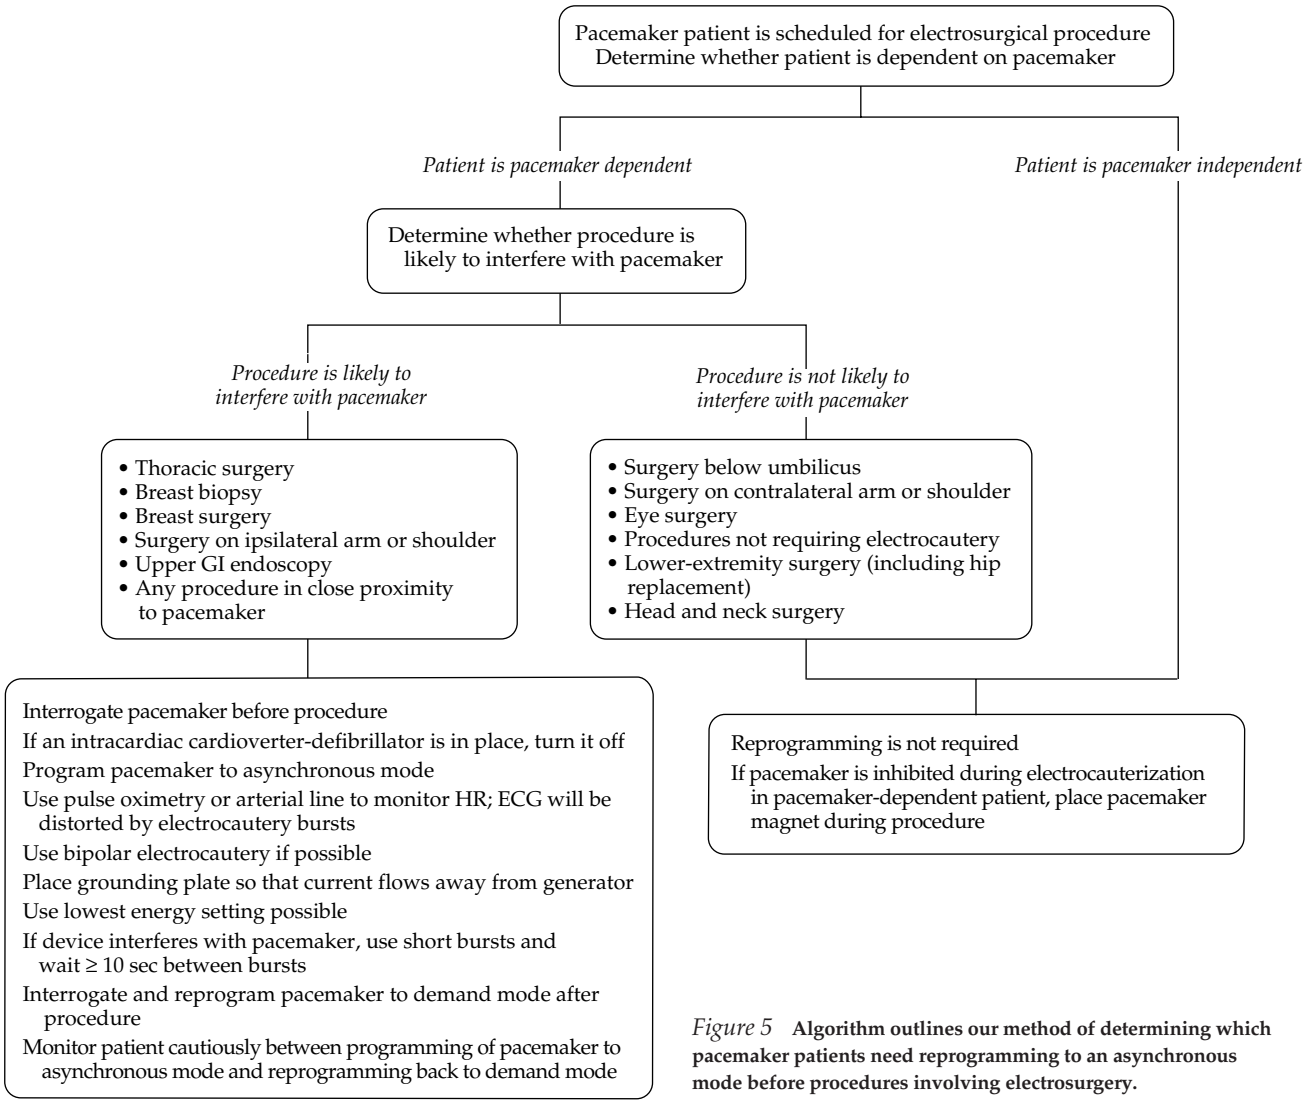

Figure 5 **Algorithm outlines our method of determining which pacemaker patients need reprogramming to an asynchronous mode before procedures involving electrosurgery.**

mon pathogens are staphylococci, especially *Staphylococcus epidermidis*. Once a pacemaker infection is established, it is difficult to eradicate with antibiotics; thus, infected pacemaker systems usually must be removed in their entirety. Patients with pacemakers in place who acquire *S. aureus* bacteremia are at significant risk for a secondary device infection.[35] If infection of an implanted cardiac device is suspected, prompt referral to an experienced center is critical.

External Interference with Pacemaker Function

To function appropriately, pacemakers must be able to sense a clean signal from the myocardium. A number of potential sources can interfere with such signals and thereby affect pacemaker function.[36,37] The most significant of these is EMI, which can have several detrimental effects on pacing systems. The most common detrimental effect of EMI is inhibition of pacing: the pacemaker senses the EMI and interprets it as cardiac activity. In a pacemaker-dependent patient, this misinterpretation can have catastrophic consequences. Other detrimental effects include reversion to an asynchronous pacing mode, reversion to a backup pacing mode, inappropriate activation of other features, and damage to the pacemaker circuitry. Modern pacemakers with bipolar leads are less susceptible to EMI; in addition, they often contain filters and other features designed to protect the patient from device malfunction.

SOURCES OF EMI

Sources of EMI can be divided into household sources, industrial sources, and medical sources [*see Table 4*]. In general, household appliances such as microwave ovens, hairdryers, and television remote controls are safe for pacemaker recipients to use.[38-40] Medical sources of EMI are common in both noninvasive and invasive procedures. MRI scans are generally contraindicated in pacemaker patients; they should be performed only in life-threatening situations and with close monitoring.[41,42] Surgical procedures involving electocauterization are important sources of EMI and often necessitate pacemaker reprogramming before and after the procedure.[43] As a rule, only patients who are pacemaker dependent require reprogramming. The location of the procedure in relation to the pacemaker generator is also an important consideration in deciding whether reprogramming is indicated. On the basis of case reports and our own clinical experience, we have developed an approach we use to determine who needs pacemaker reprogramming before surgery [*see Figure 5*].

The Future

Pacemaker technology is advancing on many fronts.[44,45] Devices are becoming smaller and more sophisticated. Improvements in pacemaker software are allowing closer imitation of normal physiologic cardiac function. New automatic features (e.g., automatic mode switching in response to atrial fibrillation, automatic capture verification, and automatic sensing) are leading to greater reliability and simplified follow-up. New indications for pacing (including cardiac resynchronization therapy for heart failure and treatment of sleep apnea) are evolving. Pacemaker and implantable cardioverter-defibrillator technologies are converging. New information technology is allowing improved collection, storage, and analysis of pacemaker patient data. Internet-based patient management systems are being developed that will include automatic wireless interrogation performed at the patient's home.

VIII ACUTE MYOCARDIAL INFARCTION

Peter B. Berger, m.d.
James L. Orford, m.b.chb., m.p.h.

In the 1970s, coronary angiography demonstrated that almost all cases of acute myocardial infarction were caused by thrombotic occlusion of a coronary artery. This discovery has led to the development of therapies to restore coronary blood flow in the occluded artery, which has dramatically reduced the morbidity and mortality associated with acute myocardial infarction.

Epidemiology

In the past decade, the number of people who die each year of myocardial infarction has decreased significantly. Both in-hospital mortality and out-of-hospital mortality have declined as a result of substantial increases in the use of aspirin, heparin, thrombolytic therapy, and coronary angioplasty, as well as a reduction in the risk factors for coronary artery disease (e.g., hypertension, hyperlipidemia, smoking, and sedentary lifestyle) [*see* Risk-Factor Modification, *below*]; however, it must be emphasized that there is, unfortunately, persistent discordance between existing guidelines for management of acute coronary artery disease syndromes and current clinical practice.[1,2]

Despite these advances, approximately 1.5 million people in the United States suffer acute myocardial infarction each year, and nearly 500,000 of these patients die of coronary artery disease.[3] Nearly half of these deaths occur before the patients receive medical care either from emergency medical technicians or in a hospital.[3,4]

Pathogenesis

The factors responsible for the sudden thrombotic occlusion of a coronary artery have only recently been elucidated.[5-7] Atherosclerotic plaques rich in foam cells (lipid-laden macrophages) are susceptible to sudden plaque rupture and hemorrhage into the vessel wall, which may result in the sudden partial or total occlusion of the coronary artery. Although severe stenosis of a coronary artery (i.e., stenosis ≥ 70% of the diameter of the artery) is generally required to produce anginal symptoms, such stenoses tend to have dense fibrotic caps and are less prone to rupture than mild to moderate stenoses, which are generally more lipid laden. Studies of patients in whom angiography was performed before and after a myocardial infarction revealed that in most cases, acute coronary artery occlusion occurred at sites in the coronary artery circulation with stenoses of less than 70%, as demonstrated on the preinfarction angiogram.[8] Although patients who have unstable anginal syndromes with increasingly frequent and severe angina are clearly at increased risk for myocardial infarction, the ability of physicians to predict which patients with stable anginal syndromes are likely to experience infarction and which coronary artery stenoses are likely to result in acute thrombotic occlusion is poor.

Diagnosis

According to the World Health Organization, the diagnosis of myocardial infarction requires at least two of the following three criteria: (1) a clinical history of ischemic-type chest discomfort, (2) serial electrocardiographic tracings indicative of myocardial infarction, and (3) a rise and fall in serum cardiac markers.[9] However, the advent and widespread adoption of novel diagnostic tools, including highly sensitive and specific serologic biomarkers and precise imaging techniques, have necessitated reevaluation of this established definition. The Joint European Society of Cardiology/American College of Cardiology Committee for the Redefinition of Myocardial Infarction has integrated these diagnostic modalities and published updated definitions of acute myocardial infarction, evolving or recent myocardial infarction, and established myocardial infarction that more accurately reflect current clinical practice [*see Table 1*].[10]

Clinical Manifestations

Patients with acute myocardial infarction often describe a heaviness, pressure, squeezing, or tightness in the chest that has persisted for more than 30 minutes. The discomfort may radiate or be located primarily in the arms, neck, or jaw. Chest pain, particularly severe or stabbing chest pain, and pain that causes writhing are unusual for coronary artery ischemia and should lead the clinician to consider causes other than myocardial infarction. Many patients with acute myocardial infarction, particularly those with inferior infarction, are diaphoretic; nausea and emesis are common as well. Dyspnea is also a common associated symptom. Syncope may occur and is more frequent with inferior than anterior infarction, in part because of the more frequent occurrence of bradyarrhythmias, heart block, and tachyarrhythmias with inferior infarction. Elderly patients with

Table 1 Clinical Definitions of Myocardial Infarction as Determined by the Joint European Society of Cardiology/American College of Cardiology Committee[10]

Acute, Evolving, or Recent Myocardial Infarction
Biochemical markers of myocardial necrosis (i.e., typical rise and gradual fall of troponin or more rapid rise and fall of CK-MB) with at least one of the following:
Ischemic symptoms
Development of pathologic Q waves on the ECG
ECG changes indicative of ischemia (ST segment elevation or depression)
Coronary artery intervention (e.g., primary coronary angioplasty)
Pathologic findings of an acute myocardial infarction
Established Myocardial Infarction
Development of new pathologic Q waves on serial ECGs; the patient may or may not remember previous symptoms; biochemical markers of myocardial necrosis may have normalized, depending on the length of time that has passed since the infarct developed
Pathologic findings of a healed or healing myocardial infarction

CK-MB—creatine kinase–myocardial band

infarction often present with symptoms that differ from the symptoms of infarction in younger patients; more than half of elderly patients present with shortness of breath as their main complaint, and many others present with dizziness or symptoms of arrhythmia rather than the classic symptoms of acute myocardial infarction.[11]

Approximately two thirds of patients describe the new onset of angina or a change in their anginal pattern in the month preceding infarction.[12] However, in approximately one fourth of patients, myocardial infarction is associated with only mild symptoms or no symptoms at all.[13]

PHYSICAL EXAMINATION

The patient with acute myocardial infarction often appears anxious and in distress. Vital signs are often normal, but sinus tachycardia is not uncommon. The pulse may be rapid or slow if arrhythmias are present. Either hypotension caused by left or right ventricular dysfunction or arrhythmia or hypertension caused by adrenergic discharge may be present. The respiratory rate may be elevated because of anxiety or pain or because of hypoxia in patients with significant congestive heart failure. The jugular venous pressure may be elevated, reflecting right ventricular dysfunction caused by right ventricular involvement (more common with inferior infarction); arrhythmia in which atrioventricular dissociation is present may produce so-called cannon A waves, which are abnormally high jugular venous waves caused by atrial systole occurring when the atrioventricular valves are closed. The lung examination is typically normal, but moist rales indicative of congestive heart failure resulting from left ventricular dysfunction may be present. The cardiac examination may reveal a dyskinetic apical pulsation on palpation; a fourth and, less commonly, a third heart sound may be audible. The murmur of ischemic mitral regurgitation may be present. If a left bundle branch block is present, abnormal splitting of the second heart sound may be heard.

It must be emphasized that the physical examination in acute myocardial infarction is generally most useful in excluding other potentially serious causes of the patient's chest discomfort, including pulmonary embolism, aortic dissection, spontaneous pneumothorax, pericarditis, and cholecystitis, rather than in confirming a diagnosis of acute myocardial infarction.

ELECTROCARDIOGRAPHY

ECG is a valuable tool both in confirming the diagnosis of acute myocardial infarction and in selecting the most appropriate therapy for the patient. Although rhythm and conduction disturbances may be present, the presence and type of repolarization abnormalities are most useful in identifying myocardial infarction. If ST segment elevation is present in a patient with chest pain typical of acute myocardial infarction, the likelihood that the patient has acute myocardial infarction is greater than 90%.[14] Other findings, such as ST segment depression, T wave inversion, and bundle branch block, are less specific but may also support a diagnosis of acute myocardial infarction, particularly when typical symptoms are present [*see Figure 1*]. Fully 50% of patients with myocardial infarction do not have ST segment elevation on their ECGs, although the ECG is seldom normal even at an early stage.[15] In such patients, the ECG can help predict complications and early mortality.[16] Patients with ST segment depression are at high risk; 30-day mortality in such patients is nearly as high as in patients with anterior ST segment elevation.[17] Patients with other nonspecific ECG abnormalities are at lesser

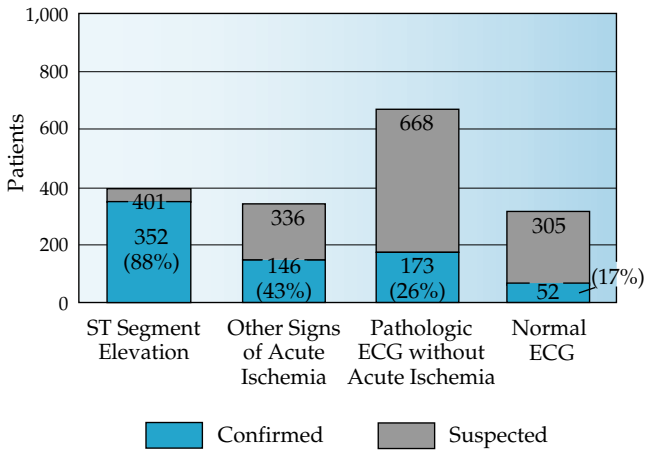

Figure 1 **Relation between the initial electrocardiographic changes and the development of infarction in 1,715 patients strongly suspected of having an acute myocardial infarction. Each column shows the total number of patients and the number of patients later found to have had an infarction. Although infarction is less frequently confirmed in patients without ST segment elevation than in those with ST segment elevation, even patients with normal ECG findings may suffer acute myocardial infarction.[14]**

risk; those with normal ECGs who suffer infarction generally have the best prognosis [*see Figure 2*]. Regardless of the findings on the initial ECG, the most important element in the evaluation of a patient with suspected acute myocardial infarction is the patient's description of symptoms. All patients suspected of having acute myocardial infarction should be admitted to the hospital and receive rapid and appropriate therapy.

LABORATORY FINDINGS

Injury to myocardial cells results in the release of intracellular enzymes into circulating blood, permitting their detection by blood tests. Traditionally, the serum cardiac marker creatine kinase (CK) and an isoenzyme, creatine kinase–myocardial band (CK-MB), which are found in high concentration in myocardial cells, have been used to diagnose myocardial infarction in its earliest stages.[18] Rapid assays of these enzymes have been developed, permitting the determination of the blood levels of these enzymes within 30 to 60 minutes. Drawbacks to the use of CK-MB include its lack of specificity for cardiac muscle and the time required for CK-MB levels to rise during myocardial infarction. CK and CK-MB usually require at least 3 hours of profound ischemia to rise above normal levels; patients who present early in their infarction would not be expected to have elevated CK levels. Furthermore, patients may have only partial obstruction of the infarct-related artery, or there may be extensive collateralization of the infarct-related artery, which further delays the release of these enzymes. In patients suspected of having acute myocardial infarction, it is not appropriate to delay treatment until an elevation of CK or CK-MB is present, because the goal of treatment is to prevent injury to the myocardium. The challenge facing physicians is to identify patients suffering myocardial infarction even before CK becomes elevated, because these patients require emergency therapy and stand to benefit the most from reperfusion therapy.

To overcome these limitations and more accurately and rapidly identify patients in need of emergency reperfusion therapy,

other blood tests have been developed to help identify patients with ischemia. Myoglobin is a low-molecular-weight heme protein found in cardiac muscle. Its advantage for diagnosis is that it is released more rapidly from infarcted myocardium than is CK-MB. However, myoglobin is also found in skeletal muscle, and the lack of specificity is a drawback.[19] Troponin is a cardiac-specific marker for acute myocardial infarction; an increase in serum levels of troponin occurs soon after myocardial cell injury. An elevated cardiac troponin level on admission is a predictor of subsequent cardiac events.[20,21] The recent changes to the definition of acute myocardial infarction reflect the increased emphasis on these specific biomarkers of myocardial injury [*see Table 1*].[10]

IMAGING STUDIES

Echocardiography

Echocardiography may be useful in identifying patients with myocardial infarction in the emergency department. Regional wall motion abnormalities occur within seconds of coronary occlusion and well before myocyte necrosis,[22-26] and most patients with acute myocardial infarction have regional wall motion abnormalities readily seen on echocardiography. However, echocardiographic evidence of myocardial infarction is not required in patients with symptoms and electrocardiographic evidence typical of acute myocardial infarction, and treatment should not be delayed, so that an echocardiogram can be performed. Similarly, wall motion abnormalities are not specific for acute myocardial infarction and may be caused by ischemia or prior infarction. Echocardiography may be useful in patients with left bundle branch block or abnormal ECGs without ST segment elevation whose symptoms are atypical and in whom the diagnosis is uncertain.[27]

Radionuclide Imaging

Perfusion imaging with both thallium and sestamibi in the emergency department has been reported to be both sensitive and specific in the evaluation of patients in whom the diagnosis is uncertain.[27-29] A prospective randomized trial of 2,475 patients found that resting technetium-99m sestamibi imaging reduced unnecessary hospitalization in patients with acute ischemia without reducing admission of patients with acute ischemia.[30]

Emergent Therapy

Treatments have been developed that reduce the morbidity and mortality of acute myocardial infarction, particularly when initiated early; it is therefore important to avoid delay in administering therapy.[4,31] Although the greatest delay in treatment of acute myocardial infarction is usually the time that it takes a patient to seek medical care, much of the emphasis on reducing delay has focused on the time between a patient's presentation to the emergency department and the administration of reperfusion therapy. A patient with symptoms suggestive of myocardial infarction should be evaluated within 10 minutes after arrival in the emergency department. Early steps should include the assessment of hemodynamic stability by measurement of the patient's heart rate and blood pressure; the performance of a 12-lead ECG; and the administration of oxygen by nasal prongs, I.V. analgesia (most commonly morphine sulfate), oral aspirin, and sublingual nitroglycerin if the blood pressure is greater than 90 mm Hg. The challenge facing physicians who work in emergency departments is that more than 90% of patients who present to the emergency department complaining of chest pain are not suffering myocardial infarction; many do not have a cardiac etiology for their chest pain.

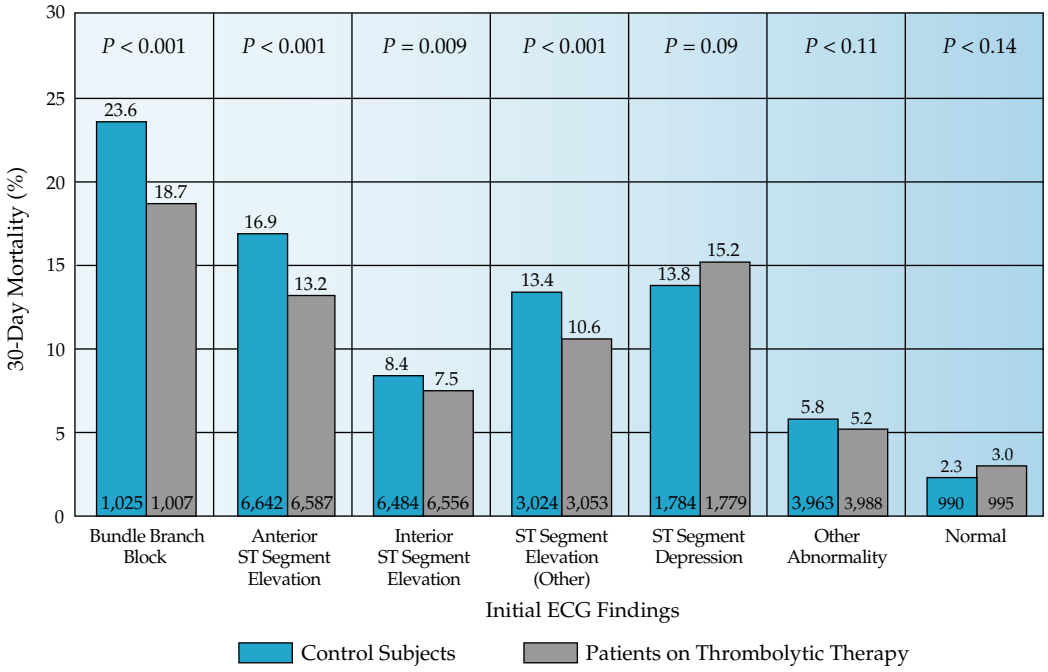

Figure 2 **Thirty-day mortality in patients with suspected acute myocardial infarction from placebo-controlled trials of thrombolytic therapy on the basis of their initial ECGs. Patients with ST segment depression are at high risk, nearly as high as patients with anterior ST segment elevation. The mortality among such patients is not reduced (and may be increased) by thrombolytic therapy. Patients with other nonspecific electrocardiographic abnormalities are at lesser risk, and those with normal ECG findings have the best prognosis.**

All patients with definite or suspected myocardial infarction should be admitted to the hospital, undergo preparation for I.V. access, and be placed on continuous ECG monitoring. High-risk patients should be admitted to a coronary care unit. In many hospitals, patients at low risk for major complications are admitted to a telemetry unit, where emergency medical care can be quickly administered, rather than to a coronary care unit. Tachyarrhythmias and bradyarrhythmias may occur even in low-risk patients, particularly in the first 24 hours. Lidocaine, atropine, an external or internal pacemaker, and a defibrillator should be readily available.

OXYGEN

Oxygen is generally recommended for all patients with acute myocardial infarction for the first several hours after admission and is mandatory for patients with pulmonary congestion or evidence of oxygen desaturation.

ASPIRIN

Aspirin should be given to all patients as soon as a diagnosis of myocardial infarction is made.[17] In the second International Study of Infarct Survival (ISIS-2), aspirin was found to be nearly as effective as streptokinase, reducing 30-day mortality 23% in 17,000 patients with acute myocardial infarction; the benefit was additive in patients receiving both aspirin and streptokinase [*see Figure 3*].[17] Other studies have revealed similar benefit from immediate aspirin therapy.[32] The beneficial effect of aspirin is the result of its antiplatelet effect, which is achieved through the rapid inhibition of thromboxane A_2 production.

Patients should be maintained on aspirin indefinitely. Prolonged administration of aspirin in patients with a history of myocardial infarction is associated with a 25% reduction in death, nonfatal reinfarction, and stroke.[32]

ANALGESIA

Pain relief should be among the initial therapies offered to patients with acute myocardial infarction. Persistent chest discomfort is generally caused by ongoing myocardial ischemia; although the ultimate goal of therapy is to eliminate ischemia, analgesia should be administered without delay. In addition to making patients more comfortable, pain relief may reduce the outpouring of catecholamines characteristic of the early stages of acute myocardial infarction and thereby reduce myocardial oxygen demand. Intravenous morphine sulfate is commonly used for pain relief in this setting.

Reperfusion Therapy

REPERFUSION STRATEGIES AND OUTCOMES

Importance of Time to Reperfusion

Many important predictors of early clinical outcome in myocardial infarction are independent of treatment. Most of the early mortality is explained by factors such as the age of the patient, initial heart rate and blood pressure, initial Killip classification [*see Table 2*], and infarct location. However, the time to administration of reperfusion therapy is a critical determinant of outcome and one of the few determinants of early clinical outcome under the control of the physician. Many studies have revealed that patients with myocardial infarction treated most rapidly have a lower mortality and, among survivors, reduced infarct size [*see Figure 4*].[33] This observation has led to recommendations that the time between a patient's presentation to the emergency department and the administration of thrombolytic therapy not exceed 60 minutes; ideally, this period should not exceed 30 minutes.[34] The most critical interval is the time between symptom onset and the achievement of reperfusion, not the time to the initiation of therapy. Thus, therapy that takes longer to initiate (e.g., primary coronary angioplasty) may actually be superior if it

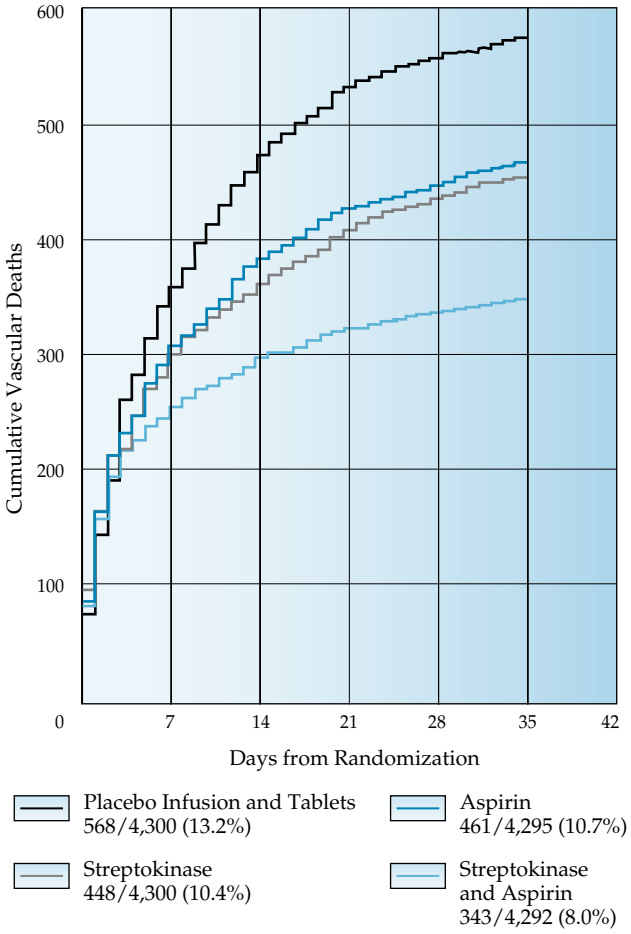

Figure 3 **Mortality at 35 days in 17,187 cases of suspected acute myocardial infarction in the second International Study of Infarct Survival (ISIS-2). In this study, aspirin reduced 30-day mortality by 23% and was nearly as effective as streptokinase; the benefit was additive in patients receiving both aspirin and streptokinase.[17]**

Table 2 Killip Classification of Acute Myocardial Infarction

Class I	No clinical heart failure
Class II	Findings consistent with mild or moderate heart failure (e.g., isolated S_3 gallop, bilateral rales in up to 50% of lung fields)
Class III	Pulmonary edema, rales in all lung fields, acute mitral regurgitation
Class IV	Cardiogenic shock (e.g., stuporous state of consciousness, systolic blood pressure < 90 mm Hg, decreased urine output, pulmonary edema, and cold, clammy skin)

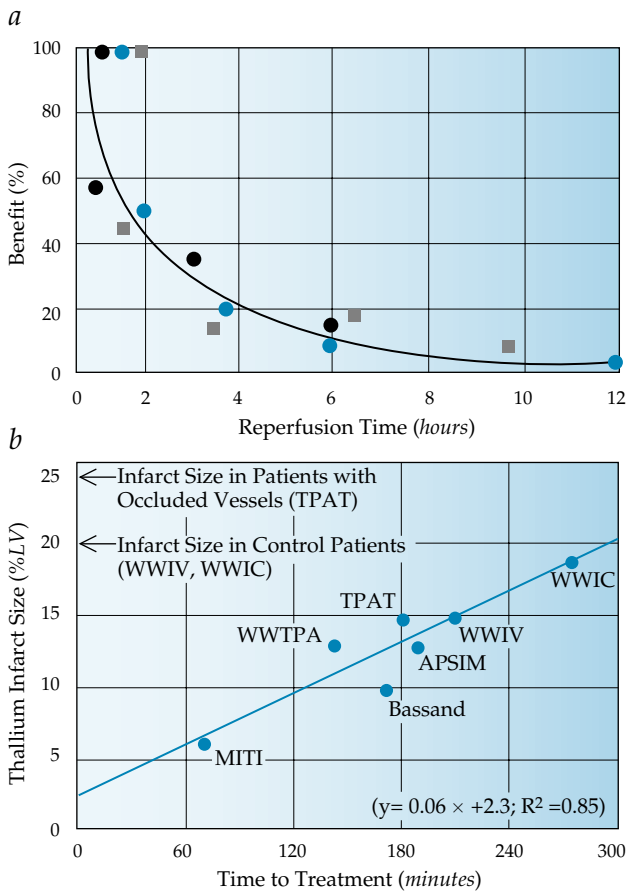

Figure 4 **Many studies have revealed lower mortality (*a*) and reduced infarct size among survivors (*b*) of myocardial infarction treated most rapidly. The equation shows the linear relation between infarct size and time to treatment.[33] (APSIM—APSAC dans l'Infarctus du Myocarde; Bassand—Bassand study; MITI—Myocardial Infarction Triage and Intervention; TPAT—Tissue Plasminogen Activator, Toronto trial; WWIC—Western Washington Intracoronary streptokinase trial; WWIV—Western Washington Intravenous streptokinase trial; WWTPA—Western Washington Tissue Plasminogen Activator trial)**

achieves reperfusion more rapidly than another therapy that can be initiated more rapidly (e.g., thrombolytic therapy).

The importance of avoiding hospital delay in performing primary coronary angioplasty was evident in the Global Use of Strategies to Open Occluded Arteries (GUSTO-IIb) substudy, which compared primary coronary angioplasty with tissue plasminogen activator (t-PA) therapy.[35] There was a clear relation between the length of time until angioplasty was performed after enrollment in the study and 30-day mortality [*see Figure 5*]. Analysis of 27,080 patients in the second National Registry of Myocardial Infarction also revealed a relation between time to treatment with primary percutaneous transluminal coronary angioplasty (PTCA) and survival, even after adjusting for other mortality risk factors.[36] In that study, the volume of patients treated with angioplasty at the hospital was also a predictor of outcome; a lower mortality was seen at hospitals in which a high number of patients with acute myocardial infarction were treated with coronary angioplasty. There have been studies in which unacceptably high mortality was seen at hospitals when primary angioplasty was not performed rapidly; reducing delay led to a reduction in mortality.[37] Therefore, as is the case with thrombolytic therapy, the speed with which reperfusion is achieved appears to be an important determinant of clinical outcome. The best reperfusion therapy (coronary angioplasty or thrombolytic therapy) is not necessarily the one that can be most rapidly initiated but, rather, the one that achieves coronary patency most rapidly. Clinicians should know, at their own institution, whether coronary angioplasty is more rapid or less rapid than thrombolytic therapy at restoring flow to the infarct-related artery; in general, the therapy that restores flow most rapidly should be preferred. At institutions where a skilled catheterization team is on call 24 hours a day and can be rapidly assembled, coronary angioplasty would most likely be able to restore coronary blood flow in more patients more rapidly than thrombolytic therapy. Elsewhere, thrombolytic therapy may be preferable.[38-40]

Transfer for Primary Angioplasty versus Immediate Thrombolytic Therapy

Time to reperfusion is an important modifiable predictor of clinical outcome for both thrombolysis and primary angioplasty, although it has the greatest impact on patients treated with thrombolytic therapy. An alternative treatment strategy for patients with ST segment elevation myocardial infarction (STEMI) initially assessed at a hospital without on-site cardiac surgery facilities is immediate transfer for primary percutaneous coronary intervention (PCI). Although immediate transfer is intuitively an attractive option, reasonable concerns regarding the unavoidable delay before transfer and the risk of transporting such critically ill patients during the acute phase of myocardial infarction have mandated formal evaluation of this strategy.

The PRAGUE-2 investigators randomized 850 patients with acute STEMI presenting within 12 hours to a hospital without a catheterization laboratory to either immediate thrombolysis or transfer for primary PCI.[41] The investigators determined that in the acute phase of STEMI, long-distance transport from a community hospital to a facility with PCI is safe and is associated with decreased mortality in patients presenting more than 3 hours after symptom onset. Similarly, the Danish Trial in Acute Myocardial Infarction (DANAMI)–2 trial investigators concluded that immediate transfer for primary PCI, in preference to immediate thrombolysis, was safe and efficacious.[42]

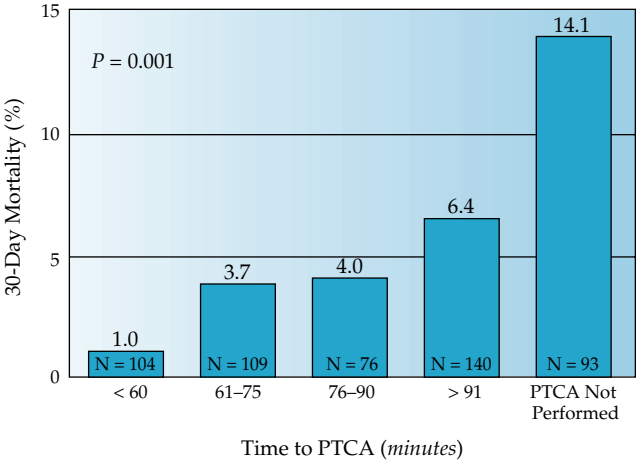

Figure 5 **Relation between the time from study enrollment to the first balloon inflation and 30-day mortality in the GUSTO-IIb substudy. Patients assigned to angioplasty in whom angioplasty was not performed are also shown.[35] (PTCA—percutaneous transluminal coronary angioplasty)**

However, data from these trials need to be understood within the context of the individual trial designs and their actual conduct. The maximum transport distance in the PRAGUE-2 trial was 120 kilometers, and the time from transport to balloon inflation was only 97 ± 27 minutes. In the DANAMI-2 trial, the time from arrival to initiation of treatment in the thrombolysis arm of the study was 51 minutes, whereas the time required to transfer patients for primary PCI was 155 minutes ($P < 0.0001$). In contrast, a report from the National Registry of Myocardial Infarction (NRMI)–4 (http://www.nrmi.org/nrmi_data.html) revealed a median door-to-balloon time of 185 minutes for patients transferred for primary PCI in the United States and a door-to-balloon time of less than 90 minutes in only 3% of patients. It is reasonable to assume that the reported benefit associated with this particular treatment strategy in the aforementioned randomized, controlled clinical trials (i.e., PRAGUE-2 and DANAMI-2) can be realized only if similar transfer times and door-to-balloon times are reproduced in clinical practice; the findings of the NRMI 4 investigators are not reassuring in this regard.

Coronary Angiography after Uncomplicated Myocardial Infarction

The role of coronary angiography after uncomplicated myocardial infarction remains controversial for patients who have received thrombolytic therapy. Coronary angiography in patients initially treated with thrombolytic agents has been studied in the second Thrombolysis in Myocardial Infarction (TIMI II) study, the Should We Intervene Following Thrombolysis? (SWIFT) study, the Treatment of Post-thrombolytic Stenoses (TOPS) study, and, most recently, a German study.[43-46] It is clear from these studies that patients treated with thrombolytic therapy in whom complications do not occur are at low risk for reinfarction and death after discharge and that the routine performance of coronary angiography and coronary angioplasty does not reduce the occurrence of these adverse events. Despite the publication of these well-designed studies, there has been considerable reluctance among physicians to accept their results, and there remains considerable variability throughout the United States and the world in the frequency with which coronary angiography is performed in such patients.

Many cardiologists feel more comfortable caring for patients who have suffered a myocardial infarction if the patient's coronary anatomy is known. Patients at low risk may be discharged from the hospital more rapidly. Patients who have left mainstem or multivessel disease, particularly those who have reduced ventricular function, may be referred for coronary artery bypass surgery or percutaneous revascularization. Patients with persistent occlusion of the infarct-related artery may benefit from revascularization because of favorable effects on remodeling, a reduction in ventricular arrhythmia, and the improved ability of the infarct-related artery to provide collateral blood flow to other coronary arteries in the future. Nonetheless, until the benefits of cardiac catheterization are demonstrated in asymptomatic patients after an uncomplicated myocardial infarction, a conservative strategy is recommended in patients who have been given thrombolytic therapy, and coronary angiography is recommended only for patients with hemodynamic instability or for patients in whom spontaneous or exercise-induced ischemia occurs; such a strategy is safe and is associated with a good clinical outcome.

Patients who are not given thrombolytic therapy are at higher risk for reinfarction and death than those receiving thrombolytic therapy. The role of coronary angiography in patients with acute myocardial infarction not receiving thrombolytic therapy has not been studied. In such patients whose infarctions are complicated by hemodynamic compromise or postinfarction chest pain or in patients in whom multivessel disease or reduced ventricular function is believed to be present, coronary angiography is probably helpful. It remains unclear whether coronary angiography should be performed in patients not treated with thrombolytic therapy who do not have these high-risk characteristics. It is impossible to be definitive about recommendations in the absence of appropriate studies, and not surprisingly, practice patterns vary widely throughout the United States and the world in such patients.

Reperfusion Therapy in Patients without ST Segment Elevation

Primary PTCA has not been appropriately studied in patients without ST segment elevation, and it is not possible to be definitive about its use in this setting. However, regardless of the findings on ECG, PTCA is widely believed to be beneficial in patients with ischemic-type chest discomfort that persists despite medical therapy. Many patients with prolonged chest pain without ST segment elevation are not suffering from myocardial infarction; the likelihood that infarction is present is increased if repolarization abnormalities are present on the ECG and the patient has risk factors for coronary artery disease. In patients with critical coronary artery stenoses, immediate PTCA or bypass surgery may be appropriate. In patients without significant coronary artery disease, immediate angiography can also be extremely useful and can lead to the withdrawal of cardiac med-

Table 3 Class I Recommendations for the Use of an Invasive Strategy in the Management of Patients with Unstable Angina or Non–ST Segment Elevation Myocardial Infarction

An early invasive strategy is recommended for patients who have unstable angina or non–ST segment elevation myocardial infarction (NSTEMI) without serious comorbidity and who have any of the following high-risk indicators (level of evidence: A):

- Recurrent angina/ischemia at rest or with low-level activities despite intensive anti-ischemic therapy
- Elevated levels of troponin T or troponin I
- New or presumably new ST segment depression
- Recurrent angina/ischemia with symptoms of congestive heart failure, an S_3 gallop, pulmonary edema, worsening rales, or new or worsening mitral regurgitation
- High-risk findings on noninvasive stress testing
- Depressed left ventricular systolic function (e.g., ejection fraction < 0.40 on noninvasive study)
- Hemodynamic instability
- Sustained ventricular tachycardia
- Percutaneous coronary intervention within 6 mo
- Prior coronary artery bypass grafting

In the absence of any of these findings, an early conservative strategy or an early invasive strategy may be offered in hospitalized patients without contraindications for revascularization (level of evidence: B)

Note: Class I recommendations pertain to conditions for which there is evidence or general agreement that a given procedure is useful and effective. Level A evidence (highest)—Derived from multiple randomized clinical trials. Level B evidence (intermediate)—Derived from limited number of randomized clinical trials, nonrandomized studies, or observational registries.

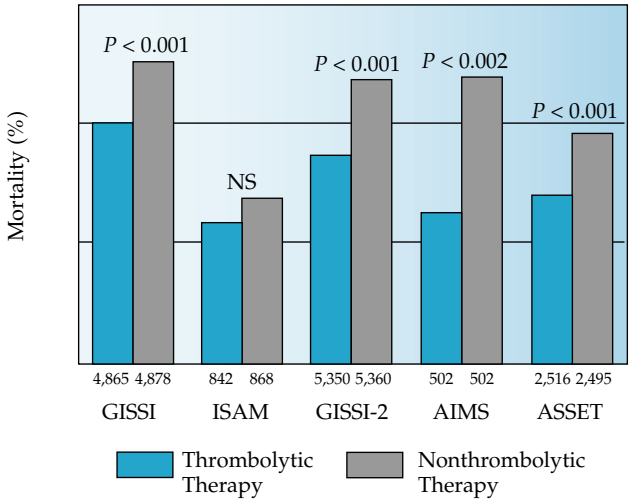

Figure 6 **Data from five controlled megatrials of thrombolytic therapy large enough to detect a mortality difference between the thrombolytic and nonthrombolytic control arms of the trials. Pooled data from these five trials (not shown) reveal a 29% mortality reduction in patients treated within 6 hours of symptom onset.[53] (AIMS—APSAC International Mortality Study; ASSET—Anglo-Scandinavian Study of Early Thrombosis; GISSI—Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico; GISSI-2—Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Myocardico; ISAM—Intravenous Streptokinase in Acute Myocardial Infarction; NS—not significant)**

ications, discharge from the coronary care unit, and appropriate diagnostic evaluation, in many cases as an outpatient. Immediate angiography is recommended in all patients with hypotension, severe congestive heart failure, or cardiogenic shock regardless of the initial ECG results, because immediate revascularization appears to reduce mortality in this setting.[47] In addition, there is a compelling case to be made for routine invasive evaluation of all patients who are admitted with unstable angina or non–ST segment elevation myocardial infarction (NSTEMI).[48]

In the TIMI-IIIb study, an early intervention strategy was compared with a conservative strategy in 3,000 patients with either unstable angina, recent non–Q wave myocardial infarction, or prolonged chest pain without ST segment elevation on ECG.[49] Patients were randomized to receive either early angiography or medical therapy; only those patients who subsequently experienced recurrent chest pain or had an exercise test underwent angiography. Although death and myocardial infarction occurred with similar frequency in the two groups, the study showed that the initial hospitalization was longer and the need for rehospitalization more frequent in the group receiving conservative therapy. More recently, in the second Fragmin and Fast Revascularization during Instability in Coronary Artery Disease (FRISC-II) trial, an early invasive strategy was shown to reduce both mortality and myocardial infarction at 1 year.[50] In the Treat Angina with Aggrastat [tirofiban] and Determine Cost of Therapy with Invasive or Conservative Strategy—Thrombolysis in Myocardial Infarction–18 (TACTICS-TIMI-18) study, an early invasive strategy was found to reduce the combined end point of death or myocardial infarction.[51] In both the FRISC-II and TACTICS-TIMI-18 studies, patients at greatest risk, such as those with positive troponin values and with ST segment depression at study entry, had the highest event rates and derived the greatest benefit from an invasive strategy.

The 2002 ACC/AHA unstable angina guideline update has summarized the data regarding early invasive versus early conservative strategies in patients with unstable angina or NSTEMI and issued an updated set of recommendations to guide clinical decision making in this setting [*see Table 3*].[52]

THROMBOLYTIC THERAPY

Thrombolytic therapy has been widely studied in prospective, randomized, controlled trials involving more than 50,000 patients and has been proved to reduce mortality 29% in patients with ST segment elevation treated within 6 hours after the onset of chest pain [*see Figure 6*].[53] The survival benefit of thrombolytic therapy is maintained for years.[54] The benefit of thrombolytic therapy is achieved through rapid restoration of blood flow in an occluded coronary artery.[55-57]

Thrombolytic therapy is strongly recommended for patients with ST segment elevation in two or more contiguous leads who have had less than 6 hours of chest pain; for patients with classic symptoms of infarction in whom a bundle branch block precludes detection of ST segment elevation[53]; and for patients presenting with 6 to 12 hours of chest pain, although the expected benefits for this last group of patients are fewer. The potential benefits should be weighed against the potential risks in patients with relative contraindications to thrombolytic therapy (see below).[17,58] It is important to calculate the duration of infarction as the time from the last pain-free interval. The infarct-related artery often opens and closes spontaneously during the early stages of infarction, which the patient may experience as alternating pain-free and painful intervals; the window of benefit from thrombolytic therapy may be greater than 12 hours if antegrade flow was even briefly restored.

Contraindications to Thrombolytic Therapy

Contraindications to thrombolytic therapy include all conditions that predispose a patient to significant bleeding. The most feared bleeding complication is intracerebral hemorrhage, which is fatal in over half of cases. Risk factors for intracerebral bleeding include advanced age, low body weight, hypertension, warfarin use, and previous stroke.[53,59] Patients with gastrointestinal bleeding and those who have recently undergone surgery are also at increased risk for bleeding. Even when risk factors for bleeding are present, however, the potential benefits of thrombolytic therapy may still outweigh the risks. For example, although the elderly have a higher risk of intracerebral bleeding than younger patients, elderly patients should certainly be considered candidates for thrombolytic therapy, because their increasing absolute mortality results in a greater reduction in absolute mortality with thrombolytic therapy than is seen in younger patients.[53]

In patients with ECG findings other than ST segment elevation or bundle branch block, thrombolytic therapy has been found to be either of no use or deleterious; its use is not recommended in such patients.[17,53]

Choice of Thrombolytic Agent

Many different thrombolytic regimens have been proved effective for the treatment of acute myocardial infarction, and many more are being studied. In principle, the preferred thrombolytic regimen would restore normal antegrade blood flow to an occluded coronary artery most rapidly and in the greatest number of patients, would have the lowest reocclusion rate, and would be associated with the lowest risk of severe hemorrhagic

complications. The first Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Arteries (GUSTO-I) trial evaluated four thrombolytic regimens to determine which was associated with the greatest overall survival and stroke-free survival at 30 days: (1) a regimen of front-loaded, weight-adjusted t-PA and I.V. heparin, (2) a regimen of streptokinase and I.V. heparin, (3) a regimen of streptokinase and subcutaneous heparin, and (4) a combination of I.V. t-PA and streptokinase given concurrently with I.V. heparin. Front-loaded t-PA was found to be moderately superior to the other thrombolytic regimens [*see Figure 7*].[56] However, because of the approximately 10 times greater cost of t-PA than I.V. streptokinase and the low margin of superiority of t-PA (one life saved per thousand patients treated), some physicians prefer the less expensive streptokinase therapy, particularly for patients at low risk of dying (such as those with uncomplicated inferior infarctions) and the elderly, who are more likely to have hemorrhagic complications with t-PA than with streptokinase; t-PA is associated with a greater frequency of intracerebral hemorrhage than streptokinase.[56] The recommendation of streptokinase in these patient groups is largely driven by its lower cost; if the costs of t-PA and streptokinase were similar, t-PA would most likely be the preferred therapy in all patient subgroups, with the possible exception of those at increased risk for intracerebral hemorrhage, in whom streptokinase might be preferred.

Streptokinase therapy is contraindicated in patients who have recently received a dose of streptokinase because of antibodies that form against the drug; these antibodies limit the efficacy of repeat doses and increase the risk of allergic reactions. It has been suggested that the drug not be readministered for at least 2 years.

New thrombolytic agents are continuously being developed in the hope of finding safer and more effective therapies. One such agent, reteplase, is a recombinant tissue plasminogen activator (rt-PA) that is a mutant of alteplase. Reteplase is easier to administer than alteplase; because of its longer half-life, it can be administered as two 10 mU boluses given 30 minutes apart, with concomitant aspirin and I.V. heparin administration. Several pilot studies suggest that reteplase has an early patency rate that is superior to the patency rates of streptokinase and alteplase. In the International Joint Efficacy Comparison of Thrombolytics (INJECT) trial, 6,010 patients with acute myocardial infarction received either reteplase or streptokinase within 12 hours after the onset of symptoms.[60] Mortality at 35 days, the primary end point of the study, was 9.02% for patients given reteplase, compared with 9.53% for patients given streptokinase, a nonsignificant difference (95% confidence interval, 1.98 to 0.96). This lack of significant difference indicates that reteplase was at least as effective as streptokinase.

In the GUSTO-III trial, reteplase was compared with t-PA in 15,059 patients with acute myocardial infarction who presented within 6 hours of symptom onset.[61] Patients received either reteplase or an accelerated infusion of t-PA. For patients receiving reteplase, the mortality at 30 days was 7.47%, compared with 7.24% for patients receiving t-PA ($P = 0.54$; odds ratio, 1.03; 95%

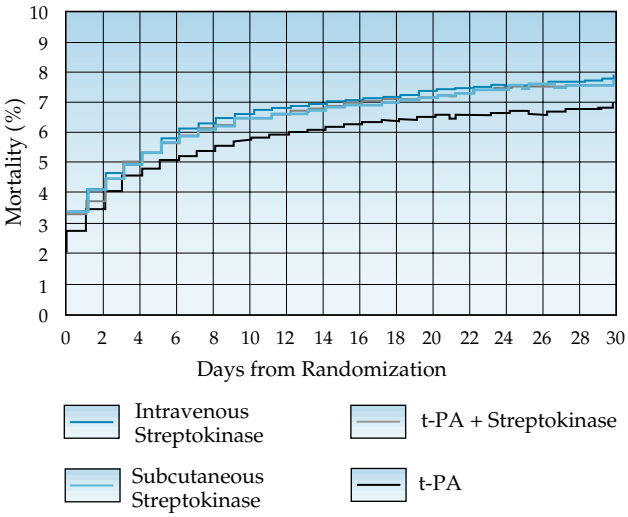

Figure 7 **The frequency of death or disabling stroke in the 30 days after enrollment in 41,021 patients in the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Arteries (GUSTO-I) trial. Front-loaded t-PA was found to be superior to the other thrombolytic regimens.[56]**

confidence interval, 0.91 to 1.18). The mortality rates with the two agents were therefore similar, and the two agents are probably, although not definitely, equivalent in efficacy.

Combination Therapy

Combination therapy, defined as the use of a thrombolytic agent and a glycoprotein IIb/IIIa inhibitor, has been proposed as an alternative to thrombolytic therapy alone for the primary treatment of STEMI. This strategy is supported by data from a number of trials that demonstrated improved rates of TIMI-3 flow after combination therapy, as compared with thrombolytic therapy alone.[62,63] However, the results of two randomized, controlled trials evaluating clinical outcomes after the respective aforementioned reperfusion strategies have been somewhat disappointing.

The GUSTO-V trial randomized 16,588 patients who presented within 6 hours after symptom onset with STEMI to either standard-dose reteplase or half-dose reteplase and full-dose abciximab.[64] At 30 days, the incidence of death in the reteplase arm was 5.9%, compared with 5.6% in the combination-therapy arm ($P = 0.43$), suggesting no mortality benefit associated with combination therapy. However, five of 16 prespecified secondary end points were reduced to a statistically significant degree ($P < 0.05$), suggesting a beneficial impact of combination therapy on the incidence of recurrent ischemic events and the mechanical and electrical complications of acute myocardial infarction (e.g., nonfatal reinfarction, recurrent ischemia, ventricular fibrillation, sustained ventricular tachycardia, and atrioventricular block). However, these clinical benefits were offset by an increased incidence of bleeding of any kind (13.7% with monotherapy versus 24.6% with combination therapy; $P < 0.0001$); severe or moderate, spontaneous, nonintracranial bleeding (1.9% versus 4.3%, $P < 0.0001$); severe bleeding (0.5% versus 1.1%; $P < 0.0001$), and bleeding sufficient to require blood transfusion (4.0% versus 5.7%; $P < 0.0001$). Furthermore, there were subgroups of patients in whom intracranial bleeding was increased by combination therapy; there was a significant ($P = 0.033$) association between age (< 75 or ≥ 75 years) and intracranial hemorrhage in the combination-therapy arm.

The Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT)–3 trial randomized 6,095 patients to one of three treatment regimens: full-dose tenecteplase and enoxaparin, half-dose tenecteplase and weight-adjusted low-dose unfractionated heparin infusion plus 12-hour infusion of abciximab, or full-dose tenecteplase and weight-adjusted unfractionated heparin infusion for 48 hours.[65] In-hospital mortality was not significantly different between the three groups. The abciximab treatment regimen reduced in-hospital rates of reinfarction and refractory ischemia. Although rates of intracranial hemorrhage were similar, other types of major bleeding were significantly higher in the abciximab arm of the trial. The enoxaparin arm suggested that there is a higher rate of intracranial bleeding in the elderly; this finding was corroborated by the ASSENT-PLUS study, which necessitated a change in dose of enoxaparin when administered with a thrombolytic agent in elderly patients.[66]

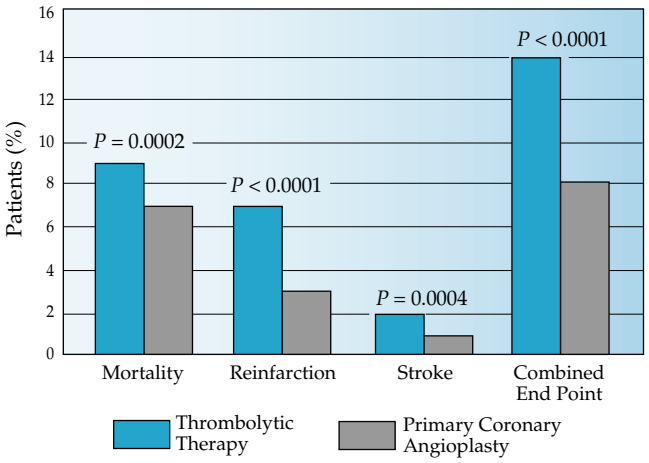

Figure 9 **Results from a quantitative review of 23 randomized trials of primary angioplasty versus intravenous thrombolytic therapy for acute myocardial infarction.[72] Clinical outcome was improved in patients who received angioplasty.**

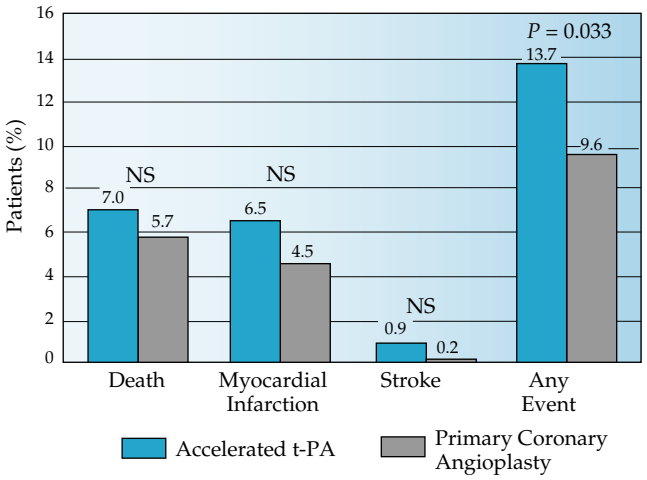

Figure 10 **Results from the GUSTO-IIb substudy trial comparing primary coronary angioplasty and accelerated t-PA indicate that primary angioplasty was associated with a lower mortality, reinfarction rate, and frequency of stroke in the 30 days after enrollment than was accelerated t-PA.[73] (NS—not significant)**

PRIMARY CORONARY ANGIOPLASTY

Coronary angioplasty without antecedent thrombolytic therapy, termed primary or direct coronary angioplasty, has been studied in the treatment of acute myocardial infarction [*see Figure 8*]. In prospective, randomized trials comparing primary coronary angioplasty with different thrombolytic agents, primary coronary angioplasty was associated with a lower morbidity and mortality than thrombolytic therapy.[67-71] Although most of the individual trials were too small to detect statistically significant differences in mortality, pooled data from these trials suggest that primary coronary angioplasty is the preferred therapy for acute myocardial infarction at institutions where it can be performed without delay [*see Figure 9*].[72]

The GUSTO-IIb trial was designed to be large enough to confirm the reduction in mortality found in the smaller randomized trials.[73] The results of the study indicate that compared with thrombolytic therapy, primary coronary angioplasty is associated with a lower mortality, reinfarction rate, and frequency of stroke in the 30 days after enrollment [*see Figure 10*]. However, the degree of benefit associated with primary coronary angioplasty was much smaller than that seen in the earlier randomized studies; this finding was in part related to the lower frequency with which patients assigned to undergo angioplasty in GUSTO-IIb actually underwent the procedure and in part relat-

ed to the lower frequency with which normal antegrade coronary blood flow was achieved in patients who did undergo coronary angioplasty.

The consistency of the results favoring primary coronary angioplasty and the greater speed and frequency with which coronary angioplasty can restore flow to an occluded coronary artery support the conclusion that primary coronary angioplasty is preferable to thrombolytic therapy at institutions where it can be performed quickly with a high success rate.[74] Studies have shown that excessive delay in performing primary coronary angioplasty and operator inexperience lead to a higher mortality than that seen when primary coronary angioplasty is performed rapidly by experienced operators.[36] It has been recommended that primary angioplasty be performed only in hospitals where a high success rate and low complication rate can be demonstrated and where primary angioplasty is performed in at least 80% to 90% of patients in whom acute myocardial infarction is confirmed.[72,75] The need for surgical backup is controversial, as excellent results have been obtained at centers without surgical backup.[76] However, surgical backup is recommended because approximately 5% of patients with acute myocardial infarction who undergo immediate coronary angiography require emergency surgery either for angioplasty that has failed or, more commonly, because lethal coronary anatomy precludes primary angioplasty.

Immediate transfer for primary angioplasty is an alternative treatment strategy for patients with STEMI initially assessed at a hospital without on-site cardiac surgery facilities. The DANAMI-2 investigators randomized STEMI patients to thrombolysis or primary angioplasty.[42] This included a prespecified substudy of patients admitted to a hospital without primary angioplasty facilities; these patients were randomized to immediate thrombolytic therapy or ambulance transfer for primary angioplasty (providing this procedure could be performed within 3 hours of randomization). Among patients who were randomized to hospitals without primary angioplasty facilities, the primary end point of death, myocardial infarction, or disabling stroke at 30 days was reached in 8.5% of the patients in the primary angioplasty group, as compared with 14.2% of those in the fibrinolysis group ($N = 1,129$; $P = 0.002$). Similarly, the PRAGUE-2 investigators concluded that long-distance transport from a community hospital to a facility with angioplasty facilities in the acute phase of STEMI is safe and is associated with decreased mortality in patients who present more than 3 hours after symptom onset.[41]

Glycoprotein IIb/IIIa Inhibitor Therapy and Primary Angioplasty for Acute Myocardial Infarction

The role of the platelet glycoprotein inhibitor abciximab in conjunction with primary coronary angioplasty has been examined in the Randomized, Placebo-Controlled Trial of Abciximab with Primary Angioplasty for Acute Myocardial Infarction (RAPPORT), the Intracoronary Stenting and Antithrombotic Regimen–2 (ISAR-2) study, the Abciximab before Direct Angioplasty and Stenting in Myocardial Infarction Regarding Acute and Long-term Follow-up (ADMIRAL) study, and, most recently, the Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications (CADILLAC) study.[77-80] The results of the four studies differ, in part because the trials used different end points, in part because of the high frequency of noncompliance with the protocol in some trials, and in part because of differences in the treatments utilized (balloon angioplasty alone versus balloon angioplasty followed by stent placement).

The largest of the four studies, the CADILLAC study, found that abciximab is beneficial at reducing major adverse events, but the benefit appeared to be limited to patients undergoing balloon angioplasty without stent placement. The apparent lack of benefit following treatment with abciximab in patients in the CADILLAC trial who received a coronary stent is contrary to the results of the ISAR-2 and ADMIRAL trials, in which abciximab was found to be beneficial in patients receiving stents. There are data suggesting that stent placement in the setting of acute myocardial infarction slightly reduces the frequency with which normal antegrade blood flow in the infarct-related artery is achieved.[81] This would suggest that glycoprotein IIb/IIIa inhibitors should be beneficial in this setting. Taken together, the results of these studies that are currently available suggest that abciximab is beneficial in patients with acute myocardial infarction but that the benefit in patients undergoing balloon angioplasty alone may differ from that in patients who undergo balloon angioplasty with stent placement. Clearly, however, stents markedly reduce the frequency with which a repeat revascularization procedure is needed in the months after the angioplasty procedure.[81] The combined use of stents and platelet glycoprotein inhibitors may maximize the frequency with which normal antegrade blood flow is achieved while reducing the need for repeat procedures in the following year.

One study compared the outcome of thrombolytic therapy using t-PA with that of primary angioplasty utilizing both stents and abciximab.[82] The reduction in infarct size was far greater in the group undergoing primary angioplasty; the clinical outcome was also better in the patients who underwent angioplasty.

CORONARY ARTERY BYPASS SURGERY

Coronary artery bypass surgery can restore blood flow in an occluded infarct-related artery. However, because of the time required to perform coronary angiography and to transport patients to the operating room, reperfusion is achieved more slowly with bypass surgery than with thrombolytic therapy and primary coronary angioplasty.[83] Emergency coronary artery bypass surgery should generally be reserved for patients in whom immediate angiography reveals coronary anatomy that precludes primary coronary angioplasty; for patients in whom angioplasty has failed; and for patients with a ventricular septal defect, severe mitral regurgitation, or myocardial rupture.

RESCUE CORONARY ANGIOPLASTY

Depending on the regimen used, only 33% to 60% of patients treated with thrombolytic therapy have restoration of normal antegrade flow in the infarct-related artery 90 minutes after the initiation of therapy.[55] Accordingly, immediate coronary angiography has been studied to determine whether patients with persistent occlusion of the infarct-related artery benefit from coronary angioplasty; this procedure has been termed rescue angioplasty. A single small, randomized trial has examined the clinical outcome of patients with anterior infarction and coronary occlusion that persist despite thrombolytic therapy.[84] Patients were randomized to either undergo rescue coronary angioplasty or receive continued medical therapy alone. The results of the trial suggested improved outcome with rescue angioplasty, although the benefits were not compelling. Three additional randomized trials evaluated the role of rescue angioplasty.[85-87] Analyzed together, the four trials suggest that rescue angioplasty offers benefit, although the data are not compelling. Although use of coronary stents and platelet glycoprotein inhibitors improves the results of percutaneous revascularization

procedures and would be expected to further increase the benefit of angioplasty after failed thrombolytic therapy, this has not yet been proved. There are insufficient data to recommend immediate angiography and angioplasty in all patients early after thrombolytic therapy. Immediate angiography is most likely to be beneficial in patients with large myocardial infarctions in whom persistent pain, ST segment elevation, or hemodynamic compromise is present more than 90 minutes after the administration of a thrombolytic agent.

The routine performance of angioplasty immediately after the administration of thrombolytic therapy in all patients with a significant residual stenosis (not just those patients with occluded coronary arteries) has been well studied in three prospective, randomized trials and has been found to be either of no benefit or deleterious.[43,88] Angioplasty should not be routinely performed in such patients.

Stents appear to improve the ability to achieve arterial patency early after thrombolytic therapy, as compared with balloon angioplasty alone[89]; therapy with a glycoprotein IIb/IIIa inhibitor may also do so, although an increase in bleeding has been seen when glycoprotein IIb/IIIa inhibitors are used early after full-dose thrombolytic therapy.[90] Data from several pilot studies suggest that the combination of a fibrin-specific thrombolytic agent, either t-PA or reteplase, combined with the glycoprotein IIb/IIIa inhibitor abciximab, may actually facilitate the performance of angioplasty rather than reduce its safety and efficacy, as was seen when balloon angioplasty was performed after thrombolytic therapy.[62,63] Hence, the term facilitated angioplasty has been coined for the routine performance of angioplasty after the combination of half-dose thrombolytic therapy with a glycoprotein IIb/IIIa inhibitor.

The Plasminogen-activator Angioplasty Compatibility Trial (PACT) investigators randomized 606 patients to a reduced dose of a short-acting fibrinolytic regimen (50 mg bolus of reteplase) or a placebo followed by immediate angiography with angioplasty, if needed.[91] In the group receiving reduced-dose reteplase, there was no increase in the incidence of stroke or major bleeding, and convalescent left-ventricular ejection fraction was higher, as evidenced by a patent infarct–related artery (TIMI-3 flow) on arrival in the catheterization laboratory (62%) or a TIMI-3 flow that was achieved by angioplasty within 1 hour after administration of the drug bolus (58%). However, only 12% of successful angioplasty procedures resulted in a patent infarct–related artery within 1 hour, because of routine delay in transfer to the catheterization laboratory, and there was no difference between the two treatment groups by a traditional intention-to-treat analysis.

The Southwest German Study in Acute Myocardial Infarction III (SIAM III) investigators randomized 163 patients initially treated with thrombolysis at a community hospital with no on-site PCI facilities either to hospital transfer and immediate stenting within 6 hours of thrombolysis or to delayed, elective stenting approximately 2 weeks after acute myocardial infarction.[92] Transfer and immediate stenting were associated with a statistically significant reduction in the incidence of the composite primary end point (i.e., death, reinfarction, ischemic events, and target-lesion revascularization at 6 months), as compared with delayed stenting (25.6% versus 50.6%; $P = 0.001$). The difference in outcome was driven by events occurring during the 2 weeks that patients waited for elective stenting in the deferred PCI group. This trial design does not address whether PCI performed 1 to 2 days after thrombolytic therapy, as is usual in the United States, is as effective as PCI performed immediately after thrombolytic therapy. A randomized trial that analyzed the use of combination therapy (half-dose thrombolytic therapy with full-dose abciximab) before routinely performing primary PCI was recently reported.[93] In the Bavarian Reperfusion Alternatives Evaluation (BRAVE) Trial, patients with STEMI were randomly assigned to receive either half-dose reteplase and full-dose abciximab or abciximab alone, and all patients underwent PCI as rapidly as possible. No advantage was seen with combination therapy; in fact, more bleeding complications occurred in this group. The results argue against the use of a facilitated PCI approach using the combination regimen of reteplase and abciximab.

Adjunctive Medical Therapy

INTRAVENOUS HEPARIN

The need for I.V. heparin after thrombolytic therapy varies with the thrombolytic agents used. A retrospective analysis of the GUSTO-I trial suggested that I.V. heparin with a partial thromboplastin time of 50 to 70 seconds was associated with the best clinical outcome in patients treated with t-PA.[94] Data from GUSTO-I also suggest that I.V. heparin is not required when I.V. streptokinase is used, although heparin is recommended in patients with large anterior infarctions to prevent the development of apical mural thrombus and embolization.[56] In patients in whom I.V. heparin is not administered, subcutaneous heparin should be administered during the period of bed rest to reduce the risk of deep vein thrombosis.[95]

The optimal duration of I.V. heparin therapy is unclear. Standard practice was to administer I.V. heparin for 3 to 5 days, although patients are now often discharged after only 3 days. It is recommended that heparin be discontinued more than 24 hours before patient discharge from the hospital because of the possibility of a rebound effect and recurrent thrombosis within 24 hours after cessation of heparin therapy.[96]

Randomized studies from the prethrombolytic era suggested that administration of I.V. heparin reduces mortality and reinfarction in patients not treated with thrombolytic agents.[95] Aspirin and beta blockers were not routinely administered in those early trials; consequently, the true benefits of heparin when these drugs are administered are unknown. However, on the basis of the early data, I.V. heparin is generally recommended for patients with suspected myocardial infarction who are not treated with thrombolytic therapy.[75]

LOW-MOLECULAR-WEIGHT HEPARIN

Low-molecular-weight heparins (depolymerized unfractionated heparin with a mean molecular weight of approximately 5,000) have a number of potential pharmacokinetic advantages over the parent molecule, including decreased binding to plasma proteins, decreased sensitivity to platelet factor 4, enhanced factor Xa activity, and improved bioavailability. These factors are associated with a predictable dose-response relationship and, combined with the ease of administration (once or twice daily S.C. dosing regimens) and lower rates of heparin-induced thrombocytopenia, have increased investigators' interest in low-molecular-weight heparins in preference to unfractionated heparin for the treatment of myocardial infarction. The results of four large randomized trials comparing three different low-molecular-weight heparins with unfractionated heparin have suggested that low-molecular-weight heparin is at least as effective

in reducing ischemic events in patients with NSTEMI acute coronary syndromes. Following patients with STEMI, the second trial of Heparin and Aspirin Reperfusion Therapy (HART II) and the Acute Myocardial Infarction–Streptokinase (AMI-SK) trial demonstrated evidence of improved rates of reperfusion when the low-molecular-weight heparin enoxaparin was combined with t-PA or streptokinase, respectively.[97,98] The ASSENT-3 trial compared three regimens: full-dose tenecteplase and enoxaparin, full-dose tenecteplase and unfractionated heparin, and half-dose tenecteplase and abciximab for the treatment of thrombolytic-eligible STEMI; the study revealed that enoxaparin fared better than unfractionated heparin in terms of 30-day mortality, in-hospital reinfarction, and in-hospital refractory ischemia (P = 0.0001) at 30 days.[99] However, at 1 year, the benefits had diminished, and the mortality with enoxaparin was identical to that with unfractionated heparin. In addition, when the data from ASSENT-3 and ASSENT-3–PLUS (a study examining the administration of tenecteplase with enoxaparin in the prehospital setting) were pooled, a marked and prohibitive increase in the risk of intracerebral hemorrhage was seen in the elderly.[66,99] As a result, ongoing trials utilizing enoxaparin with a fibrinolytic agent have adjusted the dose of enoxaparin downward in elderly patients. At present, the adjunctive anticoagulant that should be administered with fibrinolytic therapy and its optimal dose are not known.

DIRECT THROMBIN INHIBITORS

Direct thrombin inhibitors are an attractive alternative to indirect thrombin inhibitors, such as heparin or low-molecular-weight heparins, particularly because they block both circulating and clot-bound thrombin. A collaborative meta-analysis of phase-3 trials of direct thrombin inhibitors for the treatment of acute coronary artery syndromes demonstrated superiority over unfractionated heparin for the prevention of the composite end point of death or myocardial infarction.[100] The Hirulog and Early Reperfusion or Occlusion (HERO)–2 trial demonstrated a similar benefit in a comparison of bivalirudin with heparin in patients with STEMI.[101] Bivalirudin was associated with a 30% reduction in the incidence of reinfarction, but mortality did not decrease; however, the bivalirudin arm of the study exhibited a trend toward more bleeding events.

BETA BLOCKERS

Numerous studies of beta-blocker therapy in patients with acute myocardial infarction have documented significant reductions in in-hospital and long-term mortality. Early administration of beta blockers has been promoted because it may reduce infarct size by reducing heart rate, blood pressure, and myocardial contractility, all of which diminish myocardial oxygen demand. Meta-analysis of the effects of early administration of I.V. beta blockers in 27,486 patients with acute myocardial infarction enrolled in 28 randomized trials revealed a 14% reduction in mortality during the first week of therapy; reinfarction was reduced by 18%.[102]

The TIMI-II study compared immediate beta-blocker therapy with deferred beta-blocker therapy in acute myocardial infarction; all patients also received I.V. t-PA.[103] Results indicated that immediate beta-blocker therapy reduced the incidence of nonfatal reinfarction and recurrent ischemia, compared with oral metoprolol therapy begun on the sixth hospital day; as in earlier studies, only about 40% of patients with acute myocardial infarction were eligible for acute beta-blocker therapy.[43] There are also data suggesting that immediate beta-blocker therapy reduces the risk of intracranial hemorrhage after lytic therapy.[104] It is recommended that all patients with acute myocardial infarction without contraindications receive I.V. beta blockers as early as possible, whether or not they receive reperfusion therapy.

In patients in whom contraindications preclude early beta-blocker therapy, reevaluation should take place before discharge. Many patients will no longer have contraindications at the time of discharge. Patients without contraindications should be routinely started on beta-blocker therapy before discharge from the hospital. The optimal duration of benefit remains unclear, but it appears that the benefit of beta-blocker therapy is maintained for years. Patients with the largest infarctions benefit the most from the use of beta blockers. Current recommendations are that beta-blocker therapy be continued indefinitely in the absence of contraindications or side effects.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Several large randomized, controlled clinical trials evaluating the use of angiotensin-converting enzyme (ACE) inhibitors early after acute myocardial infarction have been performed; all but one trial revealed a significant reduction in mortality. Meta-analysis of these large trials and many smaller trials, which together included over 100,000 patients, suggested a 6.5% reduction in deaths, with an absolute reduction in mortality of 4.6 deaths per 1,000 patients among those treated with an ACE inhibitor.[105] All patients with significant ventricular dysfunction (an ejection fraction < 40%) without contraindications should be treated with an ACE inhibitor; treatment should begin within the first 48 hours of infarction and be increased cautiously to avoid hypotension. If hypotension results from the early administration of ACE inhibitors, short-term mortality may be increased.[106]

The benefit of ACE inhibitors is clear in patients with large anterior infarctions and an ejection fraction less than 40%; whether patients with an ejection fraction greater than 40% benefit from ACE inhibitor therapy is less clear. However, the results of two large trials suggest that patients with a normal ejection fraction after myocardial infarction, as well as even patients with coronary artery disease without a previous myocardial infarction, have a reduction in mortality when treated with an ACE inhibitor. In the Heart Outcomes Prevention Evaluation (HOPE) study, 9,297 patients 55 years of age or older with vascular disease (or with diabetes and another cardiovascular risk factor) without a low ejection fraction or congestive heart failure were randomly assigned to receive either the ACE inhibitor ramipril or placebo for a mean of 5 years.[107] The reduction in the combined end point of death from cardiovascular causes, myocardial infarction, or stroke with ramipril was remarkable; it occurred in 17.7% of placebo-treated patients versus 14.1% of patients receiving ramipril (relative risk, 0.78; 95% confidence interval, 0.70 to 0.86; $P < 0.001$). A statistically significant reduction was also present in the individual end points of cardiovascular death, myocardial infarction, and stroke. The study was stopped prematurely by the Data Safety Monitoring Board when clear evidence of a beneficial effect of ramipril was found. These findings are supported by the results of the European Trial on Reduction of Cardiac Events with Perindopril in Patients with Stable Coronary Artery Disease (EUROPA) trial, which randomized 12,218 patients with stable coronary artery disease and no evidence of congestive heart failure to 8 mg of perindopril or conventional therapy.[108] Treatment with perindopril was associated with a highly statistically significant reduction in the

incidence of fatal and nonfatal myocardial infarction at 4 years. Whether these favorable results are unique to tissue-specific ACE inhibitors or represent a class effect is unknown.

INTRAVENOUS NITROGLYCERIN

Randomized studies examining the role of I.V. nitroglycerin in acute myocardial infarction revealed beneficial effects on left ventricular function and a reduction in infarct size and mortality.[109] However, these studies were small and were performed before the reperfusion era. To determine whether nitroglycerin therapy is beneficial in patients treated with reperfusion, 58,050 patients with acute myocardial infarction in the fourth International Study of Infarct Survival (ISIS-4) were randomized to receive either oral controlled-release mononitrate therapy or placebo; thrombolytic therapy was administered to patients in both groups.[105] The results of this study revealed no benefit to the routine administration of oral nitrate therapy in this setting. Similar results were seen among 19,000 patients in the third Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI-3) study, in whom I.V. nitroglycerin was administered for the first 24 hours, followed by transdermal nitrates.[110] Whether these disappointing results in the ISIS-4 and GISSI-3 trials were caused by the routes of administration of the nitroglycerin preparation or the administration of thrombolytic therapy is unknown. However, on the basis of existing data, it does not appear that the routine administration of nitroglycerin to patients receiving early thrombolytic therapy is beneficial. I.V. nitroglycerin is probably most likely to be beneficial in patients with persistent or recurrent chest pain after reperfusion therapy and in patients in whom reperfusion therapy is not administered.

PROPHYLACTIC ANTIARRHYTHMIC THERAPY

Previously, routine prophylactic antiarrhythmic therapy with I.V. lidocaine was recommended for all patients in the early stages of acute myocardial infarction. However, studies have revealed that prophylactic therapy with lidocaine does not reduce and may actually increase mortality because of an increase in the occurrence of fatal bradyarrhythmia and asystole.[111] Neither I.V. lidocaine nor other antiarrhythmic agents are recommended as prophylactic therapy for patients without malignant ventricular ectopy.[111,112]

CALCIUM CHANNEL ANTAGONISTS

Calcium channel antagonists should not be routinely administered for acute myocardial infarction. Calcium channel antagonists have been studied in prospective, double-blind, placebo-controlled trials; and neither verapamil,[113,114] nifedipine,[115,116] nor diltiazem[117] appears to reduce postinfarction mortality. Verapamil and diltiazem may be useful in patients with preserved left ventricular function and no heart failure in whom contraindications to beta blockers exist.[118,119] However, the data are insufficient to recommend the routine administration of these agents. On the basis of existing data, treatment with calcium channel blockers should be reserved for patients with ischemia that persists despite use of aspirin, beta blockers, nitrate therapy, and I.V. heparin and for patients with other indications for their administration.

MAGNESIUM

Magnesium has been studied in many prospective, randomized trials of acute myocardial infarction, and the results have been conflicting. Magnesium is involved in hundreds of enzymatic steps and produces systemic and coronary vasodilatation, inhibits platelet function, and reduces reperfusion injury. Meta-analysis of seven prospective, randomized trials revealed a significant reduction in mortality with the use of magnesium (odds ratio, 0.44; confidence interval, 0.27 to 0.71).[120] Subsequently, the second Leicester Intravenous Magnesium Intervention Trial (LIMIT-2) revealed a 25% reduction in mortality with the use of magnesium in over 2,000 patients who had acute myocardial infarction.[121] However, in ISIS-4, in which 58,050 patients were randomized to receive either I.V. magnesium or no magnesium, there was no reduction in 30-day mortality.[105] It is possible that the later administration of magnesium in this study, compared with the previous studies, and the concomitant use of thrombolytic therapy in 70% of patients contributed to the lack of efficacy of magnesium in ISIS-4; only one third of patients in the LIMIT-2 study received thrombolytic therapy. A subsequent small randomized trial reexamined the role of magnesium in patients in whom reperfusion therapy was not administered and did find a mortality reduction associated with its use.[122] However, the Magnesium in Coronaries (MAGIC) trial investigators, who randomized 6,213 patients with STEMI to a 2 g intravenous bolus of magnesium followed by a 17 g infusion over 24 hours or matching bolus and 24-hour placebo infusions failed to demonstrate any statistically or clinically significant effect on 30-day mortality.[123] Therefore, on the basis of the existing evidence, current recommendations are that magnesium not be routinely given to patients in whom reperfusion therapy is administered. It is possible that magnesium is of benefit, particularly in patients not receiving reperfusion therapy. Magnesium is clearly indicated in patients with myocardial infarction who have torsade de pointes–type ventricular tachycardia and in patients with magnesium deficiency.

Complications of Acute Myocardial Infarction

VENTRICULAR ARRHYTHMIAS

Ventricular arrhythmias are a frequent cause of death in the earliest stages of acute myocardial infarction. The development of coronary care units, continuous ECG surveillance, and defibrillators in the 1960s led to a reduction in mortality from acute myocardial infarction through the prompt identification and treatment of ventricular arrhythmia; and emergency medical technicians have reduced outpatient mortality in the earliest minutes of myocardial infarction. In cities with well-developed emergency response systems, such as Seattle, Washington, and Rochester, Minnesota, where the average response time is less than 5 minutes, survival of patients with myocardial infarction complicated by cardiac arrest has increased.[4] In fact, long-term survival of patients who have undergone rapid defibrillation after out-of-hospital cardiac arrest is similar to that of age-, sex-, and disease-matched patients who did not have out-of-hospital cardiac arrest; the quality of life of the majority of survivors is similar to that of the general population.[124]

Ventricular Fibrillation

In the setting of acute myocardial infarction, ventricular fibrillation is often described as either primary, when it occurs in the absence of hypotension or heart failure, or secondary, when hypotension or heart failure is present. Primary ventricular fibrillation occurs in approximately 3% to 5% of patients with acute myocardial infarction; the peak incidence is in the first 4 hours of infarction. Primary ventricular fibrillation is infrequent more

than 24 hours after symptom onset. Mortality is increased in patients who suffer this complication.[125,126] In patients who are successfully resuscitated and survive to hospital discharge, however, the long-term prognosis does not appear to be affected.[125] Although lidocaine was shown to reduce the occurrence of primary ventricular fibrillation, mortality in patients receiving lidocaine increased because of an increase in fatal bradycardia and asystole; therefore, prophylactic lidocaine is no longer recommended if defibrillation can rapidly be performed.[111] Beta blockers may reduce the early occurrence of ventricular fibrillation and should be administered to patients who have no contraindications.

Hypokalemia is a risk factor for primary ventricular fibrillation and should be rapidly corrected if present. When ventricular fibrillation occurs, rapid defibrillation with 200 to 300 joules should be attempted, and repeated shocks of 360 joules should be administered. The Advanced Cardiac Life Support (ACLS) guidelines recommend medical therapy, including epinephrine, lidocaine, and bretylium; in addition, I.V. amiodarone should be considered in patients in whom defibrillation is initially unsuccessful.

Secondary ventricular fibrillation is associated with a high mortality, in part because of the underlying hypotension and heart failure. Treatment must be aimed not only at terminating the arrhythmia but also at treating the hemodynamic abnormalities and their causes.

Ventricular Tachycardia

Ventricular tachycardia (three or more consecutive ventricular ectopic beats) is common in patients with acute myocardial infarction; however, short runs of nonsustained ventricular tachycardia are no longer believed to predispose a patient to sustained ventricular tachycardia or ventricular fibrillation. In patients in whom sustained or hemodynamically significant ventricular tachycardia occurs, prompt electrical cardioversion should be performed. If the ventricular tachycardia is monomorphic, synchronic cardioversion with 100 joules should first be attempted. As with ventricular fibrillation, polymorphic ventricular tachycardia should be treated with unsynchronized discharge. Prolonged runs of asymptomatic ventricular tachycardia can be initially treated with I.V. lidocaine, procainamide, or amiodarone. These medications may also be helpful in reducing recurrent ventricular tachycardia.

ATRIAL ARRHYTHMIA

Atrial Fibrillation

Atrial fibrillation is the most common atrial arrhythmia in acute myocardial infarction, occurring in 10% to 16% of patients. Atrial fibrillation may result either from an acute increase in left atrial pressure caused by left ventricular dysfunction or from atrial ischemia as a result of occlusion of a coronary artery (usually the right coronary artery) proximal to the origin of atrial branches. The incidence of atrial fibrillation is decreased in patients given thrombolytic therapy.[56]

The treatment of atrial fibrillation in acute myocardial infarction should be similar to the treatment of atrial fibrillation in other settings. When there is hemodynamic compromise caused by loss of atrial systole or a rapid ventricular response with a reduction in cardiac output, cardioversion should be performed immediately. In patients with preserved left ventricular function in whom the atrial fibrillation is well tolerated, beta-blocker therapy is indicated. Verapamil and diltiazem may also be effective in such patients. In patients with congestive heart failure, digoxin is a reasonable alternative and may slow the ventricular response. If atrial fibrillation recurs, antiarrhythmic agents may be used, although their impact on clinical outcomes is unproved. The Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) investigators randomized 4,060 patients to either rhythm-control or rate-control treatment strategies.[127] The rhythm-control strategy achieved no survival advantage over the rate-control strategy and there were both fewer hospital admissions and fewer adverse drug reactions in the rate-control group.

BRADYARRHYTHMIAS AND HEART BLOCK

Sinus bradycardia is common in acute myocardial infarction, particularly in patients with inferior myocardial infarction. However, treatment with atropine and a temporary pacemaker is required infrequently and, generally, only in patients with significant hemodynamic compromise manifested by increased angina, hypotension, or congestive heart failure.

High-degree (second- or third-degree) heart block occurs in approximately 20% of patients with inferior infarction; it is uncommon with infarction at other sites.[128] About half of the cases of heart block seen with inferior infarction are Wenckebach-type second-degree heart block; the remainder are cases of third-degree heart block. The heart block is often easily treated with atropine, but a temporary pacemaker is required in as many as 50% of cases. The heart block generally lasts for hours to days; placement of a permanent pacemaker is needed in fewer than 1% of cases. However, the development of heart block with inferior infarction is associated with a threefold to fourfold increase in in-hospital mortality over inferior infarction without heart block.[128,129] The increased mortality appears to result from the association between heart block and more severe left and right ventricular infarction rather than from the heart block itself or treatment of the heart block.

Heart block during anterior infarction is uncommon, occurring in fewer than 1% of cases. It is generally associated with extensive left ventricular myocardial infarction involving the conduction system below the atrioventricular node and carries a very poor prognosis.

MITRAL REGURGITATION

Mitral regurgitation may result from injury to any of the components of the mitral valve apparatus, including the papillary muscles and ventricular walls to which they attach. Mild mitral regurgitation is common in acute myocardial infarction and is present in nearly 50% of patients. Severe mitral regurgitation caused by acute myocardial infarction is rare and generally results from partial or complete rupture of a papillary muscle. The characteristic murmur of severe chronic mitral regurgitation may not be present with acute rupture of a papillary muscle. Instead, a decrescendo systolic murmur is often present, extending less throughout systole as systemic arterial pressure falls and left arterial pressure rises. In many cases, the significance of the murmur is not recognized. The blood supply of the anterior papillary muscle arises from branches of both the left anterior descending and the circumflex arteries; therefore, rupture of the anterior papillary muscle is rare. However, the posterior papillary muscle receives blood only from the dominant coronary artery (the right coronary artery in nearly 90% of patients); thrombotic occlusion of this artery may cause rupture of the posterior papillary muscle, resulting in severe mitral regurgitation. Severe mitral regurgitation is 10 times more likely to occur with inferior in-

farction than with anterior infarction. Acute severe mitral regurgitation is poorly tolerated and generally results in pulmonary edema, often with cardiogenic shock. Prompt surgical repair is recommended. Although the mortality associated with mitral valve surgery is high in this setting, approaching 50%, survival appears to be greater than with medical therapy alone. Therapy aimed at reducing left ventricular afterload, such as use of I.V. nitroprusside and an intra-aortic balloon pump, reduces the regurgitant volume and increases forward blood flow and cardiac output and may be helpful as a temporizing measure.

VENTRICULAR SEPTAL DEFECTS

Ventricular septal defects are slightly more frequent in patients with anterior infarction than in patients with inferior infarction. The characteristic holosystolic murmur of ventricular septal defects may be difficult to distinguish from that of severe mitral regurgitation; however, ventricular septal defects are generally better tolerated and less frequently result in severe congestive heart failure. Surgical repair is recommended and results in the best outcome when repaired emergently in the hemodynamically compromised patient. As with acute severe mitral regurgitation, therapy aimed at reducing afterload, including I.V. nitroprusside and an intra-aortic balloon pump, may be beneficial. Repair of the septum is generally more difficult when associated with inferior infarction, because there may not be a viable rim of myocardial tissue beneath the defect to facilitate repair. The surgical mortality associated with repair of a postinfarction ventricular septal defect is approximately 20% but is largely related to the age of the patient, whether cardiogenic shock is present, the infarction site, and the severity of the underlying coronary artery disease.

MYOCARDIAL RUPTURE

As more and more patients survive the acute phase of myocardial infarction because reperfusion therapy reduces myocardial infarct size, myocardial rupture has increased in frequency as a cause of early death. Myocardial rupture has been reported to account for more than 20% of in-hospital deaths in some series in the thrombolytic era. Physicians must have a heightened awareness of the diagnosis if a patient is to survive this catastrophic occurrence, because emergency surgery is required. Symptoms suggestive of rupture include repetitive vomiting, pleuritic chest pain, restlessness, and agitation. ECG evidence of rupture includes a deviation from the normal pattern of ST segment and T wave evolution. Resolution of ST segment elevation and T wave inversion, with maximal T wave negativity in the leads with maximal ST segment elevation, should normally occur; however, in patients with rupture, there is progressive or recurrent ST segment elevation and persistently positive T wave deflections or reversal of initially inverted T waves.[130] Echocardiography can quickly confirm the diagnosis. Even when emergency surgery is performed, fewer than 50% of patients survive to discharge.

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction occurs in approximately one third of patients with acute inferior left ventricular infarction and is hemodynamically significant in approximately 50% of affected patients.[131] Hemodynamically significant right ventricular infarction associated with anterior infarction or isolated right ventricular infarction is rare. The classic findings associated with hemodynamically significant right ventricular infarction are hypotension with clear lung fields and an elevated jugular venous pressure, often with the Kussmaul sign. Although nearly all patients with right ventricular infarction suffer both right and left ventricular infarction, the characteristic hemodynamic findings of right ventricular infarction generally dominate the clinical course and must be the main focus of therapy. Right ventricular involvement during inferior myocardial infarction is associated with a significant increase in mortality, and aggressive attempts at early reperfusion should be pursued.[128,131] Prompt recognition of right ventricular involvement is clinically important because therapy that reduces right ventricular filling, such as use of nitrates or diuretics, should be avoided. Volume therapy should be administered to maintain cardiac output; in patients whose hypotension is refractory to volume therapy, dopamine may be beneficial. Heart block, which occurs in as many as 50% of patients with right ventricular infarction, should be treated rapidly, and maintenance of atrioventricular synchrony with dual atrial and ventricular pacing is often required to maintain filling of the ischemic noncompliant right ventricle and an adequate cardiac output.

Cardiogenic shock resulting from right ventricular infarction is generally reversible with these measures. Improvement in right ventricular function generally occurs over time, particularly in patients in whom reperfusion therapy was successful in achieving vessel patency.[125] In patients who survive the initial hospitalization, left ventricular function is the most potent predictor of long-term outcome.

STROKE

Extensive infarction of the anterior wall and apex of the left ventricle leads to thrombus formation in the apex of the left ventricle in approximately 30% of patients; systemic embolization occurs in about 15% of these patients. Left ventricular thrombus formation is much less common after inferior infarction. The thrombus generally appears within the first several days after infarction; it is more likely to embolize and cause stroke if it is pedunculated, protrudes into the left ventricular cavity, or is mobile. Left ventricular thrombus is an indication for anticoagulation with I.V. heparin, followed by warfarin therapy for 3 to 6 months.

Therapy that reduces infarct size, such as thrombolytic therapy, reduces the frequency of thrombus formation and therefore the risk of systemic embolization and stroke. However, in 0.3% to 1.0% of patients, thrombolytic therapy causes hemorrhagic stroke, most commonly in the 24 hours after its administration, which is fatal in more than 50% of cases. Hemorrhagic stroke is rare in acute myocardial infarction except as a consequence of thrombolytic therapy, although an ischemic stroke may become hemorrhagic because of thrombolytic, antiplatelet, and anticoagulation therapy. Hemorrhagic stroke, the most feared complication of thrombolytic therapy, is more likely in elderly patients; in patients with low body weight, with hypertension, or who have previously had a stroke; and in those on warfarin.[53,59] Although thrombolytic therapy decreases the risk of ischemic stroke, there is a slight net increase in the overall risk of stroke because of the risk of hemorrhagic stroke. Primary coronary angioplasty is believed to reduce the incidence of ischemic stroke without increasing the risk of hemorrhagic stroke.

Predischarge Exercise Testing

In patients with spontaneous postinfarction angina, congestive heart failure, hypotension, or malignant ventricular arrhythmia, exercise testing should generally be deferred and coronary angiography should be performed. However, in patients with-

out these high-risk characteristics, exercise testing is generally recommended before discharge from the hospital to assess a patient's functional capacity and ability to return to activities of daily living and work.[132] Most data indicating that predischarge exercise testing can identify patients at increased risk for cardiac events after discharge are from the prethrombolytic era, when the risk of adverse cardiac events was much higher. In the modern era, in which thrombolytic therapy or primary coronary angioplasty is frequently performed and in which aspirin, beta blockers, ACE inhibitors, and lipid-lowering agents are routinely administered—all of which reduce the frequency of adverse events in the years after discharge—it is difficult to identify patients at risk, because the adverse event rate is so low. Nonetheless, exercise testing is generally recommended to provide a measure of comfort to both the patient and the physician, to help determine the appropriateness of medical therapy, and to facilitate entry of the patient into a cardiac rehabilitation program.

Although predischarge exercise testing has been the standard of care in the United States for some time, only recently has a study examined whether therapy based on the results of a predischarge exercise test improves clinical outcome. The Danish Trial in Acute Myocardial Infarction (DANAMI) was the first study to examine the usefulness of exercise testing in patients treated with thrombolytic agents (a low-risk group) and to provide support for what has been the standard of care in the United States [*see Figure 11*].[133] The results of this study revealed that clinical outcome was improved in patients who received angiography and coronary angioplasty, compared with those who received medical therapy alone. Use of the results of exercise testing to decide whether or not to employ revascularization in patients without spontaneous angina is less common outside of the United States.

Patients with acute myocardial infarction who do not receive thrombolytic therapy or do not undergo primary angioplasty are at greater risk for adverse events after discharge from the hospital, and predischarge exercise testing is of even greater utility in such patients.

Prognostic variables indicating increased risk during exercise testing are exercise-induced angina or ST segment depression, particularly when it occurs during exercise at a low work load, and an abnormal drop in systolic blood pressure. However, electrocardiographic, symptomatic, and scintigraphic risk markers of ischemia (e.g., ST segment depression, angina, or a reversible perfusion defect) are less sensitive for identifying morbid and fatal outcomes than markers of left ventricular dysfunction or heart failure (e.g., exercise duration, impaired systolic blood pressure response, and peak left ventricular ejection fraction).[134] The patients at greatest risk are those unable to exercise; such patients have the highest mortality after discharge.[135]

The type of exercise test that should be performed has been the subject of controversy. It is generally recommended that only simple treadmill testing be performed before discharge; in patients with abnormalities in the baseline ECG, stress testing with perfusion imaging or stress echocardiography may be helpful. In patients without widespread abnormalities on the ECG, perfusion imaging or stress echocardiography is generally deferred until at least 4 weeks after discharge, when a more vigorous exercise test can be performed. Whether the predischarge treadmill test should be a low-level test or a more vigorous symptom-limited test is unclear. It has been shown that a symptom-limited Bruce protocol exercise test detects ischemia more frequently than a submaximal test; however, it is not known which test has

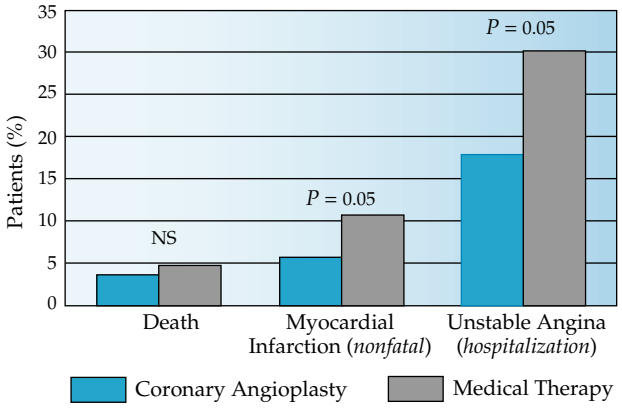

Figure 11 **In the Danish Acute Myocardial Infarction (DANAMI) study, 1,008 patients treated with thrombolytic therapy in whom exercise-induced ischemia was present on a predischarge exercise test were randomized to receive either coronary angioplasty or medical therapy alone. Clinical outcome was improved in patients in the invasive arm of the study. (NS—not significant)**

the greater positive and greater negative predictive value for identifying patients at risk. Currently, a lower-level exercise test is preferred, although a more vigorous test may be appropriate in patients likely to resume a more active and vigorous lifestyle shortly after discharge and in whom a low-level test may not cause the patient to expend the amount of energy he or she will be using during activities of daily living.

There has been concern that the use of beta blockers before the predischarge exercise test may mask the presence of significant coronary artery disease and prevent the identification of high-risk patients. This concern does not appear to be significant enough to outweigh the benefits of early beta-blocker therapy.

Secondary Prevention

PHARMACOTHERAPY

Lipid-Lowering Therapy

Recent studies have demonstrated that in patients with coronary artery disease, lipid-lowering therapy with HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A) reductase inhibitors reduces not only fatal and nonfatal infarction but also mortality from all causes. The Scandinavian Simvastatin Survival Study revealed a 42% reduction in cardiac mortality and a 30% reduction in all-cause mortality in 4,444 men and women with coronary artery disease over the 5.4 years of the study.[136] The reductions in mortality were similar in patients in the lowest and those in the highest quartiles of serum low-density lipoprotein (LDL) cholesterol. It has been demonstrated that postinfarction patients with an LDL cholesterol level at or above 130 mg/dl benefit from lipid-lowering therapy within as little as 2 years after the initiation of such therapy.[137] Initial measurement of cholesterol should be made within 24 hours after myocardial infarction; measurement of lipids 24 hours or more after myocardial infarction can be misleading in that cholesterol levels may be reduced below baseline levels during this period and remain low for up to 1 month. Early initiation of statins may be more beneficial than later initiation.[138] Exercise, weight reduction in overweight patients, avoidance of dietary saturated fat and cholesterol, and

smoking cessation have all been reported to favorably influence blood lipid levels and should be recommended whether or not lipid-lowering medications are prescribed [*see CE:III Reducing Risk of Injury and Diseases and CE:IV Diet and Exercise*].

Anticoagulation Therapy

Several prospective, randomized trials revealed that warfarin therapy reduces mortality after discharge from the hospital in patients with acute myocardial infarction. However, in these studies, in which warfarin therapy was compared with placebo, aspirin was not administered in either arm of the study.[139,140] The Coumadin Aspirin Reinfarction Study (CARS) revealed that the risk of reinfarction in patients treated with aspirin alone was similar to that in patients treated with aspirin and either low-dose (1 mg) or higher-dose (3 mg) warfarin.[141] Warfarin is also ineffective at preventing coronary reocclusion in patients in whom thrombolytic therapy was successful.[142] The routine administration of warfarin is not currently recommended to prevent reinfarction in patients who have survived myocardial infarction.

Antiarrhythmic Therapy

Although Holter monitoring before discharge can help identify patients at increased risk for sudden cardiac death, antiarrhythmic therapy has not been shown to decrease the risk of death in such patients, and in fact, it increased mortality in the Cardiac Arrhythmia Suppression Trial (CAST).[143] Since CAST, several prospective, randomized studies have been performed that have examined the role of amiodarone in patients at increased risk for sudden death. Taken together, the results of those studies do not indicate that amiodarone reduces mortality. Further studies are needed before the routine use of amiodarone can be recommended in high-risk patients, such as those included in these trials.

Automated, Implantable Cardioverter-Defibrillator

Automated implantable cardioverter-defibrillators are of proven benefit in patients with coronary artery disease, reduced left ventricular ejection fraction, nonsustained ventricular tachycardia, and inducible ventricular tachycardia.[144] It has been proposed that patients with a prior myocardial infarction and advanced left ventricular dysfunction may benefit from prophylactic implantation of a defibrillator (in the absence of electrophysiologic testing to induce arrhythmias). The Multicenter Automatic Defibrillator Implantation Trial (MADIT)–II investigators randomized 1,232 patients with a prior myocardial infarction and a left ventricular ejection fraction of 0.30 or less to an implantable defibrillator or conventional medical therapy. During an average follow-up of 20 months, the mortality rates were 19.8% in the conventional-therapy group and 14.2% in the defibrillator group (P = 0.016). Prophylactic implantation of a defibrillator is a recommended therapy in this patient population.[145]

RISK-FACTOR MODIFICATION

An important and often neglected aspect of medical care after a myocardial infarction is the identification and modification of risk factors for atherosclerosis. Hypertension and hypercholesterolemia should be treated. Cessation of smoking [*see CE:III Reducing Risk of Injury and Disease*] has been shown to prolong life in patients who have survived a myocardial infarction; behavior modification and group therapy can increase the likelihood of kicking the habit. Cardiac rehabilitation and the establishment of a healthier lifestyle with an exercise program[146] [*see CE:IV Diet and Exercise*] can further reduce the likelihood of a return to smoking. Hypercholesterolemia should be aggressively treated as described above.

Although there are few data that conclusively indicate that patients who participate in a cardiac rehabilitation program after discharge have increased survival, an exercise rehabilitation program appears to improve a patient's sense of well-being and hasten return to work and leisure activities. A cardiac rehabilitation program can also help improve diet and aid weight reduction in overweight patients, help smokers refrain from smoking, and help establish an exercise program that the patient can maintain long after the formal rehabilitation program has ended. In summary, participation in a cardiac rehabilitation program often leads to the establishment of a healthier lifestyle.

Long-term Prognosis

Long-term prognosis after myocardial infarction is determined primarily by the severity of left ventricular dysfunction, the presence and degree of residual ischemia, and the potential for malignant ventricular arrhythmia. These adverse prognostic factors are related to each other but are also independently associated with death after discharge. Age is also an important determinant of outcome. Most deaths that occur in the first year after discharge occur in the first 3 months, a fact that stresses the importance of assessing risk and optimizing therapy before discharge from the hospital. However, there can be substantial improvement in ventricular function in the weeks and months after acute myocardial infarction, particularly in patients in whom early reperfusion was achieved. Therefore, measurement of ventricular function 2 to 3 months after myocardial infarction is a more accurate predictor of long-term prognosis than measurement of left ventricular function in the acute stages.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

IX CHRONIC STABLE ANGINA

Paul R. Sutton, m.d., ph.d., f.a.c.p.
Stephan D. Fihn, m.d., m.p.h., f.a.c.p.

Definitions

Angina pectoris is the cardinal symptom of myocardial ischemia. Ischemia occurs when the coronary blood supply is inadequate to meet the metabolic demands of the myocardium. This mismatch of coronary blood supply and myocardial metabolic demand usually results from narrowing or occlusion of one or more coronary arteries, but in rare cases, it may be caused by coronary vasospasm or solely by excessive myocardial oxygen demand in the absence of significant coronary atherosclerosis.

Angina is typically a substernal, pressurelike discomfort or pain, but it may also take the form of discomfort in the jaw, shoulder, back, or arm. Usually, it is precipitated by physical exertion or emotional stress, and it is promptly relieved by rest or by taking nitroglycerin. Chronic stable angina refers to a pattern of chest pain or discomfort that does not change appreciably in frequency or severity over 2 months or longer and in which the episodes of pain are provoked by exertions or stresses of similar intensity.[1] Unstable angina, by contrast, is defined as rest angina, severe angina of new onset, or an increase in the severity or frequency of previously stable angina. Certain patients with symptoms of unstable angina are at an increased risk for myocardial infarction (MI) or death [*see* Epidemiology, *below*]. Chronic stable angina precedes MI in about half of cases and is common afterward. Although angina is a cardinal symptom of ischemic heart disease (IHD), MI or sudden death is the initial presentation of IHD in as many as half of patients.

Epidemiology

IHD is the leading cause of mortality in the United States and the rest of the developed world; it is responsible for more than 20% of deaths.[2] In the United States, approximately one million persons suffer an MI, and 500,000 coronary deaths occur each year. IHD is the leading cause of death in the United States for both sexes in both white and black populations.

The prevalence of IHD increases with age and is higher in men than in women in every age group. The American Heart Association (AHA) conservatively estimates that more than six million persons in the United States experience angina.[3]

In addition to posing an increased risk of MI and premature death, chronic stable angina often limits affected persons' capacity for work and other activities, which, in turn, negatively affects their quality of life. The direct and indirect costs of hospitalization, diagnostic procedures, and revascularization related to angina are substantial. Estimates of direct hospital costs for Medicare patients with a history of chronic stable angina exceed $7 billion annually.[1] Of patients with angina who undergo a coronary revascularization procedure, 30% or more never return to work.[4]

The major modifiable risk factors for IHD are dyslipidemias—in particular, elevated levels of low-density lipoprotein (LDL) cholesterol and low levels of high-density lipoprotein (HDL) cholesterol—as well as hypertension, diabetes mellitus, and cigarette smoking.[5,6] Other important, but immutable, risk factors are increasing age, a family history of premature coronary disease, and male sex. Obesity, physical inactivity, and atherogenic dietary habits also contribute to cardiovascular risk, although it is difficult to distinguish the risks conferred by these risk factors independently of the risks conferred by the major cardiovascular risk factors because of the potential interaction of these factors. Patients with combinations of risk factors may be at particular risk for developing IHD. Patients with the metabolic syndrome, which consists of obesity (particularly abdominal adiposity), hypertension, dyslipidemia (i.e., elevated triglyceride levels and low HDL levels), and insulin resistance, are at particularly high risk for IHD.[7] It is estimated that in the United States, the metabolic syndrome affects nearly 25% of all persons and 43.5% of adults 60 years of age or older.[8]

Numerous clinical trials have identified important risk factors and effective therapies for coronary artery disease; however, few of these studies have included sufficient numbers of women to draw meaningful conclusions about coronary disease in women.[9] Thus, much of the evidence that supports contemporary recommendations for testing, prevention, and treatment of coronary disease in women is extrapolated from studies conducted predominantly in middle-aged men.

Although it has been proposed that 50% or more of patients with IHD lack any of the traditional major risk factors, two studies have challenged this notion; these studies indicate that the vast majority of patients who experience cardiac events (either fatal or nonfatal) have one or more major risk factors.[10,11] Nevertheless, interest remains in identifying additional laboratory markers of risk of IHD and, in particular, risk of acute coronary syndromes. In observational studies, several measures of inflammation, including C-reactive protein (CRP) levels, interleukin-6 (IL-6) levels, and levels of soluble cellular adhesion molecules, have been associated with risk of IHD and cardiovascular events.[12,13] Measures of fibrinogen, platelet activator inhibitor, and components of the coagulation/fibrinolysis cascade may ultimately be of use in predicting risk of cardiovascular events.[12] A number of genetic polymorphisms and candidate genes that may increase the risk of MI have been identified in specific populations. Currently, however, it is uncertain whether these or other laboratory measurements represent truly independent risk factors or whether they will prove useful in clinical practice.[14]

Pathophysiology and Pathogenesis

Angina occurs as a result of myocardial ischemia, which occurs when cardiac blood supply is insufficient to meet myocardial oxygen demand. Stable angina commonly occurs in the setting of narrowing or partial occlusion of segments of coronary arteries by atherosclerotic plaque. Significant occlusion is defined as a reduction of the diameter of a major coronary artery by 70%, which corresponds to a 50% reduction in vessel lumen surface area; such occlusion is often sufficient to cause angina. Coronary atherosclerosis and angina often progress over time, reflecting both gradual and more abrupt changes in luminal diameter of coronary vessels. Incremental changes in coronary atherosclerosis reflect the progression of existing lesions and the appearance of new stenoses. Abrupt changes in vessel diameter

may be associated with sudden changes in anginal symptoms, termed unstable angina. Unstable angina is commonly caused by rupture of vulnerable atherosclerotic plaque with associated platelet thrombosis. Unstable angina may also be caused by endothelial injury, thrombosis of severely stenotic coronary arteries, or coronary artery spasm. Although angina is usually associated with coronary artery disease (CAD), it may also occur in persons with normal or near-normal coronary arteries; in these settings, angina may occur as a result of increased myocardial oxygen demand associated with aortic stenosis, hyperthyroidism, or anemia.

Myocardial ischemia, regardless of cause, is associated with intracardiac release of adenosine. Adenosine release slows atrioventricular conduction and reduces contractility, which are adaptive changes in the setting of myocardial ischemia. Stimulation of adenosine receptors in the chest is believed to be responsible for the sensation of angina.

Angina occurs most often in the setting of coronary atherosclerosis. Atherosclerosis occurs as a result of vascular injury and subsequent responses to injury. Vascular injury may result from the mechanical stress of blood flow or from direct endothelial injury from toxins, such as those in cigarette smoke. Traditional cardiovascular risk factors, such as smoking, hypertension, hyperlipidemia, and diabetes, increase coronary risk, at least in part by potentiating vascular injury or altering the subsequent response to injury. Direct endothelial injury produces a sequence of events similar to chronic inflammation: the endothelium elaborates procoagulants, vasoactive molecules, growth factors, and cytokines. Platelets, inflammatory cells (e.g., monocytes and T cells), and smooth muscle cells are attracted to the site of injury.[15] This cascade of events is initially adaptive, resulting in repair of endothelial injury; however, repeated cycles of injury and repair can result in progressive atherosclerosis and luminal narrowing.

Support for the inflammatory hypothesis of atherosclerosis comes from clinical studies that suggest a correlation between the risk of future cardiovascular events and the presence of markers of inflammation, including CRP.[12,13] Inflammation may also play a role in acute coronary syndromes (i.e., unstable angina and acute MI). In some studies, levels of CRP during episodes of unstable angina are associated with a greater risk of MI or death,[16] although it is not clear whether inflammation (and corresponding elevations of CRP) contributes to the etiology of unstable coronary syndromes or is simply a consequence of myocardial ischemia and injury.[17]

Histologically, atherosclerotic plaques are composed of a fibrous cap derived from smooth muscle cells; the cap covers a core of oxidized lipids, inflammatory cells, and cellular debris. Immature plaques consist of a necrotic, lipid-rich core surrounded by a thin, fibrous capsule. These so-called vulnerable plaques may not be visible angiographically, but they are prone to disruption and thrombus formation and, thus, are associated with unstable coronary syndromes. In fact, many of the plaques responsible for myocardial infarction may not be associated with significant coronary stenosis.[18] Mature atherosclerotic plaques, by contrast, have less necrotic cores and thicker, more stable fibrous caps. These plaques tend to cause greater degrees of coronary stenosis and are the lesions typically identified by coronary angiography; they are generally less susceptible to fracture and are associated less with acute coronary syndromes than are immature plaques. Atherosclerotic lesions may be associated with chronic stable angina, either because of luminal narrowing or because of dysfunctional vascular reactivity.

Table 1 Grading of Angina Pectoris by the Canadian Cardiovascular Society Classification System[18]

Class I

Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.

Class II

Slight limitation of ordinary activity. Angina occurs while walking or climbing stairs rapidly; while walking uphill; while walking or climbing stairs after meals in cold or in wind; while under emotional stress; or only during the first several hours after waking. Angina occurs while walking more than two blocks on level grade and climbing more than one flight of ordinary stairs at a normal pace and in normal condition.

Class III

Marked limitations of ordinary physical activity. Angina occurs while walking one or two blocks on level grade and climbing one flight of stairs in normal conditions and at a normal pace.

Class IV

Inability to engage in any physical activity without discomfort. Anginal symptoms may be present at rest

Clinical Manifestations

A cardinal manifestation of IHD, angina is characterized by substernal pain or discomfort that may radiate to the neck, jaw, epigastrium, back, or arms. Words characteristically used to describe the sensation of angina include "squeezing," "vicelike," "heavy," "griplike," and "suffocating." Angina ordinarily lasts only a few minutes. Typical angina has three key characteristics: (1) substernal chest discomfort of characteristic quality and duration that is (2) provoked by exertion or emotional stress and is (3) relieved by rest or nitroglycerin. Atypical angina has two of the three characteristics of typical angina; noncardiac chest pain has one or none of the characteristics of typical angina.

The severity of angina is graded according to the Canadian Cardiovascular Society (CCS) classification [*see Table 1*].[19] Angina grade provides a useful way to evaluate functional limitation, treatment efficacy, and stability of symptoms over time.

Anginal chest pain is further characterized as stable or unstable. Unstable angina presents as prolonged angina at rest; new-onset angina that is severe, prolonged, or frequent; and established angina that has become distinctly more frequent, longer in duration, or more easily provoked. Some patients with unstable angina are at increased risk for acute MI and death [*see Table 2*]; the pathophysiology of unstable angina in these patients is often the result of plaque rupture and thrombosis. Patients with unstable angina and intermediate-risk or high-risk clinical features are best evaluated in the hospital.[20]

Differential Diagnosis

Given the potentially life-threatening sequelae of angina and the availability of effective therapies, it is important to consider angina in all patients presenting with chest pain. One approach to chest pain is to consider the differential diagnosis anatomically [*see Table 3*]. Various diseases of the heart and pericardium cause chest pain. Arrhythmias and valvular heart disease cause typical angina; pericarditis often causes pleuritic pain (i.e., pain that worsens on inspiration), but it may produce angina that is

relieved by sitting up and leaning forward. Dissection of the great vessels can cause a characteristic, sudden, excruciating "tearing" pain in the chest or back. Diseases of the esophagus, such as esophageal spasm and acid reflux, may cause chest pain that is often postprandial or that occurs with recumbence. Esophageal spasm, in particular, can mimic angina and may respond to nitrates or calcium channel blockers. Diseases of lungs and pleura, including pulmonary embolism, pneumonia, pleuritis, and empyema, can cause chest pain that is often pleuritic. Chest wall syndromes, such as costochondritis, can cause substernal chest pain, typically reproduced with palpation. Herpes zoster may cause neuralgia that is localized to the chest; the pain may precede the appearance of the characteristic rash. Patients with panic disorder may describe chest pain or tightness accompanied by shortness of breath, diaphoresis, and other symptoms suggesting cardiac disease.

Diagnosis and Risk Stratification

PRELIMINARY EVALUATION

The evaluation of patients with chest pain should take into account symptom characteristics and cardiovascular risk factors, because these indicate the probability of angina and IHD [*see* Patient History and Its Use in Determining Risk for IHD, *below*]. If the history and physical examination suggest the presence of angina and IHD, patients are further evaluated by noninvasive tests, such as exercise treadmill testing or coronary angiography. Noninvasive testing serves to refine the probability of the diagnosis of IHD and stratify patients according to their risk for near-term cardiovascular events [*see* Noninvasive Testing, *below*].[21]

Patient History and Its Use in Determining Risk for IHD

Determining the pretest probability of significant IHD, which is defined as greater than 70% stenosis of one or more of the major epicardial coronary arteries, is an essential step in the evaluation of patients with suspected IHD. Decisions regarding testing and management are strongly influenced by estimates of the probability of significant IHD [*see Figure 1*].[21]

Estimates of the pretest probability of significant IHD can be accurately derived from a description of the chest pain syndrome and the presence or absence of cardiovascular risk factors.[22] It is important to characterize suspected angina by location, quality, duration, associated symptoms, and factors that exacerbate or relieve the pain [*see Table 4*]. Typical angina is substernal, lasts less than 5 minutes, is dull and aching, and is worse with exertion or emotional stress. Atypical angina has some but not all features of anginal chest pain. For example, a patient with aching substernal chest pain that lasts minutes but is unrelated to exertion is considered to have atypical angina. Similarly, a patient with sharp, exertional chest pain may also have atypical angina. Nonanginal pain is chest pain that does not have any features of angina: it is pleuritic or positional, unrelated to exertion, and is fleeting or lasts for many minutes. A detailed chest pain history allows the clinician to classify a patient's chest pain syndrome as typical angina, atypical angina, stable angina, unstable angina, or nonanginal chest pain. Among patients presenting to a clinician with chest pain, the presence of typical angina substantially increases the probability of significant IHD (likelihood ratio, 5.6), whereas the presence of atypical angina does not substantially alter the probability of significant IHD (likelihood ratio, 1.3).[23]

Once a detailed history of chest pain is obtained, cardiovascular risk factors are assessed; risk factors include increased age, male sex, menopausal status, cigarette smoking, hyperlipidemia, diabetes, hypertension, cerebrovascular disease, peripheral vascular disease, and a family history of premature coronary disease.[24] Cardiovascular risk factors greatly affect the pretest probability of significant IHD, particularly for women, younger patients, and patients with atypical chest pain syndromes [*see Table 5*]. For example, a 55-year-old man with atypical angina and no risk factors has a pretest probability of clinically significant IHD of 45%, whereas a 55-year-old man with typical angina and multiple cardiovascular risk factors has a 95% pretest probability of significant IHD.

Estimating the pretest probability of significant IHD is essential to determine whether further testing is warranted. For example, further diagnostic testing of the patient with a 45% probability of IHD would likely clarify the presence or absence of IHD. On the other hand, further testing of the patient with a 95% probability of IHD would be unlikely to alter the diagnosis of IHD, although further testing might help assess risk of cardiovascular events [*see* Risk Stratification in Patients with Chronic Stable Angina, *below*]. In general, further testing is not recommended for patients with a

Table 2 Short-Term Risk of Death or Nonfatal Myocardial Infarction in Patients with Unstable Angina[19]

High Risk	*Intermediate Risk*	*Low Risk*
At least one of the following features must be present: Prolonged ongoing (> 20 min) rest pain Pulmonary edema, most likely related to ischemia Angina with new or worsening MR murmur Angina with S_3 or new/worsening rales Angina with hypotension	No high-risk features but must have any of the following: Prolonged (> 20 min) rest angina, now resolved, with moderate or high likelihood of CAD Rest angina (> 20 min or relieved with sublingual nitroglycerin) Nocturnal angina New-onset CCSC III or IV angina in the past 3 wk with moderate or high likelihood of CAD Pathologic Q waves or resting ST depression ≤ 1 mm in multiple lead groups (anterior, inferior, lateral) Age > 65 yr	No high- or intermediate-risk feature but may have any of the following: Increased angina frequency, severity, or duration Angina provoked at a lower threshold New-onset angina with onset 2 wk to 2 mo before presentation Normal or unchanged ECG

Note: Estimation of the short-term risks of death and nonfatal myocardial infarction in unstable angina is a complex multivariable problem that cannot be fully specified in a table such as this. Therefore, the table is meant to offer general guidance and illustration rather than rigid algorithms.
CAD—coronary artery disease CCSC—Canadian Cardiovascular Society Classification MR—mitral regurgitation

very low pretest probability of significant IHD, as determined by a clinical assessment of patient history and risk factors.

Estimates of the risk of cardiovascular events can also be determined from clinical variables; the Framingham risk equations are commonly used for this purpose [*see Figure 2*].[25] This multivariate model estimates the 10-year risk of developing IHD on the basis of a patient's age; gender; total cholesterol level; and history of diabetes, hypertension, and smoking. This model is widely used, is readily available, and has been validated across a variety of populations.

The decision to pursue further testing in patients with possible angina appropriately incorporates patient preferences regarding diagnosis or intervention and an assessment of comorbidities [*see* Patients Warranting Noninvasive Testing, *below*].

Physical Examination

The physical examination of patients with chronic stable angina is often normal but may indicate the presence of hypertension (e.g., elevated blood pressure, enlarged or laterally displaced point of maximum impulse, S_4 gallop, or retinal vascular changes) or coexisting peripheral vascular disease (e.g., diminished pulses or bruits). In younger patients with premature coronary disease, there may be stigmata of genetic dyslipidemia syndromes (e.g., xanthelasma associated with familial hypercholesterolemia). For patients with chest pain, the presence of any of these findings increases the likelihood of significant IHD.

It is particularly helpful to examine a patient during an episode of angina. The presence of an S_4 or S_3 gallop, a mitral regurgitation murmur, a paradoxically split S_2 heart sound, bibasilar crackles, or a chest wall heave makes IHD more likely, particularly if the finding disappears when the pain goes away.[26] Physical examination findings that wax and wane with anginal symptoms are of particular significance, because they may indicate significant myocardial dysfunction at low work loads.

Laboratory Tests

A resting 12-lead electrocardiogram should be performed in all patients with suspected angina, although the results are normal in 50% of patients with chronic stable angina.[27] The presence of pathologic Q waves is virtually pathognomonic of

Table 3 Differential Diagnosis of Chest Pain

Diagnosis	*Characteristics*	*Comments*
Ischemic heart disease	Typical or atypical angina	Caused by diminished coronary blood flow and/or increased myocardial oxygen demand
Nonischemic heart disease		
Arrhythmias	Palpitations or typical angina	Tachycardia
Valvular heart disease	Typical angina, often exertional	Heart murmur present
Aortic dissection	"Tearing" pain, often abrupt onset	Widened mediastinum, often with hypertension
Pericarditis	Often pleuritic pain, but may be anginal; relieved by sitting up and leaning forward	Friction rub may be present; diffuse ST segment elevation (PR segment depression) on ECG
Pulmonary disease		
Pulmonary embolus	Pleuritic pain, associated dyspnea	Hypoxia/hypoxemia, pulsus paradoxus, and risk factors for thromboembolic disease
Pneumothorax	Acute onset, pleuritic pain, associated dyspnea	Hyperresonance on examination; tension pneumothorax is associated with distended neck veins, hypotension, and tachycardia
Pneumonia	Pleuritic pain	Associated with fever and productive cough
Gastrointestinal disease		
Esophageal disease	May be indistinguishable from angina	Often diagnosed following a negative evaluation for ischemic heart disease
Acid peptic disease	May be indistinguishable from angina	Pain often related to meals
Biliary disease	Right upper quadrant pain that radiates to the back or scapula	Typically worse following meals; right upper quadrant tenderness may be present
Pancreatitis	"Boring" epigastric pain, may radiate to the back	Chronic pancreatitis pain may occur without signs of systemic illness
Chest wall or dermatologic pain	Characteristically reproduced with palpation or movement	Reproduction of pain does not exclude angina
Costochrondritis		
Rib fracture		
Sternoclavicular arthritis		
Herpes zoster		Pain may precede rash
Fibrositis		Characteristic point tenderness
Psychiatric disorders	May be indistinguishable from angina	Often diagnosed following a negative evaluation for angina
Anxiety disorders		Often associated with palpitations, sweating, and anxiety
Affective disorders (e.g., depression)		
Somatoform disorders		
Thought disorders (e.g., fixed delusions)		
Factitious disorders (e.g., Munchausen syndrome)		

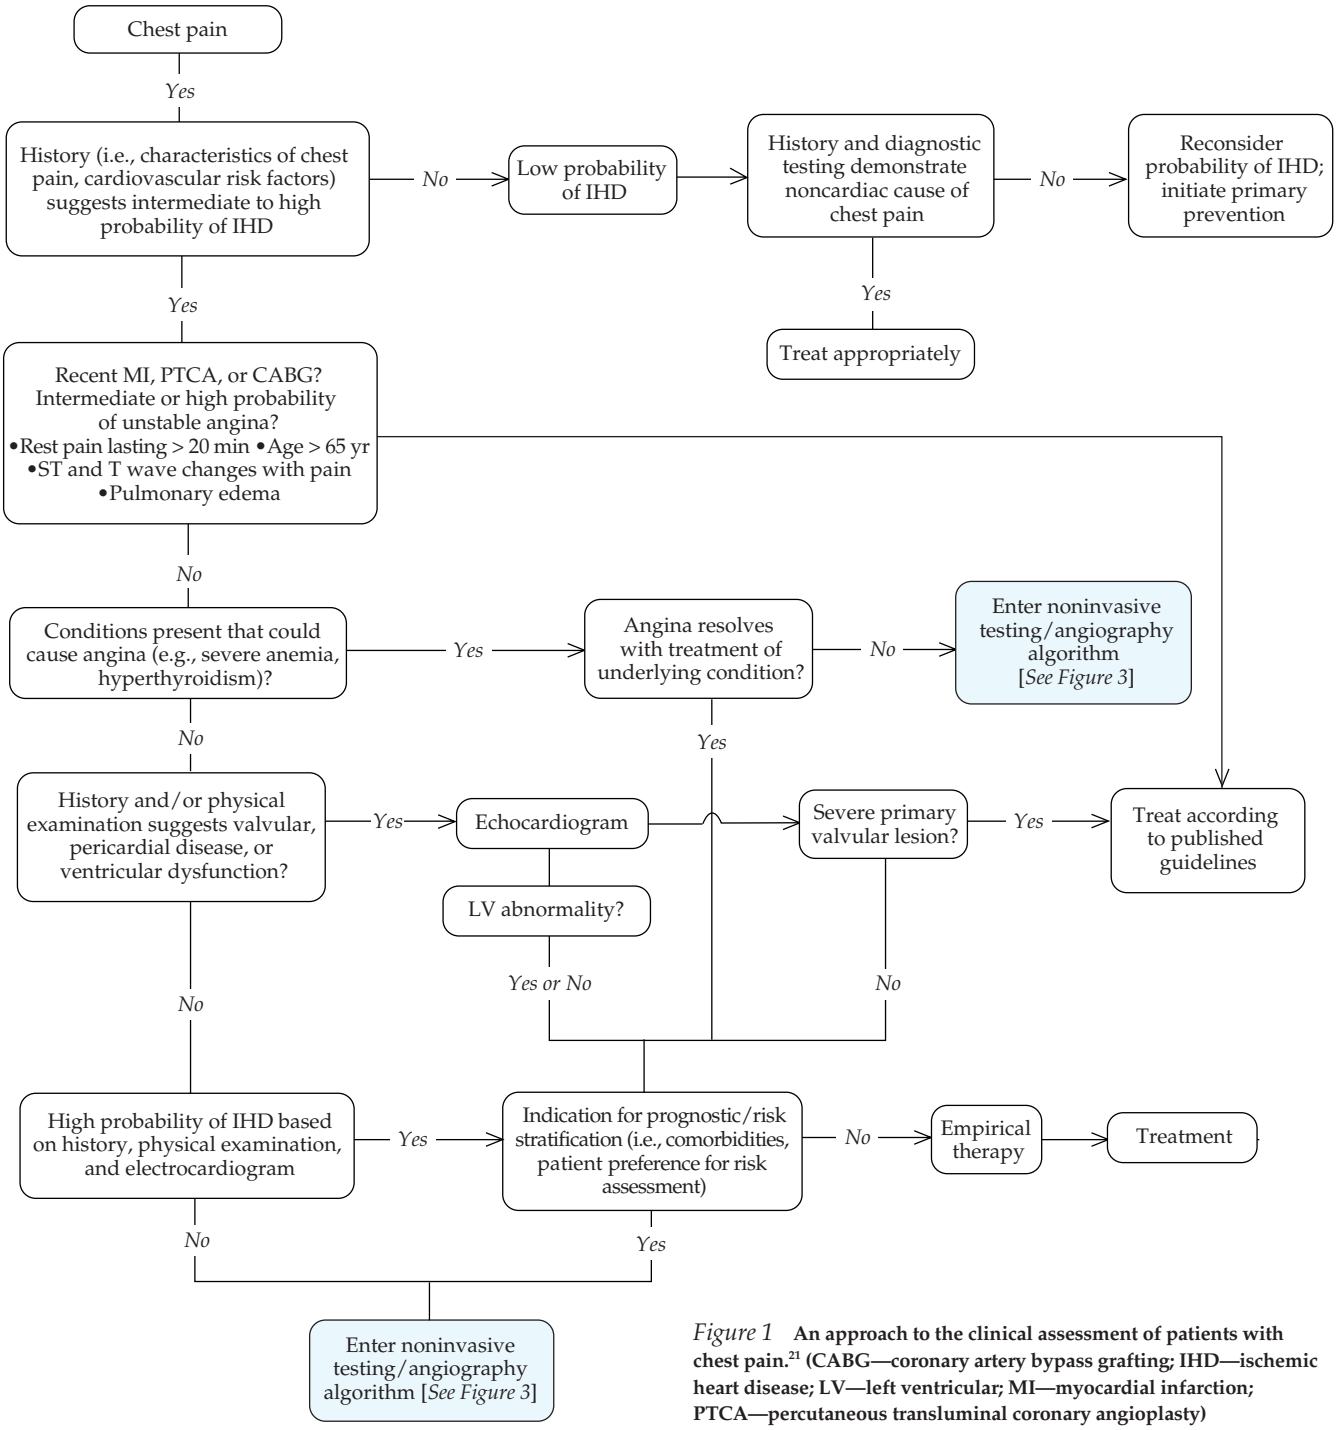

Figure 1 **An approach to the clinical assessment of patients with chest pain.[21] (CABG—coronary artery bypass grafting; IHD—ischemic heart disease; LV—left ventricular; MI—myocardial infarction; PTCA—percutaneous transluminal coronary angioplasty)**

clinically significant IHD, although isolated Q waves in lead III or a QS pattern in leads V1 and V2 is nonspecific. Several other ECG findings increase the clinical probability of IHD; ST segment depression, T wave inversions, and left ventricular hypertrophy (LVH) favor the diagnosis of angina.[28] Arrhythmias, including atrial fibrillation, ventricular tachyarrhythmias, bundle branch blocks, and atrioventricular block, increase the likelihood of IHD somewhat but are nonspecific.

As with the physical examination, an ECG obtained during an episode of pain may be particularly informative. About half of patients with a normal resting ECG will have an abnormality suggestive of ischemia during an episode of chest pain. Suggestive abnormalities include ST segment depression, T wave inversion, or "pseudonormalization" of these abnormalities during pain.[29] Abnormalities on a resting ECG that disappear with resolution of pain may indicate severe IHD, because they suggest ischemia at low work loads or unstable coronary syndromes.

Recommended laboratory tests include measurement of hemoglobin and fasting glucose levels and a fasting lipid panel (including measurement of levels of total cholesterol, HDL cholesterol, triglycerides, and calculated LDL cholesterol).[1] Hyperlipidemia is an important risk factor for IHD; the risk for IHD increases 1% for each 1 mg/dl increase in serum LDL cholesterol.[30] Similarly, patients with impaired glucose tolerance or

Table 4 Features of Typical Angina

Feature	*Typical Angina*	*Comments*
Location	Substernal but may radiate to neck, jaw, shoulder, or arms	The symptom of angina is typically felt below the ears and above the umbilicus
Duration	Typically less than 5 min	Longer-lasting chest pain raises concern for MI but may also be nonanginal
Quality	Dull, aching, pressurelike pain that is difficult to localize precisely	Levine sign, a clenched fist held over the chest well, represents the location and quality of typical angina
Exacerbating or relieving factors	Worsens with exertion or emotional stress and is relieved by rest or nitroglycerin; pain is often precipitated by a reproducible amount of exertion	Typical angina that occurs at lower than the usual amounts of exertion raises concern for unstable angina
Associated symptoms	Diaphoresis, nausea, palpitations, light-headedness, and dyspnea	Palpitations and light-headedness raise concern for arrhythmia; dyspnea suggests left ventricular or valvular dysfunction

frank diabetes are at increased risk for IHD. Normal hemoglobin excludes anemia. Thyroid function tests are indicated in patients who have signs or symptoms compatible with hyperthyroidism.

Imaging Studies

Chest radiography is of limited value in most patients with suspected angina[31]; however, a chest radiograph or other imaging study, such as computed tomography, is indicated in patients with signs or symptoms of congestive heart failure (CHF), valvular heart disease, or pericardial disease or in patients with possible aortic dissection or aneurysm. Echocardiography or multigated equilibrium radionuclide angiography should be obtained in any patient with suspected left ventricular impairment.

Patients Warranting Noninvasive Testing

Noninvasive testing usually has two objectives: to ascertain the probability of clinically important IHD and to estimate the risk of a serious cardiovascular event (e.g., MI or death) in the near future. These two objectives are often pursued concurrently, but it is useful to distinguish between diagnostic testing and testing for purposes of risk stratification.

Noninvasive testing is most likely to influence clinical decision making when the pretest probability of IHD is in the intermediate range. For example, a positive exercise treadmill test in a 55-year-old man with atypical chest pain and no other risk factors (pretest probability of clinically significant IHD, approximately 50%) would significantly increase the suspicion of clinically important IHD (posttest probability, 85%), whereas a negative exercise treadmill test would significantly reduce the suspicion of clinically significant IHD (posttest probability, 15%).

On the other hand, an abnormal exercise treadmill test in a 35-year-old woman with atypical chest pain and no other risk factors (pretest probability of clinically significant IHD, < 5%) would likely be falsely positive and could prompt use of unnecessary medications or potentially invasive diagnostic testing; a negative test would simply support a low clinical suspicion of disease. Therefore, further testing in such a low-risk patient would not be indicated. Similarly, further testing of high-risk patients is not likely to provide information that would alter the diagnosis of IHD. For example, because of the likelihood of significant coronary disease in a 65-year-old man with typical angina (pretest probability, 94%), a positive exercise test would only confirm the high clinical suspicion of IHD; a negative result would only lower the estimate into the moderate range and would not exclude the diagnosis of significant IHD.

Noninvasive testing is commonly obtained in persons with a high clinical probability of having significant IHD. In this setting, however, noninvasive testing is useful to assess risk and establish prognosis but not to establish or refute the diagnosis of coronary disease, as is the case for patients with an intermediate clinical probability of significant IHD.

Table 5 Comparison of Pretest Likelihood of IHD in Low-Risk Symptomatic Patients and High-Risk Symptomatic Patients[49]

Age (yr)	*Nonanginal Chest Pain (%)**		*Atypical Angina (%)**		*Typical Angina (%)**	
	Men	Women	Men	Women	Men	Women
35	3–35	1–19	8–59	2–39	30–88	10–78
45	9–47	2–22	21–70	5–43	51–92	20–79
55	23–59	23–59	45–79	10–47	80–95	38–82
65	49–69	49–69	71–86	20–51	93–97	56–84

*Each value represents the percentage with significant IHD. The first number given in each range (e.g., 3–35) is the percentage for a low-risk, mid-decade patient who does not have diabetes, does not smoke, and does not have hyperlipidemia. The second number in each range is the percentage for a same-age patient who does have diabetes, does smoke, or does have hyperlipidemia. Both high- and low-risk patients have normal resting ECGs. If ST-T wave changes or Q waves are present, the likelihood of IHD is higher in each entry of the table.

Figure 2 **Estimates of major cardiovascular risk for men and women, based on the Framingham risk equations.[25]**

For purposes of deciding on a course of noninvasive testing, there is no precise definition of the upper and lower boundaries of intermediate probability of IHD; rather, this is a matter of clinical judgment in individual situations. Relevant issues include the degree of uncertainty acceptable to the physician and patient, the probability of an alternative diagnosis, the costs and risks of additional testing, and the benefits and risks of treatment in the absence of additional testing.[32] It is reasonable to consider a risk of clinically significant IHD of 10% to 20% or lower as low probability and of 80% to 90% risk or greater as high probability.[32]

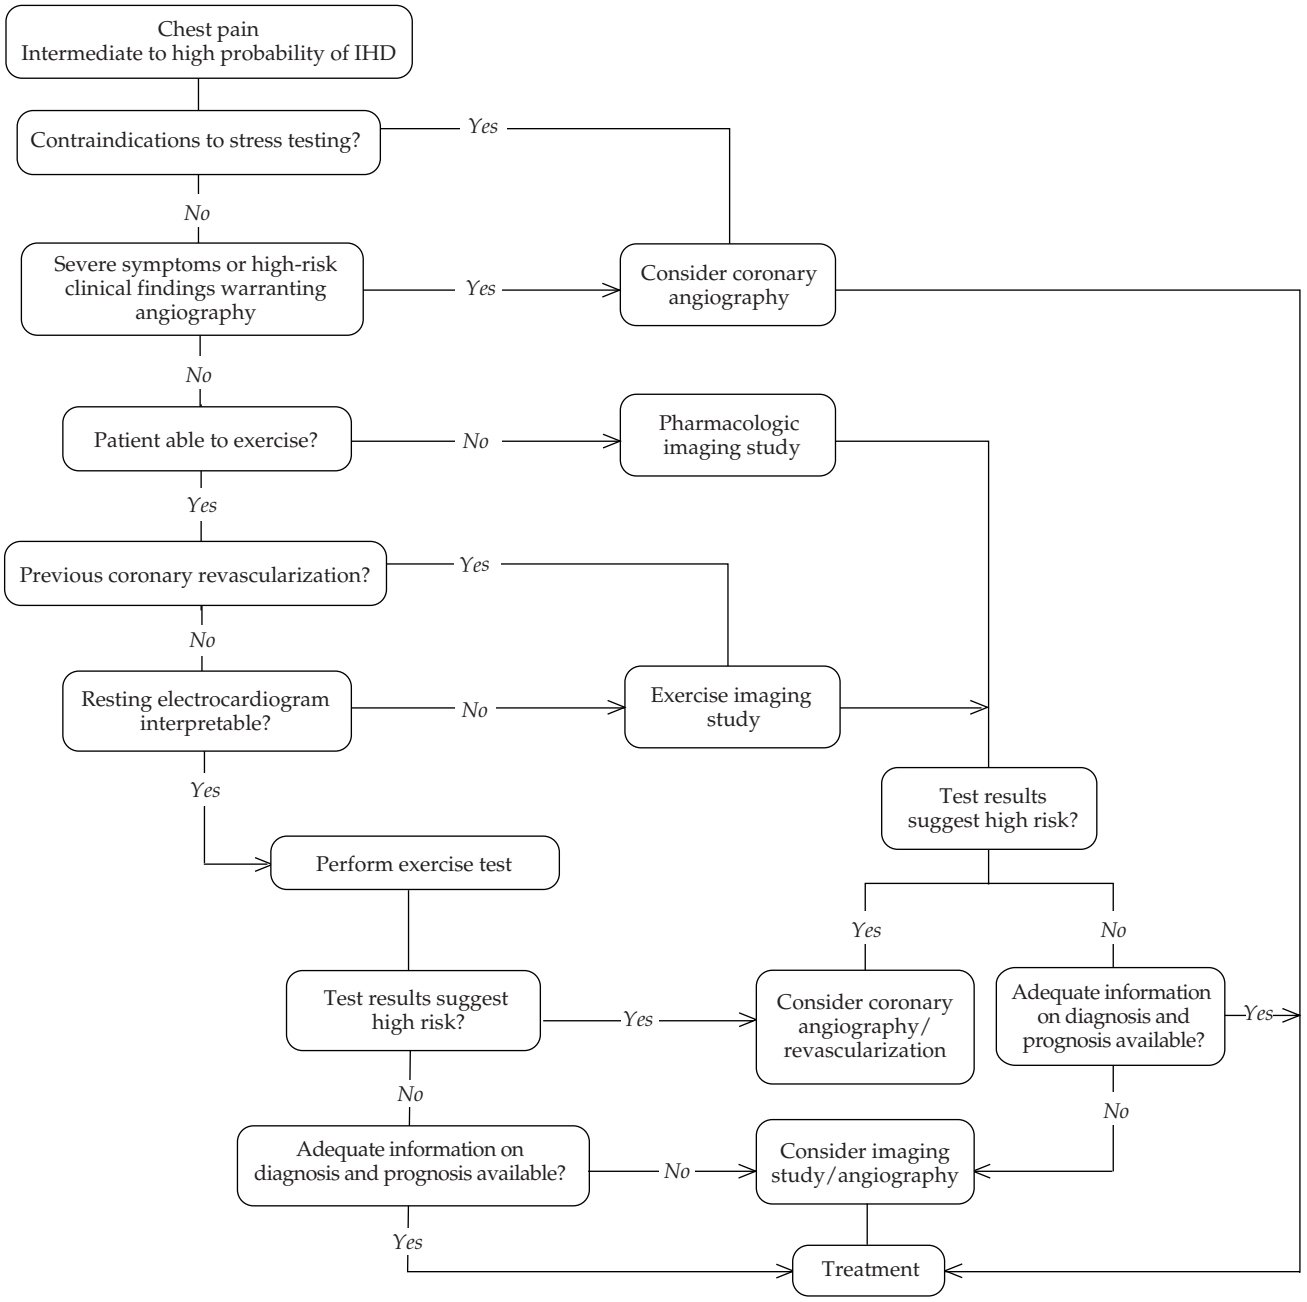

Figure 3 **Noninvasive testing and angiography in the evaluation of patients suspected of having ischemic heart disease.[21]**

NONINVASIVE TESTING

Patients whose history, physical examination, and ECG results indicate an intermediate or high probability of IHD usually should undergo further diagnostic evaluation [*see Figure 3*]. Noninvasive testing in patients with an intermediate probability of IHD provides important information about diagnosis (i.e., the presence or absence of coronary disease). In patients with an intermediate or high probability of IHD, noninvasive testing helps to stratify risk for major cardiovascular events. This stratification helps determine treatment strategies.

Commonly performed noninvasive studies include exercise ECG testing, stress radionuclide myocardial perfusion imaging, and stress echocardiography. The performance characteristics of various noninvasive tests and posttest probabilities of IHD for a range of pretest probabilities are listed [*see Table 6*].

ECG Exercise Testing

Guidelines from the American College of Cardiology/American Heart Association/American College of Physicians (ACC/AHA/ACP) recommend exercise ECG as the first-choice diagnostic test for the average patient with an intermediate pretest probability of IHD and a normal resting ECG.[32,33] Exercise testing has imperfect sensitivity and specificity (68% and 77%, respectively), but it is widely available and inexpensive. In addition, it readily identifies patients at high risk for IHD and provides important prognostic information [*see* Risk Stratification in Patients

with Chronic Stable Angina, *below*]. Exercise testing is generally safe; MI or death occurs with a frequency of less than 1 in 2,500 tests.[34] Symptom-limited exercise testing is safe in patients with unstable angina who lack evidence of MI and CHF and who are free of chest pain at the time of testing.[32] Specific absolute and relative contraindications for exercise testing can be found in guidelines from the ACC/AHA.[1] Other noninvasive tests are preferred in patients who are unable to exercise, in those who previously underwent coronary revascularization, and in those with specific resting ECG abnormalities that would interfere with the interpretation of an exercise ECG (such abnormalities include ST segment depression of greater than 1 mm at rest, preexcitation syndrome, electronically paced rhythm, left bundle branch block, and left ventricular hypertrophy with repolarization abnormalities).[32]

Interpretation of the exercise test depends on the patient's exercise capacity, symptoms, the reasons for stopping the test, the hemodynamic response, any pertinent findings on physical examination (e.g., exercise-induced S_3 heart sound or mitral regurgitation), and any changes in the ECG. Patients who stop the test because of the onset of angina are very likely to have significant IHD. Exercise-induced falls in blood pressure or the development of an exercise-induced S_3 heart sound are strongly suggestive of ischemic left ventricular dysfunction. Specific exercise-induced ECG changes suggestive of IHD include a horizontal or downward-sloping ST segment depression or elevation of greater than 1 mm during or after exercise.[1] Exercise-induced changes in lead V5 are most reliable for the diagnosis of IHD.[1]

Stress Radionuclide Myocardial Perfusion Imaging

Although exercise ECG continues to be recommended as the diagnostic test of choice for most patients with suspected angina, stress myocardial perfusion imaging using single-photon emission computed tomography (SPECT) is the most common noninvasive test performed in the United States. SPECT imaging following exercise or pharmacologic stress (e.g., using dipyridamole, adenosine, or dobutamine) has greater sensitivity for IHD than exercise testing, particularly in patients with an abnormal resting ECG; in addition, SPECT can define vascular regions in which stress-induced coronary flow is limited. Furthermore, SPECT imaging allows an estimation of left ventricular (LV) systolic size and function.

Exercise myocardial perfusion SPECT is preferred for patients who have baseline ECG abnormalities that interfere with the interpretation of an exercise ECG. Such abnormalities include a resting ST segment depression greater than 1 mm and LVH; digoxin therapy and ventricular preexcitation can also cause ECG abnormalities.[35] Myocardial perfusion SPECT with pharmacologic stress is preferred in the setting of left bundle branch block or ventricular pacing.[35] Because of its greater sensitivity, stress myocardial perfusion imaging is an option after a nondiagnostic exercise ECG. Stress myocardial perfusion imaging can also further stratify the risk of IHD in patients with an abnormal exercise ECG.[36]

Stress Echocardiography

Stress echocardiography (i.e., echocardiography performed after exercise or dobutamine administration) is another option for noninvasive testing to establish the diagnosis of IHD. Stress induces regional wall motion abnormalities in the myocardial regions supplied by stenotic coronary vessels; stress echocardiography defines such regions of the left ventricular wall. Stress echocardiography, like myocardial perfusion imaging, is a good choice for patients with ECG abnormalities that might interfere with the interpretation of an exercise ECG.[37] The sensitivity of stress echocardiography, as with that of stress myocardial perfusion imaging, is in the range of 80% to 85%. Exercise echocardiography is marginally more specific than other noninvasive diagnostic tests.[38]

Test Selection

Although exercise ECG remains the recommended initial noninvasive test for most patients with suspected IHD, clinical decision making should also take into account individual patient characteristics, local expertise, and availability. Stress echocardiography and exercise ECG can be performed in a physician's

Table 6 Posttest Probability of Significant IHD Based on Pretest Probabilities of IHD and Normal or Abnormal Results of Noninvasive Studies

Test Result	*Posttest Probability of IHD (%)*					
	20% Pretest Probability		*50% Pretest Probability*		*80% Pretest Probability*	
	Men	Women	Men	Women	Men	Women
Exercise ECG

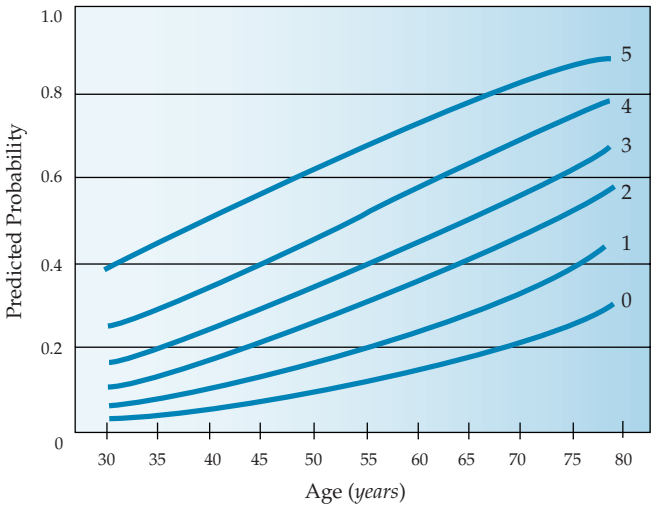

Figure 4 **Nomogram showing the probability of severe coronary disease (i.e., three-vessel disease or left main coronary artery disease) on a five-point score. One point is awarded for each of the following variables: male gender; typical angina; history or electrocardiographic evidence of myocardial infarction; diabetes; and use of insulin. Each curve shows the probability of severe coronary disease as a function of age.[50]**

office, whereas radionuclide myocardial perfusion imaging requires a specialized setting. In addition, myocardial perfusion imaging is considerably more expensive than exercise ECG.

Specific noninvasive tests are preferred in certain patient subsets. Patients unable to exercise should undergo some form of pharmacologic noninvasive test. Pharmacologic stress echocardiography using dipyridamole, adenosine, or, less commonly, dobutamine is an option for patients who are unable to exercise. Nonspecific perfusion image defects may be more common with exercise myocardial perfusion imaging in patients with left bundle branch block; pharmacologic stress imaging or echocardiography is preferred in these patients.[32] Exercise ECG is less accurate in establishing the diagnosis of IHD in women, and some authors have suggested that SPECT imaging and stress echocardiography are more accurate diagnostic tests for women with an intermediate probability of having IHD.[39,40] The ACC/AHA/ACP expert panel concluded, however, that insufficient data are available to recommend stress imaging or echocardiography over standard exercise ECG in women with suspected angina.[32]

Echocardiography is less sensitive in very obese patients, and examination tables used for SPECT imaging often have weight limitations. Planar scintigraphy, positron-emission tomography, and coronary angiography are testing options for obese patients. Planar scintigraphy is less sensitive than SPECT, and positron emission tomography is less well characterized than other modalities. There is some rationale for performing stress imaging or echocardiography in patients with angina whose histories suggest they are at high risk for major cardiovascular events (e.g., patients who experience angina at low work loads or whose angina is progressive); in such patients, determination of LV systolic function and anatomic distribution of IHD are important considerations in anticipation of a possible need for revascularization. For these patients, it may be appropriate to proceed directly to coronary angiography [*see* Invasive Testing, *below*].

Beta blockade reduces the sensitivity of all noninvasive tests, particularly exercise ECG[41]; it is recommended that, whenever possible, beta blockers be withheld for four half-lives (approximately 48 hours) before noninvasive testing is undertaken. Digoxin causes resting ST segment depression and reduces the specificity of exercise ECG.

In general, it is cost-effective to perform exercise ECG as the initial test in most patients, followed by additional imaging for patients in whom further diagnostic or prognostic testing is warranted.[42] Noninvasive testing is not generally recommended as a screening test in asymptomatic persons. Specific exceptions include patients whose occupation requires periodic stress testing (e.g., pilots, firefighters, competitive athletes, and police).

Imaging Studies under Investigation

Several CT and magnetic resonance imaging techniques are currently under study for use in diagnosing patients with suspected angina or in stratifying such patients for risk of cardiac events. Of these techniques, the most widely used is electron-beam computed tomography (EBCT), which detects coronary artery calcification. Although the sensitivity of EBCT for the diagnosis of significant coronary artery stenosis is high, the specificity of EBCT for significant coronary artery stenoses ranges from only 41% to 76%, yielding many false positive results. Some studies suggest that the "calcium score" derived from EBCT predicts the extent of angiographically detected CAD.[43] Studies that correlate calcium scores with risk of future cardiac events have been fraught with methodologic problems[44,45]; it is not clear whether EBCT adds significantly to clinical risk assessment using validated tools such as the Framingham risk score.[46] To date, no prospective, population-based studies have investigated a potential association between calcium score derived from EBCT and risk of future coronary events; likewise, no studies have shown that screening for IHD with EBCT reduces mortality.

Asymptomatic patients identified as being at potentially high risk for cardiac events on the basis of EBCT may suffer anxiety and undergo unnecessary procedures as a result of the study. Estimates of the cost efficacy of EBCT relative to current strategies for diagnosis and risk stratification are varied and are sensitive to the prevalence of disease in a screened population; currently, the clinical benefits of screening asymptomatic patients are uncertain.[47] The ACC/AHA guidelines do not recommend EBCT and other imaging procedures, such as MRI angiography, in asymptomatic patients.[48] Although EBCT testing is currently not recommended as a screening test, it is reasonable to evaluate patients who have undergone EBCT and who have been found to have severe coronary calcification with some form of noninvasive testing.

INVASIVE TESTING

Coronary angiography provides unequaled detail of coronary anatomy, including detail sufficient to enable evaluation for possible revascularization; however, angiography is invasive and expensive compared with noninvasive testing. In addition, although angiography identifies the degree and distribution of coronary stenoses, it provides inconsistent assessment of the functional significance and stability of a particular coronary lesion[32]; for example, plaques that can possibly rupture and thereby cause acute coronary syndromes are commonly angiographically insignificant.[18] Moreover, studies have called into question the reliability of angiographic measurements of coronary stenosis in some settings.[49]

The decision to pursue angiography should be based on preferences of the patient and provider, coexisting illnesses, esti-

mates of the probability of high-risk IHD, and the urgency to confirm or refute a possible diagnosis of IHD.

Direct referral for coronary angiography is recommended for patients who have survived sudden death, because of the high probability of multivessel IHD in these patients.[32] Other patients for whom angiography is recommended as a diagnostic test include those for whom the diagnosis of IHD remains uncertain despite noninvasive testing, provided the benefit of a more certain diagnosis outweighs the risk and cost of angiography; patients who cannot undergo noninvasive testing because of disability, illness, or morbid obesity; patients with suspected nonatherosclerotic angina (e.g., coronary dissection, coronary anomaly, Kawasaki disease, and coronary artery spasm); and patients with a high pretest probability of disease of the left main coronary artery or three-vessel IHD [*see* Prognostic Value of Coronary Angiography, *below*].[32]

DIAGNOSIS OF CHRONIC STABLE ANGINA

The presence of clinically stable, typical angina for a period of 2 or more months is adequate to establish the diagnosis of chronic stable angina. As mentioned [*see* Preliminary Evaluation, *above*], an accurate estimate of the likelihood of significant IHD can be established from simple clinical criteria (i.e., characteristics of chest pain and cardiovascular risk factors). For patients with an uncertain diagnosis after undergoing clinical assessment, particularly patients with some cardiovascular risk factors and an atypical angina syndrome, noninvasive testing is valuable for establishing the diagnosis of IHD. IHD can be confirmed by coronary angiography, which is also helpful in defining the severity of coronary atherosclerosis [*see* Risk Stratification in Patients with Chronic Stable Angina, *below*].

RISK STRATIFICATION IN PATIENTS WITH CHRONIC STABLE ANGINA

Risk stratification that determines the prognosis for MI or death is essential in determining treatment recommendations for patients with chronic stable angina. In general, a patient's coronary risk is determined by the interplay of four factors[32]: (1) left ventricular systolic function; (2) the extent and severity of atherosclerotic occlusion of the coronary tree (i.e., ischemic burden); (3) plaque stability (i.e., risk of plaque rupture); and (4) coexisting medical conditions. Clinical parameters, results of noninvasive testing, and coronary angiography provide important prognostic and diagnostic information.

Clinical Parameters Indicating High Risk

Although noninvasive testing and coronary angiography are the mainstays of risk stratification, clinical parameters alone are sufficient to identify some patients as having a high probability of severe IHD (i.e., three-vessel disease or left main CAD). Hubbard and colleagues developed a simplified algorithm for predicting the probability of severe IHD on the basis of six clinical parameters: age, gender, presence of typical angina, presence of diabetes, insulin use, and prior MI (as indicated by history or ECG) [*see Figure 4*].[50] Older patients with multiple risk factors have a greater than 50% chance of having severe IHD and should be considered for direct referral for coronary angiography. In one study, a previous history of MI and the presence of a carotid bruit (a marker for peripheral vascular disease) more than doubled the probability of severe IHD.[51] Direct referral for coronary angiography is estimated to be cost-effective when the pretest probability of severe IHD is high.[52]

Follow-up Noninvasive Testing

Noninvasive testing is a sensible approach for the majority of patients without high-risk characteristics. Available diagnostic modalities predict death more accurately than cardiovascular events such as MI. Patients with IHD are stratified according to their risk of death into three categories: those at low risk (< 1% mortality a year); those at intermediate risk (1% to 3% mortality a year); and those at high risk (> 3% mortality a year). Persons estimated to be at low risk for death generally may be managed medically without further diagnostic testing unless their condition deteriorates.[32] Persons estimated to be at intermediate or high risk after initial noninvasive testing may need to undergo additional studies for the purpose of further risk stratification.

Left ventricular systolic function Declining left ventricular systolic function is the strongest single predictor of long-term mortality in patients with IHD.[53] Patients with an ejection fraction of less than 35% have a mortality in excess of 3% a year. Left ventricular function can be assessed by echocardiography, stress myocardial perfusion imaging with SPECT, angiographic ventriculography, or gated nuclear medicine studies. As noted, not all patients with angina require evaluation of left ventricular function. Patients with a normal resting ECG and no history of MI or CHF are very likely to have normal left ventricular systolic function (92% to 95% probability).[54] Patients with a history of CHF, MI, or ECG evidence of prior MI should undergo evaluation of left ventricular function.

Exercise treadmill ECG In addition to the diagnostic information it provides, exercise treadmill ECG testing supplies useful prognostic information. Exercise capacity during a treadmill test is one of the strongest predictors of cardiovascular risk. Exercise capacity is influenced, in part, by LV function, both at rest and with exercise. Several measures of exercise capacity are used: exercise duration, maximum heart rate, exercise duration × heart rate, and estimates of work measured in metabolic equivalents (METs). Other important variables include ECG measures of exercise-induced ischemia, as reflected in ST segment depression or elevation, and the duration of ST segment deviation during the recovery phase of the exercise protocol.

The Duke treadmill score (DTS) combines these exercise test variables and is the most widely used prognostic treadmill score.[55] The DTS is calculated as follows:

Exercise time (in min) – (5 × the ST segment deviation [in mm]) – (4 × the angina index)

The angina index equals 2 when angina is the reason for stopping the exercise test; it equals 1 when angina occurs during the test or the recovery period; and it equals 0 if no angina occurs. In patients with a low-risk DTS (i.e., ≥ +5), the 4-year survival is 99% (average annual mortality, 0.25%) [*see Table 7*]. Patients with a high-risk DTS (< –10) have a 4-year survival rate of 79% (average annual mortality, 5%). In one study, more than two thirds of outpatients with suspected IHD had low-risk scores, and only 4% of patients had high-risk scores.[55] Available data suggest that patients with frequent ventricular ectopy or a slow heart rate recovery time following exercise testing are also at increased risk for death during subsequent follow-up,[56] although it remains uncertain how best to incorporate this information into the stratification of risk.

Stress testing Stress myocardial perfusion imaging and stress echocardiography are commonly used in risk stratification

Table 7 Survival According to Risk Groups Based on Duke Treadmill Score (DTS)

Risk Group (DTS)	*Overall Survival (%)*	*4-Year Survival (%)*	*Annual Mortality (%)*
Low risk (≥ +5)	62	0.99	0.25
Moderate risk (–10 to +4)	34	0.95	1.25
High risk (< –10)	4	0.79	5.0

of patients with IHD, although their prognostic value is less known than that of exercise ECG.[57] In patients with an intermediate-risk exercise ECG (DTS < +5 and ≥ –10), annual mortality is between 1% and 3%; these patients are usually referred for additional diagnostic testing, either stress imaging or coronary angiography. In patients with a high-risk exercise ECG result (DTS < –10), annual cardiac mortality is estimated to exceed 3%; these patients are generally referred for coronary angiography. Patients with a low-risk exercise ECG (DTS ≥ +5) require no further testing and may be medically managed. It is also appropriate to obtain a stress imaging study for purposes of risk stratification for patients who are unable to exercise and for patients with uninterpretable rest ECGs. Stress imaging studies are preferred over exercise ECG for evaluating ischemia in symptomatic patients who have previously undergone revascularization.

A normal poststress myocardial perfusion imaging study, as with a low-risk exercise ECG, indicates an excellent prognosis, even among patients with chronic stable angina.[58] The number, size, and location of abnormalities on stress myocardial perfusion studies indicate the distribution and severity of coronary artery stenoses; larger and more numerous perfusion defects are associated with more severe CAD. Stress-induced LV dysfunction—a marker of severe multivessel IHD—is indicated by LV dilatation or lung uptake of radionuclide tracer.[59,60] Patients with two or more moderate to large stress-induced perfusion defects or evidence of stress-induced LV dysfunction are considered to have a high probability of severe IHD; these patients are candidates for referral for coronary angiography.

A negative stress echocardiogram also indicates a good prognosis.[61] In the presence of significant IHD, stress induces regional wall motion abnormalities in the myocardial regions supplied by the stenotic coronary vessel. Stress-induced wall motion abnormalities involving two or more segments at lower levels of stress predict high-risk IHD. As with stress myocardial perfusion imaging, stress-induced LV dilatation suggests multivessel IHD. Abnormal stress echocardiography provides diagnostic and prognostic information that is incremental to that obtained by exercise ECG,[62] although there are relatively fewer follow-up data for this test than for myocardial perfusion studies.

Prognostic Value of Coronary Angiography

The anatomic extent of IHD is a powerful indicator of prognosis. Referral for coronary angiography should be considered for patients with a high-risk exercise ECG (DTS < –10), a high-risk stress myocardial perfusion imaging study, or a high-risk stress echocardiogram, provided the patient is a candidate for revascularization.

In the Coronary Artery Surgery Study database of patients with suspected IHD who were referred for coronary angiography, the 12-year survival rate for patients with normal coronary arteries was 91%, compared with 74% for patients with one-vessel disease, 59% for patients with two-vessel disease, and 40% for patients with three-vessel disease.[63] Proximal lesions are associated with greater risk than more distal lesions.[64] LV function remains crucially important. For example, the 5-year survival of a 65-year-old man with stable angina, three-vessel coronary stenoses, and normal LV function is 93%, compared with 5-year survival of only 58% in a similar patient with an LV ejection fraction of 30%.[64] Although angiography provides detailed information about the extent and severity of stenoses, it does not define which ones are actually responsible for anginal symptoms. Furthermore, the atherosclerotic plaques most likely to rupture and to thereby cause acute coronary syndromes, including MI and death, are often missed by coronary angiography.[18]

In summary, for patients with IHD, the strongest predictor of long-term survival is LV systolic function. A second determinant of survival is the severity and distribution of coronary lesions. A third determinant is the stability of coronary plaques; plaque instability and rupture increase the short-term risk of unstable coronary syndromes and death. Currently, there is no satisfactory means to measure this third determinant.

Treatment

The two overarching goals of the treatment of patients with chronic stable angina are to reduce the likelihood of untoward clinical events (i.e., acute coronary syndromes and sudden death) and to improve quality of life by reducing anginal symptoms and enhancing function. Treatment options include lifestyle modifications, medications, and revascularization. Evidence-based guidelines have been published, and a general approach to the treatment of patients with chronic stable angina is outlined below. However, management should be individualized in accordance with a patient's risk of adverse outcomes, coexisting conditions, and preferences, as well as in consideration of the cost and effectiveness of therapeutic alternatives. An ACC/AHA/ACP expert panel developed an mnemonic for the treatment of patients with chronic stable angina [*see Table 8*].[21]

LIFESTYLE MODIFICATION

Smoking Cessation

Among nonpharmacologic interventions, smoking cessation has the greatest impact on total mortality and cardiovascular risk. A systematic review of prospective cohort studies of smokers with IHD found a striking 29% to 36% relative risk reduction in all-cause mortality for patients who were able to quit smoking.[65] Most patients in these cohort studies had previous MI, angioplasty, or coronary artery bypass grafting (CABG) at the time

Table 8 The "ABCDEs" of Treatment for Patients with Chronic Stable Angina[20]

A = Aspirin and antianginal therapy; ACE inhibitors should be considered for most patients
B = Beta blocker and blood pressure
C = Cigarette smoking and cholesterol
D = Diet and diabetes
E = Education and exercise

ACE—angiotensin–converting enzyme

of entry into the study. The magnitude of the risk reduction for smoking cessation was as great as or greater than that expected to result from use of aspirin, statins, beta blockers, or angiotensin-converting enzyme (ACE) inhibitors. Smoking cessation should be strongly and repeatedly recommended to all patients with known or suspected IHD who smoke. Physicians should become accustomed to applying effective techniques for counseling patients and using effective medications such as nicotine replacement and bupropion. Patients' efforts to quit are often more effective in the setting of a formal smoking-cessation program; therefore, internists should be familiar with local smoking-cessation resources and programs.

Physical Activity and Dietary Modifications

Physical activity Regular physical activity and dietary modifications also reduce cardiovascular risk. Physical fitness during middle age is associated with lower long-term cardiovascular mortality[66]; in addition, self-reported increases in physical activity is associated with reduced all-cause and cardiovascular mortality in elderly men.[67] In the Health Professionals Follow-up Study, half an hour or more of brisk walking each day was associated with an 18% relative risk reduction in cardiovascular events; in addition, greater duration and intensity of exercise were associated with greater reductions in risk.[68] This study also suggested that weight training was associated with a decreased cardiovascular risk. Although these observational studies are potentially subject to bias, the preponderance of evidence strongly supports recommending regular physical activity to patients.

Patients with chronic stable angina should be encouraged to include moderate aerobic activity in their daily lives.[21] Moderate physical activity consists of walking briskly for 30 minutes or more five to seven times a week or the equivalent. Unresolved questions include whether more vigorous physical activity provides greater risk reduction than moderate exercise; whether sustained aerobic exercise of 30 or more minutes is necessary for cardiovascular benefit or whether an accumulation of 30 or more minutes of physical activity during the day is sufficient; and to what extent physical activity provides reductions in risk above and beyond those achieved simply through modification of specific risk factors, such as dyslipidemia, hypertension, and diabetes.

Dietary modification Diet also has the potential to modify multiple coronary risk factors—namely, lipid levels, obesity, insulin resistance, and hypertension. Although trials assessing the effects of dietary modification on stable IHD have not uniformly demonstrated benefit, several trials have shown reductions in cardiac mortality. In the Lyon Diet Heart Study, patients who had had an MI were randomized either to adopt a Mediterranean diet rich in fresh fruits and vegetables, whole grains, olive oil, fish, and relatively little meat or to adopt a prudent Western diet low in saturated fats. At 4 years' follow-up, patients randomized to the Mediterranean diet enjoyed a 2.5% to 3% per year reduction in cardiac death and nonfatal MI.[69] Another trial randomized patients with IHD (about half of whom had a history of MI) either to adopt an Indo-Mediterranean diet rich in fresh fruits, vegetables, legumes, nuts, and whole grains and supplemented with omega-3 fatty acids or to adopt a prudent Indian diet low in saturated fats. Moderate exercise was recommended for all patients. Patients randomized to the Indo-Mediterranean diet had a 7.4% absolute reduction in the risk of MI or cardiac death at 2 years' follow-up.[70] Patients randomized to the intervention diet had significant reductions in daily intake of calories, protein, fat (mostly saturated), cholesterol, and salt; they ingested significantly more complex carbohydrates, fiber, monounsaturated and polyunsaturated fats, fruits, vegetables, legumes, nuts, and omega-3 polyunsaturated oils.

Other studies demonstrate evidence of the protective benefit of fresh fruits and vegetables. The Nurses' Health Study and Health Professionals Follow-up Study found that persons in the highest quintile of fruit and vegetable intake had a 20% relative risk reduction for nonfatal MI or cardiac death compared with the lowest quintile.[71] A review of diet and IHD concluded that three dietary strategies are effective at reducing the risk of IHD: (1) substituting unsaturated fats (particularly polyunsaturated fats) for saturated fats (e.g., animal fats) and *trans*-fatty acids (e.g., stick margarine, vegetable shortenings, many commercially prepared baked goods, and deep-fried foods); (2) increasing consumption of omega-3 fatty acids (e.g., oily fish, canola oil, soybean oil, and flaxseed oils); and (3) consuming a diet high in fruits, vegetables, nuts, and whole grains and low in refined grains.[72]

MEDICAL THERAPY TO REDUCE CARDIOVASCULAR RISK

Antiplatelet Agents

Aspirin Acute coronary events commonly result from rupture of an atherosclerotic plaque and subsequent platelet aggregation and thrombosis. Aspirin inhibits cyclooxygenase and the synthesis of prothrombotic platelet thromboxane A_2. In studies of more than 3,000 patients with chronic stable angina that compared treatment with aspirin to placebo, the use of aspirin reduced the risk of adverse cardiovascular events by 33% over 6 months.[73,74] This reduction in relative risk corresponds to a reduction in absolute risk of approximately 5%. In other words, five cardiovascular events would be prevented for every 100 persons with known cardiovascular disease treated with aspirin for 6 months.[73] In the Swedish Angina Pectoris Aspirin Trial, which involved patients with stable angina, the addition of aspirin (75 mg daily) to a regimen of sotalol resulted in a 34% decrease in MI and sudden death[75]; most of this decrease involved reductions in the incidence of first MI. In the Physician's Health Study, which involved asymptomatic middle-aged men, the use of aspirin (325 mg every other day) was associated with a decrease in the incidence of MI.[76] Doses ranging from 75 to 325 mg daily were found to offer equivalent benefit,[77] although the incidence of gastrointestinal toxicity was dose-dependent. All patients with chronic stable angina should be treated with aspirin unless there is a history of documented aspirin allergy or life-threatening gastrointestinal hemorrhage.

Aspirin alternatives Two thienopyridine derivatives, clopidogrel and ticlopidine, inhibit adenosine diphosphate–mediated activation of platelet glycoprotein IIb/IIIa. These agents, particularly clopidogrel, are reasonable alternatives for aspirin-intolerant patients with chronic stable angina. In a randomized, controlled trial of patients with symptomatic vascular disease (including patients with chronic stable angina), clopidogrel was slightly more effective than aspirin in reducing the risk of MI, vascular death, and ischemic stroke.[78] Clopidogrel is much more expensive than aspirin; in addition, approximately 200 more patients would need to be treated with clopidogrel than with aspirin for 2 years to prevent one major vascular event.[79] There are no studies demonstrating that ticlopidine reduces cardiovascu-

lar events in outpatients with chronic stable angina. Ticlopidine can cause cytopenia, and there is a reported rare association with thrombotic thrombocytopenic purpura.

Lipid-Lowering Agents

There are abundant data showing the beneficial effects of lipid-lowering therapy in patients with chronic stable angina. Each 1% reduction in total cholesterol is associated with an approximately 2% reduction in coronary events.[80] In the Scandinavian Simvastatin Survival Study, patients with documented ischemic heart disease (including chronic stable angina) and elevated total cholesterol levels (i.e., levels of 212 to 308 mg/dl) were randomized to receive either a statin or placebo.[81] A 30% to 35% reduction in mortality and major coronary events was observed in patients receiving a statin. In the Cholesterol and Recurrent Events Trial, patients with prior MI and somewhat lower cholesterol levels (i.e., mean total cholesterol and LDL cholesterol of 209 mg/dl and 139 mg/dl, respectively) had a 25% relative risk reduction in the composite outcome of fatal or nonfatal MI when treated with a statin.[82] In the Heart Protection Study, patients with IHD or conditions that confer a similarly high risk of MI or coronary death (e.g., peripheral vascular disease, cerebrovascular disease, or diabetes) were randomized to receive either simvastatin (40 mg) or placebo, irrespective of baseline LDL level.[83] Statin therapy reduced total mortality; the incidence of first MI, coronary death, and stroke; and the use of revascularization procedures among all groups of patients, including those with LDL cholesterol levels of less than 116 mg/dl at entry (3.0 mmol/L). From this study, it may be concluded that all patients with chronic stable angina should be treated with a statin, barring specific allergy. Detailed recommendations for lipid-lowering therapy are provided by the National Cholesterol Education Program Adult Treatment Program III (NCEP ATP III).[30]

The target for therapy for patients with known IHD, including patients with chronic stable angina, is a serum LDL cholesterol level of less than 100 mg/dl. Patients with diabetes, peripheral vascular disease, and cerebrovascular disease are regarded as having a risk of cardiovascular events equivalent to patients with established IHD; the target for therapy in these patients is an LDL cholesterol level of less than 100 mg/dl, which is the same as in patients with known IHD. For other patients, including patients with possible IHD (e.g., a patient with atypical angina and a nondiagnostic exercise treadmill test) or two or more cardiovascular risk factors, the aggressiveness of lipid-lowering therapy is determined by calculating cardiovascular risk from the Framingham risk calculator[30] and the Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm) [*see Figure 2*].

Available data suggest a potential benefit for more aggressive lowering of LDL cholesterol. In one study, low-risk patients with stable, mild to moderate angina were randomized to receive either atorvastatin, 80 mg daily, or percutaneous coronary intervention (PCI) followed by usual care (including lipid-lowering treatment). Patients receiving atorvastatin required fewer revascularization procedures or admissions for worsening angina with objective evidence of ischemia (13.4% versus 20.9%).[84] Patients in the atorvastatin-treated group reached an average LDL cholesterol level of 77 mg/dl, as compared with 119 mg/dl in the PCI group. A second study compared the effects of intensive lipid-lowering therapy using atorvastatin (80 mg/day) with moderate lipid-lowering therapy using pravastatin (40 mg/day).[85] Patients treated with atorvastatin (80 mg/day) achieved an average LDL cholesterol level of 79 mg/dl (2.05 mmol/L) and showed less progression of coronary atherosclerosis than patients treated with pravastatin (40 mg/day), who achieved an average LDL cholesterol level of 110 mg/dl (2.85 mmol/L).

Statin therapy is associated with several important potential adverse reactions. Elevations of liver transaminase levels have been described in patients taking statin drugs, although elevations to levels greater than three times the upper limit of normal (necessitating discontinuance) occur in fewer than 0.3% to 0.5% of patients.[86]

Rhabdomyolysis from statins is an uncommon dose-related phenomenon that usually occurs within the first few weeks of therapy, but it may occur at any time; rhabdomyolysis resolves after withdrawal of the offending drug. Clinically significant myopathy with 10-fold elevations of creatine kinase (CK) occurs in about 0.5% of patients treated with statins.[86] Massive rhabdomyolysis usually occurs only with concomitant use of clofibrate, niacin, or gemfibrozil. The incidence appears to be higher with drugs that interfere with the cytochrome P-450 system (e.g., simvastatin, lovastatin, and atorvastatin) and lower with less potent agents (e.g., pravastatin and fluvastatin). Predispositions to this adverse effect include certain P-450 polymorphisms (CYP3A4), renal failure, liver disease, hypothryoidism, concomitant medications (e.g, macrolides, azole antifungals, cyclosporine, protease inhibitors, selective serotonin reuptake inhibitors, nefazodone, verapamil, diltiazem, and amiodarone), and ingestion of grapefruit juice in quantity.[87] Myopathy can also occur without elevation of CK.[88]

Niacin, fibric acid derivatives (e.g., gemfibrozil and clofibrate), and bile acid sequestrants (e.g., cholestyramine and colestipol) reduce cholesterol an average of 6% to 15%. Niacin raises the HDL cholesterol, lowers the LDL cholesterol, and reduces the level of triglycerides. A meta-analysis of 37 studies suggests that the lipid-lowering effect of these agents is associated with reduced coronary mortality and total mortality.[89] In high-risk patients with a low HDL cholesterol level or hypertriglyceridemia, it is reasonable to consider the use of niacin or a fibric acid derivative, alone or in combination with a statin.[90-92] In the Veterans Affairs HDL Intervention Trial (VA-HIT), patients with established IHD and low HDL cholesterol levels who were randomized to receive gemfibrozil experienced a significant reduction in major cardiovascular events and cardiovascular mortality, as compared with patients who received placebo.[90] In another study, patients with established IHD and low levels of HDL cholesterol who were randomized to receive simvastatin plus niacin had fewer first cardiovascular events, as compared with patients who received placebo or simvastatin alone.[91]

Ezetimibe represents a new class of agent that inhibits intestinal absorption of cholesterol and produces moderate reductions in LDL cholesterol. Its principal indication at this time, as with the bile-acid sequestrants, is to augment the lipid-lowering efficacy of a statin.[93] Ezetimibe is associated with fewer gastrointestinal side effects than bile-acid sequestrants. Niacin commonly causes flushing, a side effect that can be mitigated by gradual titration toward a target dose and by pretreatment with aspirin. Extended-release preparations of niacin are associated with less flushing. Niacin modestly increases glucose intolerance and can cause hyperuricemia. As with statins, niacin and fibric acid derivatives are associated with a risk of elevations in transaminase

levels, as well as with infrequent hepatitis and rare myositis. Although the manufacturers of these drugs recommend routine laboratory evaluation of liver function, routine monitoring was shown to have a low yield in a primary care practice.[94]

Reduction of non-LDL cholesterol lipid fractions may also reduce cardiovascular risk, particularly in patients who have the metabolic syndrome. Although definitions vary, the metabolic syndrome is a constellation of cardiovascular risk factors, including insulin resistance, obesity, hypertension, and dyslipidemia.[95] The dyslipidemia characteristic of the metabolic syndrome consists of elevated triglycerides, a low HDL cholesterol level, and a normal (or near-normal) LDL cholesterol level. Retrospective analysis of the VA-HIT, which studied patients with established coronary disease and low HDL cholesterol levels, suggested that the benefits of treatment with gemfibrozil are most pronounced in patients with insulin resistance (whose fasting plasma insulin levels were comparable to those found in patients with the metabolic syndrome).[96] Because patients with the metabolic syndrome have elevated cardiovascular risk despite often having unremarkable LDL cholesterol levels, NCEP ATP III recommends measuring non-HDL cholesterol in patients with elevated triglyceride levels (i.e., triglyceride levels ≥ 200 mg/dl or 2.25 mmol/L) through use of the following formula:

Non-HDL cholesterol = measured total cholesterol – HDL cholesterol

The level of non-HDL cholesterol determined by this formula corresponds to the sum of LDL cholesterol and atherogenic remnant lipoproteins containing apolipoprotein B (very low density lipoprotein cholesterol). Among patients with hypertriglyceridemia, the target level for non-HDL cholesterol is less than 130 mg/dl for patients with IHD or IHD equivalent conditions, as well as for patients with two or more cardiovascular risk factors and a 10-year risk of cardiovascular events greater than 20%, as determined by the Framingham risk estimates [*see Figure 2*].[30]

In summary, numerous studies demonstrate that patients with IHD benefit from treatment with statins; this includes IHD patients with relatively normal LDL cholesterol levels. The vast majority of patients with chronic stable angina should be treated with a statin. Treatment with niacin or fibric acid derivatives should be considered in patients with a low HDL cholesterol level or an elevated triglyceride level. In view of the consistent benefits of statins across many patient subsets, it would be most reasonable to consider adding niacin or fibric acid derivatives to statin therapy.

Antihypertensive Therapy

Hypertension contributes to cardiovascular risk by increasing myocardial wall stress, oxygen demand, and endothelial injury. Treatment of hypertension in patients with IHD reduces the risk of future cardiovascular events.[97] A reduction in systolic blood pressure of 2 mm Hg is associated with a 7% reduction in mortality from IHD.[98] By lowering myocardial oxygen demand, treatment of hypertension may also improve anginal symptoms. The therapeutic target for patients with IHD is to maintain blood pressure at levels below 140/90 mm Hg.[99]

Two groups of patients with hypertension and chronic stable angina warrant particular consideration: patients with specific coexisting chronic conditions (e.g., diabetes, heart failure, or renal insufficiency) and patients with LVH. Guidelines from the Joint National Committee for the Diagnosis, Evaluation, and Treatment of Hypertension (JNC) recommend a lower therapeutic target blood pressure for hypertensive patients who have diabetes, heart failure, or renal insufficiency—namely, a level below 130/85 mm Hg.[99] Although no specific target has been promulgated for therapy for hypertension and LVH, the latter is a marker for the severity and chronicity of hypertension and is a risk factor for MI, CHF, and cardiac sudden death.[100] Treatment of hypertension results in the regression of LVH; ECG evidence of LVH regression is associated with a significantly reduced risk of cardiovascular events.[101] Patients with LVH should therefore be targeted for aggressive antihypertensive therapy.

Two classes of antihypertensives—beta-adrenergic receptor antagonists (i.e., beta blockers) and calcium channel blockers—are also effective antianginal medications. Beta blockers confer mortality benefit in patients after MI[102] and are recommended as first-line therapy for most patients with chronic stable angina.[32] Calcium channel blockers (e.g., diltiazem, verapamil, and long-acting dihydropyridines) are also effective antihypertensive and antianginal medications. Current ACC/AHA/ACP guidelines recommend beta blockers as first-line antihypertensive therapy in patients with chronic stable angina. Long-acting calcium channel blockers are an acceptable alternative, particularly in patients without a history of MI.[102]

ACE Inhibitors

Results of the Heart Outcomes Prevention Evaluation (HOPE) trial demonstrated that ACE inhibitors reduced MI, stroke, and cardiovascular death in patients at high cardiovascular risk. In this study, patients with a history of IHD, diabetes, stroke, or peripheral vascular disease and at least one additional cardiovascular risk factor (e.g., hypertension, dyslipidemia, cigarette smoking, or microalbuminuria) were randomized to receive either ramipril (10 mg daily) or placebo; patients were followed for an average of 4 years. Total mortality was reduced 1.8% in the ramipril-treated group; in terms of numbers needed to treat (NNT), this means that 56 patients would need to be treated for 4 years to prevent one death. The primary outcome of MI, stroke, or cardiovascular death was reduced by 3.8% (NNT of 26). This study indicated that a broad range of patients at high risk for IHD who had normal left ventricular function obtained an impressive survival benefit from the use of ACE inhibitors. The magnitude of benefit was greater than might have been expected for the small decrement in average blood pressure observed in the study, suggesting a mechanism at work other than reduction in blood pressure.[103] In the European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease (EUROPA), patients with stable coronary disease and no known congestive heart failure or uncontrolled hypertension were randomized to receive either the ACE inhibitor perindopril or placebo.[104] Combined cardiovascular end points were significantly reduced in the perindopril group; in addition, there was a nonsignificant reduction in total mortality. On the basis of the HOPE and EUROPA trials, it can be concluded that most patients with chronic stable angina should be treated with an ACE inhibitor, barring renal insufficiency, hyperkalemia, or an allergy to ACE inhibitors. Angiotensin receptor blockers may offer a similar benefit, but these agents have not been extensively studied in this regard.

MEDICAL THERAPY FOR ANGINAL SYMPTOMS

The major classes of medications for the treatment of angina include beta blockers, calcium channel blockers, and nitroglycerin/nitrates. Randomized trials demonstrate that beta blockers

and calcium channel blockers are equally effective in relieving angina and improving exercise tolerance.[105,106] Current guidelines, however, recommend beta blockers as first-line therapy[32,33] because they improve survival and reduce cardiac events in patients who have had a previous acute MI[107] and in elderly patients with systolic hypertension[108]; no similar benefits have been demonstrated for calcium channel blockers or nitrates. In addition, beta blockers improve survival and reduce the risk of stroke and congestive heart failure in patients with hypertension.[109] Beta blockers should be considered as initial antianginal therapy in patients with chronic stable angina.

Beta Blockers

Beta blockers decrease heart rate, myocardial contractility, blood pressure, and myocardial oxygen demand by inhibiting cardiac and peripheral beta-adrenergic receptors. Beta blockers delay the onset of angina and increase exercise capacity in patients with exertional angina.[110,111] They are titrated to a dose adequate to reduce the resting heart rate to 55 to 60 beats/min. Titration to lower heart rates may be necessary in patients with more severe angina, provided patients do not develop heart block or symptoms of severe bradycardia.

Beta blockers are generally well tolerated by patients with chronic obstructive pulmonary disease; however, they may exacerbate bronchospasm in patients with severe asthma. Beta blockers are well tolerated in patients with diabetes, and in these patients, they can reduce macrovascular events[112]; theoretically, however, beta blockers can mask the adrenergically mediated symptoms of hypoglycemia insulin (e.g., tachycardia).

Beta blockers are contraindicated in the presence of severe bradycardia, high-degree atrioventricular block, sinus node dysfunction, and uncompensated congestive heart failure. Patients with extensive peripheral vascular disease and claudication may experience worsening of their symptoms. Beta blockers are also contraindicated in the small subset of patients with pure variant or vasospastic angina (i.e., angina occurring in the absence of fixed obstruction of the coronary arteries), in whom beta blockade is unlikely to alleviate symptoms. In these patients, beta blockers may actually worsen angina as a result of unopposed alpha-adrenergic effects. Calcium channel blockers are the preferred first-line agent in this patient group [*see* Calcium Channel Blockers, *below*].

Calcium Channel Blockers

Calcium channel blockers reduce smooth muscle tone and cause coronary and peripheral vasodilatation, improving coronary blood flow and reducing peripheral vascular resistance. Calcium channel blockers can be used as monotherapy in the treatment of chronic stable angina, although combinations of beta blockers and calcium channel blockers relieve angina more effectively than either agent alone. Combination therapy with a beta blocker may blunt the reflex tachycardia that can occur with dihydropyridine calcium channel antagonists. All calcium channel blockers exert some negative inotropic effect, although this effect is typically most significant clinically with the nondihydropyridine agents verapamil and diltiazem. Calcium channel blockers are contraindicated in the presence of decompensated congestive heart failure, although the vasoselective dihydropyridine agents amlodipine and felodipine are tolerated in patients with clinically stable LV dysfunction.[113] Verapamil and diltiazem have a pronounced effect on heart rate and conduction; they should be used with caution in combination with beta blockers because of the increased risk of heart block associated with the combined use of these agents. Constipation and peripheral edema are common side effects of calcium channel blockers.

Nitrates and Nitroglycerin

Nitrates and nitroglycerin dilate coronary arteries and their collateral vessels, directly improve myocardial perfusion, diminish afterload, and increase venous capacitance. These agents exert antianginal effects by improving coronary blood flow and by reducing myocardial oxygen demand. Long-acting nitrate preparations, in tablet or patch form, reduce the severity and frequency of angina and improve exercise tolerance; however, they often induce a reflexive increase in sympathetic tone and increase heart rate. Therefore, long-acting nitrates are often used in combination with beta blockers or calcium channel blockers. Short-acting nitroglycerin tablets or spray is appropriate for the immediate relief of exercise-induced or rest angina. They may also prevent angina when taken several minutes before exertion sufficient to cause angina.

Nitroglycerin and nitrates should not be used within 24 hours of taking sildenafil (Viagra) or other phosphodiesterase inhibitors used in the treatment of erectile dysfunction, because of the potential for life-threatening hypotension.[114] It is important to discuss this interaction with patients taking nitrates or sildenafil. Nitroglycerin and nitrates are relatively contraindicated in patients with severe aortic stenosis or hypertrophic obstructive cardiomyopathy because of an increased risk of syncope resulting from diminished cardiac output. Continued use of long-acting nitrates results in tachyphylaxis; the mechanism of this is unclear. An adequate nitrate-free period (8 to 12 hours each day) is necessary to minimize this effect. Headaches are common and often limit nitroglycerin and nitrate therapy; with continued use, headaches will diminish in up to 80% of patients. Hypotension may occur, particularly in hypovolemic patients.

In general, patients who are found to be at low or moderate risk for cardiovascular complications during risk stratification should be treated aggressively with medical therapy. Medical therapy should not be considered to have failed until the patient has been treated with full therapeutic doses of a beta blocker, a calcium channel blocker, and a long-acting nitrate and continues to experience angina or develops unacceptable adverse effects.

PATIENTS WITH DIABETES MELLITUS

IHD therapy for patients with diabetes merits special consideration. Cardiovascular events are the leading cause of death in patients with diabetes, and this patient group is at particularly high risk for MI. Middle-aged persons with diabetes and no history of MI have a risk of MI and cardiac death equivalent to that of nondiabetic patients with a history of MI.[115] A substudy of the Heart Protection Study demonstrated that treatment with statins reduced major coronary and major vascular events, even among diabetic patients without a prior diagnosis of ischemic heart disease and among diabetic patients with LDL cholesterol levels lower than 116 mg/dl (3 mmol/L).[116] Treatment with statins resulted in a relative risk reduction for major coronary events (nonfatal MI and coronary death [27%]), stroke (25%), and first revascularization procedures (17%). A HOPE substudy demonstrated the benefits of ACE inhibitors in patients with diabetes and one or more cardiovascular risk factors.[117] Treatment with an ACE inhibitor resulted in a 25% reduction in MI, stroke, or cardiovascular death. Total mortality was reduced 24%; progression to overt nephropathy was reduced by 24%. In the United Kingdom

Prospective Diabetes Study, beta blockers were found to be equivalent to ACE inhibitors in reducing the risk of macrovascular complications.[112] Another study found that cardiovascular events were more common in patients with type 2 diabetes mellitus and hypertension who were randomized to receive a dihydropyridine calcium channel blocker, as compared with patients who received an ACE inhibitor.[118] It remains uncertain whether to attribute this result to a higher risk of cardiovascular events among the group taking the calcium channel blocker amlodipine or to a reduced risk of cardiovascular events among the group taking the ACE inhibitor fosinopril. Nevertheless, most experts consider calcium channel blockers to be third-line agents for patients with diabetes and hypertension. Results of the Hypertension Optimal Treatment (HOT) study support aggressive blood pressure reduction in patients with diabetes; the target blood pressure for these patients is 135/80 mm Hg or lower.[119]

Although it remains uncertain when to initiate antiplatelet therapy in diabetic patients, it is reasonable to treat diabetic patients who have any additional cardiovascular risk factor with aspirin or an equivalent antiplatelet therapy.[120] The American Diabetes Association and the NCEP recommend a target LDL cholesterol level of 100 mg/dl (2.59 mmol/L) or lower.[31,121]

REVASCULARIZATION

Techniques for revascularization include PCI, using catheter-based methods with or without placement of intracoronary stents, and CABG. For most patients with angina, survival with optimal medical therapy is equivalent to that resulting from revascularization; in addition, CABG results in excellent symptom relief. For a select few patients with chronic stable angina, revascularization is associated with improved survival, as compared with that achieved with medical therapy.[122] Among 2,649 patients with left main coronary stenoses or multivessel coronary artery disease and reduced LV systolic function, those who were treated with CABG in randomized trials had an absolute mortality at 5 years that was more than 5% lower than that of patients assigned to medical management (10.2% versus 15.8%).[123] This benefit persisted at 10 years' follow-up. There is much weaker evidence to suggest that patients with proximal stenoses of the left anterior descending coronary artery and normal LV function also experience lower mortality with CABG. One randomized trial showed no difference in mortality among patients assigned to CABG, PCI, or medical management.[124] In two trials comparing CABG with PCI, survival was equivalent; however, the patients who underwent surgery had fewer symptoms and required fewer antianginal medications and subsequent revascularization procedures.[125,126] Initial costs and short-term (procedure-related) mortality were higher in patients who underwent CABG. Most of the patients enrolled had two-vessel CAD and normal LV systolic function. In one study, survival was improved in patients with diabetes who underwent CABG, as compared with patients who underwent PCI.[125]

Randomized trials comparing PCI with medical management in patients with one- or two-vessel CAD and normal LV systolic function have demonstrated equivalent survival.[127,128] Relief of symptoms was generally greater with PCI than that seen with medical therapy, although PCI was associated with an increased risk of procedure-related MI and death[127,128] and substantially greater cost.[129]

On the basis of a limited number of randomized trials, it appears that only the subgroup of patients with severe coronary disease (defined as two- or three-vessel disease) and impaired LV function can confidently expect improved average survival after revascularization and that improvement is seen only with CABG. Thus, evaluation for revascularization is generally recommended for patients who are at moderate or high risk of death and who are willing to undergo a revascularization procedure.[32] Patients meeting these criteria who are found to have either extensive areas of ischemia on noninvasive testing or reduced LV systolic function should then be considered candidates for angiography. It should be recognized, however, that the results of currently available studies comparing PCI, CABG, and medical therapy do not reflect recent advancements in all three forms of treatment. For example, restenosis rates with PCI using stents, drug-eluting stents, and platelet inhibitors are lower than previously reported rates with angioplasty techniques.

In general, medical therapy is preferred in patients who are determined through risk stratification by noninvasive testing to be at low risk for death. There is no evidence that revascularization improves survival in such patients. For this reason, currently available evidence suggests that many revascularization procedures conducted in the United States may not be warranted.

COMPLICATIONS

Chronic stable angina, as the name suggests, is a long-standing stable or progressive condition caused, in most instances, by atherosclerotic narrowing of the coronary vessels. Coronary atherosclerosis, however, is a risk factor for acute coronary syndromes, including MI and sudden cardiac death. Much of the diagnostic evaluation of patients with chronic stable angina is undertaken to determine the intermediate-term risk of acute coronary events. Much of the treatment of patients with chronic stable angina is intended to reduce the risk of acute coronary complications, principally MI and sudden cardiac death. Another major complication of chronic stable angina is CHF. Major causes of CHF include MI and hypertension—common conditions in patients with IHD.[130] Finally, patients with IHD are at risk for other vascular diseases, namely stroke and peripheral vascular disease.

It is also important to consider complications of conditions that predispose patients to IHD. For example, diabetes is a major risk factor for IHD and is often complicated by peripheral vascular disease, renal insufficiency, neuropathy, and retinopathy. In addition to increasing the risk of IHD, cigarette smoking confers a significant risk of chronic pulmonary disease, cancer, and peripheral vascular disease.

FOLLOW-UP

Patients with chronic stable angina should be regularly followed in a primary care setting. There is little evidence to recommend a particular frequency of follow-up visits, although ACC/AHA/ACP guidelines suggest regular visits at 4- to 12-month intervals for patients with chronic stable angina.[21] The expert panel recommends addressing the following questions at each visit[21]:

- Has there been a change in the level of activity since the last visit?
- Have anginal symptoms increased in severity or frequency?
- Is current therapy well tolerated?
- Has the patient been successful at modifying cardiac risk factors?
- Has the patient developed new or worsening comorbid illnesses that may have an impact on the patient's angina?

It is important to inquire about changes in anginal symptoms or activity levels to identify patients who require increased intensity of antianginal therapy or further risk stratification. For example, it would be reasonable to repeat noninvasive testing in a patient with stable class II angina who developed new class III anginal symptoms since the last clinic visit. Similarly, in a patient with new symptoms of CHF, it would be appropriate to perform echocardiography and consider referral for coronary angiography; multiple-vessel CAD with reduced left ventricular function would be an indication for CABG.

Medical therapy should be reviewed at each visit to assess adherence to recommended therapy, knowledge about doses and indications, and potential side effects. In addition, it is worth considering whether recent evidence for benefit from new therapies or new indications for existing therapies support a modification of IHD management. Patients with chronic stable angina should be encouraged to quit smoking, to eat a prudent diet, and to regularly engage in moderate exercise. Successful adoption of these interventions is challenging, but repeated encouragement from a personal physician enhances success.[131]

Vital signs (i.e., heart rate, blood pressure, and weight) should be regularly followed. The physical examination is focused on the heart, lungs, and vasculature. Findings of particular note include signs of CHF, new or changing heart murmurs, arrhythmias, or evidence of carotid or peripheral vascular disease.

Laboratory assessment should include periodic measurements of fasting lipid levels. Regular measurements of liver transaminase and CK levels are not recommended in the absence of symptoms. Other laboratory testing is indicated by comorbid conditions or changes in the patient's history and physical examination.

There is no evidence showing that regular ECG studies are helpful in the management of patients with chronic stable angina in the absence of changes in history or physical examination. ECGs are indicated when new medications are introduced that may affect cardiac conduction. Changes in anginal or syncopal symptoms and findings suggestive of dysrhythmia or conduction abnormalities should also prompt a repeat ECG.

There is little evidence to guide the use of repeat stress testing in patients with chronic stable angina. Recommendations for follow-up stress testing vary according to initial assessments of a patient's cardiovascular risk.[21] For example, patients with class II angina whose exercise treadmill test places them at low risk have an annual risk of mortality of less than 1%; these patients do not require follow-up stress testing for a period of 3 to 4 years in the absence of new and concerning symptoms or signs. Similarly, patients who underwent PCI more than 6 months earlier and who have minimal residual stenosis are unlikely to benefit from regular stress testing. It is not known whether patients at intermediate or high cardiovascular risk benefit from periodic stress testing.

Follow-up noninvasive tests are selected according to the approach outlined (see above). When possible, the same form of stress (exercise or pharmacologic) and testing (ECG or imaging) should be repeated, because this permits the most valid comparison with the original study.[21]

Patients should be referred to a cardiologist when appropriate for consideration of revascularization. Candidates for referral include patients with valvular disorders that require repair, patients with angina that is refractory to maximal medical therapy, and patients with comorbidities that complicate therapy.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

X UNSTABLE ANGINA AND NON–ST SEGMENT ELEVATION MYOCARDIAL INFARCTION

Joel Kupersmith, m.d., f.a.c.p.
Amish Raval, m.d.

Definition

Acute coronary syndromes are the constellation of symptoms, signs, and electrocardiographic and laboratory findings associated with new-onset or worsening myocardial ischemia. They include the spectrum of acute ST segment elevation myocardial infarction (MI) with or without Q waves, non–ST segment elevation MI (NSTEMI), and unstable angina. The main difference between NSTEMI and unstable angina is that in the latter, the ischemia is not severe enough to cause cardiac enzyme elevation and tissue injury; however, this difference may not be apparent on initial presentation.[1,2]

Pathophysiology

Unstable angina/NSTEMI results from an acute reduction in myocardial oxygen supply caused by rupture or erosion of an atherosclerotic coronary plaque; this plaque disruption is associated with inflammation, thrombosis, vasoconstriction, and microvascular embolization. The plaques implicated in these syndromes usually had previously produced only minor obstruction to blood flow (on angiography, up to 70% of affected vessels have less than 50% stenosis of the lumen); in addition, these plaques are characterized by a large lipid pool, reduced collagen content, a thin fibrous cap, and inflammatory cells.[3-9] Embolization of platelets and clot fragments into the microvasculature results in microcirculatory ischemia, which may account for the slight elevation of cardiac biomarkers. The events leading to unstable angina/NSTEMI also affect atherosclerotic plaques in the rest of the coronary vascular tree and other vascular territories.[10-12]

Less common causes of unstable angina/NSTEMI include intense focal epicardial spasm, cardiac emboli, and severe progressive atherosclerotic narrowing without superimposed thrombus.[1] Rarely, secondary unstable angina can be precipitated by conditions that increase myocardial demand, such as thyrotoxicosis, sepsis, fever, tachycardia, and anemia. Secondary unstable angina usually occurs in patients who also have underlying stable coronary atherosclerosis. Cocaine and amphetamines can also induce the syndrome.

Diagnosis

clinical presentation

Unstable angina/NSTEMI has three principal presentations: (1) prolonged angina at rest, usually lasting less than 20 minutes; (2) new-onset angina that is severe, disabling, and prolonged or frequent; and (3) established angina that has become distinctly more frequent, longer in duration, or more easily provoked.[13]

history and physical examination

Five clinical factors are key to establishing the diagnosis and the prognosis in patients with suspected unstable angina/NSTEMI: the anginal symptoms; any history of coronary artery disease (CAD); patient sex; patient age; and traditional risk factors for CAD [*see Table 1*].[1]

In the initial evaluation of a patient with suspected unstable angina/NSTEMI, the clinician should elicit a full description of the chest pain, including its character, onset, severity, and duration. Jaw pain, neck pain, epigastric pain, and arm pain may be experienced in isolation or in concert with the chest discomfort. In the National Registry of Myocardial Infarction, which included 440,000 patients, one third had atypical symptoms.[14] In the Alabama Unstable Angina Study of Medicare beneficiaries, which included over 4,000 patients, 51.7% of patients with unstable angina had the following atypical symptoms: dyspnea (69.4%), nausea (37.7%), diaphoresis (25.2%), syncope (10.6%), arm pain (11.5%), epigastric pain (8.1%), shoulder pain (7.4%), and neck pain (5.9%).[15] Atypical symptoms were more common in young patients (i.e., those 25 to 40 years of age), the elderly (i.e., those older than 75 years), diabetic patients, and women.[14]

Although it is important to inquire about the traditional risk factors for CAD, both to assess current risk and to guide future risk reduction, these factors are only weakly predictive of unstable angina/NSTEMI.[1] Important secondary or precipitating causes of unstable angina/NSTEMI should be ruled out, including a history of cocaine or amphetamine abuse, severe hypertension, and hyperthyroidism. Myopericarditis, hypothyroidism, and renal failure are among the conditions that may mimic acute coronary syndrome and can be associated with elevated cardiac enzyme levels.

In many cases, the physical examination will be normal. The examination is nevertheless useful to establish the presence of certain prognostic factors for the purpose of risk stratification and also to rule out such potentially devastating conditions as aortic dissection, pulmonary embolus, pneumothorax, and pericarditis.

The pulse is carefully evaluated to assess for significant bradycardia, tachycardia, or irregularity. Blood pressure is measured, to look for uncontrolled hypertension or significant hypotension (suggesting cardiogenic shock); pressure should be

Table 1 Clinical Factors for Determining Diagnosis and Prognosis in Patients with Suspected Unstable Angina or Non–ST Segment Myocardial Infarction

Nature of the anginal symptoms
History of coronary artery disease
Sex
Age ≥ 65 years
Number of traditional risk factors (smoking, diabetes, hypertension, hyperlipidemia, family history)

measured in both arms, to assess for aortic dissection [*see 1:XII Diseases of the Aorta*]. Examination of the thyroid may suggest hypothyroidism or hyperthyroidism. Heart failure should be suspected if there is evidence of pulmonary rales, an elevated jugular venous impulse, an S_3 gallop, or a displaced and diffuse apical impulse. A murmur of acute mitral regurgitation may be a consequence of ischemia. Thrills, bruits, or pulse deficits may indicate coexisting peripheral vascular disease.

LABORATORY TESTS

Biochemical Cardiac Markers

Cardiac biomarkers—specifically, troponins, cardiac creatine kinase, and myoglobin—have important diagnostic, prognostic, and therapeutic implications in unstable angina/NSTEMI and for detection of MI generally. After ischemia-induced myocardial injury, loss of myocyte membrane integrity results in the release of various intracellular molecules into the interstitial space, lymphatics, and, eventually, into the peripheral circulation. Critical to the interpretation of these tests is the precise time of onset of ischemic symptoms.

Troponin Troponin I and T (TnI and TnT) are cardiac-specific subunits of the thin filament-associated troponin-tropomyosin complex, which regulates striated muscle contraction. Troponins have become the primary biomarkers in the evaluation of patients with acute coronary syndromes. These markers are detected in about one third of patients without elevation in the level of creatine kinase–myocardial band (CK-MB). Troponins may be detectable 3 to 4 hours after the onset of ischemic symptoms; they peak at 12 to 48 hours and persist for 4 to 10 days.[16,17] Generally, they are not detectable in the blood of healthy persons. However, both TnI and TnT are exceptionally sensitive to the presence of even minor myocardial necrosis, such as in supraventricular tachycardia, heart failure, and myocarditis, and they may also be elevated in severe renal impairment. Therefore, they should be evaluated in the context of the patient's clinical presentation.

Creatine kinase Before the advent of troponin assays, CK-MB was the primary cardiac biomarker. The CK-MB assay has considerable sensitivity and specificity for detecting myocardial necrosis at 6 to 48 hours after symptom onset or earlier. Abnormal CK-MB levels can be occasionally found in patients with high total CK levels; on clinical grounds, the CK-MB in such cases is thought to originate from skeletal muscle. Elevations in levels of the CK-MB isoforms CK-MB2 and CK-MB1 are very early markers of myocardial necrosis, but these assays are generally not part of the clinical routine.[18]

Myoglobin Myoglobin is a nonspecific biomarker found both in cardiac and skeletal muscle. It is released rapidly in response to muscle injury and is detectable 2 hours after the onset of ischemia.[17] Serial determination of myoglobin is not useful, but because of its high sensitivity in early ischemia, a negative myoglobin assay could potentially rule out myocardial necrosis.

Twelve-lead electrocardiogram ECG results may be important for determining treatment; patients with acute ST segment elevation should be considered for immediate reperfusion therapy.[19] In patients with suspected unstable angina/NSTEMI, ST segment depression of 0.05 mV or more in two or more contiguous leads is highly consistent with myocardial ischemia (this is especially the case if the ST segment depression is present during chest pain and resolves with the easing of pain). Deep, symmetrical T wave inversion is also highly consistent with myocardial ischemia. Other nonspecific abnormalities, such as transient bundle branch block, atrial or ventricular arrhythmias, and QT prolongation, can also occur with unstable angina/NSTEMI but are not useful for diagnosis. Interestingly, a quarter of patients diagnosed with unstable angina/NSTEMI will go on to develop Q waves,[2] and up to 60% may have a normal 12-lead ECG.[20]

RISK STRATIFICATION

Determining whether a patient is at low, medium, or high risk for ischemic complications (e.g., full-blown MI) is important for deciding treatment of unstable angina/NSTEMI. Depending on whether the therapeutic strategy will be invasive or conservative (see below), the degree of risk can be used to determine the level of therapy. Older age, positive cardiac biomarkers, rales, ST segment depression, hypotension and tachycardia,[21] and reduced left ventricular ejection fraction (< 40%) have been associated with increased mortality. Clinical diabetes mellitus is also associated with higher risk. One specific and widely used method of risk stratification, the Antman/Thrombolysis in Myocardial Infarction (TIMI) risk score, is a seven-point scoring system that helps to predict death, reinfarction, or recurrent ischemia requiring revascularization [*see Table 2*].[22] This risk score was developed from the TIMI 11B[23] and Efficacy and Safety of Subcutaneous Enoxaparin in Non–Q-wave Coronary Events (ESSENCE)[24] trial and has been validated in two other large trials: Therapy with an Invasive or Conservative Strategy—Thrombolysis (TACTICS)–TIMI 18 and Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS).[25,26] The risk of adverse outcomes ranges from 5% to 41%, according to the simple sum of the individual variables.

Table 2 Thrombolysis in Myocardial Infarction (TIMI) Risk Score for Unstable Angina or Non–ST Segment Myocardial Infarction*

Variable	*Points*
Age ≥ 65 years	1
More than three coronary risk factors	1
History of coronary artery disease	1
ST segment deviation	1
More than two anginal events within 24 hr	1
Use of aspirin within past 7 days	1
Elevated cardiac markers	1

Total Score	*Risk of a Cardiac Event (%) Within 14 Days†*
0/1	5
2	8
3	13
4	20
5	26
6/7	41

*To determine a patient's level of risk, the clinician determines the total score, based on the presence of specific risk markers.
†Death, recurrent myocardial infarction, or recurrent ischemia requiring urgent revascularization.

Electrocardiographic Changes

Patients with unstable angina/NSTEMI and ECG findings of bundle branch block, ventricular hypertrophy, paced rhythm, or severe ST segment depression (> 0.2 mV) in multiple leads are independently at high risk for subsequent adverse events.[1,20] Considered at low risk are those with isolated T wave abnormalities or a normal ECG pattern. Continuous ECG monitoring may detect transient ischemic episodes, which have been shown in small studies to have prognostic value, but the use of this technique as a risk marker is not widely recommended.[1,27,28]

Blood Tests

Both TnI and TnT are markers of increased risk in that they reflect the presence and level of myocardial necrosis.[1,16] High-sensitivity C-reactive protein (hsCRP), which is produced by the liver in response to inflammation,[29,30] and other acute-phase reactants such as plasma fibrinopeptide, fibrinogen, serum amyloid A, and interleukin-6, have demonstrated similar predictive value for adverse outcomes.[31-33] B-type natriuretic peptide (BNP), released in response to ventricular wall stress, may also independently predict mortality.[34] Measurement of hsCRP and BNP may be of use at times, but more studies are needed to clarify the roles of these markers in routine care.

Stress Testing

Stress testing for assessment of risk may be performed in patients who have been stable and asymptomatic for 24 to 48 hours and in all patients before discharge. Stress testing is a necessary component of an early conservative strategy (see below). Briefly, stress test results that show the patient to be at high risk for significant ischemia are as follows:

1. Treadmill ECG: inability to achieve a workload of greater than two metabolic equivalents (mets); early and persistent ST segment depression of greater than 2 mm; symptom onset at less than 6.5 mets; or hypotension or ST segment elevation during exercise in the absence of Q waves
2. Stress nuclear scintigraphy: evidence of left ventricular dilation or thallium lung uptake during stress, or moderate to large reversible perfusion defects
3. Stress echocardiography: more than two myocardial wall segments demonstrating reversible impairment of thickening with stress or evidence of left ventricular dilation with stress[35]

Treatment

WHERE TO HOSPITALIZE

In most medical centers in the United States, patients with definite features of unstable angina/NSTEMI are admitted to a cardiac care unit that provides continuous ECG monitoring and specialized nursing. Patients with less than definite features of unstable angina or those in whom the chest pain has ceased by the time of arrival may be admitted to a chest pain unit with telemetry (sometimes called a step-down cardiac unit).

Ideally, patients with unstable angina/NSTEMI should be hospitalized in an institution that offers mechanical revascularization, because these procedures are frequently needed in such patients, especially those who have high-risk features. If this is not possible, high-risk patients should receive interim treatment with an intensive pharmacologic regimen until arrangements can be made for transfer to a facility with interventional capability.

INITIAL THERAPY

The initial management of unstable angina/NSTEMI includes resuscitation and supportive measures for patients who present with hemodynamic instability, as well as prompt administration of medication of proven, evidence-based value [*see* Pharmacologic Therapy, *below, and Figure 1*]. Bed rest with continuous ECG monitoring for ischemia and arrhythmia detection is a class I rec-

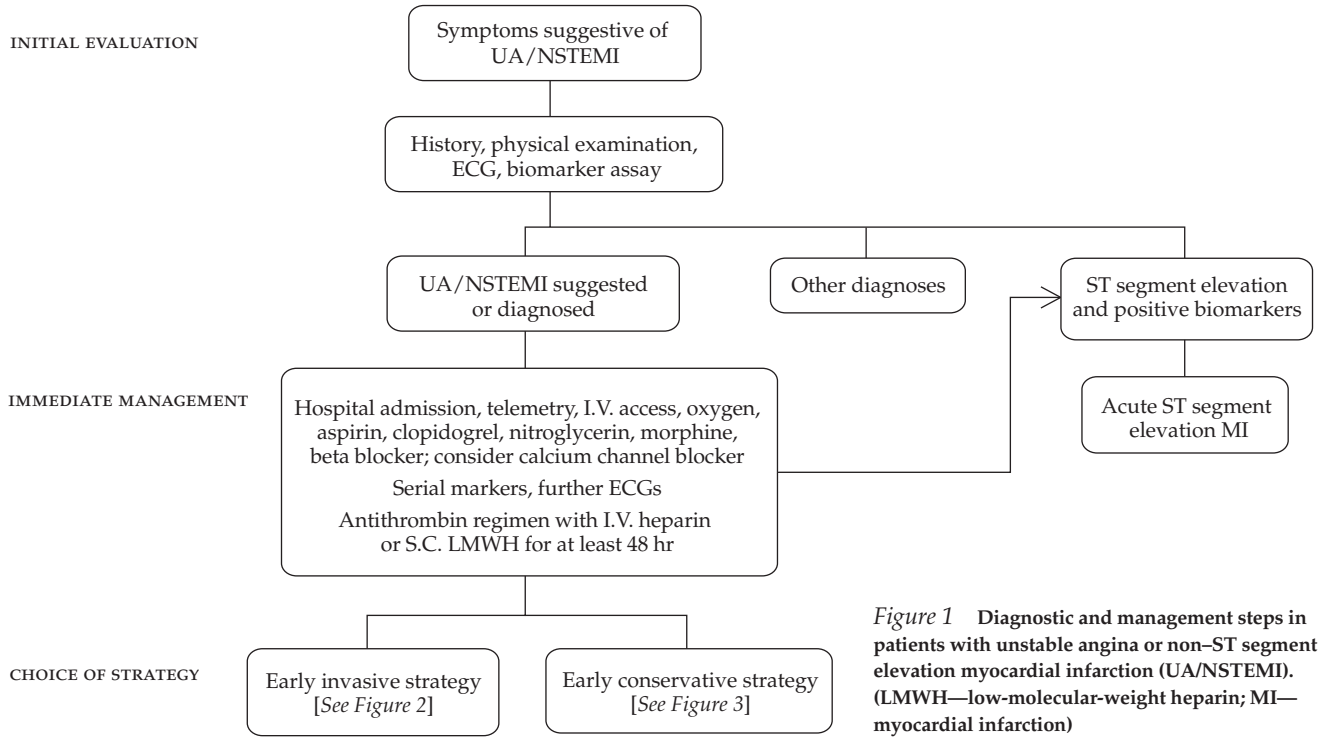

Figure 1 **Diagnostic and management steps in patients with unstable angina or non–ST segment elevation myocardial infarction (UA/NSTEMI). (LMWH—low-molecular-weight heparin; MI—myocardial infarction)**

Table 3 Recommendation Classes and Evidence Levels[1]

Class I: Conditions for which there is evidence or general agreement that a given procedure or treatment is useful and effective

Class II: Conditions for which there is conflicting evidence or a divergence of opinion about the usefulness/efficacy of a procedure or treatment

- Class IIa: Weight of evidence or opinion is in favor of usefulness/efficacy
- Class IIb: Usefulness/efficacy is less well established by evidence or opinion

Class III: Conditions for which there is evidence and/or general agreement that the procedure or treatment is not useful/effective and in some cases may be harmful

Level A: Data are derived from multiple randomized clinical trials that involved large numbers of patients

Level B: Data are derived from a limited number of randomized trials that involved small numbers of patients or from careful analyses of nonrandomized studies or observational registries

Level C: Expert consensus

ommendation for patients who have ongoing anginal pain at rest, on the basis of level C evidence [*see Table 3*]. The strictness of the bed rest requirement can be tailored to the severity of symptoms. For instance, patients can be mobilized to a chair or bedside commode when symptom free.

Oxygen Inhaled oxygen therapy should be reserved for those patients with clear respiratory distress, cyanosis, or arterial hypoxemia. In the absence of these high-risk features, time and resources need not be spent for the sole purpose of oxygen administration. Supplemental oxygen is recommended for patients with cyanosis or respiratory distress. Finger pulse oximetry or arterial blood gas measurements should be done to determine whether the patient has adequate arterial oxygen saturation ($S_aO_2 > 90\%$) or has hypoxemia and requires supplemental oxygen. These class I recommendations are supported by level C evidence.

EARLY INVASIVE VERSUS EARLY CONSERVATIVE STRATEGY

The first decision in management (and one that is often a matter of dispute) is to choose between the two reigning strategies for unstable angina/NSTEMI: early invasive management and early conservative management [*see Figures 2 and 3*]. In the early invasive strategy, early coronary angiography is performed unless contraindicated. In the early conservative strategy, angiography is reserved for those patients who have indications of being at high risk for cardiac events; such indications include evidence of significant ischemia on a noninvasive stress test and recurrent ischemia despite adequate medical therapy. It should be noted that although many patients assigned to the conservative strategy undergo angiography and receive interventions (e.g., in one study, 51% of patients underwent angiography and 36% received subsequent revascularization[25]), in these patients there was an additional indication for the angiography, based on risk, besides the diagnosis of unstable angina/NSTEMI.

Advocates of an early conservative strategy suggest that angiography—and its associated risks—can be avoided in low-risk patients and that costs and resources can be conserved by not performing these procedures in all patients. Advocates of an early invasive strategy suggest that this approach can result in superior clinical outcomes through early identification of patients with high-risk lesions, including those with critical left main coronary artery stenosis or triple-vessel coronary disease. In addition, advocates of an early invasive strategy argue that such intervention results in shorter hospital stays for patients found to have low-risk anatomy; these proponents also note that cardiac

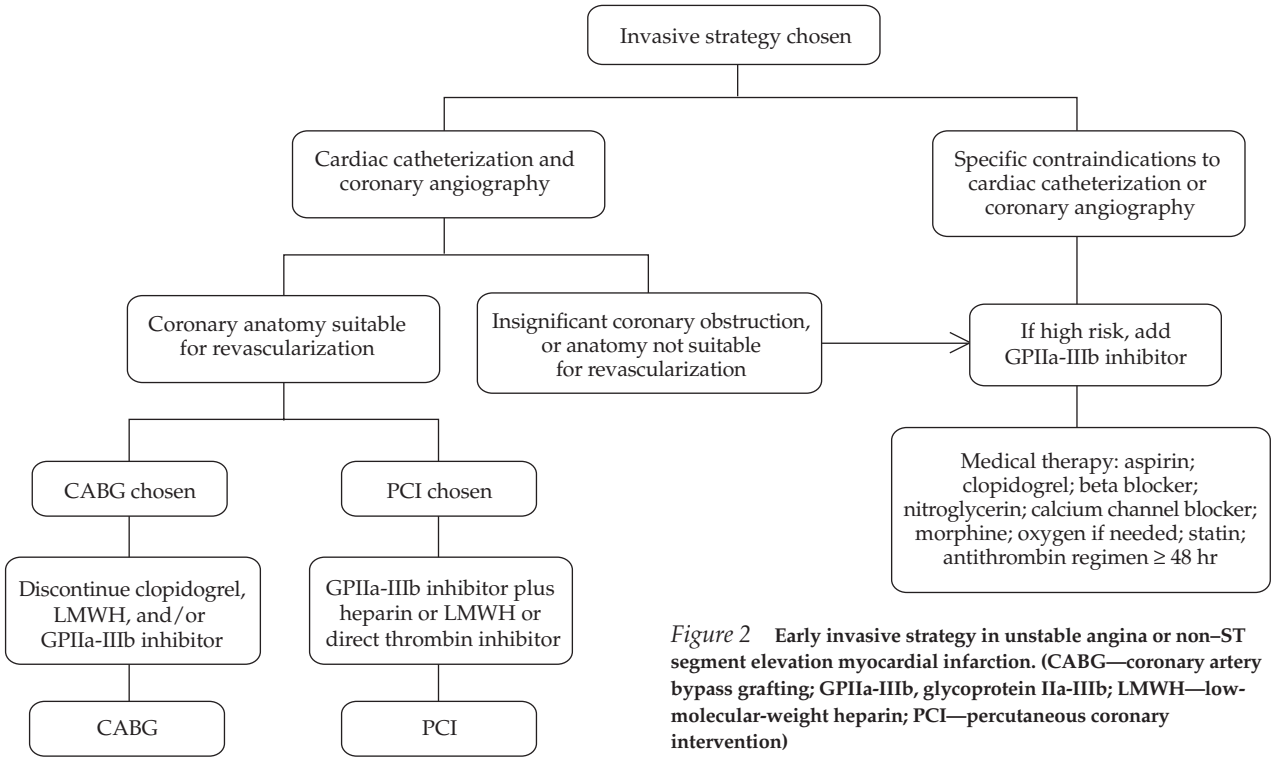

Figure 2 **Early invasive strategy in unstable angina or non–ST segment elevation myocardial infarction. (CABG—coronary artery bypass grafting; GPIIa-IIIb, glycoprotein IIa-IIIb; LMWH—low-molecular-weight heparin; PCI—percutaneous coronary intervention)**

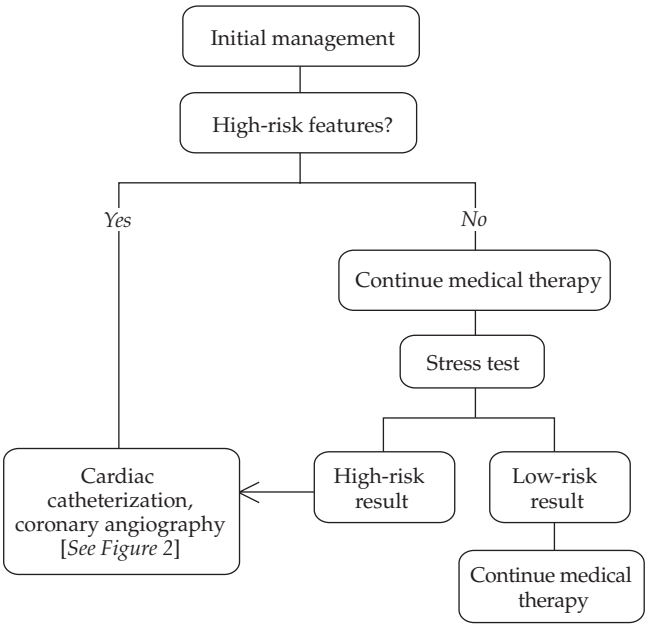

Figure 3 **Early conservative strategy in unstable angina/non–ST segment elevation myocardial infarction.**

catheterization is now available to almost all patients and that catheterization has a very low procedural risk.

Trial Results

Three initial multicenter, randomized trials found that there was no difference in outcome between an early invasive strategy and an early conservative strategy, whereas three subsequent trials showed benefit in favor of the invasive strategy. TIMI IIIB showed no difference in death or MI at 42 days with either strategy in patients with unstable angina/NSTEMI[36]; the Veterans Affairs Non–Q-Wave Myocardial Infarction Strategies In-Hospital (VANQWISH) trial showed no difference in death or recurrent MI in the early invasive versus the conservative group at 2 years' average follow-up (32.9% versus 30.3%; $P = 0.35$), although there were more deaths in the early invasive group at 1 year[37]; and the Medicine versus Angiography in Thrombolytic Exclusion (MATE) trial, conducted in patients with acute coronary syndrome who were ineligible for thrombolysis, showed no difference in clinical outcome between either strategy.[38]

The three subsequent studies have begun to move opinion toward the invasive strategy. The Fragmin in Unstable Coronary Artery Disease II (FRISC II) study was conducted in patients with unstable angina/NSTEMI who were receiving dalteparin; death or MI occurred in 9.4% of patients who received invasive treatment, as compared with 12.1% of those treated conservatively ($P < 0.031$; risk ratio, 0.78; confidence interval, 0.62 to 0.98).[39] However, a substudy of FRISC II showed that the most benefit of the early invasive strategy accrued to those patients with an ST segment shift of more than 2.5 mm or in five or more leads.[40] The Therapy with an Invasive or Conservative Strategy–Thrombolysis—TIMI 18 (TACTICS-TIMI 18) trial involved patients with unstable angina/NSTEMI who had ST or T wave changes, increased cardiac markers, and a history of coronary artery disease and who were taking aspirin, heparin, and tirofiban. This trial showed a combined end point (death, MI, or rehospitalization at 6 months) of 15.9% in the early invasive group, as compared with 19.4% in the early conservative group ($P = 0.025$; relative risk, 0.78; confidence interval, 0.62 to 0.97). Major bleeding was similar in both groups (1.9% versus 1.3%; $P = 0.24$). Subgroup analysis of the trial suggested that early invasive treatment benefited only patients whose TnI or TnT level was initially elevated.[41] Of note, median length of stay was somewhat shorter with the invasive strategy (3.9 days versus 4.3 days; $P < 0.001$). The cost of care in the invasive group was somewhat higher for the initial hospitalization ($15,714 versus $14,047 in year 2000 dollars), though the 6-month average total costs did not differ between the two groups ($21,813 for the invasive group versus $21,227 for the conservative group; P = nonsignificant).[42] In the Randomized Intervention Trial of unstable Angina–3 (RITA-3) in unstable angina/NSTEMI patients treated with enoxaparin, rates of death or MI at 4 months were lower in the early invasive group (9.6% versus 14.5%; $P = 0.001$; relative risk, 0.66; confidence interval, 0.51 to 0.85).[43]

Although the results of these three trials differed, patients who were considered to be at high risk for death or MI consistently seemed to benefit the most from a strategy of early angiography and revascularization. Because of the low event rate in patients considered to be at low risk, it is not clear that the early invasive approach offers a clear advantage over an early conservative strategy for this population. Therefore, until further evidence becomes available, an early conservative strategy may be a reasonable initial approach for the management of low-risk patients with unstable angina/NSTEMI.

Treatment Recommendations

High-risk patients A class I recommendation and level A evidence support the use of an early invasive strategy in patients with unstable angina/NSTEMI who have no serious comorbidity and have any of the following high-risk indicators:

- Recurrent angina at rest or with low-level activity despite intensive medical therapy.
- Elevated TnI or TnT levels.
- New, or presumably new, ST segment depression.
- Recurrent angina or ischemia with symptoms or signs of heart failure.
- High-risk findings on noninvasive stress testing.
- Depressed left ventricular function (ejection fraction < 40%) on noninvasive study.
- Hemodynamic instability.
- Sustained ventricular tachycardia.
- Percutaneous coronary intervention within the past 6 months.
- Previous coronary artery bypass grafting (CABG).

In the absence of any of these findings, either a conservative or an invasive strategy may be offered to hospitalized patients without contraindications for revascularization. This option is supported by a class 1 recommendation and level B evidence.

Women and the elderly There should be no difference in the management of men and women. The elderly should be treated no differently than younger patients, although management should take into consideration general health, comorbid conditions, cognitive status, life expectancy, and altered pharmacokinetics of and sensitivity to hypotensive drugs.

Table 4 Antiplatelet Therapy in Unstable Angina or Non–ST Segment Elevation Myocardial Infarction

Drug (Trade Name)	*Initial Dose*	*Route*	*Duration*	*Adverse Effects*	*Adverse Drug Reactions*	*Contraindications*
Aspirin	81–325 mg q.d.	Oral (first dose chewed)	Indefinite	Bleeding, tinnitus, rash, GI intolerance	None	Active, severe bleeding
Clopidogrel (Plavix)	300 mg loading dose, then 75 mg q.d.	Oral	1 yr	Bleeding, rare TTP	Partial inhibition of effect with statin drugs	Active, severe bleeding; major surgery within < 5 days
Ticlopidine (Ticlid)	250 mg b.i.d.	Oral	1 yr	Bleeding, TTP, rash, neutropenia, diarrhea	None	Active, severe bleeding; major surgery planned
Abciximab (ReoPro)	0.25 mg/kg bolus, then 0.125 µg/kg/min; max 10 µg/min	I.V.	12 hr	Bleeding, thrombocytopenia	None	Active, severe bleeding; major surgery planned
Eptifibatide (Integrilin)	180 µg/kg bolus, then 2 µg/kg/min	I.V.	72–96 hr or 18 hr if PCI performed	Bleeding	None	Active, severe bleeding; major surgery planned
Tirofiban (Aggrastat)	0.4 µg/kg/min bolus (× 30 min), then 0.1 µg/kg/min	I.V.	48 hr	Bleeding	None	Active, severe bleeding; major surgery planned

PCI—percutaneous coronary intervention TTP—thrombotic thrombocytopenic purpura

PHARMACOLOGIC THERAPY

Antiplatelet Drugs

Antiplatelet medications used in unstable angina/NSTEMI include aspirin, thienopyridines (clopidogrel and ticlopidine), abciximab, eptifibatide, and tirofiban [*see Table 4*].

Aspirin Aspirin is considered the benchmark antiplatelet agent for the treatment of unstable angina/NSTEMI. A class I recommendation and level A evidence suggest that aspirin be started immediately in these patients and continued indefinitely.[1,2]

Aspirin's mechanism of action is to decrease the formation of the potent platelet aggregator thromboxane A_2 by irreversibly binding cyclooxygenase-1 in platelets. The effect on platelets is rapid (occurring within 15 to 30 minutes), and it is achieved with an oral dose as low as 81 mg.

Four pivotal randomized trials that evaluated the effectiveness of aspirin in the treatment of acute coronary syndrome showed consistent and durable long-term benefit at doses ranging from 75 to 325 mg daily.[44-47] The Antiplatelet Trialists' Collaboration meta-analysis of more than 100,000 patients in 145 trials showed such benefits in several cardiovascular disorders. For example, in 4,000 patients with unstable angina, rates of so-called vascular events (nonfatal MI, nonfatal stroke, or vascular death) were reduced from 14% to 9% ($P < 0.00001$) after 6 months.[48] Furthermore, the benefit of aspirin in these high-risk patients was sustained for at least 2 years.

Aspirin dosages have varied among several trials; no dosage has been definitively shown to be preferable. For patients with suspected MI in the International Studies of Infarct Survival–2 (ISIS-2) trial, the effective dosage was 160 mg daily.[49] A dose of aspirin between 160 and 325 mg should be administered immediately; the first dose should be chewed, for rapid absorption, and subsequent doses swallowed.

Adverse effects of aspirin include allergy, which may manifest as rash, angioedema, or asthma; a tendency to bleed; gastrointestinal effects, including gastric ulcer; and, rarely, precipitation of acute gout. Contraindications include allergy (especially if the allergic reaction is in the form of asthma), active bleeding, a serious bleeding disorder, severe untreated hypertension, and an active peptic ulcer.

Thienopyridines Thienopyridines irreversibly bind the adenosine diphosphate receptor on platelets, preventing fibrinogen binding and platelet aggregation. The two thienopyridines that have been used clinically are ticlopidine (Ticlid) and clopidogrel (Plavix).

In a single open-label trial in patients with unstable angina, ticlopidine (250 mg twice daily) significantly reduced vascular death and nonfatal MI at 6 months (13.6% versus 7.3%; $P = 0.009$), compared with standard aspirin therapy.[50] Several trials have shown the value of clopidogrel. In 12,562 patients with unstable angina, all of whom were also treated with aspirin, clopidogrel (300 mg followed by 75 mg daily), administered for 3 to 12 months, reduced a combined end point of cardiovascular death, nonfatal MI, and stroke from 11.4% to 9.3% ($P < 0.001$) and also decreased the incidence of ischemia, heart failure, and revascularization procedures. Benefit occurred as early as 24 hours after initiating treatment and persisted for up to 1 year. Clopidogrel increased major bleeding from 2.7% to 3.7% ($P = 0.003$), but there was no difference in life-threatening bleeding or hemorrhagic shock. Importantly, bleeding was increased in patients who underwent CABG within 5 days after stopping clopidogrel.[51] Two other studies found that clopidogrel benefited patients treated with percutaneous coronary intervention.[52,53] The Clopidogrel for the Reduction of Events During Observation (CREDO) study examined the timing of therapy with a combination of clopidogrel and aspirin. In one arm of the study, patients received a bolus load of aspirin and clopidogrel 6 to 24 hours before undergoing percutaneous coronary intervention. In the other arm of the study, patients received a bolus load less than 6 hours before the procedure. Benefit was observed in those patients who received the bolus 6 to 24 hours before the procedure.

The dosage of ticlopidine is 250 mg orally, twice daily; the dosage of clopidogrel is 300 mg orally. Both agents should be started immediately on presentation. The duration of therapy,

which has been better defined for clopidogrel, is up to 1 year at a dose of 75 mg daily.

The principal adverse reaction that has limited the clinical use of ticlopidine is severe neutropenia; rarely, thrombotic thrombocytopenic purpura develops within the first 3 months of therapy. Both conditions are life threatening unless the drug is discontinued promptly. Clopidogrel has been associated with increased bleeding complications when administered with other antithrombotic agents, particularly when arterial puncture is performed for intervention. Bleeding during surgery is an important complication of clopidogrel use; for this reason, surgery should be avoided for 5 and preferably 7 days after the last dose, because of the prolonged duration of action.

Recommendations for the use of clopidogrel are as follows:

1. Patients with unstable angina/NSTEMI in whom a noninterventional approach is planned should receive clopidogrel for at least 1 month (this class I recommendation is supported by level A evidence) and for up to 9 months (class I recommendation, level B evidence).
2. Patients with unstable angina/NSTEMI for whom a percutaneous coronary intervention is planned and who are not at high risk for bleeding should receive clopidogrel for at least 1 month (class I recommendation, level A evidence) and for up to 9 months (class I recommendation, level B evidence).
3. Clopidogrel should be stopped for 5 to 7 days before elective surgical revascularization (class I recommendation, level B evidence).
4. When used to pretreat patients undergoing percutaneous coronary intervention, clopidogrel should be given more than 6 hours before the procedure (level B evidence).[53]

Glycoprotein IIb-IIIa receptor antagonists Abciximab, eptifibatide, and tirofiban act by specifically binding the glycoprotein (GP) IIb-IIIa receptor on platelet surfaces, thereby preventing fibrinogen binding and ultimately preventing platelet aggregation. Abciximab is the Fab fragment of a monoclonal antibody that has a short plasma half-life but irreversibly binds the GPIIb-IIIa receptor for 24 to 48 hours. The half-lives of eptifibatide and tirofiban are 2 to 3 hours, with platelet aggregation returning to normal 4 to 8 hours after drug discontinuance.

In three large clinical trials of patients with unstable angina/NSTEMI who underwent percutaneous coronary intervention, all of these GPIIb-IIIa inhibitors provided significant benefit in the composite outcome of death, MI, or urgent repeat revascularization, with the major benefit seen in recurrent MI and urgent repeat revascularization.[26,54,55] The Do Tirofiban and Reopro Give Similar Efficacy Trial (TARGET), which was conducted in patients with unstable angina/NSTEMI who underwent percutaneous coronary intervention with stenting, found that abciximab conferred greater benefit than tirofiban (although tirofiban was administered at a suboptimal dosage).[56]

For patients not undergoing planned percutaneous intervention, the results with GPIIb-IIIa inhibitors have been less impressive. Abciximab, given for 24 or 48 hours, was found to be no better than placebo in the Global Use of Strategies to Open Occluded Coronary Arteries IV (GUSTO IV) trial in patients with acute coronary syndrome.[57] On the other hand, two trials with tirofiban and eptifibatide demonstrated modest benefit in patients who did not undergo an interventional procedure[26,54]; the benefit was greatest in high-risk patients.

Abciximab, which is recommended for use during percutaneous coronary intervention, is administered as a 0.25 mg/kg intravenous bolus, followed by an infusion at 0.125 μg/kg/min for 12 hours. Eptifibatide is administered as a 180 μg/kg intravenous bolus, followed by a second bolus after 10 minutes. Thereafter, it is infused at a rate of 2 μg/kg/min for 72 to 96 hours if no percutaneous intervention is performed or for 18 hours if such a procedure is performed. Tirofiban is given in an intravenous 0.4 μg/kg/min bolus over 30 minutes, then infused at a rate of 0.1 μg/kg/min for 48 hours.

Bleeding is the most common complication of GPIIb-IIIa inhibitors. Special care should be taken to prevent bleeding in high-risk patients such as the elderly, women, those with low body weight, and those who require arterial puncture for an intervention. Because of their short half-lives, eptifibatide or tirofiban may be better suited for patients who may require surgical revascularization. Abciximab results in serious thrombocytopenia in about 0.3% of patients,[56] so serial platelet measurements are recommended in patients receiving this agent. In a meta-analysis, GPIIb-IIIa inhibitors were found to increase major bleeding from 1.4% to 2.4 % ($P < 0.0001$). There was no increase in the rate of intracranial hemorrhage.[58]

Three evidence-based recommendations can be made for the use of GPIIb-IIIa inhibitors:

1. In patients with unstable angina/NSTEMI who are to undergo a planned percutaneous coronary intervention, a GPIIb-IIIa inhibitor should be given either before or during the procedure. This class I recommendation is supported by level A evidence.
2. Patients with unstable angina/NSTEMI who have high-risk features and who are not to undergo a planned percutaneous intervention should receive eptifibatide or tirofiban (class IIa recommendation, level A evidence).
3. Patients with unstable angina/NSTEMI in whom percutaneous intervention is not planned should not receive abciximab (class III recommendation, level A evidence).

Fibrinolytic Drugs

Fibrinolytic therapy is not indicated for patients with unstable angina/NSTEMI. Level A evidence indicates that intravenous fibrinolytic therapy should not be administered to patients who do not have acute ST segment elevation, unless they have a true posterior MI or a presumed new left bundle branch block (class III recommendation).[59]

Anticoagulants

Heparin, low-molecular-weight heparin (LMWH), bivalirudin, or warfarin can be used for anticoagulant therapy in patients with unstable angina/NSTEMI [*see Table 5*].

Heparin Unfractionated heparin is composed of a number of chains of varying molecular weights that differ with regard to anticoagulant activity. Heparin generally increases the action of circulating antithrombin, which inactivates factor IIa, factor IXa, and factor Xa and prevents thrombus formation.[60]

Three randomized, placebo-controlled trials suggested that early intravenous administration of heparin leads to a modest reduction in the incidence of MI or recurrent ischemia.[61-63] A meta-analysis of six trials showed a relative risk of 0.67 (95% confidence interval, 0.44 to 1.02) in favor of the combination of heparin and aspirin.[64]

Heparin should be given in an initial intravenous bolus of 60 to 70 U/kg (maximum, 5,000 U), followed by an infusion of 12 to

Table 5 Anticoagulant Therapy in Unstable Angina/ Non–ST Segment Elevation Myocardial Infarction

Drug	*Dose*	*Route*	*Duration*	*Adverse Effects*	*Adverse Drug Reactions*	*Contraindications*
Unfractionated heparin	60–70 U/kg bolus (max 5,000 U); 12–15 U/kg/hr (max 1,000 U/hr)	I.V.	48–72 hr	Bleeding, HIT, mild thrombocytopenia	None	Active, severe bleeding; HIT
Enoxaparin	1 mg/kg b.i.d.	S.C.	48–72 hr	Bleeding, HIT	None	Active bleeding; major surgery planned
Bivalirudin	0.75 mg/kg bolus; 1.75 mg/kg/hr	I.V.	Duration of PCI	Bleeding	None	Active, severe bleeding
Warfarin	5–10 mg; dose adjusted to maintain desired INR, typically 2–3	Oral	Varies with indication	Bleeding, warfarin skin necrosis	Dose adjustment with macrolides, cimetidine, digoxin, amiodarone, other drugs	Active, severe bleeding; major surgery planned

HIT—heparin-induced thrombocytopenia INR—international normalized ratio PCI—percutaneous coronary intervention

15 U/kg/hr (maximum, 1,000 U/hr). Doses should be adjusted to maintain an activated partial thromboplastin time (aPTT) of 1.5 to 2.5 times control values.[1]

As with any anticoagulant, heparin is contraindicated in patients with active severe bleeding or who are to undergo imminent surgery. Heparin-induced thrombocytopenia (HIT) is a serious but rare (< 0.2% incidence) antibody-mediated reaction leading to reduced platelet counts and thrombosis [*see 5:XIV Thrombotic Disorders*]. HIT mandates immediate cessation of heparin, including heparinized solutions used for the flushing of intravenous ports. From 10% to 20% of patients receiving heparin may experience mild thrombocytopenia that is not associated with severe thrombosis or excessive bleeding.[1] For serious bleeding, heparin anticoagulation can be immediately reversed with intravenous protamine sulfate.

Low-molecular-weight heparin LMWHs are produced by enzymatic depolymerization of unfractionated heparin, resulting in smaller chain units. Advantages include less protein binding; longer half-life; more stable, dose-dependent clearance; and a greater anti–factor Xa effect that is associated with more thrombin inhibition. The standard aPTT assay cannot be used for LMWH, because this assay is not sensitive to the anti-Xa effects of LMWHs. Rapid factor Xa assays are not widely available, but the stable kinetics of LMWH tends to reduce the need for monitoring.

A number of trials have compared individual LMWHs with unfractionated heparin. Meta-analysis of two trials revealed a modest benefit of enoxaparin over heparin in terms of death and MI at 45 days (7.1% versus 8.6%; $P = 0.02$).[65] In trials with dalteparin and nadroparin, neither showed benefit.[66,67] FRISC showed a significant improvement in death, MI, or urgent revascularization with dalteparin (1.8% versus 4.8%; $P = 0.001$) for up to 43 days.[68] In the Integrilin and Enoxaparin Randomized Assessment of Acute Coronary Syndrome Treatment (INTERACT) trial, enoxaparin was found to be associated with less ischemia, as evidenced on ECG (14.3% versus 25.4%; $P = 0.002$), and to lead to an improvement in the composite end point of death or MI at 30 days (5% versus 9%; $P = 0.031$).[69] Several trials showed evidence of a small increase in minor bleeding with LMWH, as compared with heparin, but no difference in major bleeding was seen.[66-69] One small trial demonstrated that enoxaparin was safe with regard to serious bleeding in unstable angina/NSTEMI patients undergoing percutaneous coronary intervention.[70] Another trial showed significantly lower rates of major CABG–related bleeding with LMWH, as compared with enoxaparin, by 96 hours after percutaneous coronary intervention (1.8% versus 4.6%; $P = 0.03$).[23] When enoxaparin was added to abciximab, no difference in the rate of bleeding events and adverse ischemic outcomes was seen, as compared with historical controls.[71]

In summary, evidence to date suggests that LMWH is at least as effective as unfractionated heparin and is generally safe in patients with unstable angina/NSTEMI in whom surgery or percutaneous coronary intervention is not planned. The dosing of LMWH is simpler than that of unfractionated heparin, and LMWH therapy does not require monitoring with coagulation studies. Abundant data (e.g., from the TIMI 11B, ESSENCE, and INTERACT studies) suggest that enoxaparin is the preferred agent.[23,24,69] In patients for whom percutaneous coronary intervention is planned, LMWH may be started or continued, provided that meticulous attention is given to dosing and the timing of its administration. Enoxaparin has not found wide use in contemporary interventional practice, however, because of practitioners' uneasiness over the inability to monitor the level of anticoagulation. In patients in whom surgery is planned, LMWH should be avoided; if an LMWH has already been started, the patient should be switched to unfractionated heparin, whose effects can be monitored closely.

Enoxaparin is given subcutaneously at a dosage of 1 mg/kg every 12 hours for at least 48 hours. Percutaneous coronary intervention may be performed within 8 hours of starting the drug, without additional anticoagulation therapy. If the percutaneous procedure is performed 8 to 12 hours after starting the drug, an additional intravenous bolus of 0.3 mg/kg may be given. Dose adjustment must be made in patients with moderate to severe renal impairment.

Compared with unfractionated heparin, LMWH has a slightly higher rate of minor bleeding complications and the same rate of major bleeding complications. Although the risk of HIT seems to be lower with LMWH than with unfractionated heparin, LMWH is absolutely contraindicated in patients with a history of HIT because of the danger posed by this reaction.

A class I recommendation and level A evidence support the use of anticoagulation with intravenous heparin or subcutaneous LMWH in patients with unstable angina/NSTEMI; the anticoagulant is given in addition to aspirin, clopidogrel, or both.

Level A evidence indicates that enoxaparin is preferable to unfractionated heparin in patients without renal failure, unless CABG is planned within 24 hours (class IIa recommendation).

Direct thrombin inhibitors These agents directly bind to the fibrinogen-recognition and catalytic sites of thrombin, neutralize clot-bound thrombin, and inhibit thrombin-mediated platelet aggregation; the result is sustained anticoagulation. Hirudin and bivalirudin are the two principal agents that have undergone clinical testing, but hirudin is not used.

In the Randomized Evaluation in Percutaneous Coronary Intervention Linking Angiomax to Reduced Clinical Events–2 (REPLACE-2) trial, which involved patients undergoing percutaneous coronary intervention, bivalirudin in combination with provisional GPIIb-IIIa inhibition was found to be equivalent to unfractionated heparin plus GPIIb-IIIa inhibition in terms of death, MI, urgent repeat revascularization, and in-hospital major bleeding after 30 days of therapy.[72] Rates of in-hospital major bleeding were significantly lower with bivalirudin (2.4% versus 4.1%; $P < 0.001$), although it has been noted that activated clotting time (ACT) values in the patients who received unfractionated heparin and a GpIIb-IIIa inhibitor were higher than was seen in other trials.

Bivalirudin is given as an intravenous bolus of 0.75 mg/kg at the start of percutaneous coronary intervention; for the duration of the procedure, an infusion of 1.75 mg/kg/hr is given. Because of the predictable profile of bivalirudin, measurement of ACT levels is usually not necessary. If the ACT is measured, typical values are 300 to 400 seconds.

Although bleeding seems to occur less commonly with bivalirudin than with unfractionated heparin or GPIIb-IIIa inhibitors, any serious bleeding that does occur could be disastrous because there is no effective way to immediately reverse the anticoagulation (as can be done with protamine sulfate for heparin). However, thrombocytopenia is not a problem, and the offset of bivalirudin's effect is relatively more rapid than that of heparin (1 hour), permitting sheaths to be pulled sooner after the procedure. Mainly because of its better safety profile, some interventional cardiologists have embraced the use of bivalirudin in the catheterization laboratory, but its general use awaits further trials.

If percutaneous coronary intervention is planned, level B evidence indicates that bivalirudin may be used as an alternative to unfractionated heparin and a GPIIb-IIIa inhibitor.

Warfarin Warfarin works by inhibiting the vitamin K–dependent clotting factors II, VII, IX, and X. Achievement of the desired antithrombotic effect takes 4 to 7 days.

In a few small pilot studies, starting warfarin therapy shortly after presentation in patients with unstable angina/NSTEMI showed benefit.[1] In a large trial of patients with unstable angina/NSTEMI who had previously undergone CABG, warfarin provided no advantage over aspirin alone and was associated with excess minor and major bleeding complications.[73]

Warfarin is taken orally once daily. The dose is titrated to maintain the desired international normalized ratio (INR), which is from 2 to 3 for most indications.

Bleeding is the main complication associated with warfarin therapy. Several drugs (e.g., cimetidine, amiodarone) can markedly increase warfarin's effect. Warfarin anticoagulation is reversed by stopping the drug; reversal by administration of vitamin K or of fresh frozen plasma is usually reserved for emergent and life-threatening bleeding.

The available evidence does not support the routine use of warfarin in patients with unstable angina/NSTEMI unless there are other indications for warfarin (e.g., atrial fibrillation, mechanical prosthetic heart valve).

Anti-ischemia Therapy

The agents used for treating ischemia in patients with unstable angina/NSTEMI include nitrates, morphine sulfate, and beta blockers (e.g., metoprolol) [*see Table 6*].

Nitrates Nitroglycerin is an endothelium-independent general arterial and venous dilator. It decreases myocardial oxygen demand through increased venous capacitance and peripheral artery dilation—factors that reduce preload and afterload, respectively, and thereby reduce myocardial wall stress. Epicardial coronary vasodilation and increased collateral flow act to enhance myocardial oxygen delivery.

No large, placebo-controlled clinical trials addressing reductions in major cardiac events or symptoms in unstable angina/NSTEMI have been performed. Multiple small, uncontrolled trials, a well-characterized biologic effect, and decades of experience have made nitrates a standard of care in the early treatment of these patients.[1]

Table 6 Anti-ischemia Therapy

Drug	*Dosage*	*Route*	*Duration*	*Adverse Effects*	*Adverse Drug Reactions*	*Contraindications*
Nitrates	S.L.: 0.4 mg q. 5 min × 3; I.V.: 10 mg/min, titrate up q. 5 min; paste: 2–6 cm; patch: 0.4 mg/hr	S.L., I.V., paste, patch	15–20 min until side effects occur or symptoms resolve	Hypotension, headache, nausea, tolerance	None	Hypotension; sildenafil or vardenafil within 24 hr of nitrate use
Morphine sulfate	1–5 mg every 10–15 min	I.V.	Until side effects or symptoms resolve	Hypotension, respiratory depression, rash, pruritus, nausea	None	Severe ventilatory failure, hypotension
Metoprolol*	5 mg q. 5 min to max 3 doses, then 25–100 mg b.i.d. with titration	I.V., then oral	Symptom resolution (if MI, then indefinite)	Hypotension, bradycardia, bronchospasm, worsened claudication	None	Hypotension, bradycardia, asthma, decompensated heart failure

*Other beta blockers are equally effective, although agents with intrinsic sympathomimetic activity should be avoided. Calcium channel blockers may be used for patients in whom beta blockers are contraindicated.
MI—myocardial infarction

In the emergency department, the initial nitrate dosage in a nonhypotensive patient is typically 0.4 mg of sublingual nitroglycerin (tablet or spray) repeated approximately every 5 minutes if ischemic symptoms do not subside. If this fails to terminate the ischemia, intravenous nitroglycerin at an infusion rate of 10 μg/min is recommended. The dose is titrated upward in increments of 10 to 20 μg/min until symptoms or signs of ischemia subside, hypotension develops, or the recommended maximal dose of 200 μg/min is achieved. After the acute period, topical nitrates, such as a 0.4 mg/hr nitrate patch, can be used for long-term therapy if necessary.

Nitroglycerin can result in significant hypotension, necessitating withdrawal of the agent. It should be avoided in patients who have taken sildenafil (Viagra) or vardenafil (Levitra) in the past 24 hours, because very severe hypotension can occur. Nitrate tolerance develops with prolonged nitrate administration, so patients should have nitrate-free intervals. Other adverse reactions, including intermittent headaches and nausea, are common.

A class I recommendation and level C evidence support the use of nitroglycerin to terminate or prevent ischemic episodes. Nitroglycerin therapy should serve as a bridge to the use of other evidence-based therapies, such as revascularization.

Morphine sulfate Almost a century of experience in acute coronary syndrome (albeit in the absence of clinical trial data) has established morphine sulfate as a useful adjunct to the early management of unstable angina/NSTEMI. Besides its potent analgesic and anxiolytic effect, morphine sulfate causes venodilation and mild arterial dilation, leading to reduced preload and afterload, and it may increase vagal tone to modestly reduce heart rate. These effects make it useful for treating patients with severe pulmonary congestion.

Morphine sulfate is given in a dose of 1 to 5 mg intravenously every 10 to 15 minutes until ischemic symptoms dissipate. At the same time, consideration for intravenous nitroglycerin treatment should be made. Morphine sulfate often causes hypotension, nausea, vomiting, and respiratory depression. Effects are quickly reversible with naloxone. A class I recommendation and level C evidence support the use of morphine sulfate to relieve chest pain that is refractory to sublingual nitroglycerin, to reverse acute pulmonary edema, and to ease severe agitation.

Beta blockers Beta blockers reduce myocardial oxygen demand by reducing heart rate and contractility. Slowing of the heart rate may also permit increased coronary filling during a prolonged diastole.

Much of the evidence in favor of beta-blocker therapy for unstable angina/NSTEMI is extrapolated from the large benefit shown in major clinical trials of acute MI. A meta-analysis of trials of threatened or evolving MI revealed a 13% reduction in progression to acute MI,[74] but there was insufficient power for mortality analysis.

There is no evidence of any difference in efficacy between the various beta blockers available, although agents with intrinsic sympathomimetic activity should be avoided. The dose will vary with the agent selected. In unstable angina/NSTEMI, intravenous loading doses titrated to a target resting heart rate of 50 to 60 beats/min may be used, with rapid conversion to an oral regimen. In patients who may have difficulty tolerating the adverse effects of beta blockers, the initiating dose should be small and titration should proceed more slowly.

Bronchospasm and severe asthma are contraindications to the use of beta blockers. Significant sinus bradycardia, AV nodal block, and hypotension can also occur, typically in patients with preexisting disease of cardiac conductive tissue.

A class I recommendation and level B evidence support the use of beta blockers in patients with ongoing chest pain; in such patients, an initial intravenous dose is followed by oral therapy.

Calcium channel blockers These agents are primarily vasodilators, but they also have effects on atrioventricular nodal conduction and left ventricular contractility. The dihydropyridine calcium channel blockers (e.g., nifedipine and amlodipine) have the most peripheral vasodilatory capability and the least negative inotropic effect.

To date, the trial data generally suggest that calcium channel blockers offer symptom relief in patients with unstable angina, but a meta-analysis found no improvements with regard to death or the occurrence of MI.[75] Nifedipine, compared with a beta blocker (metoprolol), demonstrated a trend toward increased MI.[76] In unstable angina/NSTEMI, the nondihydropyridine agents are used for coronary artery spasm and may be chosen for patients who cannot tolerate beta blockade.

Doses of calcium channel blockers vary with the agent chosen. For diltiazem, the usual immediate dose is a 20 mg/kg intravenous bolus, followed 15 minutes later by a 20 to 25 mg/kg bolus. Thereafter, the drug is administered orally, in a dosage of 30 mg three to four times a day, titrated to a total daily dose of 360 mg if necessary. Long-acting formulations exist as well.

Hypotension occurs with all calcium channel blockers. Bradycardia and negative inotropic effects accompany the nondihydropyridine agents; these agents should be avoided in patients with heart failure. The dihydropyridine agents may cause reflex tachycardia and other sympathomimetic effects.

Recommendations for the use of calcium channel blockers are as follows:

1. Nondihydropyridine calcium channel blockers (i.e., verapamil, diltiazem) may be initiated in patients with continuing or frequently recurring ischemia for whom beta blockers are contraindicated, in the absence of severe left ventricular dysfunction or other contraindications of calcium channel blockade. This class I recommendation is supported by level B evidence.
2. Extended-release forms of nondihydropyridine calcium channel blockers may be used instead of a beta blocker (class IIa recommendation, level B evidence).
3. Immediate-release dihydropyridine calcium channel blockers (i.e., nifedipine) should not be used in the absence of beta-blocker treatment (class III recommendation, level B evidence).
4. Immediate-release dihydropyridine calcium channel blockers may be used, if specifically indicated, in patients who are receiving a beta blocker (class II recommendation, level B evidence).

Lipid-Lowering Agents

There is as yet no evidence from a clinical trial that indicates that the use of lipid-lowering agents in hospital confers a benefit for patients with unstable angina/NSTEMI. However, data from a large Swedish registry showed a reduction in mortality in MI patients given statin therapy before discharge.[77] In addition, pa-

tients given such therapy in the hospital are much more likely to continue it out of hospital, and in-hospital use has therefore been recommended.[78,79] The use of a fibrate or niacin in patients with a high-density lipoprotein cholesterol level of less than 40 mg/dl is supported by a class I recommendation and level B evidence. A class IIa recommendation and level B evidence support treatment with statins and diet for patients whose low-density lipoprotein cholesterol is greater than 100 mg/dl; treatment should begin 24 to 96 hours after admission and continue after hospital discharge.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors may block inflammatory processes and encourage plaque stability. In the Heart Outcomes Prevention Evaluation (HOPE) trial, use of the ACE inhibitor ramipril was associated with significant reductions in death, MI, or stroke in moderate- to high-risk patients, most of whom had normal left ventricular function.[80] The American College of Cardiology/American Heart Association (ACC/AHA) recommends ACE inhibitors for patients with unstable angina/NSTEMI and heart failure; left ventricular systolic dysfunction (ejection fraction less than 40%); hypertension; or diabetes. This class I recommendation is supported by level B evidence.

MECHANICAL REVASCULARIZATION

Coronary revascularization with percutaneous procedures or CABG is performed to relieve symptoms and improve prognosis [*see* Early Invasive versus Conservative Strategy, *above*]. Several factors influence the decision to proceed with coronary revascularization, including risk, absence of relevant comorbid conditions, disabling symptoms, viable myocardium at risk, and whether the patient's coronary anatomy is suitable for the procedure.

Percutaneous Coronary Intervention

Advances in percutaneous coronary intervention techniques and devices have improved safety and long-term vessel patency rates. Several changes in the evolution of coronary stent design, including smaller profile, increased flexibility, small strut diameter, and, the newest development, drug-eluting technology, have improved deliverability and reduced the rate of in-stent restenosis. Furthermore, the use of adjunctive antiplatelet and antithrombotic therapies, particularly in the setting of acute coronary syndrome, has improved outcomes.

The ACC/AHA guidelines for the use or avoidance of percutaneous coronary intervention in unstable angina/NSTEMI are as follows[1]:

1. Percutaneous coronary intervention (or CABG) is recommended for patients with single-vessel or two-vessel CAD without significant involvement of the proximal left anterior descending coronary artery (LAD) who have large areas of viable myocardium and high-risk features on noninvasive testing. This class I recommendation is supported by level B evidence.
2. Percutaneous coronary intervention is recommended for patients who have single-vessel or multivessel CAD, have suitable coronary anatomy, have normal left ventricular function, and do not have diabetes (class 1 recommendation, level A evidence).
3. Percutaneous coronary intervention (or CABG) is recommended for patients who have single-vessel or two-vessel CAD without significant proximal LAD involvement but who have a moderate area of viable myocardium and ischemia on noninvasive testing (class IIa recommendation, level B evidence).
4. Percutaneous coronary intervention (or CABG) is recommended for patients who have single-vessel disease with significant proximal LAD involvement (class IIa recommendation, level B evidence).
5. Percutaneous coronary intervention (or CABG) is not indicated for patients who have atypical symptoms or have no evidence of ischemia on noninvasive testing or have not received an adequate trial of medical therapy (class III recommendation, level C evidence).
6. Percutaneous coronary intervention (or CABG) is not indicated for patients with significant left main CAD who are suitable candidates for CABG (class III recommendation, level B evidence).

Surgical Revascularization

Surgical revascularization techniques and perioperative outcomes have improved over the years. Particular advances include use of internal mammary artery conduits, off-pump procedures, minithoracotomy, and, the newest development, robot-assisted procedures.

The ACC/AHA guidelines for CABG in patients with unstable angina/NSTEMI are as follows[1]:

1. CABG is indicated for patients with significant left main CAD. This class I recommendation is supported by level A evidence.
2. CABG is indicated for patients with triple-vessel CAD and abnormal left ventricular function (class 1 recommendation, level A evidence).
3. CABG is indicated for patients who have two-vessel disease with significant proximal LAD disease and abnormal left ventricular function (class 1 recommendation, level A evidence).
4. CABG or percutaneous intervention is indicated for patients who have single-vessel or two-vessel CAD without significant proximal LAD involvement but with large areas of viable myocardium and high-risk features on noninvasive testing (class 1 recommendation, level B evidence).

Diabetes and Revascularization

Overall, patients with diabetes are more likely to require repeat revascularization after percutaneous intervention, because of increased rates of restenosis; in addition, there is a trend toward higher mortality 1 year after both CABG and percutaneous intervention with stents in diabetic patients.[81] In the Bypass Angioplasty Revascularization Investigation (BARI) trial, diabetic patients with multivessel CAD were found to have better survival rates with CABG than with percutaneous intervention.[82] However, analysis of the diabetic subgroup of a randomized trial and registry of percutaneous intervention with bare metal stents versus CABG in unstable angina patients revealed no difference in 3-year survival between the groups.[83] Drug-eluting stents display markedly reduced rates of in-stent restenosis, as compared with traditional bare-metal stents, particularly in diabetic patients.[84,85]

Currently, the available evidence suggests that surgical revascularization should be offered to diabetic patients with CAD in three or more vessels, particularly if they have left ventricular

dysfunction. However, it is common practice to offer percutaneous intervention as the revascularization strategy for diabetic patients with CAD involving one or two vessels. Trials are needed to compare the most advanced drug-eluting stent technology with the most advanced surgical management to define their roles in diabetic patients with CAD.

POSTHOSPITAL CARE

Preparation for the posthospital care of a patient with unstable angina/NSTEMI should begin during the hospitalization, with appropriate education, dietary advice, psychosocial counseling, weight loss advice, exercise prescription, cardiac rehabilitation referral (if appropriate), smoking cessation counseling, and the initiation of drug therapy. Given the importance of aggressive risk modification, the entire medical staff has a responsibility to ensure that all of these therapies and advice are offered, encouraged, and established for the future.[78]

Aspirin therapy should be maintained indefinitely, and clopidogrel should be taken for 9 months. For patients who have had an MI or who have left ventricular dysfunction, beta-blocker therapy is recommended indefinitely, in the absence of contraindications. ACE inhibitor treatment is recommended indefinitely for secondary prevention in moderate- to high-risk patients with atherosclerotic disease, diabetes, a low ejection fraction, or other specific indications. Lipid-lowering therapy (e.g., with a statin drug) should be administered if the patient has a low-density lipoprotein level higher than 100 mg/dl post diet (class I, level B), or a high-density lipoprotein level lower than 40 mg/dl (class IIa, level B).[79] Blood pressure should be kept below 140/90 mm Hg unless the patient has renal disease or diabetes, in which case the target is a pressure lower than 130/80 mm Hg.[86] All patients should be prescribed sublingual nitroglycerin and instructed in its use; in particular, they should understand the importance of returning to the hospital immediately if symptoms persist despite three doses of nitroglycerin. Finally, follow-up should take place 2 to 6 weeks after discharge in low-risk and revascularized patients, or 1 to 2 weeks after discharge in higher-risk patients.[1]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

XI VALVULAR HEART DISEASE

Brian P. Griffin, m.d.

Valvular heart disease is an important cause of cardiac morbidity in developed countries despite a decline in the prevalence of rheumatic disease in those countries. Valvular heart disease can give rise to stenosis, regurgitation, or a combination of lesions at one or more valves. The more common significant anomalies currently encountered are mitral regurgitation, caused by mitral valve prolapse; aortic stenosis, caused by a congenital bicuspid valve or by senile valvular calcification; and aortic regurgitation, caused by a bicuspid aortic valve or dilatation of the aorta. Valvular lesions can occur as a result of pathologic changes in the valve leaflets or supporting structures (i.e., the chordae or papillary muscles). Ventricular or aortic enlargement can also produce valvular regurgitation as a result of annular dilatation and inadequate leaflet coaptation in the absence of any specific valve pathology. Valvular heart disease tends to progress over time as degenerative changes are superimposed on the primary pathology. Iatrogenic causes of valvular disease are increasingly recognized. Common causes of major valvular lesions are listed [*see Table 1*].[1]

Etiology

congenital disorders

Anomalies in the development of valve cusps are common at the aortic or pulmonary positions. The normal configuration of these valves is tricuspid. Stenosis is the rule when only one cusp develops, whereas bicuspid valves may be stenotic or regurgitant [*see Figure 1*]. Congenital anomalies of the atrioventricular valves are uncommon; the most common abnormality is congenital cleft mitral valve. Valvular abnormalities can be seen in specific developmental syndromes, such as pulmonary stenosis in rubella syndrome and supravalvular aortic stenosis in Williams syndrome.

myxomatous degeneration

Myxomatous degeneration most often involves the mitral or tricuspid valve. In this condition, leaflet tissue, particularly chordal tissue, is abnormally extensible and weak. The affected valves are therefore more likely to prolapse, leading to significant regurgitation. Chordal rupture is common and may precipitate a rapid clinical deterioration from sudden severe regurgitation. The precise abnormality in valvular tissue is unknown but is thought to involve the structural proteins, such as collagen.[2] A familial tendency is often noted in this disease.[3] Inherited connective tissue diseases such as Marfan syndrome produce valvular abnormalities similar to those found in myxomatous degeneration.

rheumatic heart disease

Rheumatic heart disease remains the most common cause of mitral stenosis and a frequent cause of aortic regurgitation. It is the most common cause of multivalvular heart disease. Isolated outbreaks of rheumatic fever continue to be reported in the United States, even in affluent communities.[4] Rheumatic heart disease remains a significant problem in immigrants, especially those from Latin America and Southeast Asia. Rheumatic fever appears to cause valvular heart disease by an autoimmune phenomenon whereby antibodies against streptococcal antigens cross-react with valvular tissue. Valvular involvement can present acutely as a result of edema of valvular tissue. Progressive fibrosis, superimposed calcification, and scarring with retraction of leaflet tissue lead to valvular stenosis, incompetence, or both. The interval between the occurrence of rheumatic fever and clinical manifestations varies, as does the degree of involvement. Both mitral and aortic valves are usually involved.

degenerative disease

Degenerative calcification is a cause of aortic stenosis in the elderly and in patients with renal dysfunction; it results from calcium deposition on the body of the valvular leaflets rather than on the commissures [*see Figure 1*]. Factors found to promote degenerative valvular changes are increasing age, a low body mass index, hypertension, and hyperlipidemia. Histologic changes that simulate atheroma and involve lipid deposition and inflammatory cell infiltration of the leaflets have been described in patients with early degenerative changes in the aortic leaflets. Even mild degenerative changes in the aortic valve have been reported to be adverse prognostic factors.[5] Calcification of the mitral annulus is common in the elderly; it is more common in women than in men and can produce mitral regurgitation. Occasionally, mitral annular calcification extends onto the valvular leaflets, causing stenosis.

endocarditis

Endocarditis usually occurs on previously abnormal valves, although overwhelming sepsis can infect normal valves. The predominant hemodynamic manifestation of endocarditis is valvular regurgitation. Contributory causes of endocarditis include leaflet prolapse (resulting from a large vegetation), leaflet perforation, and chronic scarring of infected tissue. In rare cases, large vegetations lead to valvular stenosis.

coronary artery disease

Mitral regurgitation is common in coronary artery disease; it has a number of causal mechanisms. Acute ischemia or infarction

Table 1 Causes of Specific Valvular Lesions

	Mitral	*Aortic*	*Tricuspid*	*Pulmonary*
Stenosis	Rheumatic disease, calcification, SLE	Calcification, congenital disease, rheumatic disease	Rheumatic disease, carcinoid tumor	Congenital disease, carcinoid tumor

of a papillary muscle or of the wall to which the papillary muscle is attached leads to impaired leaflet coaptation and mitral regurgitation. Regurgitation can be severe and can vary with the severity of the ischemia. Papillary head rupture or, more rarely, muscle rupture, leads to catastrophic regurgitation that is often fatal.

connective tissue disease

Libman-Sacks endocarditis consists of noninfected warty vegetations involving predominantly the mitral valve; it is characteristic of systemic lupus erythematosus (SLE).[6] Significant regurgitation and stenosis rarely occur acutely but are seen with scarring from chronic disease. Valvular involvement in rheumatoid arthritis is common and leads to valvular thickening but is usually not of hemodynamic significance. Aortitis in ankylosing spondylitis may produce significant aortic regurgitation.

iatrogenic causes of valvular heart disease

Iatrogenic causes include radiation therapy, the use of serotonin agonists such as methysergide, and the use of anorexiants such as fenfluramine and phentermine in combination.[7,8] Radiation leads to scarring and calcification of valvular leaflets many years after the initiating radiation. The effects of both methysergide and anorexiant agents on valvular tissue often simulate rheumatic disease, but regurgitation rather than stenosis predominates as the hemodynamically severe lesion. Serotonin is also thought to play a role in the valvulopathy produced by anorexiants; the precise mechanism by which this occurs remains to be established.

other causes of valvular heart disease

Amyloid disease causes valvular thickening but rarely causes significant stenosis. The carcinoid syndrome most often involves the valves on the right side of the heart and leads to stenosis or incompetence of the tricuspid or pulmonary valve.

secondary involvement

Left ventricular dilatation can cause dilatation of the mitral annulus and, thereby, mitral regurgitation. Common secondary causes of mitral regurgitation include coronary artery disease, aortic valvular disease, and dilated cardiomyopathy. Similarly, tricuspid regurgitation results from right ventricular enlargement secondary to pulmonary hypertension or an atrial septal defect. Dilatation of the ascending aorta, especially involving the annulus of the aortic valve, can lead to aortic regurgitation. This condition is seen in hypertension and in aneurysms of the ascending aorta.

Assessment and Management

Valvular heart disease often remains asymptomatic for many years, but once symptoms develop, survival is reduced if the lesion is not corrected. The assessment of patients with valvular heart disease can be summarized [*see Table 2*]. The evaluation of symptoms can require a stress test or stress echocardiogram in addition to a careful history. Characterization of the lesions and assessment of hemodynamic severity are often possible on physical examination but are aided by additional testing, such as Doppler echocardiography and cardiac catheterization. The auscultatory findings of common valvular lesions also can be summarized [*see Table 3*]. Doppler echocardiography measures the flow velocity across a narrowed valve. By use of the modified Bernoulli equation, the pressure gradient (P), measured in mm Hg, may be estimated from the flow velocity (v), which is measured in m / sec: $P = 4v^2$. Therefore, if the peak velocity recorded across the aortic valve by Doppler echocardiography is 4 m / sec, then the peak pressure gradient will be estimated as $4(4^2)$ or 64 mm Hg. The effects of valvular heart disease on chamber size and function are best assessed serially by echocardiography or, at the time of cardiac catheterization, by ventriculography. In cases of stenotic lesions, intervention is rarely required until symptoms occur. Indications for intervention in regurgitant lesions are more

Table 2 Assessment of Patients with Valvular Heart Disease

Parameters	*Tools*
Symptom severity	History, stress testing
Nature of valve lesion	Auscultation, Doppler echocardiography
Hemodynamic severity of lesion	Physical examination, Doppler echocardiography, cardiac catheterization
Effects of lesion on cardiac chamber size and function	Echocardiography, cardiac catheterization, stress echocardiography
Determination of the optimal time for intervention	Echocardiography, stress echocardiography
Selection of appropriate procedure / prosthesis	Echocardiography

Table 3 Auscultatory Findings Associated with Common Valve Problems

Lesion	*Cardiac Cycle*	*Quality*	*Location*	*Other Sounds*
Aortic stenosis	Systolic, mid-peaking to late peaking	Harsh	Aortic area, left sternal border, apex	Soft S_2, S_4
Aortic regurgitation	Diastolic, early decrescendo	Blowing	Left sternal border, aortic area	—

MVP—mitral valve prolapse

complex; such indications include significant symptoms or, in the absence of symptoms, increasing ventricular size, overt ventricular contractile dysfunction, or both.

All patients with even mild valvular heart disease require prophylaxis against endocarditis at the time of dental procedures or other procedures that can produce significant bacteremia. The prophylactic regimens recommended by the American Heart Association have been revised [*see Table 4*].[9]

Despite the increase in intravascular volume, pregnancy is usually well tolerated in previously asymptomatic patients with valvular heart disease.[10] During pregnancy, regurgitant lesions are better tolerated than stenosis. Prophylactic intervention to increase the valve area is recommended in patients with hemodynamically severe stenosis before pregnancy.

Patients with hemodynamically significant valvular heart disease should generally avoid participation in competitive sports. Reference should be made to the recommendations of the American College of Cardiology for more information about specific lesions.[11] Valvular heart disease is a chronic disease requiring periodic examination and follow-up, even in asymptomatic patients and in those who have had corrective surgical or other procedures. Patients with prosthetic valves should be seen at least yearly.

Specific Valvular Lesions

mitral stenosis

Normally, the cross-sectional area of the mitral valve is at least 4 cm^2. Mitral stenosis leads to a reduction in valve area and is considered severe when the valve area is less than 1 cm^2. To maintain flow through the valve, left atrial pressure rises, leading to an increase in the pressure gradient across the valve and to increased pulmonary venous and capillary pressures, with resultant dyspnea. Flow through the stenotic valve is dependent on the duration of diastole. Tachycardia shortens diastole disproportionately and causes a further elevation in left atrial pressure and can precipitate symptoms even in patients with relatively mild stenosis. Elevated left atrial pressure contributes to left atrial enlargement, which in turn predisposes the patient to atrial fibrillation, atrial thrombus formation, and thromboembolism, all of which are common complications of mitral stenosis. Severe mitral stenosis is often associated with an increase in pulmonary arterial pressure, leading to right-sided heart failure and secondary tricuspid and pulmonary incompetence. In patients with severe pulmonary hypertension, cardiac output at rest is reduced; this output reduction can cause a relatively low pressure gradient across the mitral valve even in patients with severe stenosis.

Diagnosis

Clinical manifestations Mitral stenosis is often asymptomatic at presentation and for many years thereafter. Symptomatic patients often present with dyspnea, but they can also present with angina, right-sided heart failure, atrial arrhythmia, or embolism. The physical findings in mitral stenosis depend on the severity of the stenosis, the mobility of the valve, and the rhythm. The principal sign is a rumbling diastolic murmur that is best heard at the apex with the stethoscope bell. Such a murmur is accentuated by having the patient lie on the left side and by using provocative maneuvers, such as exercise to increase the heart rate. In sinus rhythm, the murmur increases in intensity with atrial contraction (presystolic accentuation). Increased severity of stenosis is associated with a longer murmur and a thrill. With a pliable valve, an opening sound (the opening snap) is heard, and the sudden closure of the stenotic valve at end diastole gives rise to a loud first heart sound that lends a tapping quality to the apex beat. When the valve calcifies and becomes less mobile, the opening snap and loud first heart sound disappear. A loud pulmonary component of the second heart sound is heard with pulmonary hypertension. The signs and symptoms of mitral stenosis are simulated by left atrial myxoma. In this condition, functional mitral stenosis results from prolapse of a mobile tumor arising from the interatrial septum into the mitral valve opening.

Imaging studies Electrocardiography can reveal left atrial enlargement if the patient is in sinus rhythm. Left atrial enlargement, mitral valve calcification, and signs of pulmonary congestion can all be present on chest x-ray. Doppler echocardiography is the test of choice in confirming the diagnosis, establishing the severity of stenosis, detecting complications, and determining the most appropriate treatment. Echocardiography also allows accurate differentiation of mitral stenosis from a left atrial myxoma.

Typically, the stenotic mitral valve leaflets are thicker and less mobile than normal. The severity of stenosis is determined by measuring the pressure gradient across the valve with Doppler echocardiography and by calculating the valve area. Mitral stenosis should be suspected if the mean gradient exceeds 5 mm Hg; the pressure can exceed 20 mm Hg in severe stenosis. Valve area is measured by tracing the smallest opening of the valve in cross section [*see Figure 2*]. This method is the most accurate way of defining the severity of stenosis, although it is technically demanding and sometimes impossible to perform.[12] The valve area can also be calculated by Doppler echocardiography. Such evaluation is made on the basis of an empirical formula that calculates the time it takes for the pressure gradient to fall to half its initial

Table 4 Summary of American Heart Association Recommendations for Endocarditis Prophylaxis[9]

Procedure	*Patient Condition*	*Drug*	*Regimen**
Dental, oral, respiratory tract, or esophageal†	At risk	Amoxicillin	Adults, 2.0 g; children, 50 mg / kg; orally 1 hr before procedure
	At risk and unable to take oral medications	Ampicillin	Adults, 2.0 g; children, 50 mg / kg. I.M. or I.V. within 30 min before procedure
	At risk and allergic to amoxicillin, ampicillin, and penicillin	Clindamycin *or* Cephalexin‡ or cefadroxil‡ *or* Azithromycin or clarithromycin	Adults, 600 mg; children, 20 mg / kg; orally 1 hr before procedure Adults, 2.0 g; children, 50 mg / kg; orally 1 hr before procedure Adults, 500 mg; children, 15 mg / kg; orally 1 hr before procedure
	At risk and allergic to amoxicillin, ampicillin, and penicillin and unable to take oral medications	Clindamycin *or* Cefazolin	Adults, 600 mg; children, 20 mg / kg. I.V. within 30 min before procedure Adults, 1.0 g; children, 25 mg / kg. I.M. or I.V. within 30 min before procedure
Genitourinary / gastrointestinal	High risk	Ampicillin plus gentamicin	Ampicillin: adults, 2.0 g; children, 50 mg / kg *plus* Gentamicin: 1.5 mg / kg (for both adults and children, not to exceed 120 mg) I.M. or I.V. within 30 min before starting procedure *Then, 6 hr later,* Ampicillin: adults, 1 g; children, 25 mg / kg. I.M. or I.V. *or* Amoxicillin, orally: adults, 1.0 g; children, 25 mg / kg
	High risk and allergic to ampicillin and amoxicillin	Vancomycin plus gentamicin	Vancomycin: adults, 1.0 g; children, 20 mg / kg I.V.; over 1–2 hr *plus* Gentamicin: 1.5 mg / kg (for both adults and children, not to exceed 120 mg) I.M. or I.V. Complete injection / infusion within 30 min before starting procedure
	Moderate risk	Amoxicillin *or* Ampicillin	Adults, 2.0 g; children, 50 mg / kg; orally 1 hr before procedure Adults, 2.0 g; children, 50 mg / kg. I.M. or I.V. within 30 min before starting procedure
	Moderate risk and allergic to ampicillin and amoxicillin	Vancomycin	Adults, 1.0 g; children, 20 mg / kg; over 1–2 hr; complete infusion within 30 min of starting the procedure

*Total children's dose should not exceed adult dose.
†Follow-up dose no longer recommended.

value (the pressure half-time). Valve area is estimated as 220 divided by the pressure half-time. Pulmonary arterial (systolic) pressure (PAP) can be determined from the tricuspid regurgitant velocity (TRv) and the estimated right atrial pressure (RAP) (usually estimated as 5 mm Hg) by the following equation: $PAP = 4(TRv)^2 + RAP$. If the tricuspid regurgitant velocity is 3 m / sec, and RAP is estimated to be 5 mm Hg, then the estimated PAP is $4(3^2) + 5 = 41$ mm Hg. The likelihood that the valve may be successfully dilated, either with a balloon or surgically, is estimated by use of a scoring system based on the echocardiographic appearance of the valvular leaflets and supporting structures.

Transesophageal echocardiography is more useful than transthoracic echocardiography in excluding atrial thrombus and determining the severity of mitral regurgitation and is usually performed if balloon valvuloplasty is contemplated. Cardiac catheterization is rarely needed to establish the diagnosis but is used to confirm the severity of stenosis. The valve gradient is the difference between the left atrial pressure or the pulmonary arterial wedge pressure and the left ventricular diastolic pressure. Valve area can be calculated from the pressure gradient and the cardiac output.

Treatment

Once symptoms develop in mitral stenosis, the chance of survival decreases without surgical or balloon dilatation or valve replacement. In the absence of symptoms, management is directed at preventing recurrence of rheumatic fever.[13]

Medical therapy Patients in atrial fibrillation require heart-rate control with a beta blocker (e.g., atenolol, 50 mg q.d.), digoxin (0.125 to 0.25 mg q.d.), or both. Systemic anticoagulation with warfarin is definitely indicated to prevent thromboembolism when (1)

atrial fibrillation is present, (2) there is a history of embolism, or (3) a thrombus is detected in the atrium. Anticoagulation should be considered for patients with paroxysmal atrial fibrillation, a dilated left atrium (> 50 mm in diameter on echocardiography), or severe atrial stasis (as evidenced by swirling echoes or smoke in the left atrium on echocardiography).[14] Regarding symptomatic patients for whom surgical intervention poses a relatively high risk, the judicious use of diuretics and drugs to control heart rate (i.e., digoxin, calcium channel blockers, or beta blockers) may allow symptomatic relief without the need for surgical intervention.

Surgical intervention Intervention to increase valve area is indicated before the onset of symptoms of dyspnea in the following patients: women with severe stenosis who wish to become pregnant but are unlikely to tolerate the volume load of pregnancy, patients who experience recurrent thromboembolic events, and patients who have severe pulmonary hypertension. A number of interventions are currently available to increase the valve area in mitral stenosis. These interventions include percutaneous balloon valvuloplasty, performed in the cardiac catheterization laboratory; surgical commissurotomy; and replacement of the mitral valve with a prosthesis.[15]

Balloon valvuloplasty is performed by inflating a specially designed balloon catheter in the mitral orifice to split the fused commissures. Excellent symptomatic relief is obtained in suitable patients.[16] This intervention is currently the initial choice in mitral stenosis. Typically, the mitral valve area doubles in size from 1.0 to 2.0 cm^2, with a concomitant reduction in the pressure gradient [*see Figure 3*]. Complications of balloon mitral valvuloplasty include severe mitral regurgitation (3%), thromboembolism (3%), and residual atrial septal defect with significant shunting (10% to 20%). Mortality associated with the procedure is less than 1%.[17,18] Contraindications to balloon mitral valvuloplasty include significant mitral regurgitation, which will likely increase after balloon inflation; left atrial thrombus, which can be dislodged at the time of the procedure; and significant subvalvular involvement or leaflet calcification, each of which increases the risk of complications and limits the degree of dilatation produced.[19] In pregnant patients with symptomatically severe mitral stenosis that has not responded to conservative measures such as bed rest and heart-rate control, balloon valvuloplasty is the technique of choice to increase the valve area.[20]

Surgical commissurotomy is now usually performed under direct vision after cardiopulmonary bypass. Surgical commissurotomy may be feasible when balloon valvuloplasty is impossible, such as in patients with significant mitral regurgitation, subvalvular stenosis, or atrial thrombus. A number of studies comparing surgical commissurotomy with balloon commissurotomy have shown equivalent immediate and medium-term (3- to 4-year) results regarding increase in valve area, improvement in symptoms, and freedom from repeat intervention in appropriately selected patients.[19] However, commissurotomy, whether effected by a balloon or surgically, is a palliative procedure, and in most cases further intervention is eventually required. Repeat commissurotomy is sometimes feasible; but most often, mitral valve replacement is also necessary.[21]

A prosthetic replacement is indicated if the valve is heavily scarred or calcified or if severe mitral regurgitation is present. Morbidity and mortality are higher with prosthetic replacement than with either surgical or balloon commissurotomy.

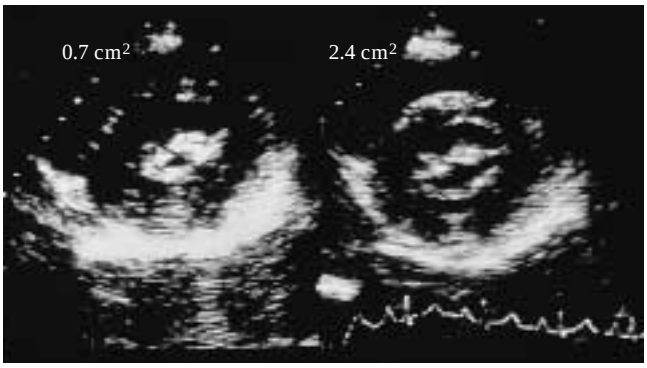

Figure 2 **Two-dimensional echocardiographic parasternal short-axis image of a mitral valve before (left) and after (right) percutaneous balloon mitral valvuloplasty. The valve area is estimated by planimetry and increases from 0.7 cm^2 before valvuloplasty to 2.4 cm^2 after valvuloplasty.**

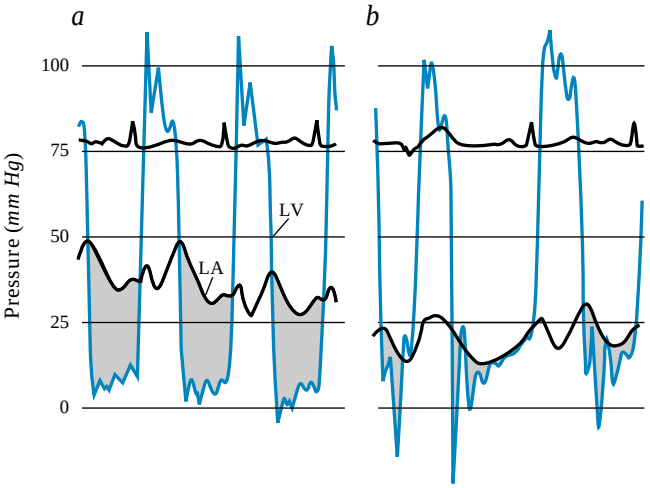

Figure 3 **Simultaneous left atrial pressure (LA, black line) and left ventricular pressure (LV, blue line) are shown (*a*) before and (*b*) after percutaneous mitral valvuloplasty. The shaded area shows the pressure gradient across the mitral valve; the pressure falls after valvuloplasty.**

mitral regurgitation

Mitral regurgitation leads to volume overload of the left ventricle, which must increase in size to achieve a normal stroke output to accommodate the leakage of blood back into the left atrium. Progressive left ventricular dilatation eventually leads to an increase in afterload, contractile impairment, reduction of cardiac output, and heart failure. In acute mitral regurgitation (such as can occur with chordal rupture, ischemia, or endocarditis), left atrial and pulmonary venous and arterial pressures increase quickly, giving rise to dyspnea and, often, acute pulmonary edema. In more chronic forms of mitral regurgitation, an increase in left atrial pressure is often offset by a concomitant increase in atrial compliance; and hence, symptoms appear late in the course of the disease. Left atrial enlargement predisposes the patient to atrial fibrillation and atrial thromboembolism. In long-standing mitral regurgitation, pulmonary hypertension can develop, which in turn leads to tricuspid regurgitation and right-sided heart failure.

Diagnosis

Clinical manifestations In most patients, mitral regurgitation remains asymptomatic for many years. Dyspnea, fatigue

from low cardiac output, and edema occur late in the course of the disease. Mitral regurgitation is recognized clinically by a systolic murmur at the apex, radiating to the axilla and increasing on expiration. In patients with a posteriorly directed jet of mitral regurgitation, the murmur is heard well at the back. In more severe cases, the murmur lasts throughout systole, the first and second heart sounds are soft or difficult to hear, and a third heart sound is present. A midsystolic click can be present in myxomatous disease; in less severe cases, this click can precede the murmur. The murmur can also be confined to late systole, with papillary muscle dysfunction. Mitral regurgitant murmurs caused by ischemia can be variable in duration and intensity, depending on the degree of ischemia and the loading conditions.

Imaging studies Doppler echocardiography is the noninvasive method of choice in confirming the presence of mitral regurgitation. Echocardiography is used to diagnose the mechanism of the regurgitation (e.g., prolapse or annular dilatation); color-flow mapping is used to provide a semiquantitative assessment of severity based on the size and penetration of the left atrium by the regurgitant jet. Additionally, echocardiography can be used to assess the effects of the regurgitation on left ventricular size and function. Quantitative measurements of regurgitation, such as the regurgitant volume, regurgitant fraction ([regurgitant volume plus stroke volume] divided by regurgitant volume), and regurgitant orifice area (the area through which the valve leaks), are now possible with newer Doppler techniques. These techniques are useful in determining the true severity of the lesion and following it over time.[22] Left ventricular size and volume, as well as contractile function assessed by the ejection fraction, are used to determine the need for surgical intervention.

However, asymptomatic mitral regurgitation is more difficult to assess and manage than other valvular lesions because in this condition, the true contractile function of the left ventricle is difficult to determine with conventional measures such as the ejection fraction. These measurements of contractility are confounded by the increase in ventricular preload caused by the extra volume of blood in the left atrium and the variable effect on afterload. Afterload is increased by left ventricular dilatation, but this effect is offset as the ventricle ejects much of its blood into a relatively low pressure system (the left atrium). The left ventricular ejection fraction can appear falsely elevated in mitral regurgitation and usually falls after surgical correction. An ejection fraction of less than 60% should be considered abnormally low in patients with mitral regurgitation.

Transesophageal echocardiography is very sensitive in the detection of mitral regurgitation and is used mainly in those patients who are difficult to evaluate by the transthoracic approach.[23] Contrast ventriculography is used to determine the severity of mitral regurgitation in patients undergoing cardiac catheterization. This procedure involves injecting radiopaque contrast medium into the left ventricle and assessing the extent and duration of opacification of the left atrium. In patients undergoing hemodynamic monitoring, large systolic V waves on the pulmonary arterial wedge tracing raise the suspicion of acute severe mitral regurgitation, as can occur in acute ischemia, but such V waves can occur in the absence of severe regurgitation.

Treatment

Indications for surgery In the management of asymptomatic mitral regurgitation, it should be borne in mind that left ventricular dysfunction is often latent and that, once present, the dysfunction cannot be corrected by operative intervention.[24] Therefore, it is important to refer patients for surgery before the onset of true left ventricular dysfunction even in the absence of symptoms.

Unfortunately, no load-independent measure of contractile function is readily available. Stress echocardiography is useful in detecting latent left ventricular dysfunction not evident on a resting study. Failure of the left ventricular ejection fraction to increase on exercise or of the left ventricular end-systolic volume to decrease on exercise is predictive of incipient left ventricular dysfunction and should be considered an indication for early surgery.[23]

Other echocardiographic indices that have been associated with a less favorable surgical outcome include an absolute end-systolic dimension that is greater than 4.5 cm or that is greater than 2.6 cm/m^2 when indexed for body surface area; an end-systolic volume of greater than 50 ml/m^2; and a resting ejection fraction of less than 60%.[23] Surgical referral should be considered if ventricular size and function approach these indices.[25] Serial echocardiographic evaluation should be performed at least yearly and should be performed more frequently as ventricular dilatation progresses in patients with severe asymptomatic mitral regurgitation. Studies indicate a better long-term survival rate in patients with severe mitral regurgitation when surgery is performed early.[26,27]

Symptomatic severe mitral regurgitation is considered an indication for surgical intervention if the valve is primarily involved. Symptomatic patients with ischemic mitral regurgitation often require mitral valve surgery in addition to revascularization. Mitral regurgitation secondary to left ventricular dilatation often improves with afterload reduction, and surgical intervention is not usually indicated.

Patients with moderately severe or severe left ventricular dysfunction (ejection fraction < 35%) and significant mitral regurgitation were thought in the past to be poor surgical candidates because of high operative risk. However, recent research has shown that there is acceptable risk associated with operations in these patients. Symptoms usually improve, but a survival benefit associated with surgery in this group has not yet been shown.[28,29] Patients who are not considered suitable for surgery because of left ventricular dysfunction often benefit from afterload reduction and diuretics.[30] However, in patients who have primary asymptomatic mitral regurgitation with preserved left ventricular function, afterload reduction has not been shown to delay surgery or improve left ventricular function in the few small studies that have addressed this issue; afterload reduction is not currently recommended to treat such patients.[31] Afterload reduction is beneficial for stabilizing patients with hemodynamically significant acute mitral regurgitation in preparation for surgery.

Surgical intervention Mitral valve repair is currently the technique of choice in the surgical management of mitral regurgitation because the operative mortality is lower, ventricular function is better preserved, and long-term complications such as thromboembolism and infection are lower with repair than with replacement [*see Figure 4*].[32-34] Valve repair is most likely to be feasible in patients with myxomatous disease, especially if such disease involves the posterior leaflet, and is least likely to be successful in patients with rheumatic disease and endocarditis.[34,35] Valve repair is accomplished by use of a variety of techniques, depending on the mechanism and etiology of the regurgitation. Such techniques include partial leaflet resection, chordal shortening or transfer, and insertion of an annuloplasty ring to reduce the size of the annulus. Long-term failure of repair occurs at a rate of 1% to 2% a year but is higher in patients with rheumatic disease. If mitral

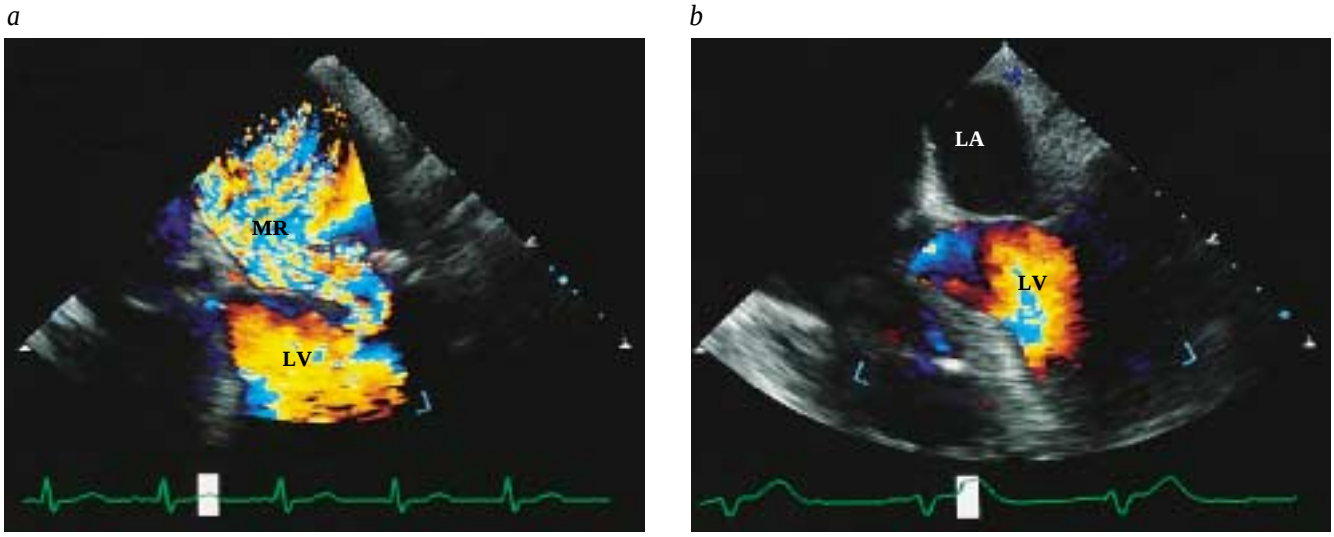

Figure 4 **Transesophageal echocardiogram of a patient with severe myxomatous mitral regurgitation (MR) (*a*) before and (*b*) after mitral valve repair.**

valve repair is not possible, a mitral prosthesis is implanted.[35] Chordal and papillary muscle preservation is increasingly being employed when a mitral prosthesis is inserted, because preserving the muscles has been shown to help conserve left ventricular function after surgery.[36]

mitral valve prolapse

Mitral valve prolapse is a common condition in which the mitral valve leaflets are displaced in systole into the left atrium.[3] It is usually caused by myxomatous degeneration of the valve and can occur in some form in up to 3% of the general population; it is more common in women than in men. In the majority of cases, mitral valve prolapse represents a benign abnormality; in a minority, mainly older men, significant mitral regurgitation results from rupture of a chord or from endocarditis and requires surgical intervention. Mitral valve prolapse is associated with low body weight, low blood pressure, and thoracic skeletal abnormalities such as pectus excavatum. Patients with mitral valve prolapse have a slightly increased risk of stroke, myocardial ischemia, and sudden death. Ventricular extrasystoles are common and can be symptomatically troublesome. Other arrhythmias, such as ventricular or supraventricular tachycardia, are reported but are uncommon.

Diagnosis

Mitral valve prolapse has been associated with multiple nonspecific symptoms, such as atypical chest pain, presyncope, anxiety, and panic attacks. These symptoms are more commonly reported by women than men. A causal relation between these symptoms and mitral valve prolapse has not been established.[3]

A midsystolic click at the mitral area during cardiac auscultation is often the finding that first brings mitral valve prolapse to the attention of the examiner. The click has been attributed to tensing of the redundant valvular tissue with cardiac contraction. A late systolic murmur can follow the click. Maneuvers that reduce intracardiac volume, such as having the patient stand or perform the Valsalva maneuver, cause the click to occur earlier in systole and cause an increase in the duration of the murmur. The typical auscultatory findings and their response to these maneuvers are sufficient to make a diagnosis of mitral valve prolapse. Two-dimensional echocardiography is the method of choice to confirm the diagnosis. Apparent systolic displacement beyond the annular plane is possible with both M-mode and two-dimensional approaches because the annulus is nonplanar and saddle-shaped. The possibility of a false positive diagnosis can be minimized by seeking systolic displacement of the leaflets in a parasternal long-axis view. Myxomatous mitral valve leaflets frequently are thicker, are more redundant, and have longer chordae than normal as seen on echocardiography. Doppler echocardiography is used to detect and quantify associated regurgitation.

Treatment

Asymptomatic mitral valve prolapse requires no specific treatment. Periodic examination is indicated to detect any progression in the severity of mitral regurgitation. Prophylaxis for endocarditis is indicated if both a click and a murmur are present but is not indicated in the absence of mitral regurgitation.[37] Symptomatic ventricular ectopy often responds to beta blockade. Many patients with atypical chest pain and other nonspecific symptoms improve when they are reassured of the relatively benign nature of the condition. Empirical treatment with small doses of beta blockers can also provide symptomatic relief. Mitral regurgitation should be treated as described earlier.

aortic stenosis

The normal aortic valve is 3 to 4 cm^2 in area when fully open. Aortic stenosis is considered severe when the valve area is 1 cm^2 or less and is considered critical when the area is less than 0.75 cm^2. Aortic stenosis causes concentric left ventricular hypertrophy as a compensatory mechanism that maintains cardiac output at rest despite the increased pressure gradient across the valve. Eventually, this compensatory mechanism is overcome, causing the left ventricle to fail and dilate and the resting cardiac output to decline.

Diagnosis

Clinical manifestations There is a variable relation between the severity of stenosis and symptoms. Many patients with critical aortic stenosis are asymptomatic, whereas patients in states of volume overload, such as pregnancy, may have symptoms with

stenosis of lesser severity. Dyspnea is often the presenting feature; it reflects increased left atrial pressure and pulmonary venous hypertension from the increased left ventricular pressure in systole and the diastolic ventricular dysfunction imposed by left ventricular hypertrophy. Angina is common even in the absence of significant obstruction in the epicardial coronary blood vessels because of impaired supply of blood to the subendocardium in the hypertrophied left ventricle. Exertional syncope also occurs with stenosis and can result from the inability to increase cardiac output sufficiently to supply both skeletal muscle and the cerebral vasculature, resulting in impaired cerebral blood supply, or from abnormal baroreceptor reflexes. Serious arrhythmia can also cause syncope and, in severe aortic stenosis, even sudden death. Fatigue is common because of low cardiac output.

In severe aortic stenosis, the carotid pulse typically is reduced in intensity and has a slow delayed upstroke. Aortic stenosis gives rise to a systolic murmur that is heard over the aortic area and that can radiate to the carotid arteries and to the apex. In severe stenosis, the murmur peaks later in systole and can be associated with a thrill. A fourth heart sound is usually present. In mobile congenitally abnormal valves, an ejection click can precede the murmur. Severe calcific aortic stenosis is often associated with a diminished intensity of the aortic component of the second heart sound. Although the physical findings are important in alerting the clinician to the presence of aortic valve disease, the degree of hemodynamic severity is more reliably determined with Doppler echocardiography.

Imaging studies The presence of left ventricular hypertrophy on electrocardiography provides useful supporting evidence for significant aortic stenosis. Doppler echocardiography is used to determine the mechanism and the hemodynamic severity of the stenosis as well as the effects on left ventricular size and function. In aortic stenosis, the opening of the aortic valve is reduced, as seen on the echocardiogram. Continuous wave Doppler echocardiography is used to measure the peak velocity across the valve and thus the aortic pressure gradient; the mean pressure gradient across the valve is often 50 mm Hg or more in patients with severe aortic stenosis. However, the pressure gradient is determined not only by the degree of stenosis but also by flow through the valve and can be relatively low despite severe aortic stenosis if cardiac output is reduced. In most instances, therefore, the valve area as well as the pressure gradient should be calculated. The valve area is estimated readily from the flow through the valve and the pressure gradient across the valve. With cardiac catheterization, the pressure difference across the aortic valve between the left ventricle and the aorta is measured directly. Valve area can be calculated from the cardiac output and the pressure gradient. Because Doppler echocardiography and invasive measurements of aortic valve severity have been shown to agree when both are performed expertly, cardiac catheterization is now used less often as the primary diagnostic tool in assessing aortic stenosis [*see Figure 5*]. Cardiac catheterization is used to confirm the echocardiographic findings in patients being considered for surgery or when there is significant discrepancy between the clinical findings and echocardiographic findings.

Treatment

Indications for surgery Aortic stenosis is a progressive disease, and patients with the disease can remain asymptomatic for many years. The rate of progression varies greatly but increases with age, associated coronary artery disease, and the severity of the stenosis.[38] Progression to symptoms or intervention is likely within 2 years in older patients with severe asymptomatic aortic stenosis.[37] Once symptoms become manifest, the survival rate without surgical treatment is reduced; mean survival is 5 years in patients with angina, 3 years in patients with syncope, and 2 years or less in patients with heart failure.[38] Operative mortality increases with severe symptoms, advanced age, and the presence of left ventricular dysfunction. The onset of symptoms, therefore, is the major indication for surgical intervention. Left ventricular dysfunction attributable to aortic stenosis is another indication for intervention because it demonstrates failure of compensatory mechanisms and incipient symptoms. Sudden death can occur with aortic stenosis, but this is rare in the absence of symptoms. Patients should be instructed to report the onset of any symptoms and should undergo regular follow-up evaluations with physical examination and Doppler echocardiography. Doppler examination should be performed at least yearly and should be performed more frequently in patients with severe stenosis and in older patients. Surgical relief of aortic stenosis usually leads to relief of symptoms and improvement in left ventricular function when such function was abnormal preoperatively.

Aortic valve surgery in the very elderly is associated with an increased mortality but provides excellent palliation of symptoms; surgery should be considered for such patients provided they are otherwise viable candidates.[39] Patients with severe left ventricular dysfunction resulting from aortic stenosis should also be considered for surgery, because significant improvement in ventricular function and symptoms often results, and without surgery the survival rate in these patients is poor.

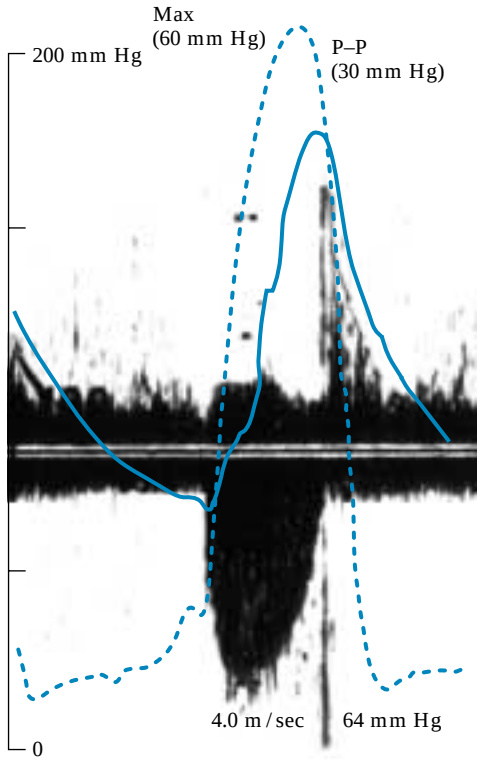

Figure 5 **Simultaneous left ventricular (broken blue line) and aortic (solid blue line) pressure tracings and continuous wave Doppler tracing in a patient with severe aortic stenosis. The pressure gradient (P–P, or 30 mm Hg) is the area between the aortic and LV tracings. Maximal pressure gradient (Max) by cardiac catheterization (60 mm Hg) is similar to that measured by Doppler echocardiography (64 mm Hg).[63]**

Surgical intervention Surgical intervention for patients with aortic stenosis usually involves insertion of a prosthesis or a human valve. In congenital aortic stenosis, valve repair or commissurotomy can be feasible, although significant aortic regurgitation can result. Balloon valvuloplasty has proved disappointing in the long-term treatment of adult calcific aortic stenosis. Valve area typically increases from 0.5 cm^2 to 0.8 cm^2 and is associated with improvement of symptoms in the majority of cases.[18] However, stenosis recurs in as many as 50% of patients within 6 months, and fewer than 25% survive more than 3 years.[40] Balloon valvuloplasty is now indicated in the palliative treatment of adult patients with aortic stenosis who are not surgical candidates because of significant comorbidity; it is also used to stabilize critically ill patients for whom surgery is planned at a later stage. Balloon dilatation is effective in young patients with congenital aortic stenosis and is an alternative to surgery in symptomatic aortic stenosis during pregnancy.

aortic regurgitation

Aortic regurgitation causes a volume overload of the left ventricle. In chronic aortic regurgitation, the volume overload is well tolerated for years. The left ventricle dilates to accommodate the increased volume load and thereby maintains a normal resting cardiac output. Unlike mitral regurgitation, the left ventricle in aortic regurgitation must expel all of the increased volume of blood into the systemic circulation; severe enlargement of the left ventricle is common. Because of a compensatory increase in ventricular compliance, left ventricular diastolic pressure often remains in the normal range despite the increase in ventricular size. The ventricle hypertrophies to maintain normal wall stress. Eventually, compensatory mechanisms fail, and contractile impairment and increased diastolic pressure result in elevated left atrial and pulmonary venous pressures and symptoms. Acute aortic regurgitation can develop as a result of sudden disruption of the valve apparatus with endocarditis or aortic dissection. This condition is poorly tolerated because the left ventricle is unable to dilate fast enough to compensate for the volume load. Left ventricular diastolic pressure rises rapidly and leads to pulmonary congestion and edema. Cardiac output falls, and shock and even death can follow.

Diagnosis

Clinical manifestations In chronic aortic regurgitation, symptomatic presentation occurs late in the course of disease; dyspnea and fatigue are the usual findings. Angina can occur in the absence of coronary artery disease because of the increased demand for oxygen caused by severe left ventricular enlargement and hypertrophy together with the reduced supply of oxygen resulting from the underperfusion of the coronary arteries. Such underperfusion is caused by the low diastolic pressure characteristic of this condition.

The cardinal physical sign of aortic regurgitation is a diastolic murmur that is high pitched and best heard with the diaphragm of the stethoscope with respiration suspended in expiration. The murmur is loudest immediately after aortic valve closure; it progressively diminishes in intensity throughout diastole, paralleling the decline in the pressure gradient between the aorta and the left ventricle. The murmur is best heard on the left of the sternal border in disease of the aortic cusps and on the right of the sternal border in disease of the aortic root. Even in the absence of significant stenosis, an aortic systolic murmur is audible, reflecting the increased flow through the valve. Severe chronic aortic regurgitation is characterized by a wide pulse pressure and an elevated systolic pressure caused by the increased stroke output; also characteristic is a reduction in the diastolic pressure, which occurs as blood leaks back into the left ventricle throughout diastole. If the aortic regurgitant jet hits the mitral valvular leaflet, it can cause partial closure of the valve, creating an apical diastolic murmur that simulates mitral stenosis (Austin Flint murmur). The ejection of a large volume of blood into the systemic circulation and its rapid leak backward into the heart cause many peripheral circulatory manifestations that confirm rather than establish the diagnosis. Acute aortic regurgitation can be more difficult to recognize because the murmur is often short, and the reduced cardiac output leads to reduced intensity of the murmur.

Imaging studies Marked cardiomegaly and prominence of the ascending aorta are often present on chest x-ray in patients with chronic severe aortic regurgitation. Doppler echocardiography confirms the mechanism and severity of aortic regurgitation and its effect on left ventricular size and function. Regurgitant volume and fraction can be quantified by echocardiographic Doppler techniques. More often, the severity of regurgitation is graded on the basis of several qualitative and semiquantitative measures, including the dimensions of the regurgitant jet in the left ventricular outflow tract and of the ventricular cavity, as determined by color flow Doppler mapping, and the presence of diastolic flow reversal in the descending thoracic aorta, as determined with pulsed wave Doppler echocardiography [*see Figure 6*].[41] In severe aortic regurgitation, early closure of the mitral valve and diastolic mitral regurgitation can occur as a result of the increased pressure in the left ventricle in diastole [*see Figure 6*]. Confirmation of the severity of aortic regurgitation is obtained by aortography, a process in which contrast medium is injected into the aortic root and the retrograde filling and clearing of contrast dye from the left ventricle is examined. Aortography is the current gold standard for assessing the severity of aortic regurgitation; it should be performed if there is any discrepancy between the clinical findings and the findings on Doppler echocardiography. Stress ventriculography and echocardiography have both been used to determine the response of the left ventricle to the effects of exercise: a significant fall in left ventricular ejection fraction or an increase in end-systolic volume suggests incipient contractile dysfunction and can be an indication for early surgical intervention.

Treatment

Chronic aortic regurgitation is well tolerated for many years.[42] Operative mortality is increased and long-term survival reduced if the left ventricle is greatly enlarged or if left ventricular dysfunction has been present for more than 1 year. Left ventricular dysfunction that is present for a shorter period is likely to improve and even resolve after surgery. Several studies have shown that asymptomatic patients with normal left ventricular function can be safely followed for a long period (up to 11 years in one study) when serial physical examination and Doppler echocardiographic examination are performed at least yearly and then performed more frequently as left ventricular dilatation progresses.[42]

Surgery is indicated when symptoms develop. In asymptomatic patients, surgery is indicated when resting left ventricular function declines or if severe left ventricular dilatation (end-systolic dimension > 5 cm; end-diastolic dimension = 7 cm) occurs.[43] Evidence suggests that these dimensions should be normalized for body size and that surgery should be considered at an earlier stage, especially in women. Afterload reduction with vasodilators such as hydralazine, captopril, and nifedipine has been shown to

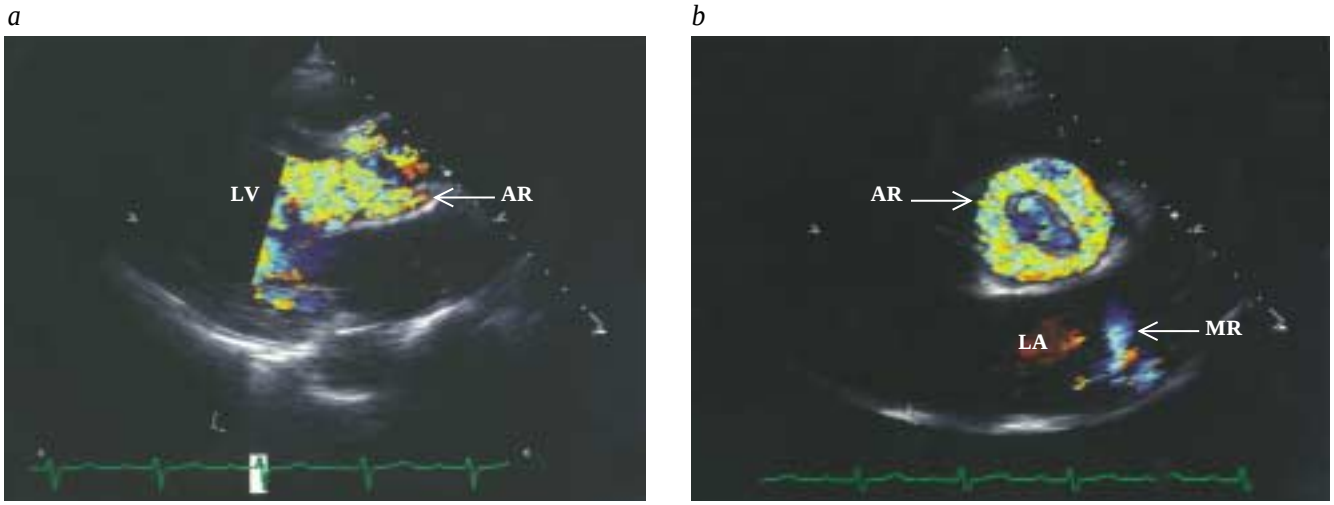

Figure 6 **Parasternal long-axis view (*a*) and short-axis view (*b*) of a severely regurgitant aortic allograft. Aortic regurgitation (AR) is seen circumferentially around the insertion site. Diastolic mitral regurgitation (MR) is also seen.**

reduce regurgitant volume and ventricular size in aortic regurgitation.[31] Treatment with nifedipine, 20 mg twice a day, has been shown to delay the need for surgical intervention in chronic asymptomatic aortic regurgitation but has not been widely used for this indication.[44] Acute severe aortic regurgitation necessitates urgent surgery. Intravenous vasodilatation with sodium nitroprusside or another vasodilator can reduce the regurgitant volume and help stabilize the patient awaiting surgery.

Surgical intervention in aortic regurgitation usually leads to improvement in symptoms and left ventricular size. Although the operative risk is increased when severe left ventricular dilatation or dysfunction is present, significant improvement in symptoms and ventricular function often occurs after surgery; the prognosis without surgery is very poor.[43] Aortic regurgitation usually requires insertion of a prosthesis or a human valve. Occasionally, repair is feasible, especially in prolapsing bicuspid valves or when the aortic ring is dilated.

Tricuspid and Pulmonary Disease

Tricuspid regurgitation is most often secondary to right ventricular dilatation and is the most common valvular problem of the right heart. Tricuspid regurgitation is recognized on physical examination by the characteristic large V waves in the jugular venous pulse and by a systolic murmur heard at the base of the xiphisternum that increases on inspiration. In severe cases, pulsatile hepatomegaly is present. Doppler echocardiography allows rapid detection and assessment of the severity of the regurgitation. Presentation often includes fatigue from reduced forward output and peripheral edema. Severe tricuspid regurgitation is usually treated with surgical repair. If a repair is not possible, a bioprosthesis is usually implanted because of the increased risk of thrombosis of a mechanical prosthesis at this position. Secondary tricuspid regurgitation can improve if the primary condition leading to pulmonary hypertension is treated and leads to a decrease in right heart size.

Tricuspid stenosis occurs in approximately 5% to 10% of patients with severe mitral stenosis. The characteristic physical findings are a large A wave in the jugular venous pressures and a diastolic murmur over the tricuspid area. Doppler echocardiography and right heart catheterization are both used to assess severity. The mean gradient across the tricuspid valve is typically greater than 5 mm Hg. In patients with significant stenosis, either balloon dilatation or surgical repair or replacement is indicated.

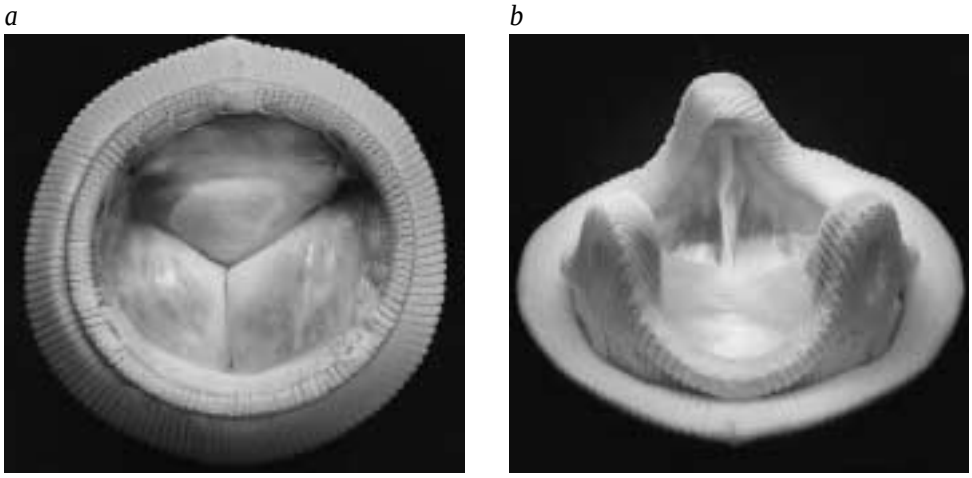

Figure 8 **(*a*) Top view of an aortic porcine xenograft that has been preserved in glutaraldehyde and mounted on a flexible plastic stent. (*b*) Bottom view of the same valve.**

Congenital pulmonary stenosis occurs in isolation or as part of various syndromes and is usually detected before adulthood. Significant pulmonary stenosis is treated with balloon dilatation or surgery. Significant pulmonary insufficiency is rare but can occur with a carcinoid tumor or endocarditis or secondary to pulmonary hypertension. Pulmonary allograft implantation is indicated for severe cases.

prosthetic valves

Prostheses can be classified into two groups—mechanical and biologic—each having different properties, problems, and indications.[45]

Mechanical Prostheses

Mechanical prostheses are of two main types: ball-in-cage and tilting-disk [*see Figure 7*]. The Starr-Edwards valve is the prototypical ball-in-cage valve that has been implanted with various modifications since the 1960s. Tilting-disk valves can consist of one or two leaflets. Single-leaflet models include the Björk-Shiley and Medtronic-Hall valves. The most commonly implanted bileaflet models are the St. Jude valve and the CarboMedics valve. The major advantage of mechanical prostheses is durability. Mechanical prostheses can remain functional for decades and are used especially in young or middle-aged patients to reduce the need for reoperation.[46] Their chief disadvantage is the associated risk of thromboembolism, which necessitates long-term anticoagulation and carries a risk of hemorrhage. An increased incidence of subsequent infection, hemolysis, thrombosis of the valve, and mechanical failure is another problem associated with mechanical prostheses.

Bioprostheses

Three classes of biologic valves are currently available. A xenograft is a prosthesis fashioned from animal tissue [*see Figure 8*]. Most xenografts consist of modified porcine valves that are preserved in glutaraldehyde and mounted on a stent.[47] Prostheses have also been constructed of pericardium and other biologic materials.[48] Stentless bioprostheses are under investigation and are postulated to improve the effective size of the prosthetic valve opening.[49] Allografts (homografts) are human valves that have been harvested postmortem and either cryopreserved or treated with antibiotics.[50] An autograft is a valve from the patient's own body that is moved to a different anatomic site.[51] The most common autograft is the pulmonary valve inserted at the aortic position. A pulmonary allograft is inserted in its place. Patients with biologic valves have a lower risk of thromboembolism than those with mechanical prostheses and do not usually require long-term anticoagulation. Biologic valves are indicated for patients in whom anticoagulation is inappropriate. Xenografts are less durable than mechanical prostheses. Xenograft durability is greatest in patients older than 60 years and improves with age.[52] Xenografts are not usually inserted in patients younger than 60 years because of the poor survival record in this group. Allografts and autografts are alternatives to mechanical prosthetic implantation at the aortic or pulmonary positions in younger patients. Insertion of these valves is technically more demanding and is not widely done. No long-term survival benefit of allografts over xenografts has been demonstrated. Autografts have proved to be durable and have the potential to grow in situ.[51] They are used in the management of pediatric and adolescent patients with aortic valve disease.[53] Both allografts and autografts result in a low reinfection rate when used in the treatment of prosthetic aortic endocarditis and are considered the valve replacement of choice for this condition.[50]

problems and complications of valve prostheses

Thromboembolism

Systemic anticoagulation with warfarin or dicumarol decreases the incidence of, but does not eliminate the occurrence of, thromboembolism with mechanical valves.[54] The incidence of thromboembolic events is lowest in patients younger than 50 years, lower with aortic prostheses than with mitral or multiple prostheses, and lower with bileaflet disk valves than with single-leaflet valves.[54] Hemorrhagic events are more common in older patients. Anticoagulation is generally monitored using the international normalized ratio (INR). Studies have indicated that the level of anticoagulation required to prevent thromboembolism is less than was previously thought. A large study of anticoagulation in patients with mechanical prostheses has suggested that an INR of between 2.5 and 4.0 is desirable in most instances and minimizes hemorrhagic and thromboembolic complications.[54] The appropriate INR for an individual patient will vary depending on the history of embolic or bleeding events; age; and type, position, and number of prostheses. Antiplatelet agents such as aspirin (81 mg

q.d.) or clopidogrel may be added to the anticoagulation regimen in patients who have sustained recurrent thromboembolic events despite adequate anticoagulation. Thromboembolic risk with xenografts is greatest in the first 3 months after surgery.[55] During this period, oral anticoagulation medications are recommended for high-risk patients (e.g., those with mitral prostheses or paroxysmal atrial fibrillation); for patients who are not at high risk, aspirin, 325 mg / day, is recommended.

Valvular Thrombosis

Acute thrombosis of a mechanical valve is more common with a single tilting-disk valve. The incidence is highest at the tricuspid position, followed by the mitral position, and is least common at the aortic position. Thrombosis of left-sided valves can lead to acute pulmonary edema and systemic thromboembolism. Reduced motion of the disk or ball is characteristic of valvular thrombosis and can be demonstrated with transesophageal echocardiography or fluoroscopy.[56,57] There is usually an increased pressure gradient across the valve. Acute thrombosis of a mechanical valve is an indication for emergency surgery to remove the thrombus and to implant another prosthesis. In patients who are not surgical candidates or who are considered at high operative risk, thrombolysis has been used successfully to increase valve opening and motion and reduce the valve gradient. Success rates greater than 70% have been reported in a number of series.[56] Thromboembolism is the most common complication of thrombolysis in this setting and occurs in 12% to 22% of patients. Further episodes of valvular thrombosis after initial successful thrombolysis have been reported.[56]

Valve Failure

In mechanical prostheses, failure of one of the mechanical parts is rare but can have catastrophic consequences. Failure is most common with tilting-disk valves, particularly with the Björk-Shiley single-leaflet tilting-disk valve, which is no longer available commercially in the United States.[58] Failure of the outlet strut in several of these models led to embolization of the disk and acute valve failure, with high morbidity and mortality. Prophylactic repeat surgery has been recommended for certain groups of patients in whom the failure rate is highest.[58] Advanced imaging techniques designed to detect sites of potential strut fractures are currently in development.[59]

Valve failure is expected with bioprostheses and allografts. Fortunately, degeneration is a slow process in biologic prostheses and is usually present for years before significant hemodynamic consequences are seen. Leaflet calcification can give rise to stenosis, whereas cusp degeneration can lead to perforation, with resultant regurgitation. Bioprosthetic degeneration is managed in the same way as stenosis or regurgitation of a native valve. Repeat surgery is indicated for significant symptoms or progressive ventricular enlargement or dysfunction.

Failure of either a mechanical or a biologic prosthesis can occur because of failure of the sutures holding the valve in place. Sutures can fail because of associated infection, but they can also fail spontaneously. A St. Jude valve in which the sewing ring was impregnated with silver nitrate to reduce the likelihood of infection was recalled because of a high incidence of paravalvular leak. The paravalvular leak resulting from suture failure can begin as a relatively mild lesion, but progression is common. In severe instances, partial or complete dehiscence can result in a characteristic rocking motion of the valve, as revealed by echocardiography. Paravalvular leaks are often accompanied by significant hemolysis as red blood cells are destroyed at the site of increased shear stress.[60] Hemodynamically significant paravalvular leaks are considered an indication for reoperation.

Infection

There is an increased risk of endocarditis with mechanical prostheses and xenografts, compared with native valves or allografts. Prosthetic valve endocarditis is often associated with abscess formation. Prosthetic vegetation and abscess formation are best evaluated by using transesophageal echocardiography, which should be performed if a diagnosis of prosthetic valve endocarditis is being considered. Prosthetic valve endocarditis is extremely difficult to eradicate with medical treatment alone; operative intervention is usually required.

Inherent or Acquired Prosthetic Stenosis

All prosthetic valves are inherently stenotic, but in an appropriately selected prosthesis, the degree of stenosis is mild and not of clinical significance. Occasionally, a smaller than desirable prosthesis is implanted because the native valve annulus is small. In such cases, patients can manifest symptoms and signs of valvular stenosis and have severely increased pressure gradients across the valve, especially during exercise. In severe cases, explanation of the prosthesis and annular reconstruction may be necessary to accommodate a prosthesis of sufficient size. In some patients with mechanical prostheses, ingrowth of a fibrous pannus can impede blood flow and lead to hemodynamic stenosis, requiring reoperation.

Problems Associated with Pregnancy

Pregnancy is contraindicated in women with mechanical prostheses because of considerable risk to mother and fetus. The risk to the mother is associated with difficulty in maintaining effective anticoagulation; the risk to the fetus is associated with potential teratogenic effects of warfarin.[61] If possible, valve repair or insertion of an allograft or autograft should be attempted in a woman of childbearing age who wishes to become pregnant. Xenografts are less durable in young patients, especially during pregnancy, and are best avoided.[62] The management of patients with mechanical prostheses who become pregnant or desire pregnancy is controversial. Warfarin is associated with embryopathy and increases the risk of fetal wastage. Optimal anticoagulation is also difficult with heparin, especially when given subcutaneously, and is associated with increased maternal risk for thromboembolism and hemorrhage.[62] Different approaches have been advocated for the management of pregnant patients with mechanical prostheses; self-administration of heparin subcutaneously throughout pregnancy (ideally, from the time of conception) is the preferred approach in the United States.[63] This approach involves administering heparin every 12 hours and keeping the activated partial thromboplastin time at 1.5 to 2.0 times the control value 6 hours after administration, unless low-molecular-weight heparin is used, thereby eliminating the need to monitor the partial thromboplastin time.

anorexiant-induced valvular disorder

Drugs that suppress appetite (anorexiants) have been reported to cause a valvular disorder similar to that caused by ergot derivatives and carcinoid syndrome. This finding was first reported in 1997, and a number of large studies since then have confirmed an increased prevalence of valvular disorders in populations treated with fenfluramine, dexfenfluramine, phentermine, or a combination of these drugs.[7,8] Over 18 million prescriptions were filled for

these drugs in 1996 alone. The precise pathophysiology of the valvular disorder is still unclear. All of these anorexiants affect central serotininergic receptors. A causal relation of serotonin in this disorder is also suggested by the disorder's similarity to carcinoid disease, in which serotonin is also implicated as a causative factor. Initial reports suggested a high prevalence of valvular disease in patients treated with these anorexiants, and they were withdrawn from the market in September 1997. The prevalence of clinically symptomatic valve-related disease in patients receiving these drugs has been reported to be 1 in 1000.[64]

Anorexiant-drug valvulopathy affects mainly the aortic and mitral valve. Leaflet thickening, restricted leaflet motion, chordal thickening, and valve regurgitation without stenosis are the most common abnormalities seen.[65] Although valvular disease severe enough to warrant surgery has been reported, in many instances the valvular lesion appears to be mild or moderate in severity. Factors thought to increase the likelihood of more severe disease are longer duration of treatment with anorexiant therapy, use of drug combinations, and higher dosages of drugs. Patients who received less than 3 months of treatment appear to have a relatively low likelihood of significant valvular disease.[66] Studies also suggest that the valvular lesions may not progress and may even regress after discontinuance of the drug.[67] Patients exposed to anorexiants should undergo a thorough cardiovascular examination for signs of mitral or aortic regurgitation. Echocardiography is indicated if the physical findings suggest valvular disease or if the duration of treatment has been more than 3 months. Patients with evidence of valvular disease on echocardiography should be followed serially and receive prophylactic antibiotics for dental and other procedures associated with significant bacteremia.

XII DISEASES OF THE AORTA

Kim A. Eagle, m.d.
William F. Armstrong, m.d.

The Normal Aorta

The normal aorta is composed of three distinct layers: the inner intima, an elastic middle layer called the media, and a thin outer layer called the adventitia. In the media, layers of elastic elements intertwine with collagen and smooth muscle cells, providing the elastic strength that enables the aorta to withstand the pulsatile stress produced by the ejection of blood during ventricular systole. During systole, the aorta is distended by the force of blood ejected into the lumen. The kinetic energy of the ejected blood is transmitted to the wall of the aorta. In diastole, the potential energy stored in the aortic wall is transformed to kinetic energy as it propels the blood forward in the aorta and to its branches. With age, the normal elastic elements of the aorta degenerate, reducing its elasticity and distensibility. The aorta is considered to consist of three anatomic segments: the ascending aorta, the aortic arch, and the descending aorta. The ascending aorta consists of the aortic annulus, the aortic cusps, the sinuses of Valsalva, the sinotubular ridge, and the tubular portion of the ascending aorta. The ascending aorta connects the cardiovascular outflow tract at the aortic valve to the aortic arch, which begins at the brachiocephalic artery. The arch provides branches to the head and neck vessels, coursing just in front of the trachea and then proceeding to the left of the esophagus and the trachea. The descending aorta begins in the posterior mediastinum at the ligamentum arteriosum and courses in front of the vertebral column as it descends to the bifurcation of the leg vessels.

Aortic Aneurysms

Aneurysms may occur at any location in the aorta but are most common in the abdominal segments. Aortic aneurysm is a potentially life threatening entity for which both effective screening and curative therapy are available.

abdominal aortic aneurysms

An aorta is considered aneurysmal when its diameter exceeds 1.5 times the expected normal diameter at any location along its length. Aneurysms are divided into those that affect the abdominal cavity and those that affect the thoracic cavity. More extensive aneurysms (termed thoracoabdominal) involve both aortic areas. In addition, aneurysms are defined as either fusiform or saccular.

Aneurysms of the abdominal aorta are more common than thoracic aortic aneurysms. Among the risk factors for aneurysms, perhaps the most important is age. The incidence of aneurysms increases in men older than 55 years and in women older than 70 years. Overall, men are four to five times more likely to develop aortic aneurysms. Additional risk factors are hypertension, smoking, elevated cholesterol, and a family history suggesting a genetic predisposition to aneurysms.[1] Several reports show that aneurysms develop in as many as 25% of first-degree relatives of patients with abdominal aortic aneurysms.[2] The infrarenal aorta is the most commonly affected region.

screening for abdominal aortic aneurysms

Current recommendations are for noninvasive screening of patients of appropriate age, which is typically defined as older than 65 years but younger if there is a significant family history of or risk factors for aneurysms. Screening may be particularly effective for obese patients, in whom abdominal palpation is of limited value. A large-scale (67,900 patients) randomized trial of ultrasound screening in men 65 to 74 years of age demonstrated a substantial reduction (i.e., 43%; 95% CI, 22 to 58; $P = 0.0002$) in aneurysm-related death with a strategy of routine testing.[3] The cost-effectiveness of various screening strategies has yet to be demonstrated.[4] Careful abdominal palpation is probably cost-effective, particularly in men older than 55 years who are at risk for developing vascular disease. A related issue concerns which patients should undergo noninvasive imaging when the abdominal examination is difficult to perform.

Clinical Presentation

Most abdominal aortic aneurysms produce no symptoms and are discovered during a routine physical examination or as a result of noninvasive screening. The most common symptom is pain, often described as a steady, gnawing discomfort in the lower back or hypogastrium. Generally, the pain is not affected by movement.

In some patients, the abdominal aortic aneurysm is first discovered during a period of rapid expansion or an impending rupture, which is often marked by severe discomfort in the lower abdomen or back, radiating to the buttocks, groin, or legs. Rupture is accompanied by the abrupt onset of back and abdominal pain, abdominal tenderness, the presence of a palpable pulsatile mass, hypotension, and shock. However, only one third of aneurysms present in this fashion. Of note, a ruptured aneurysm may mimic other conditions, including abdominal colic, renal colic, diverticulitis, and gastrointestinal hemorrhage. Not surprisingly, more than 25% of patients presenting with rupture or expansion of an aortic aneurysm are initially misdiagnosed.

Patients with impending or actual rupture must be managed as a surgical emergency in a manner similar to that used for patients with major trauma. Such patients rapidly experience hemorrhagic shock, manifested by peripheral vasoconstriction, hypotension, mottled skin, diaphoresis, oliguria, disorientation, and cardiac arrest. Patients with retroperitoneal rupture may show evidence of hematomas on the flank and in the groin. Although rare, rupture into the duodenum may present as massive upper or lower gastrointestinal hemorrhage.

Diagnostic Evaluation

Physical examination The abdominal aorta is usually detectable on deep palpation, particularly in thin persons. In obese patients, the normal aortic impulse may not be palpable. Obese patients may harbor a large aneurysm without any symptoms or findings on physical examination, unless the aneurysm is exerting pressure on an adjacent structure. Thin patients, in contrast, often feel a pulsatile mass in the abdomen when an abdominal aneurysm has developed.

When palpable, an aneurysm will be identified as a pulsatile mass extending from as high as the xiphoid process to the

suprapubic area. Because of the layers of tissue between the examiner's fingers and the aneurysm, measurements of the transverse diameter of the aneurysm are typically overestimated. Also, it is difficult to differentiate ectatic aorta from aneurysm. Some aneurysms are sensitive to palpation and may be tender if they have recently expanded or are in impending rupture. Thus, palpation should be done with consideration of patient discomfort. Patients with aneurysms often have evidence of other peripheral vascular disease, such as femoral bruits and poor peripheral pulses.

Imaging studies Several diagnostic tools can help identify and measure the size of abdominal aortic aneurysms. For years, aortography was considered the gold standard of diagnostic techniques for evaluating aortic aneurysms. One advantage of aortography is that it can be used to evaluate associated iliofemoral disease and involvement of the renal and mesenteric branches of the aorta. However, aortography is invasive and requires intravascular contrast, which carries a risk of nephrotoxicity. Its use has declined with the development of abdominal ultrasonography, computed tomography, and especially magnetic resonance angiography.

Abdominal ultrasonography is the most frequently used method and the most practical.[5] Ultrasonography has a sensitivity of nearly 100% for diagnosing aneurysms of significant size and can discriminate size to within ± 3 mm. Ultrasonography is inexpensive and noninvasive but may be inadequate for evaluating the most superior or inferior extent of an aneurysm and is generally considered inadequate as a sole diagnostic technique for planning surgical resection.

CT can discriminate aneurysm size to within ± 2 mm. Because CT scanning can determine the inferior and superior extent of the aneurysm and its shape, this method is more useful for planning surgical repair. However, the need for radiographic contrast is a relative disadvantage. When a CT image is compared with an image derived from abdominal ultrasonography, the size of the aneurysm determined by CT is larger by approximately 2.7 mm.[6] New diagnostic techniques such as fast spiral CT have improved the resolution of CT scanning. Magnetic resonance angiography can be successfully used for both screening and surgical planning. It identifies the size and extent of an aneurysm with a high degree of accuracy.

Anatomic landmarks are easily distinguished in the three-dimensional images created with MR angiography, which correctly defines the distal and proximal extent of an aneurysm in more than 75% of the cases examined.[7]

Management to Reduce Risk of Aneurysm Rupture

Current management of abdominal aortic aneurysm is directed at reducing the risk of rupture by intervening with timely surgical resection. Natural history studies show that the likelihood of rupture is greatest in patients with symptomatic, large, or rapidly expanding aneurysms. Aneurysms smaller than 4 cm in diameter have a low (< 2%) risk of rupture. Aneurysms exceeding 10 cm in diameter have a 25% risk of rupture over 2 years. Because aneurysms tend to expand with time, current strategies call for identifying and observing aneurysms that are asymptomatic and are small enough to have a low risk of rupture. The median rate of expansion is slightly less than 0.5 cm a year.[8] However, the tendency for expansion is variable and may not be linear. The more rapidly expanding aneurysms are more likely to rupture than are the stable aneurysms. Aneurysms larger than 6 cm in diameter are generally referred for surgery, whereas aneurysms less than 4 cm in diameter are generally watched.[9-11] Evidence of expansion, particularly if the diameter of the aneurysm has exceeded 5.0 to 5.5 cm, is often taken as an indication to operate.[12] Current data support careful observation and serial noninvasive testing of patients with aneurysms between 4.0 and 5.5 cm in diameter.[13]

Surgical Treatment

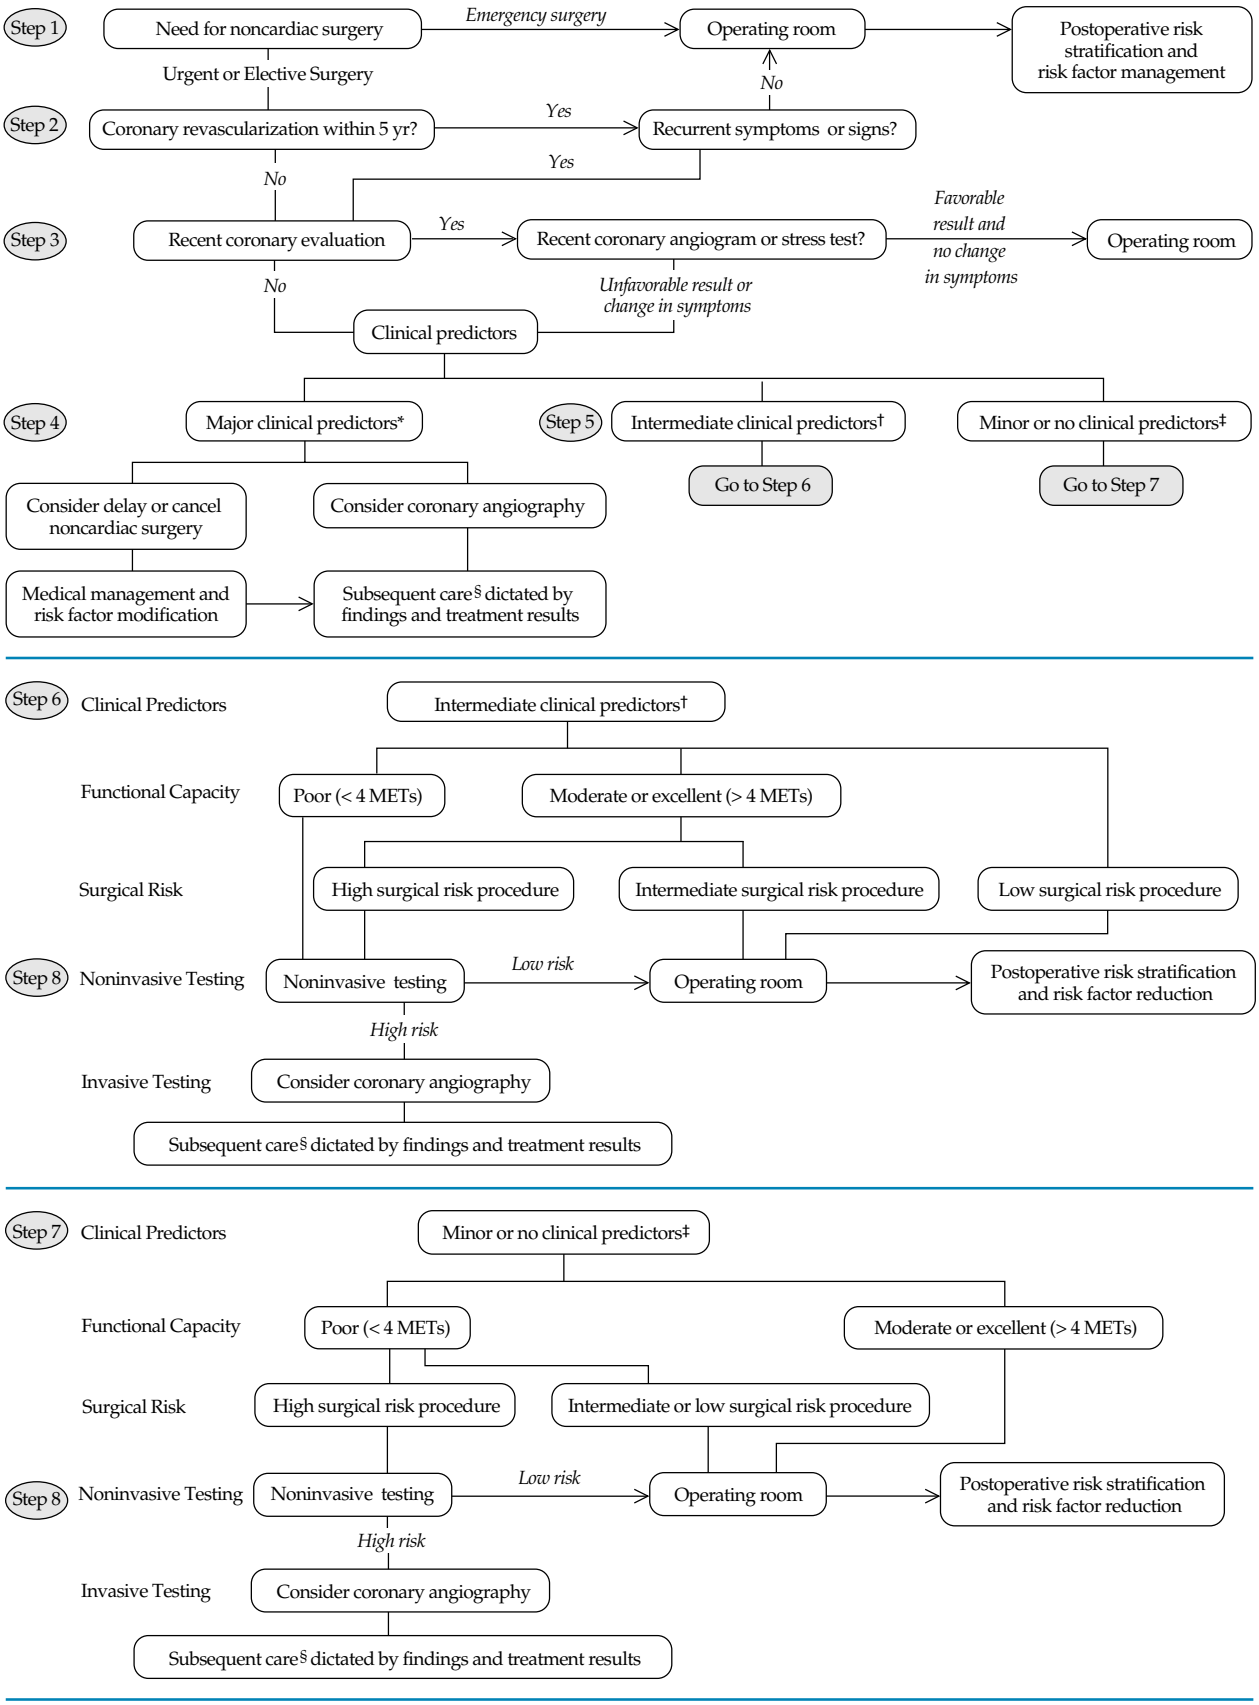
Surgical treatment consists of resection of the aneurysm with insertion of a synthetic (Dacron) graft. Additional distal surgery is often necessary, with resection and interposition of grafts into one or both iliac arteries. For most large aneurysms, the aneurysm wall is left intact, and the Dacron graft is placed inside the aneurysm. The surgical treatment of abdominal aneurysms carries an average operative mortality of 4% to 6%. Surgical mortality is 2% in low-risk patients but may be as high as 20% in patients with impending rupture. For patients in shock with aneurysm rupture who require emergency surgery, operative and perioperative mortality may be as high as 50%.

A therapeutic option is percutaneous placement of implantable endovascular stents, which are similar to those used in patients with coronary artery, renal artery, and peripheral artery stenoses. Some centers are using endovascular stents in nearly 50% of patients referred for treatment of abdominal aortic aneurysms.[14] Larger stents have been used successfully to isolate abdominal aortic aneurysms in patients for whom the risk of surgical resection is unacceptable. However, widespread application of stenting awaits further evaluation of long-term outcomes.[15]

Preoperative evaluation and management Appropriate preoperative evaluation and management of a patient before undergoing elective aortic aneurysm resection are critical. Reports suggest that one third to two thirds of perioperative deaths can be attributed to coronary artery disease. A guideline published by the American College of Cardiology and the American Heart Association reviewed the literature regarding preoperative assessment and presents a simple algorithm to help determine which patients should be considered for preoperative noninvasive testing for coronary disease [*see Figure 1*].[16]

The first consideration is whether the vascular surgery is urgent or emergent. By definition, emergent surgery cannot be delayed, and risk will be higher. In either case, the usual medical approach is to assume the patient may have preexisting coronary disease. Unless contraindicated, beta blockers should be used to treat such patients. Ideally, beta blockers should be started days to several weeks before surgery, titrating the dose to achieve a target heart rate of 50 to 60 beats a minute.[17] The clinical status, electrocardiographic findings, and hemodynamics of these patients should be monitored carefully after surgery.

For determination of perioperative risk, the first issue to address is whether the patient has had a recent coronary revascularization. If the patient has had coronary bypass surgery within the past 6 years and no subsequent coronary symptoms, the risk of perioperative events is relatively low. A second issue is whether the patient has had a recent coronary evaluation. Further preoperative testing is not usually required for patients whose recent stress test or coronary angiogram indicates minimal or no coronary disease, particularly if the evaluation was performed within the previous 2 years and the patient has undergone no change in status.



* Major clinical predictors: unstable coronary syndrome, decompensated CHF, significant arrhythmias, severe valvular disease.
† Intermediate clinical predictors: mild angina pectoris, prior MI, compensated or prior CHF, diabetes mellitus.
‡ Minor clinical predictors: advanced age, abnormal ECG, rhythm other than sinus, low functional capacity, history of stroke, uncontrolled systemic hypertension.
§ Subsequent care of patient may include cancellation or delay of surgery, coronary revascularization followed by surgery, or intensified care.

Figure 1 **Stepwise approach to cardiac assessment. (CHF—congestive heart failure; METs—metabolic equivalents; MI—myocardial infarction)**

Other patients with known prior coronary disease (prior myocardial infarction [MI] or angina), diabetes, or prior congestive heart failure should be more thoroughly evaluated. If such patients have poor functional capacity and have not undergone recent coronary evaluation, they should undergo a preoperative stress test to evaluate the severity of coronary disease and to determine the status of left ventricular function. When possible, exercise is generally the preferred method of stress testing[18] and appears to be safe in most patients. For patients who are unable to exercise, pharmacologic stress testing with either dobutamine echocardiography or adenosine thallium imaging is appropriate. Risk of cardiac events is directly related to the presence and extent of left ventricular (LV) dysfunction and ischemia.

The relative risk of perioperative cardiac morbidity or mortality is low (1% to 5%) in patients with no inducible ischemia and without evidence of fixed perfusion defects or wall motion abnormalities. In patients with extensive areas of ischemia or prior infarction detected during preoperative testing, perioperative event rates (death and MI) may be as high as 20% to 40%. Such patients should probably undergo coronary angiography and possibly coronary revascularization before undergoing major operative procedures.

Although the indications for coronary bypass surgery or percutaneous coronary interventions are generally the same for the preoperative patient and the general population, evaluation for potential heart disease before aneurysm resection may be the patient's first such evaluation. Coronary artery disease must be treated to the fullest extent before undertaking a potentially stressful noncardiac operation on the aorta.

Postoperative modification of risk factors A frequently forgotten issue in the management of patients undergoing abdominal aortic aneurysm resection is long-term modification of cardiovascular risk factors. The preoperative period represents an excellent opportunity to identify and treat hypertension, diabetes, hypercholesterolemia, smoking, obesity, and poor functional status. All patients identified as having vascular disease should take aspirin daily to prevent long-term cardiovascular events. Often, beta blockers are prescribed for patients with coronary artery disease, and the cholesterol profiles of such patients should be routinely assessed. Studies suggest that secondary prevention of vascular disease is enhanced by aggressive treatment of hypercholesterolemia, particularly in persons with a low-density lipoprotein cholesterol level exceeding 100 mg/dl. Currently, the best evidence suggests that the broad class of statin drugs (3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitors) are effective. Beta blockers have been championed as therapy both to reduce risk of MI and to potentially reduce the risk of expansion of aneurysms that may develop or be present elsewhere in patients who previously had significant aneurysms.

THORACIC AORTIC ANEURYSMS

Thoracic aortic aneurysms are less common than abdominal aneurysms. They are classified according to the involvement of the ascending aorta, the descending aorta, or a combination of the two. Aneurysms of the descending aorta are the most common. The etiology of thoracic aneurysms correlates with their location. Aneurysms of the ascending aorta are usually associated with cystic medial necrosis. This association is particularly common in patients with Marfan syndrome, Ehlers-Danlos syndrome, and annuloaortic ectasia, which represents the loss of elastic tensile strength in the aorta. Descending thoracic aortic aneurysms are often seen in hypertensive patients with extensive atherosclerosis. They usually originate beyond the left subclavian artery and may be either fusiform or saccular. Aneurysms of the arch are often contiguous with aneurysms of the ascending or descending thoracic aorta.

Clinical Presentation

More than half of thoracic aortic aneurysms are symptomatic; the rest are discovered only incidentally, often after a routine chest x-ray. Symptoms usually reflect pressure on a contiguous structure or consequences such as concomitant aortic insufficiency. Local mass effects may include a superior vena cava syndrome, caused by obstruction of the superior vena cava; pressure on the trachea, leading to cough or wheezing; and, occasionally, dramatic hemoptysis, resulting from fistula formation between the aneurysm and a major airway. Pressure on the esophagus may produce dysphagia. Pressure on the recurrent laryngeal nerve may result in hoarseness from vocal chord paralysis. Chest pain is usually caused by direct pressure of the aneurysm on an intrathoracic structure or by erosion of a bony structure. Normally, this pain is steady and often severe. Rarely, aortitis may first present as an aortic aneurysm.[19]

A leaking or ruptured aneurysm usually presents with dramatic symptoms. Most such aneurysms leak or rupture into the left pleural space or pericardial space, resulting in hypotension and sudden onset of severe pain. Aortoesophageal fistulas may produce life-threatening gastrointestinal bleeding.

Diagnostic Evaluation

Physical examination The thoracic aorta is generally not palpable unless there is a significant pathologic process. Most often, this pathologic process consists of an ascending aortic arch aneurysm, and the aortic impulse can be palpated just above the sternum or at the right upper sternal border.

Imaging studies The diagnosis of thoracic aortic aneurysms is rarely suspected on physical examination. It is more often initially suspected on chest x-ray and then confirmed with noninvasive or invasive imaging. On chest x-ray, most aneurysms appear as a widening of the mediastinal silhouette. Small aneurysms may not be detected. MRI and spiral CT scanning are the most commonly used methods for delineating the size and extent of thoracic aneurysms. Transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) are also used to diagnose, measure, and monitor ascending aortic aneurysms. TTE can evaluate only the proximal 3 to 5 cm of the ascending aorta, and neither TTE nor TEE is useful for evaluating aneurysms below the diaphragm.

Management to Reduce Risk of Aneurysm Rupture

The natural history of a thoracic aneurysm can shed light on the disease process that has led to the aneurysm, on the risk factors that may affect the rate of aneurysm expansion, and on the concomitant presence of other vascular disease, including peripheral and coronary disease, that might affect long-term survival. Because size is a critical issue in terms of the risk of rupture, the initial size and potential growth of an aneurysm are important factors in the decision whether to operate on asymptomatic aneurysms. Aneurysms that are invading local structures or creating a marked vascular effect should usually be resected. Careful control of blood pressure is crucial for all pa-

tients and may require medical therapy, particularly with beta blockers, which may also slow the rate of aneurysm growth.[20]

The initial size of a thoracic aneurysm is an important predictor of subsequent growth. In general, small aneurysms tend to grow slowly, whereas large aneurysms have a higher probability of expansion and rupture. On average, thoracic aneurysms grow at 0.4 cm/yr, but the growth rate varies greatly.[21] Small aneurysms (i.e., < 5 cm in diameter) grow at about 0.1 cm/yr. Large aneurysms (i.e., > 5 cm) grow at about 0.5 to 1.0 cm/yr. Although these average growth rates are reassuring, it should be emphasized that rapid expansion can occur and can dramatically affect the natural history and management. In general, thoracic aneurysms smaller than 5 cm in diameter are unlikely to rupture, whereas those larger than 7 cm are at high risk for rupture. Currently, most thoracic centers recommend surgery for aneurysms that exceed 5.5 to 6 cm in an otherwise reasonable surgical candidate.[22,23] Because of their relatively young age, absence of associated disease, and low surgical risk of elective repair, patients with Marfan syndrome should undergo surgery when aneurysms reach 5 cm, particularly if the aneurysm is expanding. Some centers wait until aneurysms reach 6.5 or 7 cm before operating on high-risk surgical candidates. As in the case of treatment of abdominal aneurysm, the use of percutaneously placed aortic stent grafts may emerge as an attractive option in some patients with thoracic aneurysms.[24]

Surgical Treatment

The surgical approach to thoracic aortic aneurysms depends on the site. For ascending aortic aneurysms, the major issue is whether the aortic valve is competent and whether reimplantation of the coronary arteries will be necessary. With the availability of aortic homografts and stentless valves, surgical approaches to thoracic aortic aneurysm are undergoing rapid evolution. Individual patient characteristics and surgical preferences have a great deal to do with a given surgical approach.

Postoperative Complications

Neurologic sequelae are the most serious of potential postoperative complications. Currently, the risk of stroke after thoracic aneurysm resection ranges from 3% to 7%.[25] Efforts to reduce diffuse brain injury caused by prolonged periods of aortic cross clamping include hypothermic arrest and the use of retrograde cerebral perfusion by way of a superior vena cava cannula.[26] Efforts to reduce CNS embolic events focus on meticulous surgical technique to avoid dislodging atheroemboli present in the aortic margins and to avoid air embolism during surgery. The above issues are especially pertinent in aneurysms of the ascending aorta and the arch. Surgery on the posterior thoracic aorta carries a different neurologic risk—namely, postoperative paraplegia as a result of interrupting the supply of arterial blood to the spinal cord—and occurs in more than 5% of patients. Several methods have been devised to deal with this risk, but no definitive solution has yet emerged. Some centers have suggested that reattaching critical intercostal arteries leads to improved outcome,[27] whether or not the spinal cord is treated under epidural cooling during surgery.[28]

Aortic Dissection

The incidence of recognized aortic dissection in the United States is estimated to be 10 to 20 per million population, or about 5,000 cases a year. We stress, however, that the incidence of MI is greater than 500,000 cases annually; that is, MI is at least 100 times more common than aortic dissection. For most patients, dissection entails a tear in the intima, with the subsequent development of a propagating hematoma between the intima and the adventitia. Approximately two thirds of aortic dissections are initiated by a tear in the intima just above the aortic valve. Most of the remaining cases develop in the descending aorta at the attachment of the ligamentum arteriosum. Often, multiple communication sites are present between the true lumen and the false lumen. The dissection often spirals as it courses retrograde or antegrade along the aorta. Approximately 10% to 15% of aortic dissections are caused by intramural hematoma, which is spontaneous rupture of the vaso vasorum within the media, creating a hematoma in the media. This hematoma may extend a variable distance and may eventually rupture into the lumen, resulting in a more typical dissection.

CLASSIFICATION

Aortic dissections are classified as acute or chronic and according to their location. Dissections are termed acute when they are diagnosed within 2 weeks after the onset of symptoms; dissections diagnosed after 2 weeks of symptom onset are termed chronic. A key feature for classification is involvement of the ascending aorta, regardless of where the dissection began. Ascending aortic dissections are also called type A dissections. Dissections not involving the ascending aorta are typically classified as distal, or type B, dissections. Ascending aortic involvement identifies a patient population with high mortality if not treated surgically. A subset of patients with isolated aortic arch dissection has also been described. Normally, the life-threatening condition is caused by communication of the ascending aorta with the pericardial space, creating cardiac tamponade, or by spontaneous rupture or hemorrhage, leading to shock.

The predisposing factors for type A and type B dissections differ somewhat. Disorders of the media that result in cystic medial necrosis are a common precursor of type A dissection. Affected patients may include those with Marfan syndrome or other heritable disorders, such as Ehlers-Danlos syndrome, Noonan syndrome, and Turner syndrome. Another risk factor for ascending aortic dissection is aortic valve disease, such as bicuspid valve disease or prosthetic aortic valve disease. Although these conditions are classically associated with aortic dissection, over 90% of patients with acute aortic dissection do not have any recognized substrate for dissection. Distal, or type B, aortic dissection is most often seen in patients with longstanding hypertension. Patients with type B dissection are older on average than patients with type A dissection. An unexplained relation between aortic dissection and pregnancy also exists, perhaps because of changes in cardiac output, blood pressure, or blood volume or the effects of pregnancy on the aortic wall itself.[29] Aortic dissection after inhalation of crack cocaine has also been reported.

CLINICAL PRESENTATION

The most common distinguishing clinical feature of aortic dissection is the abrupt onset of pain.[30] The abruptness of onset is one of the clinical features reliably distinguishing the pain of aortic dissection from that accompanying other cardiovascular pathology (e.g., myocardial ischemia). This instantaneous pain may begin in the chest or back and may migrate to involve the neck, head, back, and legs as the dissection propagates. The classic combination of abrupt tearing pain, with pulse deficits and

apparent aortic insufficiency, is seldom observed in actual practice.[30,31] Other presentations of type A dissection are sudden syncope or hypotension, resulting from dissection into the pericardial space; stroke, resulting from interruption of the blood supply to one or both internal carotid arteries; and, in rare instances, isolated congestive heart failure, when the dissection involves the ascending aorta and interrupts aortic valve function.

The most typical presentation of type B dissection is onset of severe interscapular pain, which may radiate down the back toward the legs. Type B dissection is frequently accompanied by hypertension, whereas type A dissection more often occurs in the presence of normal or low blood pressure.[30] Spinal cord ischemia, ischemic extremities, and mesenteric ischemia are most frequently encountered in type A dissection that has extended to involve the descending aorta. Whereas aortic insufficiency is noted on auscultation in 35% to 50% of the cases of ascending aortic dissection, it is rather unusual in cases of type B dissection. Pulse deficits are seen in about 25% of patients with type A dissection and in perhaps 5% to 10% of patients with type B dissection.[31]

Acute dissection remains a highly lethal entity. Mortality is commonly quoted as 1% per hour for the first 24 hours. Advanced age, hypotension, and limb and visceral ischemia are all predictors of greater mortality.[32,33] A published review of 500 patients with acute type A dissection identified a number of clinical factors that are predictors of death [*see Figure 2*]. Mortality in the study cohort ranged from 10% to 18%, depending on the number of adverse risk factors.[29]

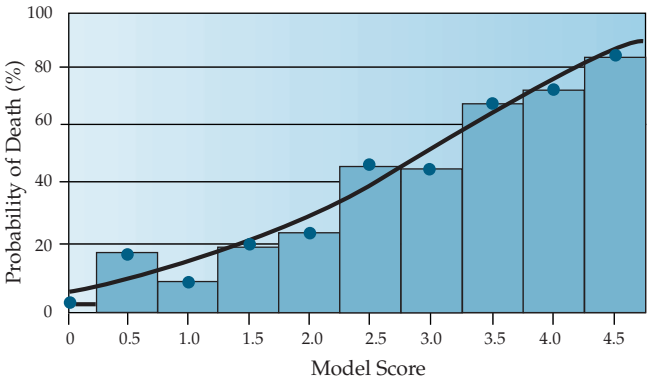


Figure 2 **Graphic demonstration of the increasing mortality in type A dissection when multiple risk factors are present. There is an observed increase in mortality in type A dissection that parallels that of the predictive model. The total risk score was the sum of individual risk factors that was determined from regression analysis to be significantly linked to outcome. The individual factors and their individual scores (in parentheses) were as follows: renal failure (1.6), hypotension/shock/tamponade (1.1), abrupt onset of pain (1.0), pulse deficit (0.7), abnormal ECG (0.6), age ≥ 70 (0.5), female (0.3). (bars—observed findings; line—model probabilities)**

DIAGNOSTIC EVALUATION

Because acute aortic dissection is a life-threatening emergency, rapid and accurate diagnosis is crucial to patient survival. Therefore, sophisticated imaging modalities may be required. Routine ECG in patients with suspected aortic dissection usually reveals only nonspecific abnormalities. Although type A dissection will affect one of the coronary arteries and lead to a transmural MI in 1% to 2% of patients, most patients have nonspecific ST-T wave changes or a finding of left ventricular hypertrophy related to long-standing hypertension.

The typical chest x-ray reveals widening of the mediastinal silhouette and may also demonstrate evidence of a pleural effusion, cardiomegaly, or congestive failure if severe aortic regurgitation is present. A normal-appearing chest x-ray is seen in more than 10% of documented acute aortic dissections.[30] Other laboratory abnormalities are generally nonspecific. An increase of smooth muscle myosin is present in more than 85% of patients presenting within 3 hours after onset of acute aortic dissection.[34] This serum assay, if further developed, may become a useful adjunctive tool to early assessment of suspected aortic dissection.

After a careful history and physical examination, the key to diagnosis is rapid identification of the aortic dissection, ascertainment of whether the ascending aorta is involved, and urgent cardiac surgery if proximal aortic dissection is diagnosed. The importance of rapid diagnosis and institution of definitive therapy for aortic dissection cannot be overemphasized. Given the 1% to 2% mortality per hour in the first 24 hours after presentation, even brief delays to achieve diagnostic imaging are unacceptable.[30,35]

Currently, four diagnostic tools are used to evaluate patients with suspected dissection[36]: CT scanning, echocardiography, MRI, and aortography. In general, the choice of which imaging modality to initially employ will depend on local expertise and availability. In most hospitals, the choice is either CT or TEE.

CT scanning is widely available in most community and tertiary care hospitals. Spiral or ultrafast CT scanning gives even greater resolution than the older scanners and has a reported sensitivity and specificity for aortic dissection exceeding 95%.[37] TEE offers significant advantages in diagnosis [*see Figures 3 and 4*].[38] The primary attractiveness of TEE is its portability, making it suitable for performance in the emergency department, intensive care unit, or operating room. Thus, imaging can be achieved substantially faster with TEE than with other modalities.[39] Second, TEE is highly sensitive for the identification of type A dissection. TEE is also potentially useful when involvement of the aortic valve and the status of the left ventricle, pericardial space, and right and left coronary artery ostia are unknown.[40]

TEE can be very useful in detecting the mechanism of aortic insufficiency and detecting the feasibility of repair.[41,42] Valves in which aortic insufficiency is the result of sinotubular dilatation or extension of the dissection into the sinus are often candidates for repair. Patients with intrinsic disease of the aortic valve leaflets are less optimal candidates for repair.

MRI is less commonly used unless the MRI scanner is part of the emergency department. For most hospitals, however, the delay required in getting a patient into the MRI suite and completing the study makes this technology less efficient than TEE or chest CT.

Finally, although aortography is still used in some hospitals, it is seldom the initial test for aortic dissection. The reported false negative rate for aortography is in the range of 5% to 15%.[43] Aortography frequently misses lesions such as an intramural hematoma. In addition, the time required to get a patient to an angiography suite and complete the study is generally considerably longer than that for TEE. Our medical center and many others follow an algorithmic approach to evaluation and treatment of a suspected aortic dissection [*see Figure 5*].

TREATMENT

The treatment of aortic dissection includes aggressive medical therapy for all patients and definitive surgical therapy in selected patients. The decision to perform surgery depends first and foremost on the site of the aortic dissection [*see Figure 5*].

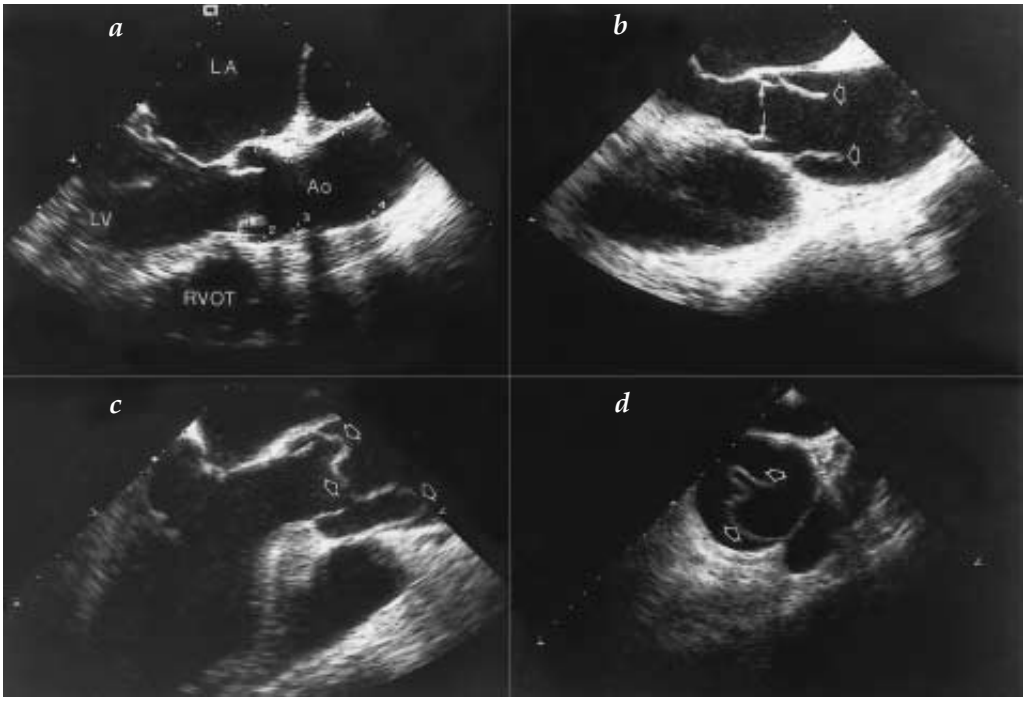

Figure 3 **Transesophageal echocardiograms from a patient with a normal ascending aorta (panel A) and three different ascending aortic dissections (panels B through D). In the normal ascending aorta, the cardiac chambers are noted. The ascending aorta is well visualized, including its annulus (point 1), the coronary sinuses (point 2), the sinotubular junction (point 3), and the true ascending aorta (point 4). Note that the aorta dilates at the level of the sinuses, narrows at the sinotubular junction to a dimension equivalent to that of the annulus, and then slightly dilates further in the ascending aorta. Shown is a normal aortic valve in its open position. Panel B was recorded in a patient with a proximal aortic dissection. The orientation is identical to that in panel A. The solid arrows denote the position of an open aortic valve leaflet. The open arrows represent the margins of a dissection that originated at the sinotubular junction and extended distally. Panel C was recorded in a patient with an ascending aortic dissection (orientation identical to that in panels A and B), and the aortic valve is open. In this instance, a convoluted intimal flap (open arrows) is clearly visualized in the proximal ascending aorta. Panel D was recorded in the short axis of the aorta in a patient with an aortic dissection. In the circular ascending aorta, multiple convolutions of an intimal flap are clearly visualized (open arrows). Note that a communication point (between the downward pointing arrow and the wall of the aorta) allows free communication of flow between the two lumens. (LA—left atrium; Ao—ascending aorta; RVOT—right ventricular outflow tract; LV—left ventricle)**

Surgical Repair

Type A aortic dissection Any involvement of the ascending aorta carries with it a much greater risk of rupture into the pericardial space; development of coronary or cerebral ischemia, aortic regurgitation, and congestive heart failure; or free rupture of the aorta into the thorax. Thus, definitive surgical repair is carried out as quickly as possible for patients with proximal or type A aortic dissection who are appropriate candidates for the procedure.

For patients with type A dissection complicated by malperfusion, medical therapy plus percutaneous reperfusion utilizing aortic stenting or fenestration, or both, and selective branch stenting may allow stabilization and reduce risk associated with the operation. After a period of recovery, repair of the patient's ascending aorta may be undertaken.[44,45]

Definitive aortic repair includes resection of the dissected aorta and insertion of a conduit. The procedure often includes implanting a prosthetic aortic valve. Repair and resuspension of the aortic valve have proved feasible in many patients. For most patients, repair includes reimplantation of the coronary arteries. In some patients, this repair includes resection and placement of a graft to the aortic arch. Even in the best of centers, surgical mortality will range from 10% to 35%, depending on comorbidity.[30,32,46]

Type B aortic dissection Surgery for type B dissection is indicated for patients with life-threatening complications that require a surgical approach. Examples include patients who experience ischemia of both kidneys, leading to reversible renal failure; development of ischemic bowel; ischemia involving one of the legs or arms; development of a progressive aneurysm; impending rupture; and recurrent extension of the dissection. In some centers, percutaneous insertion of aortic stents has been used to stabilize dissections of the descending aorta. This strategy may be preferable to surgery in some candidates.[47-49] In particular, stenting may promote thrombosis of the false channel and thereby reduce the long-term risk of aneurysm formation and aortic rupture. Surgical placement of an endoprosthesis, or so-called elephant trunk, has also been advocated as a preferred strategy for operative type B dissection.[50,51]

Postoperative Complications

In the management of aortic dissection, surgical complica-

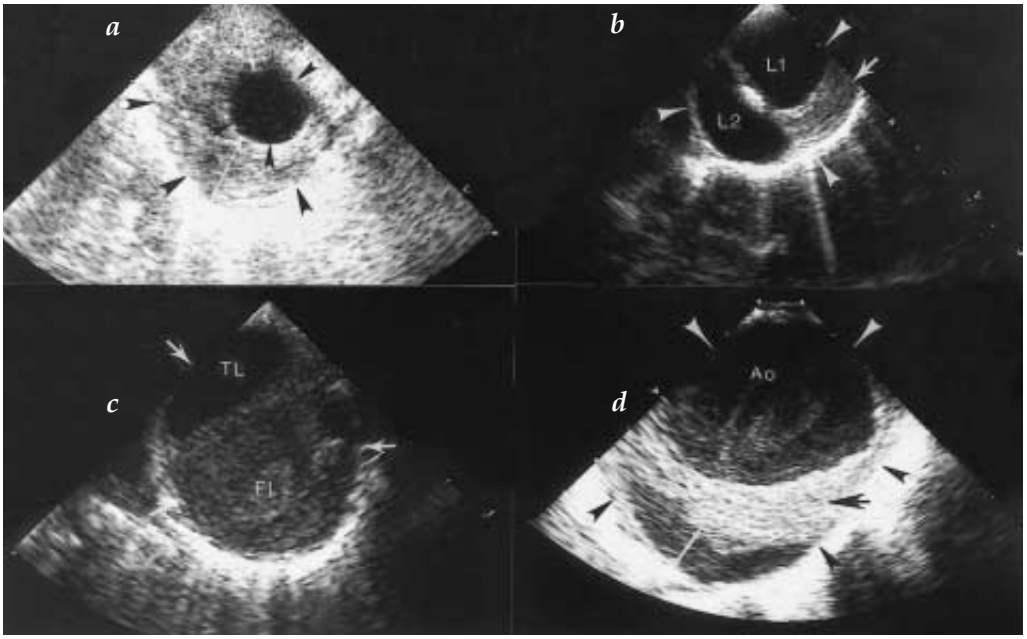

Figure 4 **Panels A through D represent four transesophageal echocardiograms recorded in a short-axis view of the descending thoracic aorta in patients with aortic pathology. Panel A was recorded in a patient with an ascending aortic aneurysm and a large periaortic (adventitial) hematoma extending distally along the thoracic aorta. The smaller black arrows denote the boundaries of the normal-diameter descending thoracic aorta. The larger black arrows pointing inward mark the full dimension of the periaortic hematoma; the full dimension is also noted by the double-headed white arrows. In this instance, the intima of the descending thoracic aorta was not involved in the dissection process. However, a large periadventitial hematoma ruptured along the course of the descending thoracic aorta. Panel B was recorded in a patient with an aortic dissection localized to the descending thoracic aorta. The maximum external dimensions of the aorta are noted by the large white arrowheads. The white arrow notes an area of atherosclerosis and thrombus within the aorta. Two distinct lumens (L1 and L2) can be seen at this level. Panel C was recorded in a patient with an aortic dissection extending from the aortic valve to the bifurcation of the aorta. The large white arrows denote the outer dimension of the aorta. There is an echo-free lumen, or true lumen (TL), and a false lumen (FL) with early thrombus formation. Note the vague echo densities within the false lumen. Panel D was recorded in a patient with a large descending thoracic aortic aneurysm and intramural hematoma. The large arrowheads (black and white) denote the outer dimensions of the aorta. The dilated aortic lumen (Ao) is also noted. The black arrow denotes an area of marked atherosclerosis within the aorta, and the double-headed white arrow denotes an area of intramural hemorrhage, characterized by a lower echo density than the atherosclerotic components. Note also the low-density echoes, which represent stagnant blood flow within the aorta.**

tions can be divided into the sequelae of operations involving the ascending aorta and those of operations involving the arch or descending aorta. Because some period of circulatory arrest is often required to approach the ascending aorta or arch, the most severe complication of surgery in this region is cerebral anoxia, with postoperative neurologic dysfunction. Currently, most aortic centers of excellence perform this operation under conditions of deep hypothermia and circulatory arrest, along with retrograde cerebral perfusion by way of the jugular veins. This technique has dramatically diminished the incidence of severe neurologic injury after aortic surgery.

For surgery on the descending thoracic aorta, the most serious complication is interruption of the blood supply to the spinal cord, with resultant paraplegia. Procedures to reduce this complication include the use of shunts and the careful isolation of ostia of the spinal arteries with reimplantation. This complication remains the one most feared in descending-aorta surgery. Additional risks are acute renal failure, mesenteric ischemia, distal atheroembolic events, and pulmonary complications.

Medical Therapy

All patients with aortic dissection receive aggressive medical therapy. This treatment is first directed at controlling the blood pressure. For hypertensive patients, administration of intravenous beta blockers followed by oral beta blockers, along with the concomitant administration of intravenous or oral vasodilators, is imperative. Patients who are normotensive should maintain a low-normal blood pressure and a low heart rate. The likelihood for propagation of dissection is believed to be in part related to acceleration of flow in the aorta—that is, the force of the aortic jet per unit time (i.e., dp/dt). Accordingly, beta blockers have been the most important therapy for the medical treatment of aortic dissection. Such therapy should maintain heart rates at or below 60 beats/min and keep blood pressure as low as possible while allowing perfusion of the brain, kidneys, and other vital organs. Also important are careful measurements of urine output and filling pressures of the heart.

Long-term management of aortic dissection requires aggressive medical therapy and careful surveillance. Patients who retain patency in the false channel of the aorta after either medical

treatment or surgical repair have a significant risk of aneurysm formation and rupture of the false channel, especially in the first 6 months after initial therapy.[52] Expansion, rupture, or both are more common in patients who are older and have poorly controlled hypertension and chronic obstructive pulmonary disease.[53] Aggressive treatment of blood pressure and heart rate and careful monitoring of the patient's status with physical examination and noninvasive imaging are essential. At many centers, either CT scanning or MRI is performed on a regular basis after initial treatment of the dissection. For instance, the patient might be seen at 2 to 4 weeks after admission for adjustment of dosages of antihypertensive medications and beta blockers. At our center, spiral CT scanning is repeated 3 to 6 months after surgery to screen for the development of aneurysm in the false channel or at the margins of a surgical repair. After this, patients undergo aortic imaging annually, and scrupulous attention is directed to antihypertensive therapy.

Atypical Aortic Dissection

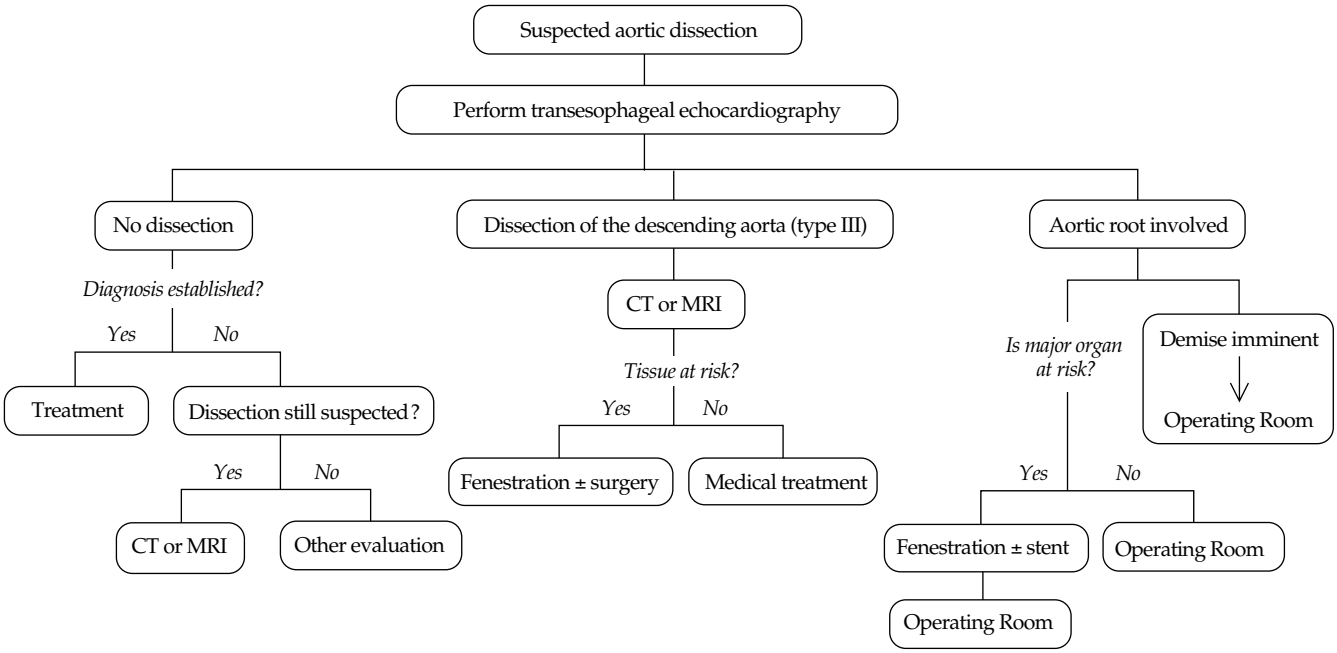
AORTIC DISSECTION WITHOUT INTIMAL TEAR

About 10% to 15% of patients presenting with symptoms suggestive of aortic dissection actually have aortic dissection without an intimal tear (intramural hematoma).[54] This hemorrhage into the medial layer of the aorta may produce a localized or discrete hematoma or may extend for a various distance by dissecting along the plane of the aortic media. Clinically, this hemorrhage mirrors aortic dissection in terms of both its risk factors and its presentation. Intramural hematoma is generally not identified on aortography. It is most easily diagnosed with ultrafast CT scanning. With noncontrast imaging, the hematoma appears as a crescent-shaped high-attenuation area along the aortic wall; moreover, this region cannot be enhanced with contrast imaging. MRI reveals the same crescent-shaped high-intensity area [*see Figure 4*], whereas on TEE, intramural hematoma may appear as a circular or crescentic thickening.[55]

Studies of the natural history of the intramural hematoma suggest that the outcome is similar to that of classic aortic dissection,[56,57] although some recent studies have suggested a more benign prognosis.[58] By 30 days, the rate of aortic expansion or death in patients with medically treated ascending aortic intramural hematoma approaches 50%. Patients with aneurysmal aortas—that is, those with aortas measuring more than 5 cm in diameter—are at particular risk.[59] By contrast, the mortality for intramural hematoma in the descending aorta appears to be between 10% and 15%, a rate similar to that for type B aortic dissection.

PENETRATING ATHEROSCLEROTIC ULCER

A second form of aortic disease that may have an acute pre-



Indications for Surgical Intervention in Aortic Dissection

Ascending Aorta Only	*Ascending and Descending Aorta*	*Descending Aorta Only*
Emergent repair in appropriate candidates	Emergent repair if any of following are present: Aortic insufficiency with CHF Hypotension Pericardial effusion with compromise If ischemia in kidney, CNS, bowel, or major limb, attempt stabilization with stent or fenestration before surgery	Emergent repair if any of following are present: Rupture Impending rupture Uncontrolled pain Major organ at risk (stabilization with stent or fenestration not feasible)

Figure 5 **Decision algorithm for evaluation and treatment of a suspected aortic dissection. Type III dissection originates in the descending aorta and extends distally down the aorta or, in rare instances, retrograde into the aortic arch and ascending aorta. (CHF—congestive heart failure)**

sentation is a penetrating atherosclerotic ulcer.[60] Penetrating ulcers result from erosion of the intima of the aorta, usually because of extensive atherosclerosis. Ulcer formation may produce a hematoma in the media that extends several centimeters from its origin up or down the aorta. Occasionally, pseudoaneurysms are created that may extend into the adventitia and, in rare instances, may rupture. This aortic process develops gradually in elderly patients with extensive atherosclerosis and often is heralded by chest pain or back pain and hypertension. Because it usually presents as a localized process, it is seldom associated with other symptoms of aortic dissection, such as pulse deficit, aortic valve regurgitation, or neurologic defects. Symptomatic penetrating atherosclerotic ulcer rarely requires surgery. Asymptomatic patients who experience progressive enlargement or recurrent atheroemboli may require surgical therapy. For most patients, however, medical therapy suffices and entails aggressive treatment of atherosclerotic risk factors, including cessation of smoking, control of hypertension, lipid-lowering therapy, and careful surveillance. The role of antiplatelet or anticoagulant therapy for this condition is not clear.

Aortic Atheromatous Emboli

Atherosclerosis of the aorta may be so extensive that it leads to overlying thrombosis and subsequent dislodgment of thrombi, cholesterol particles, or fibrinous material into the cerebrovascular or peripheral circulation. Risk factors are hypertension, diabetes, hyperlipidemia, advanced age, and other vascular diseases. Atheromatous disease is most common in the distal aorta but may also occur in the ascending aorta and arch. Evidence of ulceration of atherosclerotic plaques is an independent risk factor for stroke, as is the identification of a mobile, large, protruding aortic atheroma detected with TEE.[60] Plaques more than 4mm in dimension (whereas diameter is used to define the size of the aorta, dimension refers to the maximum size of the atheroma that protrudes into the lumen of the aorta) in the ascending aorta are particularly associated with an increased risk of ischemic stroke.[61] Atheroemboli or cholesterol-particle emboli may also involve the peripheral extremities, leading to ischemic lesions on the feet or toes (so-called blue-toe syndrome). These emboli may present as abdominal pain as a result of ischemic bowel. Acute nonoliguric renal failure is another occasional manifestation, as is gastrointestinal bleeding or pancreatitis. Cutaneous involvement may produce a characteristic skin lesion called livedo reticularis.

Cholesterol embolism syndrome is particularly common after manipulation of the aorta. It is most common in patients undergoing cardiac catheterization or other angiographic procedures in which catheters or wires are manipulated within the aorta. Because the occurrence of atheroemboli may be delayed after aortic manipulation, the relation between the two may not be apparent when the patient is first examined. If cutaneous manifestations are present, a biopsy of the lesions will often identify needle-shaped clefts in the arteriolar lumen characteristic of cholesterol embolization.

Treatment of cholesterol embolism syndrome begins with avoidance of further aortic manipulation (e.g., cardiac catheterization), if this has been a precipitant. Aggressive treatment of hypercholesterolemia is warranted. A search for an aortic aneurysm or protruding mobile atheromas is appropriate in patients for whom the syndrome develops without a concomitant iatrogenic source. Occasionally, recurrent emboli warrant the resection of an aneurysm or of a severely diseased segment of atheromatous aorta.[62] The role of anticoagulant and antiplatelet drugs in this syndrome is uncertain.

Takayasu Arteritis and Giant Cell Arteritis

TAKAYASU ARTERITIS

Takayasu arteritis is a rare inflammatory condition that affects the aorta and its major branches. Other names include aortic arch syndrome, pulseless disease, and young female arteritis.[63] Although Takayasu arteritis is seen throughout the world, most cases occur in Asia and Africa. A specific etiologic agent has yet to be identified, but current evidence favors an autoimmune mechanism. Some studies suggest it may be linked to rheumatic fever, streptococcal infections, certain HLA subtypes, rheumatoid arthritis, and other collagen vascular diseases. Takayasu arteritis is more prevalent in women than in men. By definition, most patients are young, with an average age of 29 years. Takayasu arteritis has been divided into three types.[64] Type I involves the aortic arch and its branches, type II involves the distal aorta and spares the arch, and type III may affect both the ascending aorta and the descending aorta. A suggested fourth category involves the pulmonary arteries.

Pathophysiology

Takayasu arteritis generally involves a granulomatous arteritis of the aorta and its branches, with subsequent involvement of the media and adventitia. Later, the disease may progress to a sclerotic stage in which the intima is hyperplastic, the media degenerates, and the adventitia develops fibrosis. This late fibrotic process may encroach on the lumen of the aorta or its branches. Common areas of involvement are the main aorta and branch points of its major branch vessels. The pulmonary artery may also be involved. The coronary arteries are affected in fewer than 10% of patients. In some patients, involvement of the ascending aorta may lead to aortic valve regurgitation.

Clinical Presentation

The initial symptoms are often typical of an acute or systemic inflammatory process, including fever, loss of appetite, weight loss, night sweats, and arthralgias. Involved vessels may have accompanying localized tenderness over them. By the time the diagnosis is established, most patients have reached a sclerotic phase, in which vascular insufficiency is causing the predominant symptoms. It may involve the upper or lower extremities. Hypertension occurs in more than half of patients. Congestive heart failure occurs in 25% of patients because of hypertension, aortic valve insufficiency, or involvement of the coronary arteries.

Diagnostic Evaluation

Laboratory findings in patients with Takayasu arteritis generally include an elevated erythrocyte sedimentation rate, mild anemia, and a slightly increased white blood cell count. The chest x-ray may demonstrate a rim of calcification around the involved vessels. Aortography often shows an irregular intimal surface with stenoses of the aorta or its branch arteries. Poststenotic dilatation or frank arterial aneurysms may be visible. Similar diagnostic features can also be detected by TEE and MRI.[65] Among the established criteria for the clinical diagnosis of Takayasu arteritis is that patients must be no older than 40 years.

Treatment

The management of Takayasu arteritis begins with high-dose glucocorticoid therapy, which usually leads to abatement of constitutional symptoms and the laboratory signs of inflammation. Serial sedimentation rates are useful for monitoring the benefits of treatment. For patients who fail to respond to steroid therapy, cyclophosphamide at a dosage of 2 mg/kg/day has been used. Alternatively, low-dose methotrexate may enhance the efficacy of steroids or allow steroid tapering. Surgery may be necessary to treat unremitting peripheral ischemia or aortic valve disease or to treat renal artery stenosis that causes severe hypertension. For patients with involvement of the coronary ostia, bypass surgery may be indicated as well.[66] Percutaneously placed arterial stents have successfully treated segmental disease in a variety of vessels in patients with this syndrome.

GIANT CELL ARTERITIS

Giant cell arteritis is another form of aortoarteritis. In contrast to Takayasu arteritis, this illness is more commonly seen in Europe and the United States and in patients older than 50 years (the mean age at onset of disease is 67 years).

Pathophysiology

This form of arteritis often affects the branches of the proximal aorta, particularly the branches supplying the head and neck, the extracranial structures (including the temporal arteries), and the upper extremities. Aortic involvement often coexists with temporal arteritis and polymyalgia rheumatica. Unlike Takayasu arteritis, giant cell arteritis seldom has a sclerotic phase progressing to occlusion of vessels. However, giant cell arteritis may lead to aneurysm formation, aortic regurgitation, or aortic dissection.[67,68]

Clinical Presentation

The classic presentation of giant cell arteritis consists of headache, tenderness over involved arteries in the scalp or the temporal region, jaw claudication, difficulty combing one's hair, and constitutional symptoms. Fever is common, and the blood vessels involved are thick and tender. Pulses may be diminished, and bruits may be present. Occasionally, signs of aortic valve regurgitation are present.

A serious complication of this syndrome is blindness, which results when arteritis affects the ophthalmic artery. The progression to total blindness may be rapid. Visual symptoms of some type occur in as many as 50% of patients. An initial high dose followed by prolonged therapy with corticosteroids remains the treatment of choice.[69] In rare instances, giant cell arteritis may lead to reduced upper extremity pulses and blood pressure along with arm or leg claudication. It also may cause coronary ischemia or abdominal angina in rare cases. Unlike Takayasu arteritis, giant cell arteritis virtually never affects the kidneys. Aortic aneurysms occur in 15% of patients with giant cell arteritis, most commonly involving the ascending aorta. Such aneurysms may develop late in the disease, leading to rupture, aortic dissection, or severe aortic valve regurgitation.

Diagnostic Evaluation

An above normal erythrocyte sedimentation rate is characteristic of this disease, and the diagnosis is confirmed by biopsy of an involved artery, usually the temporal artery. Clinicians need to be aware, however, that temporal artery biopsy may be negative in as many as 15% of patients with confirmed disease; therefore, a second biopsy may be necessary in patients with a high likelihood of temporal arteritis.

Treatment

Standard therapy for giant cell arteritis is high-dose glucocorticoid therapy (e.g., prednisone, 40 to 60 mg/day). Methotrexate may be used to reduce the need for steroids or to treat patients who respond inadequately to steroids. Cyclophosphamide may also be useful for reducing the need for glucocorticoids. Surgery is typically reserved for patients who experience progressive ischemic symptoms or aortic aneurysms.

Traumatic Disease of the Aorta

Finally, a relatively common form of aortic pathology is partial or complete transection as a result of major blunt thoracic trauma, most commonly as a result of a high-speed motor vehicle accident. Most patients with complete aortic transection do not survive long enough for hospital evaluation. If rapidly diagnosed, patients with partial transection may survive long enough to undergo surgical correction. Evidence of aortic trauma is often obscured by other major organ trauma. Patients with aortic transection are typically in shock and may have diminished lower extremity pulses. The transection is usually located at the distal arch, immediately after the origin of the left subclavian artery.

Rapid diagnosis is the key to the survival of patients with aortic transection. The routine chest x-ray typically reveals a widened mediastinum, often with pleural effusions. The gold standard for diagnosis of this disorder remains aortography, but TEE,[60,70] CT,[71] and MRI have also been used successfully.[72] Successful treatment requires vigorous fluid and blood resuscitation and surgical repair of the aortic transsection.

XIII DISEASES OF THE PERICARDIUM, CARDIAC TUMORS, AND CARDIAC TRAUMA

E. William Hancock, m.d.

Diseases of the Pericardium

The pericardium provides a protective sac around the heart. The sac contains a thin layer of fluid that permits the heart to move with minimal friction during the cardiac cycle. Neither the sac nor the fluid appears to be necessary for normal function. When one or more of the cardiac chambers dilate acutely, the pericardium restrains the heart. In chronic dilatation of the heart, however, the pericardium stretches and therefore does not exert a restraining effect, except during exercise or other acute stresses.

Pericardial disease results from diverse causes, many of which lead to responses to injury that are pathologically and clinically similar. There are three clinicopathologic responses to injury: acute pericarditis, pericardial effusion, and constrictive pericarditis.

acute pericarditis

Viral infection is usually assumed to be the cause of acute pericarditis that occurs as an apparently primary illness. Because most cases follow a brief and uncomplicated natural course, the syndrome is often termed acute benign pericarditis. Cases resulting from other conditions or treatments, such as rheumatic disease or radiotherapy, often exhibit clinical features similar to those of acute benign pericarditis.

Diagnosis

Clinical manifestations The clinical diagnosis of acute pericarditis rests primarily on the findings of chest pain, pericardial friction rub, and electrocardiographic changes. The chest pain of acute pericarditis typically develops suddenly and is severe and constant over the anterior chest. In acute pericarditis, the pain worsens with inspiration—a response that helps distinguish acute pericarditis from myocardial infarction. Low-grade fever and sinus tachycardia also are usually present.

A pericardial friction rub can be detected in most patients when symptoms are acute. Pericardial friction rubs are typically triphasic: systolic and early diastolic components are followed in later diastole by a third component associated with atrial contraction.

ECG findings Electrocardiographic changes are common in most forms of acute pericarditis, particularly those of an infectious etiology in which the associated inflammation in the superficial layer of myocardium is prominent. The characteristic change is an elevation in the ST segment in diffuse leads. The diffuse distribution and the absence of reciprocal ST segment depression distinguish the characteristic pattern of acute pericarditis from acute myocardial infarction. However, the normal variant pattern of ST segment elevation often complicates the differential diagnosis [*see Figure 1*]. Depression of the PR segment, which reflects superficial injury of the atrial myocardium, is as frequent and specific as ST segment elevation and is often the earliest electrocardiographic manifestation.[1]

Treatment

Analgesic agents, such as codeine (15 to 30 mg taken orally every 4 to 6 hours) or hydrocodone (5 to 10 mg taken orally every 4 to 6 hours), are usually effective in providing symptomatic relief. Salicylates given at an initial dosage of 4 to 6 g a day or a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen given at an initial dosage of 800 mg three times daily is often effective in reducing pericardial inflammation.[2] Corticosteroids such as prednisone given at an initial dosage of 40 to 60 mg/day often greatly relieve symptoms; however, steroid therapy should be reserved for severe cases that are unresponsive to other therapy, because symptoms may recur after steroid withdrawal. The corticosteroid dose should be reduced as soon as a clinical response is observed and should be tapered to zero over a period of 2 to 4 weeks.

Other Forms of Acute Pericarditis

Relapsing pericarditis Acute pericarditis of any etiology may follow a recurrent or chronic relapsing course. In many instances, subjective manifestations (e.g., weakness, fatigue, or headache) are present in addition to the chest discomfort. Analgesic agents provide symptomatic relief, and a very slow tapering of the dose of a corticosteroid usually resolves the relapsing course eventually. Treatment with 1 mg of colchicine daily, methylprednisolone in 1 g pulses daily for 3 days, or an immunosuppressant such as prednisone (60 to 100 mg daily) or azathioprine (50 to 100 mg daily) has proved successful in patients with relapsing pericarditis, particularly in patients whose symptoms are mainly related to withdrawal of prednisone.[2,3]

Progression to constriction In a few instances, acute pericarditis progresses to subacute or chronic constrictive pericarditis. In such cases, the pericarditis may be idiopathic or have a bacterial, viral, rheumatoid, radiation-induced, or dialysis-related origin. These patients usually have subacute rather than acute pericarditis initially; pericardial effusion is present at onset, usually with some degree of cardiac tamponade. Acute benign pericarditis unaccompanied by tamponade or substantial pericardial effusion in the acute phase rarely progresses to constrictive pericarditis.

pericardial effusion and cardiac tamponade

Fluid may accumulate in the pericardial cavity in virtually any form of pericardial disease. The fluid may be a transudate or an exudate and is often serosanguineous in neoplastic, idiopathic, dialysis-related, radiation-induced, and tuberculous cases. The fluid is serosanguineous or frankly bloody in cases of coagulopathy, trauma, rupture of acute myocardial infarction, and aortic dissection. Chylopericardium and pneumopericardium also can occur, although rarely.[4] Cardiac tamponade or compression of the heart by effusion is the most important complication of pericardial effusion.

Pathophysiology

The physiologic effect of the accumulation of pericardial fluid depends on whether the fluid is under increased pressure.[5] If ef-

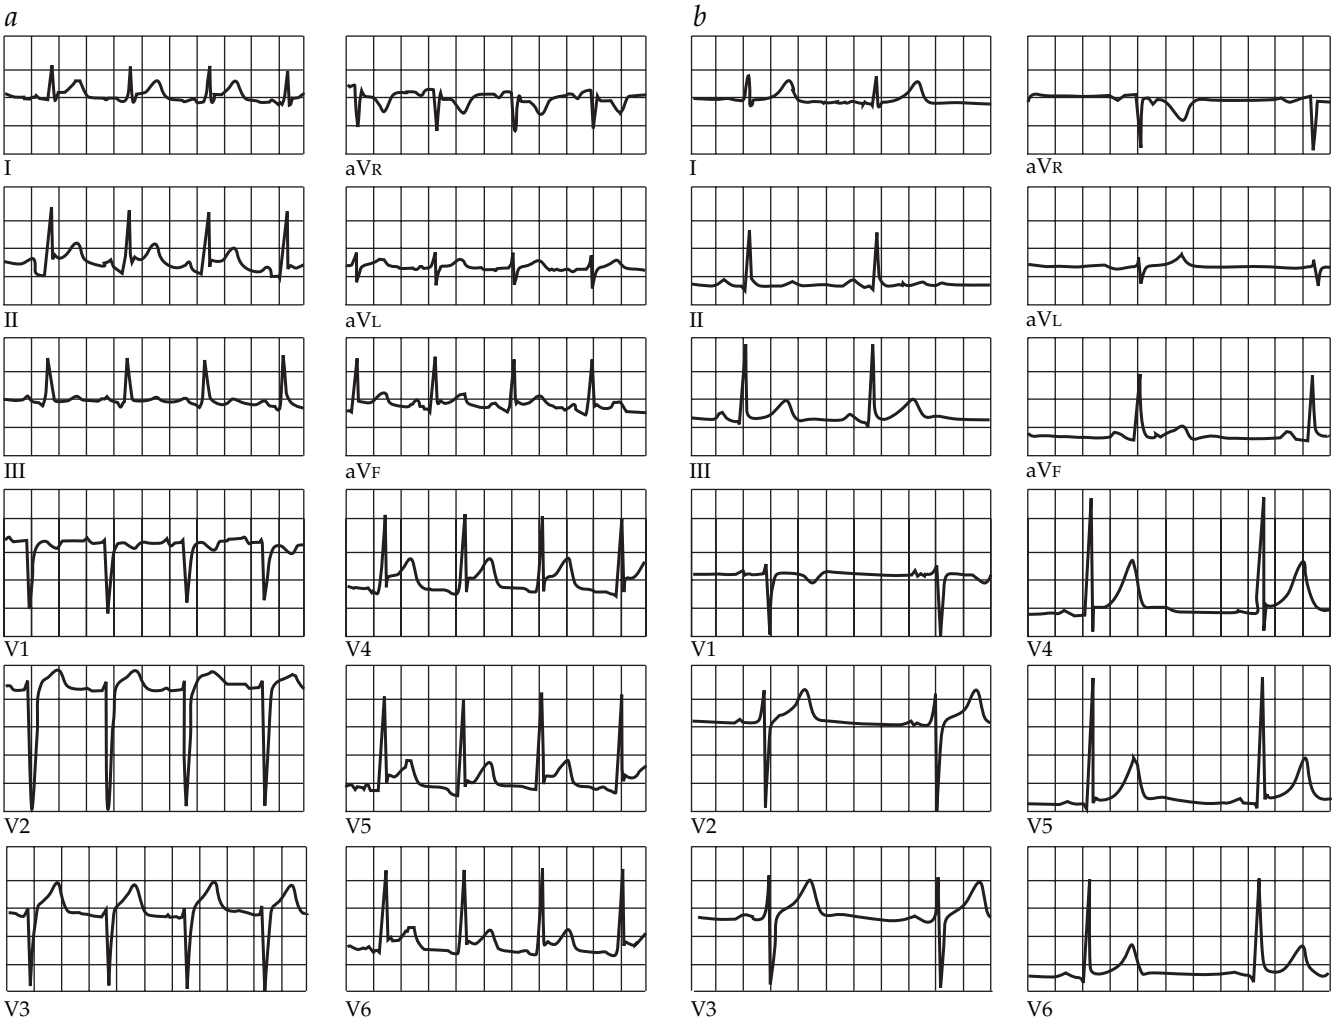

Figure 1 **Electrocardiograms contrast the pattern of ST segment elevation characteristic of acute pericarditis (*a*) with the normal variant (early repolarization) pattern of ST segment elevation (*b*). The normal variant pattern is associated with a normal or slow heart rate and has relatively tall R waves and T waves in V4, V5, and V6. The ST segment elevation is less than 25% of the T wave amplitude. In contrast, the acute pericarditis has PR depression and lower T wave amplitude.**

fusion develops gradually, the pericardium stretches enough to accommodate volumes that may exceed 2,000 ml. However, if the effusion develops acutely, as little as 200 ml of accumulated fluid may raise the intrapericardial pressure and cause cardiac tamponade.

As the pericardial fluid pressure rises, the right atrial and central venous pressures increase correspondingly. Thus, reading the central venous pressure gives an accurate reflection of the intrapericardial pressure.

Cardiac tamponade should be viewed as a spectrum of hemodynamic abnormalities of various severities rather than an all-or-none phenomenon. Depending on the severity of the tamponade, the blood pressure may be lowered or maintained near the normal range; in patients with preexisting hypertension, it may even be increased. The central venous pressure is almost always increased, except in the rare instances of low-pressure cardiac tamponade, which may occur when intravascular volume is depleted.

As a rule, paradoxical pulse—a marked decrease in arterial pressure during inspiration—is present in patients with cardiac tamponade, although it may not be easy to detect on clinical examination [*see Figure 2*]. The arbitrary value of 10 mm Hg is commonly used to indicate the upper limit of the normal decrease in arterial pressure with inspiration.

The inspiratory drop in arterial pressure reflects a selective impairment of diastolic filling of the left ventricle, probably the combined effects of two factors. First, when the filling of the right ventricle is augmented in inspiration, the simultaneous filling of the left ventricle is limited because the entire heart is enclosed in a fixed volume. Second, during inspiration, blood is sequestered in the lungs and pulmonary veins as a result of impaired transmission of changes in intrapleural pressure to the left atrium and to the intrapericardial portions of the pulmonary veins.

Diagnosis

Pericardial effusion Echocardiography is the most accurate and easily applied method for the clinical detection of pericardial effusion [*see Figure 3*]. Echocardiograms detect effusions as small as 20 ml and show characteristic findings with effusions larger than 100 ml. Computed tomography is also a reliable method for detecting both pericardial effusion and pericardial thickening. Magnetic resonance imaging provides information

similar to that provided by CT [*see Figure 4*].[6]

Electrocardiograms usually show low voltage in patients with large pericardial effusions, but this finding is nonspecific. Electrical alternans occurs occasionally when the pericardial effusion is large and permits a beat-to-beat oscillation of the heart from one position to another within the pericardial sac [*see Figure 5*]. Electrical alternans is most common with effusion caused by neoplasm. This type of electrical alternans must be differentiated from other types, such as that occurring in supraventricular tachycardias or alternating intraventricular conduction defects.

Cardiac tamponade The diagnosis of cardiac tamponade is often difficult.[7] The diagnosis is one of the most common important diagnoses made at autopsy but not during life.[8] This diagnosis should be based on a synthesis of various clinical findings, because no single finding is pathognomonic or necessarily present. Echocardiography, although essentially definitive for the demonstration of pericardial effusion, is not as certain a method of assessing tamponade. Several echocardiographic features are helpful, however, particularly the observation of an early diastolic inward motion (so-called collapse) of the right atrial wall or right ventricular wall, indicating similarity of intracavitary and intrapericardial pressures.[9] Another useful sign is an exaggerated respiratory variation in the velocity of flow through the mitral and tricuspid valves or in the left ventricular ejection, as detected in pulsed Doppler recordings [*see Figure 6*]. This phenomenon has the same significance as paradoxical pulse. A third sign suggestive of cardiac tamponade is plethora of the inferior vena cava, which occurs in the more severe cases and is a better guide to the need for pericardiocentesis than the other echocardiographic features.[10]

Loculated pericardial effusions may selectively compress one or more chambers of the heart, producing regional cardiac tamponade. This condition is seen most frequently after cardiac surgery, when bloody fluid accumulates behind the sternum and selectively compresses the right atrium and right ventricle[11]; less often, the left ventricle and left atrium are compressed locally. Similar conditions may occur after closed chest trauma. Fluid accumulations in the mediastinum can compress the heart even when they are not truly within the pericardial space. Transesophageal echocardiography is superior to transthoracic echocardiography in demonstrating such local fluid accumulations, particularly those along the right heart border.

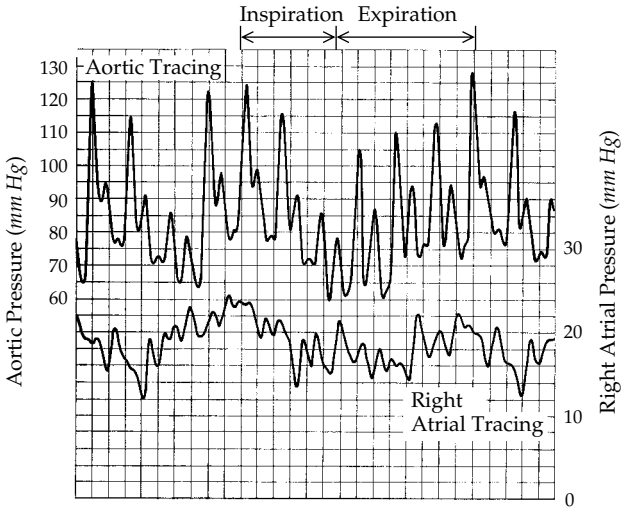

Figure 2 **The aortic pressure and right atrial pressure are recorded during quiet breathing in a patient with cardiac tamponade. The marked fall in arterial pressure that occurs during inspiration is a paradoxical pulse. The decrease in pulse pressure, defined as the difference between systolic and diastolic pressures, that accompanies the fall in systolic pressure indicates that left ventricular stroke volume decreases during inspiration. Central venous pressure, as indicated by the right atrial pressure, also falls during inspiration.**

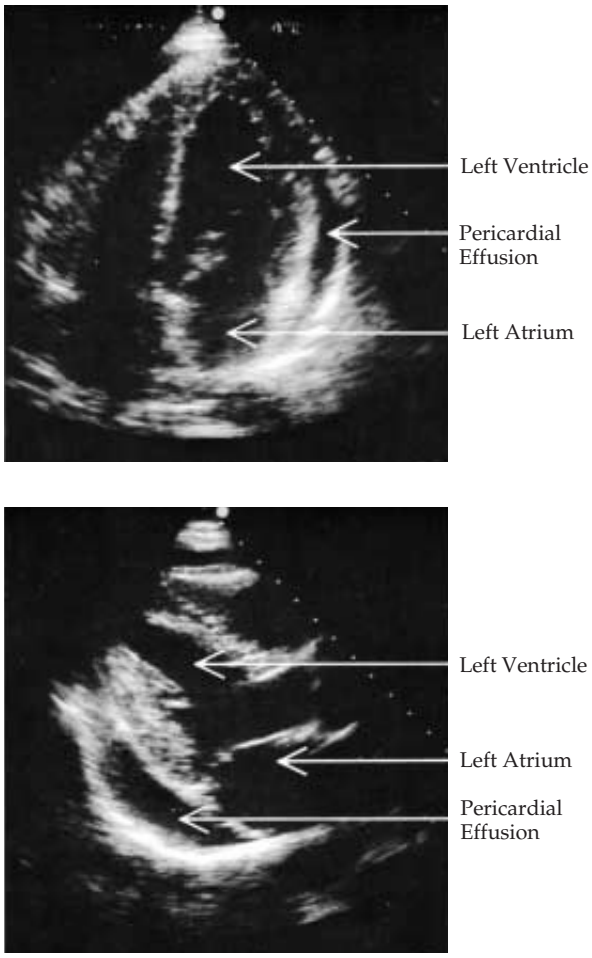

Figure 3 **Pericardial effusion is seen in the two-dimensional echocardiogram as an echo-free space outside the cardiac chambers. Two characteristic sites are lateral to the left ventricle in the apical four-chamber view (top) and posterior to the left ventricle in the parasternal long-axis view (bottom).**

Treatment

Pericardial effusion Occasionally, a syndrome of idiopathic chronic large pericardial effusion is seen, usually without tamponade. Colchicine may be effective in such cases.[12]

In patients with pericardial effusion but no tamponade, pericardiocentesis is rarely performed for the sole purpose of providing diagnostic studies of the fluid, because such specific diagnoses are uncommon in those patients, at least in regions of the world where tuberculous pericarditis has become rare.[13] Pericardial biopsy can be obtained by any of the usual surgical methods. However, pericardiocentesis can be useful in diagnosing infection or neoplastic disease. In addition, pericardioscopy can be

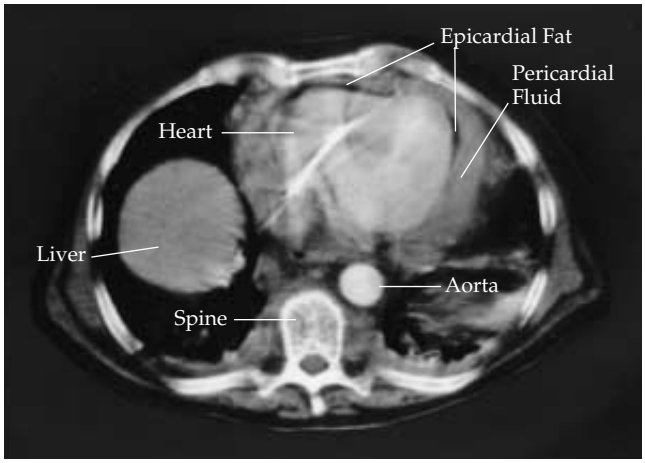

Figure 4 **In a CT scan of the chest of a patient with pericardial effusion, pericardial fluid appears less dense than the heart and is separated from the myocardium by epicardial fat in some areas.**

performed in association with subxiphoid pericardiostomy; biopsy under direct vision may permit the diagnosis of tuberculosis or neoplasm in some instances in which studies of the fluid alone might be inconclusive.[14] Surgery is usually not necessary in chronic idiopathic pericardial effusion in the absence of tamponade and effusive-constrictive disease.[15]

Cardiac tamponade Mild cardiac tamponade may be managed conservatively in some cases, but removal of the fluid is required for definitive treatment and should be carried out in most instances when the central venous pressure is increased. Pericardial fluid may be removed by needle pericardiocentesis or by a surgical technique (subxiphoid pericardiostomy, thoracoscopic pericardiostomy, or thoracotomy).[16,17]

The most acute forms of cardiac tamponade, such as hemopericardium secondary to aortic dissection, penetrating cardiac trauma, or rupture of acute myocardial infarction, require immediate surgery. Tamponade caused by cardiac perforation during invasive intravascular procedures can usually be managed by pericardiocentesis.[18] Pericardiocentesis is effective in most subacute forms of tamponade, such as those associated with idiopathic or viral acute pericarditis, rheumatic diseases, dialysis, or neoplasm.

Thoracoscopy and thoracotomy are usually reserved for patients with recurrent tamponade after an initial pericardiocentesis or subxiphoid pericardiostomy, usually for neoplastic disease. Pericardiostomy by means of a balloon catheter as part of a pericardiocentesis is another alternative for such cases.[19]

SPECIAL ETIOLOGIC FORMS OF ACUTE PERICARDITIS AND PERICARDIAL EFFUSION

Pericarditis Related to Renal Failure and Dialysis

Acute pericarditis with pericardial effusion occurs in patients with end-stage renal disease and in patients who are on chronic dialysis [*see 10:X Chronic Renal Failure and Dialysis*]. In dialysis patients, conservative management with more intensive dialysis and NSAIDs is usually successful. An unexpected decrease in blood pressure during a dialysis session may be the clue to the presence of tamponade. Pericardiocentesis is occasionally necessary for the relief of tamponade, although fluid overload and left ventricular failure are often important factors associated with causing increased central venous pressure. Cardiac catheterization in combination with pericardiocentesis is often useful in assessing the hemodynamic significance of those factors that contribute to an increase of pulmonary and systemic venous pressure in dialysis patients.

Radiation-Induced Pericardial Effusion

Pericardial effusion develops relatively frequently in patients with Hodgkin disease, other lymphomas, or breast carcinoma who survive for long periods after receiving large doses of radiation to the mediastinum. Radiation-induced effusion may evolve into chronic constrictive pericarditis after many years, usually with other forms of myocardial, coronary arterial, valvular, and pulmonary damage.[20]

Neoplastic Pericardial Effusion

Neoplastic pericardial effusion accounts for about one half of the cases of cardiac tamponade in patients who are seen in an internal medicine setting [*see 12:XII Oncologic Emergencies*]. Lung cancer and breast cancer account for the majority of the cases; lymphoma and leukemia account for most of the remainder.[21] In most cases, the primary neoplasm has been previously diagnosed; patients in whom pericardial effusion is the first manifestation of the disease usually have primary cancer of the lung. Cytologic examination of the pericardial fluid is highly accurate in diagnosing common carcinomas but less accurate in diagnosing

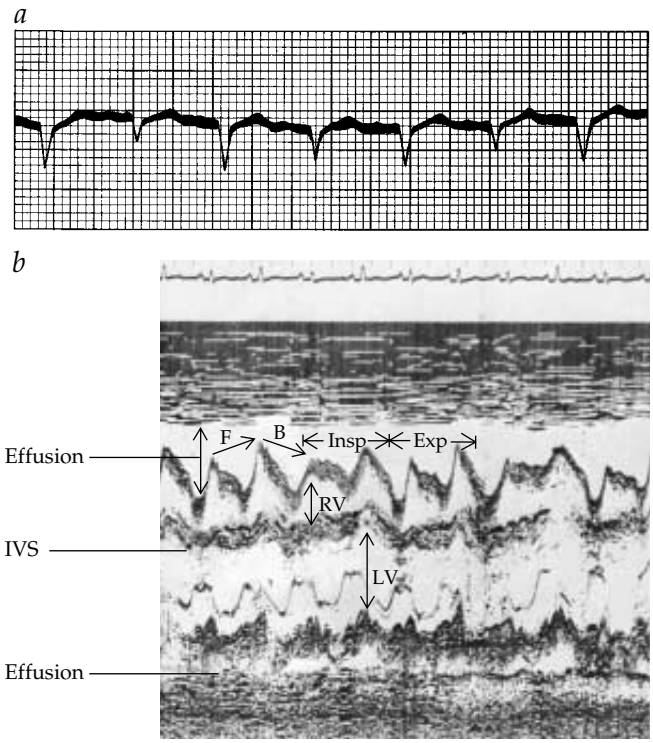

Figure 5 **The electrocardiogram (V2 lead) from a patient with pericardial effusion caused by malignant melanoma reveals a low voltage and electrical alternans (*a*). The echocardiogram (*b*) demonstrates that the heart moves forward (F) and backward (B) within the effusion on alternate beats, thus producing the alternation of the QRS axis characteristic of electrical alternans. The heart also moves with inspiration (Insp) and expiration (Exp), which accounts for a change in anterior wall motion with every two cardiac cycles.**

other neoplasms, especially the lymphomas and leukemias.[22]

Neoplastic pericardial effusion often can be managed conservatively when no symptoms directly related to the pericardial effusion are present. Symptomatic tamponade can be managed palliatively with pericardiocentesis, although recurrent effusion is more likely to form in such cases than in many other types of pericardial effusion. Subxiphoid pericardiostomy is often the preferred procedure, leading to a pericardial reaction that produces adhesion of the parietal and visceral layers of pericardium and thus prevents recurrent effusion. Balloon pericardiostomy is an alternative. Chemotherapy or radiotherapy may be of value, depending on the nature of the primary neoplasm. Intrapericardial instillation of chemotherapeutic agents has often been used with apparent success, but no results from controlled trials are available. Few patients survive longer than a year, and whether pericardiocentesis has a major effect on their longevity is difficult to determine, even when tamponade is relieved.[23]

Purulent Pericarditis

Tamponade is usually present in purulent bacterial pericarditis; after pericardiocentesis, the effusion is highly likely to recur rapidly and progress to constrictive pericarditis. Purulent pericarditis therefore usually requires a surgical drainage procedure; a partial pericardiectomy by a limited left lateral thoracotomy is often the best choice. Surgery may not be required for patients in whom tamponade or constriction does not develop, because antibiotics enter the pericardial cavity in effective concentrations. Active tuberculous pericarditis with effusion is particularly likely to progress to constriction and to require pericardiectomy in addition to antituberculous chemotherapy.[24,25] AIDS is a common cause of large pericardial effusions, the majority of which are not caused by identifiable opportunistic infective agents.[26] However, the incidence of tuberculous and other forms of bacterial pericarditis has increased in the United States as a result of AIDS.

Drug-Induced Pericarditis

Several drugs have been implicated in the etiology of pericardial disease, including procainamide, which leads to a lupuslike syndrome; minoxidil, which has been linked to pericardial effusion; and methysergide, which may lead to constrictive pericarditis.

Pericarditis after Cardiac Surgery

The postcardiotomy syndrome presents primarily as acute pericarditis. Whether it has an infective or autoimmune cause is unclear. A similar condition occurs after blunt or penetrating trauma, hemopericardium from other causes, or epicardial pacemaker implantation. Cardiac tamponade and constrictive pericarditis occur occasionally.

Pericardial Complications of Invasive Procedures

Cardiac tamponade occurs as a complication of various invasive procedures in the cardiac catheterization laboratory and in the intensive care unit. Particularly important, and usually preventable, is the perforation of the heart by central venous catheters that have been allowed to lie in the right atrium rather than in the superior vena cava.[27] The use of newer devices (e.g., stents) and procedures (e.g., rotational atherectomy) has increased the incidence of percutaneous coronary interventions with cardiac tamponade complications.[28] Most of these cases are managed successfully by pericardiocentesis.[18]

CONSTRICTIVE PERICARDITIS

Constrictive pericarditis was formerly widely considered to be primarily a tuberculous lesion and is still so regarded in many areas of the world. Most cases now seen in the United States are idiopathic or are related to previous cardiac surgery or radiotherapy.[29,30] Fewer cases result from purulent pericarditis, rheumatic diseases, dialysis, and various rarer conditions.

In the classic form of chronic constrictive pericarditis, fibrous scarring and adhesion of both pericardial layers obliterate the pericardial cavity. The resulting fibrotic lesion has been likened to a rigid shell around the heart, particularly when there is considerable calcification of the pericardium, a feature seen in longstanding cases. The subacute form of constrictive pericarditis is now more common than the chronic calcific type. In the subacute variant, the constriction is rather fibroelastic and may be produced by fibrous contracture of the visceral pericardial layer (epicardium) alone. The fibroelastic constriction may also exist in combination with persisting loculated or totally free pericardial effusion; this form is termed effusive-constrictive pericarditis, and it can be documented by measuring pericardial and central venous pressures before and after removal of the fluid.

Pathophysiology

The pathophysiology of constrictive pericarditis is similar to that of tamponade in that both conditions impede diastolic filling of the heart and lead to increased venous pressure and ultimately to reduced cardiac output. Differences exist in the diagnostic signs, however. Paradoxical pulse is a regular feature of cardiac tamponade but may be inconspicuous or absent in constrictive pericarditis. The Kussmaul sign (an increase in venous pressure with inspiration) is seen in some patients with constrictive pericarditis but not in patients with pure cardiac tamponade. When tamponade is present, the venous pulse shows a predominant systolic dip, whereas in constrictive pericarditis, the early diastolic dip is the more prominent deflection [*see Figure 6*].

An early diastolic sound (pericardial knock) is often heard in constrictive pericarditis but not in tamponade; this sound is directly related to the extent to which ventricular filling is restricted to early diastole, being abruptly checked at the peak of early filling when the heart reaches the fixed volume imposed by the constricting shell surrounding it.

Diagnosis

ECG and imaging studies Constrictive pericarditis is difficult to diagnose, frequently being misdiagnosed for prolonged periods as liver disease or idiopathic pleural effusion. Clinical diagnosis of constrictive pericarditis depends on the recognition of increased venous pressure in a patient who may not have other obvious signs or symptoms of heart disease. The heart size and lung fields often appear normal in the chest radiograph, and the ECG shows only minor nonspecific abnormalities. Echocardiography is also nondiagnostic in many instances, although the appearance of abnormal septal motion and pericardial thickening often provide clues. Transesophageal echocardiography and chest CT are superior to echocardiography for the demonstration of pericardial thickening [*see Figure 7*]; however, the pericardium is not measurably thicker than normal in noninvasive imaging studies in some patients with constriction.[31]

As in cardiac tamponade, pulsed wave Doppler studies show exaggerated respiratory variation in the mitral and tricuspid diastolic flow velocity in most cases of constrictive pericarditis. Doing the study in the upright position improves the sensitivity of

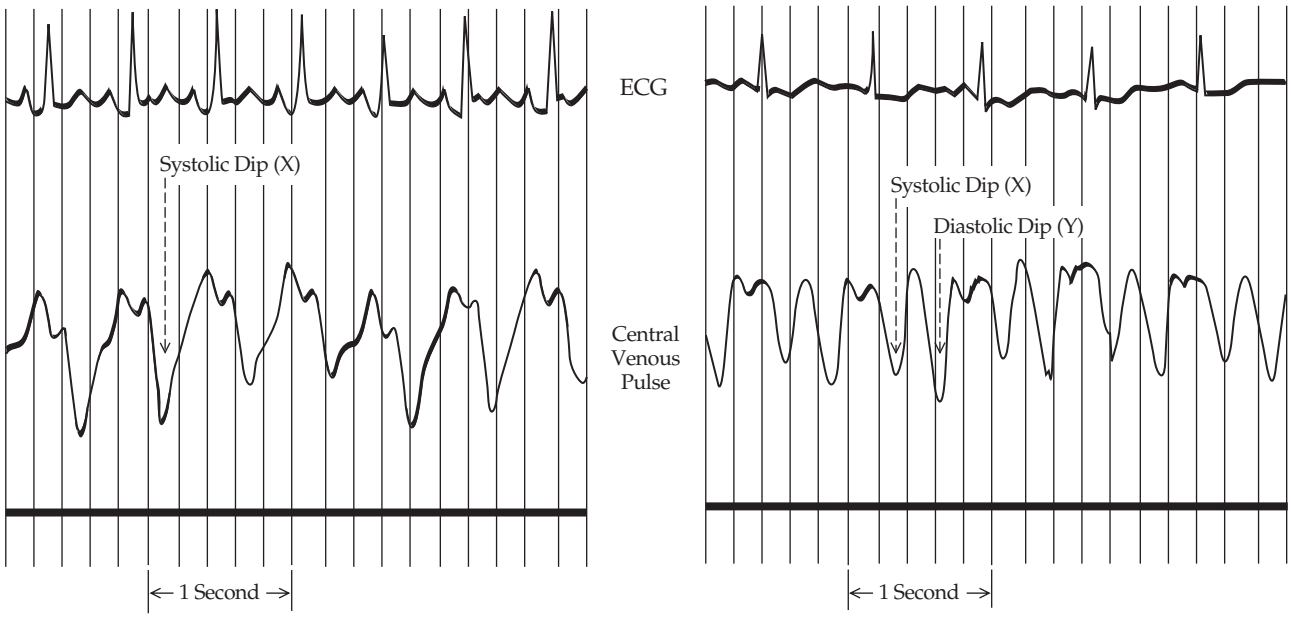

Figure 6 **Differences between the central venous pulse contours characteristic of cardiac tamponade (left) and chronic constrictive pericarditis (right) provide the basis for differential diagnosis. The pressure contour in a patient with pericardial effusion and tamponade has a prominent systolic dip (X) but little or no diastolic deflection. The central venous pulse pattern in a patient with chronic constrictive pericarditis displays an M or W contour consisting of both systolic dip (X) and diastolic dip (Y), with the Y descent being more prominent.**

this test.[32] False positive results occur in patients with chronic obstructive pulmonary disease, but that can be recognized by performing Doppler studies of flow velocity in the superior vena cava; the changes in velocity with respiration are much greater in pulmonary disease than in constrictive pericarditis.[33]

Cardiac catheterization Cardiac catheterization shows characteristic abnormalities, with increased central venous pressure, nondilated and normally contracting right and left ventricles, and near equilibration of the cardiac filling pressures of the right and left sides. These features may also be present in idiopathic restrictive cardiomyopathy or in specific myocardial diseases, especially cardiac amyloidosis; in such cases, the demonstration of pericardial thickness by CT or MRI and the use of endomyocardial biopsy are helpful.[34] Many other clues can assist in this differential diagnosis [*see Table 1*]. The increased interdependence of the two ventricles in constrictive pericarditis causes the right and left ventricular systolic pressures to vary out of phase with each other in respiration; in conditions other than constrictive pericarditis, the two systolic pressures increase and decrease together with respiration. This is perhaps the most useful information yielded by cardiac catheterization in patients with suspected constrictive pericarditis.[35]

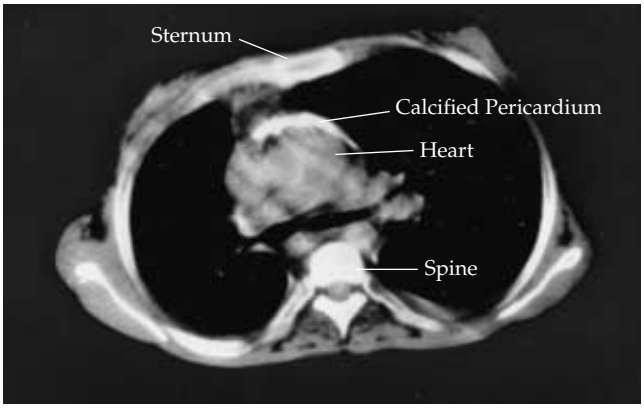

Figure 7 **In this CT scan of the chest of a patient with chronic constrictive pericarditis, the dense layer on the anterior surface of the heart represents thickened and partially calcified pericardium.**

Treatment

Constrictive pericarditis occasionally resolves spontaneously when it develops as a complication of acute pericarditis.[35] In nearly all instances, however, relief of constrictive pericarditis requires surgical stripping and removal of both layers of the adherent, constricting pericardium. This operation is far more difficult to perform than the operation for relief of pericardial effusion. The operation must be thorough, which carries the risk of hemorrhage from perforations in the wall of the heart. Inadequate long-term relief after surgical removal of the pericardium may reflect the presence of associated myocardial disease, particularly in instances of radiation-induced pericardial disease.[36] In most other forms of constrictive pericarditis, however, myocardial function is normal.

Cardiac Tumors

Cardiac tumors may be either primary or secondary, and they may be either benign or malignant. Metastatic cardiac involvement occurs 20 to 40 times more frequently than primary tumors. However, primary tumors are often benign and curable by surgery.

METASTATIC TUMORS

About 10% of patients who die of malignant disease have metastatic cardiac involvement, but the metastases produce symptoms in only 5% to 10% of the affected patients. Neoplasms

Table 1 Clinical Features That Differentiate Constrictive Pericarditis from Amyloidosis and Idiopathic Restrictive Cardiomyopathy

Clinical Feature	*Constrictive Pericarditis*	*Cardiac Amyloidosis*	*Idiopathic Restrictive Cardiomyopathy*
Early diastolic sound (S_3 or pericardial knock)	Frequent	Occasional	Occasional
Late diastolic sound (S_4)	Rare	Frequent	Frequent
Atrial enlargement	Mild or absent	Marked	Marked
Atrioventricular or intraventricular conduction defect	Rare	Frequent	Frequent
QRS voltage	Normal or low	Low	Normal or high
Mitral or tricuspid regurgitation	Rare	Frequent	Frequent
Paradoxical pulse	Frequent but usually mild	Rare	Rare
Exaggerated variation in mitral and tricuspid flow velocity with respiration, out of phase	Usual	Rare	Rare

particularly likely to metastasize to the heart are cancers of the lung or breast, melanoma, leukemia, and lymphoma.[37]

The most frequent clinical manifestation is pericardial effusion with cardiac tamponade. In such cases, the mass of the tumor is often relatively small. Extensive solid tumor in and around the heart is less common but may resemble constrictive pericarditis or effusive-constrictive pericarditis. Invasion of the myocardium most often manifests clinically as arrhythmias; atrial flutter and atrial fibrillation are particularly common.

Usually, the only effective treatment in metastatic involvement of the heart is relief of cardiac tamponade. Otherwise, treatment depends on the nature of the primary tumor.

PRIMARY BENIGN TUMORS

Eighty percent of all primary cardiac tumors are benign; myxomas account for more than half of these in adults, whereas rhabdomyomas and fibromas are the most common benign cardiac tumors in children.[38-40] Cardiac rhabdomyomas in infancy and childhood have a high incidence of spontaneous regression; although they are sometimes responsible for a remarkable syndrome of paroxysmal ventricular tachycardia in infancy, this syndrome can be cured by surgical removal of the tumor. Echocardiography and MRI are both excellent methods for demonstrating intracardiac tumors [*see Figures 8 and 9*].

Myxoma Myxomas consist of scattered stellate cells embedded in a mucinous matrix. They are found in the cavities of the heart, attached to the endocardial wall (or, in rare cases, attached to one of the heart valves) by either a narrow stalk or a broader pedicle. The tumor often shows considerable movement within the cardiac chamber during the cardiac cycle [*see Figure 8*]. About 70% of myxomas are in the left atrium; the rest are mostly in the right atrium. Echocardiography is a reliable method with which to predict tumor size and morphology.[41]

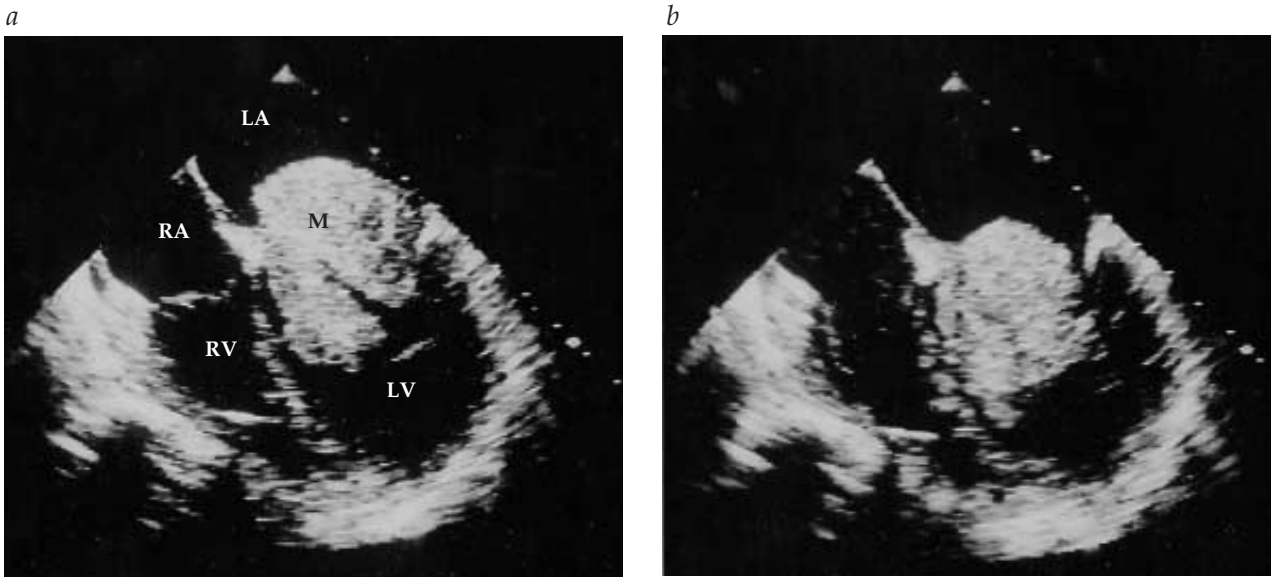

Figure 8 **This transesophageal echocardiogram demonstrates a large myxoma (M) in the left atrium (LA) of a 23-year-old man. The picture on the left (*a*) was taken during early systole, and the picture on the right (*b*) was taken during early diastole. The marked mobility of the tumor is evident as it moves from the left atrium to the left ventricle (LV). The right atrium (RA) and right ventricle (RV) are also visible.**

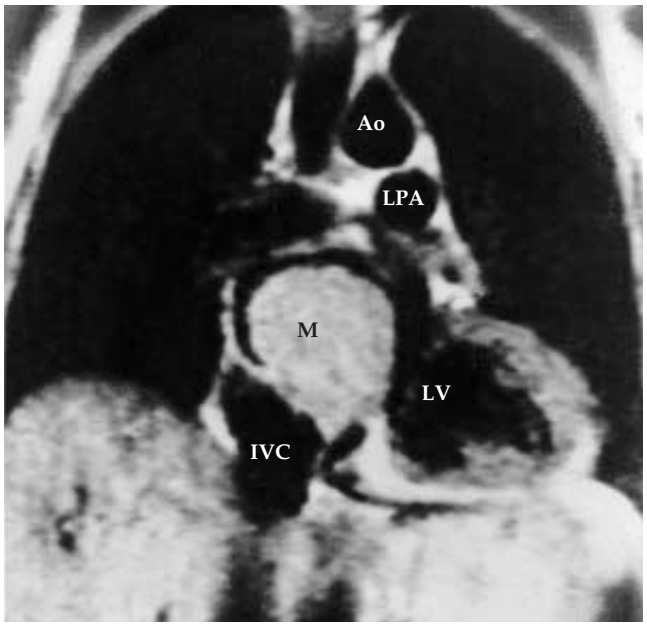

Figure 9 **This magnetic resonance image, coronal view, shows a large left atrial myxoma (M). The left ventricle (LV), aorta (Ao), left pulmonary artery (LPA), and inferior vena cava (IVC) are also visible.**

Myxomas are most often manifested clinically by mechanical hemodynamic effects, which often simulate mitral or tricuspid stenoses when they obstruct the valve orifice. They may simulate mitral or tricuspid regurgitation when they interfere with valve closure or cause a so-called wrecking-ball type of trauma to the mitral or tricuspid valve. Intermittent obstruction of the valve orifice can lead to such dramatic symptoms as syncope or to remarkable changes in physical signs that are sometimes related to changes in body position.

Myxomas also cause thromboembolic complications when portions of the tumor or thrombi from the surface of the tumor are detached. Another manifestation is a constitutional disturbance consisting of fatigue, fever, erythematous rash, myalgias, and weight loss, accompanied by anemia and an increased erythrocyte sedimentation rate. The constitutional symptoms may be caused by production of interleukin-6 by the myxoma.[42]

About 5% of cases of cardiac myxoma are familial, multicentric, or associated with a genetic syndrome that includes cutaneous lentiginosis, cutaneous myxomas, myxoid fibroadenomas of the breast, pituitary adenomas, adrenocortical micronodular hyperplasia with Cushing syndrome, and Sertoli cell tumors of the testis. These cases are referred to as complex myxoma, myxoma syndrome, or the Carney complex. A genetic mutation underlying this syndrome has been identified.[43]

Surgical treatment of cardiac myxomas is usually curative, particularly if the resection includes the portion of the atrial septum or atrial free wall from which the tumor has arisen. Recurrence and distant metastases are rare except in myxoma syndrome.[44]

Papillary fibroelastoma Papillary fibroelastomas are small tumors, usually attached to cardiac valves, that can be a cause of cardioembolic stroke. They have been recognized with increasing frequency since echocardiography has come into more widespread use.[45] Surgery may be indicated, especially if embolism recurs.

PRIMARY MALIGNANT TUMORS

Most malignant tumors of the heart are sarcomas, of either the spindle cell or the round cell type. Spindle cell tumors include fibrosarcomas, hemangiosarcomas, leiomyosarcomas, rhabdomyosarcomas, and fibromyxosarcomas. Round cell tumors include lymphosarcomas or reticulum cell sarcomas. Primary lymphoma of the heart, which is usually seen only in immune-compromised patients, is increasing in incidence.[46]

Malignant tumors are more apt to occur in the right side of the heart than in the left, being about equally frequent in the right atrium and the right ventricle. Signs and symptoms usually stem from intracavitary growth of the tumor, causing obstructive phenomena that simulate congestive heart failure. Pericardial effusion and tamponade are also common.

Malignant pericardial mesothelioma usually presents as pericardial effusion with tamponade or as subacute constrictive pericarditis.

Although surgical excision of malignant cardiac tumors is often attempted, cure is only rarely achieved. The tumors are usually unresponsive to radiation or chemotherapy, and most are fatal within a few months.

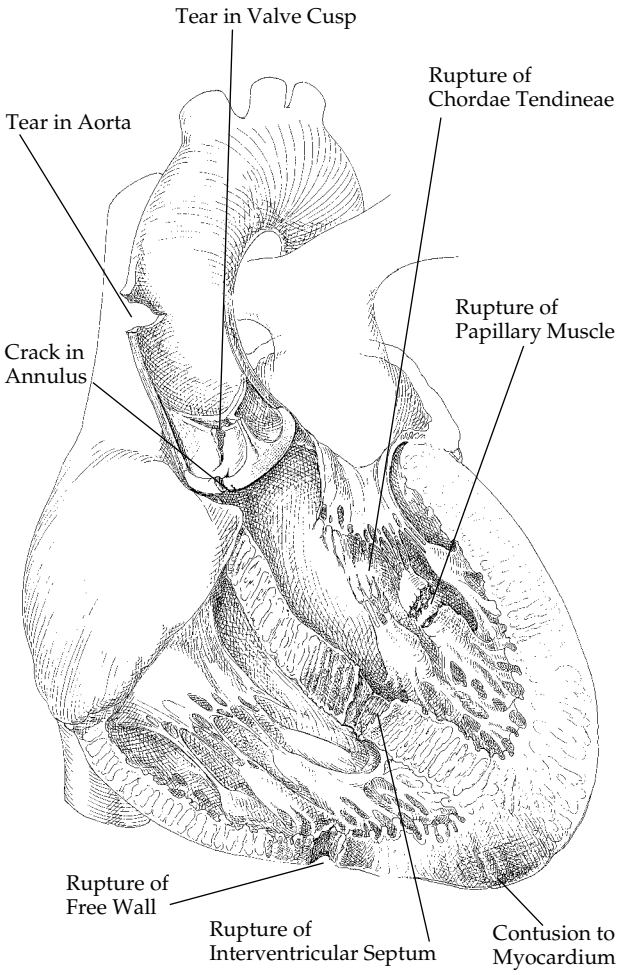

Figure 10 **Blunt trauma, such as that caused by the impact of the chest against the steering wheel in an automobile accident, may injure various cardiac structures. Myocardial contusion is the most frequent injury, but rupture may occur at several sites, including the interventricular septum, the walls of the cardiac chambers, the papillary muscles, and the chordae tendineae. The shearing forces that accompany abrupt deceleration may also cause tearing of the aorta and the valve cusps and cracking of the annulus.**

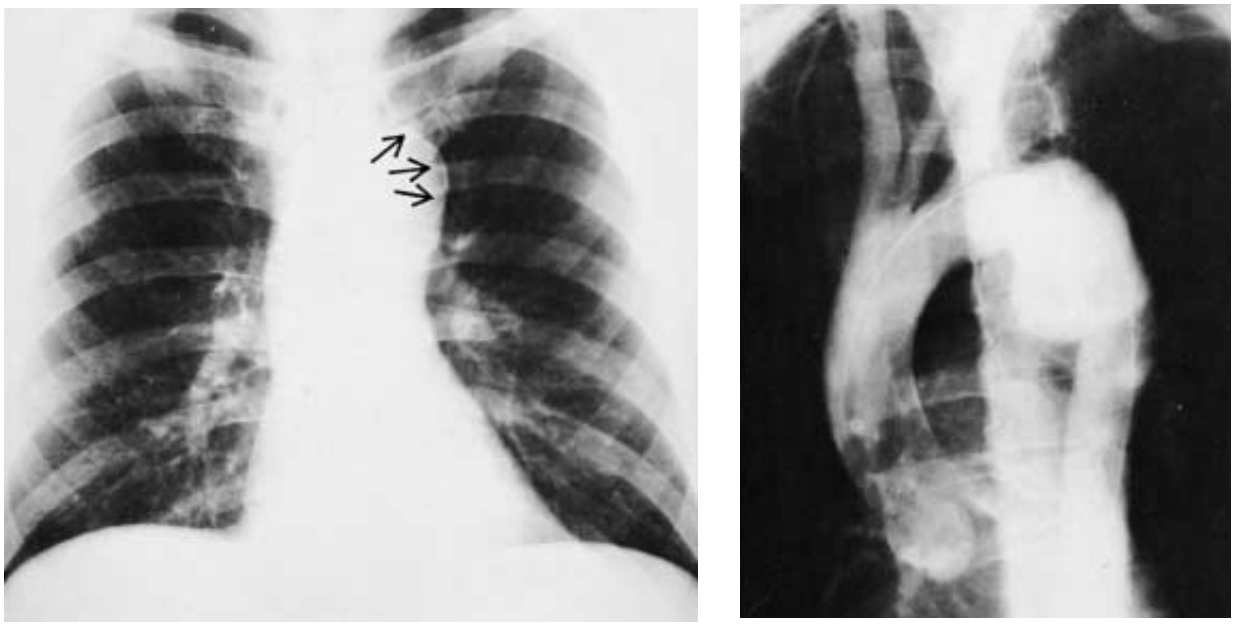

Figure 11 **A posteroanterior chest x-ray (left) reveals a posttraumatic aortic aneurysm at the aortic isthmus. Calcification (arrows) is evident in the wall of the aneurysm, which arose in a 45-year-old policeman who had sustained chest injuries in a motorcycle accident 24 years earlier. The lesion had gradually enlarged during a 10-year period of observation after its discovery. The aneurysm, outlined by angiography (right), was successfully excised.**

Cardiovascular Trauma

Cardiovascular injury may be either blunt (i.e., nonpenetrating) or penetrating.[47] Automobile accidents are the most common cause of blunt cardiovascular trauma; gunshots and stabbings are the most common causes of penetrating trauma. Both types of injury can damage the myocardium, the valves, the coronary arteries, the pericardium, and the great vessels, especially the aorta [*see Figure 10*]. Diagnosis in such instances is often difficult because the associated injuries can mask the cardiovascular trauma; cardiac trauma should therefore be suspected in all patients with chest injuries or severe generalized trauma.

BLUNT CARDIAC TRAUMA

Myocardial Contusion

Myocardial contusion is the most common blunt injury.[48] The right ventricle, because of its immediately substernal location, is the chamber most often involved. The pathologic changes in myocardial contusion consist of myocardial necrosis with hemorrhage, which may range in severity from scattered petechiae to intramural extravasations with associated transmural necrosis. In some instances, coronary arterial occlusion with secondary myocardial infarction is present. Seemingly innocuous blows to the chest by missiles such as baseballs or hockey pucks may cause sudden arrhythmic death, probably when they strike directly over the heart during the vulnerable portion of the T wave and induce ventricular fibrillation.[49]

The most important complication of myocardial contusion is cardiac arrhythmia. Hypotension, intracardiac thrombus, congestive heart failure, and cardiac tamponade occur occasionally.

Myocardial contusion is best recognized clinically by echocardiography, which shows localized areas of impaired wall motion. Transesophageal echocardiography is often superior to the transthoracic evaluation.[50] The abnormalities of wall motion usually resolve within a few days. Increases in the concentrations of creatine kinase (CK) and its MB fraction (CK-MB) in the blood are difficult to interpret because of the release of CK from injured skeletal muscle. Cardiac troponin-I is a more specific marker.[51] Diffuse nonspecific ST-T abnormalities in the electrocardiogram are common in injured patients, even in the absence of echocardiographically detected abnormalities in wall motion. However, localized changes, especially ST segment elevation, are more specific for contusion. Patients with Q wave infarct patterns and irreversible wall motion defects are likely to have a coronary arterial occlusion secondary to trauma with myocardial infarction. Severe contusions may also lead to the formation of traumatic left ventricular aneurysms or pseudoaneurysms that are sometimes detected months or years after the initial trauma. Management of myocardial contusion is conservative unless one or more specific complications (e.g., arrhythmia, tamponade, aneurysm, or perforation) are present.

Valvular Injury

Blunt trauma may injure any of the cardiac valves and lead to valvular regurgitation. Traumatic valvular regurgitation is more likely to be recognized after the patient has recovered from the acute injuries; it is less likely to play a major role in the early postinjury course.[52]

Aortic Injury

Injuries of the aorta result from abrupt deceleration in violent thoracic trauma and are relatively common. The most common injury results from a tear in the wall of the aorta at a point just distal to the left subclavian artery, where the aorta is fixed to the dorsal thoracic cage. Usually, complete transection of the aorta is quickly fatal. Less extensive tears can result in a localized hematoma or a localized false aneurysm. Such aneurysms may be recognized months or years after the initial injury, when they cause symptoms by gradually enlarging, or may be discovered incidentally by chest radiography [*see Figure 11*].

A widened mediastinal shadow in the chest radiograph is often the first clue to the presence of a traumatic aortic rupture. The chest CT and the transesophageal echocardiogram are useful aids in making the diagnosis.

At least 50% of patients with aortic rupture die before they reach a hospital, often of injuries unrelated to the aortic trauma. Surgical therapy should be undertaken as soon as possible, even if the bleeding from the ruptured aorta has stabilized; such therapy results in survival of about 80% of those patients who are still alive when they reach a medical facility. Resection of the injured segment and replacement with a prosthetic graft are usually required.

Usually, false aneurysms that are diagnosed long after the initial injury should be resected electively. Their natural history in most instances is to enlarge gradually and eventually rupture.

PENETRATING TRAUMA

Penetrating injuries of the heart and great vessels are caused either by stab wounds or by gunshot wounds. Any of the cardiac chambers or great vessels may be punctured, and injury of multiple structures is common. The most common sites of involvement, in order of decreasing frequency, are the right ventricle, the left ventricle, the right atrium, and the left atrium.

Stab wounds and, especially, bullet wounds of the heart often are immediately fatal. However, if the penetrating wound is relatively small, cardiac tamponade can occur, and the buildup of pressure in the pericardial sac may help reduce the severity of bleeding and thus increase the chance of survival.

Other sequelae of penetrating trauma include laceration of the aorta or the pulmonary artery; defects in the ventricular or atrial septum; fistulas between the great vessels and between the coronary arteries and the cardiac chambers; coronary arterial fistulas; puncture of any of the heart valves; and atrioventricular block as a result of disruption of the conduction system. Occasionally, a missile that lodges in a cardiac chamber or in one of the great arteries will embolize to a distal site, whereas missiles that initially lodge in distal sites may work their way through the veins to lodge in the chambers of the heart or the pulmonary artery.

The existence of intracardiac shunts, fistulas between the heart and great vessels, coronary arterial fistulas, or valve disruption is usually suggested by the presence of new murmurs. Echocardiography and Doppler studies generally allow precise definition, localization, and quantitation of the lesions.

Penetrating cardiac trauma usually requires prompt surgical intervention, even performance of a thoracotomy in the emergency department. The immediate availability of echocardiography in the emergency department or trauma unit is extremely valuable in management of penetrating wounds of the heart. The survival rate of patients who reach the hospital alive is about 50% for those with knife wounds of the heart and 30% for patients with gunshot wounds.[53]

ELECTRICAL INJURY

Electrical injury, a special type of cardiac trauma, is produced by a direct electrical effect on the tissues, the generation of heat from the passage of current from a high-voltage source through tissue with high electrical resistance, extreme release of catecholamines, or extreme autonomic stimulation. Sudden cardiac arrest occurs with exposure to either household AC current or a lightning strike. Lightning strikes also cause myocardial injury, which may be extensive; in such cases, ECG patterns change, concentrations of cardiac enzymes increase, and wall motion exhibits abnormalities. Pericarditis and pericardial effusion also occur. The abnormalities usually resolve within several weeks.[54]

XV CONGENITAL HEART DISEASE

Larry T. Mahoney, m.d.
David J. Skorton, m.d.

Congenital diseases of the heart and vasculature are the most common birth defects, occurring in approximately eight per 1,000 live births. Some patients with congenital heart defects (CHDs) remain asymptomatic for many years; others survive to adulthood, thanks to the impressive progress in medical and surgical management made in recent decades. This relatively high incidence, coupled with improved management, has resulted in a large adult population of these patients: it has been estimated that almost one million adults with CHDs are currently living in the United States.[1] A broad range of clinicians must now become more knowledgeable about the care of these patients,[2] including issues such as endocarditis prophylaxis[3] [*see Sidebar* Selected Internet Resources for Congenital Heart Disease]. This chapter reviews CHDs most likely to be encountered in adult patients.

Acyanotic Disorders—Shunts

Atrial Septal Defects

Atrial septal defects (ASDs) occur in three main locations [*see Figure 1*]: the region of the fossa ovalis (such defects are termed ostium secundum ASDs); the superior portion of the atrial septum near the junction with the superior vena cava (SVC) (sinus venosus ASDs); and the inferior portion of the atrial septum near the tricuspid valve annulus (ostium primum ASDs). The ostium primum ASDs are considered to be part of the spectrum of atrioventricular septal defects (AVSDs) [*see* Atrioventricular Septal Defects, *below*].

Ostium secundum ASDs are the most common variety, accounting for over half of ASDs. A frequent accompanying defect is mitral valve prolapse. Relatively less prevalent is the sinus venosus defect. Anomalous pulmonary venous return is a common associated abnormality. The proximity of the sinoatrial node to the ASD may lead to sinoatrial node dysfunction and atrial arrhythmias.

Pathophysiology

ASDs are associated with left-to-right shunts of varying degrees. The main determinants of the direction and magnitude of shunt flow are the size of the defect and the relative compliances of the left ventricle (LV) and right ventricle (RV).[4]

Clinical Presentation

Most patients with ostium secundum or sinus venosus ASD are asymptomatic through young adulthood. As the patient reaches middle age, compliance of the LV may decrease, increasing the magnitude of left-to-right shunting. Long-standing atrial dilatation may lead to a variety of atrial arrhythmias, including premature atrial contractions, supraventricular tachycardia, and atrial fibrillation. A substantial number of middle-aged patients will report dyspnea, particularly with exertion, even if they do not have pulmonary hypertension. Approximately 10% of patients with ostium secundum ASDs will progress to pulmonary hypertension associated with pulmonary vascular obstructive disease (Eisenmenger syndrome) [*see* Eisenmenger Syndrome, *below*]. As the pulmonary pressure rises, the left-to-right shunt will diminish and eventually be replaced by a right-to-left shunt; cyanosis and pulmonary hypertension will develop.

The hallmark of the physical examination in ASD is the wide and fixed splitting of the second heart sound. A systolic murmur (from increased pulmonary flow) is common, and if a large left-to-right shunt is present, the additional flow across the tricuspid valve may lead to a diastolic rumble reminiscent of tricuspid stenosis.

Laboratory Tests

All patients with suspected ASD should have an electrocardiogram, a chest x-ray, and an echocardiogram.

Electrocardiography The QRS axis usually is normal in ostium secundum ASD but may be slightly rightward, and an rSR′ pattern is common in the right precordial leads. In sinus venosus ASD, the axis may be normal or relatively horizontal (less than 30°). Ectopic atrial rhythms or other evidence of sinoatrial node dysfunction may be seen.

Radiologic studies The chest x-ray reveals enlargement of the right atrium (RA), the RV, and the main pulmonary artery. The pulmonary vessels exhibit diffuse enlargement because of increased pulmonary blood flow. Magnetic resonance imaging, magnetic resonance angiography (MRA), or cardiac catheterization will identify anomalous pulmonary veins; these modalities should be considered when there is suspicion of this associated abnormality in patients with sinus venosus ASD.

The patient with secundum ASD who has pulmonary hypertension may benefit from right-sided heart catheterization to ascertain the level of pulmonary arterial pressure and resistance.

Echocardiography Echocardiography can confirm the presence of an ASD, determine its size, permit calculation of shunt flow through it, and identify any associated anomalies.

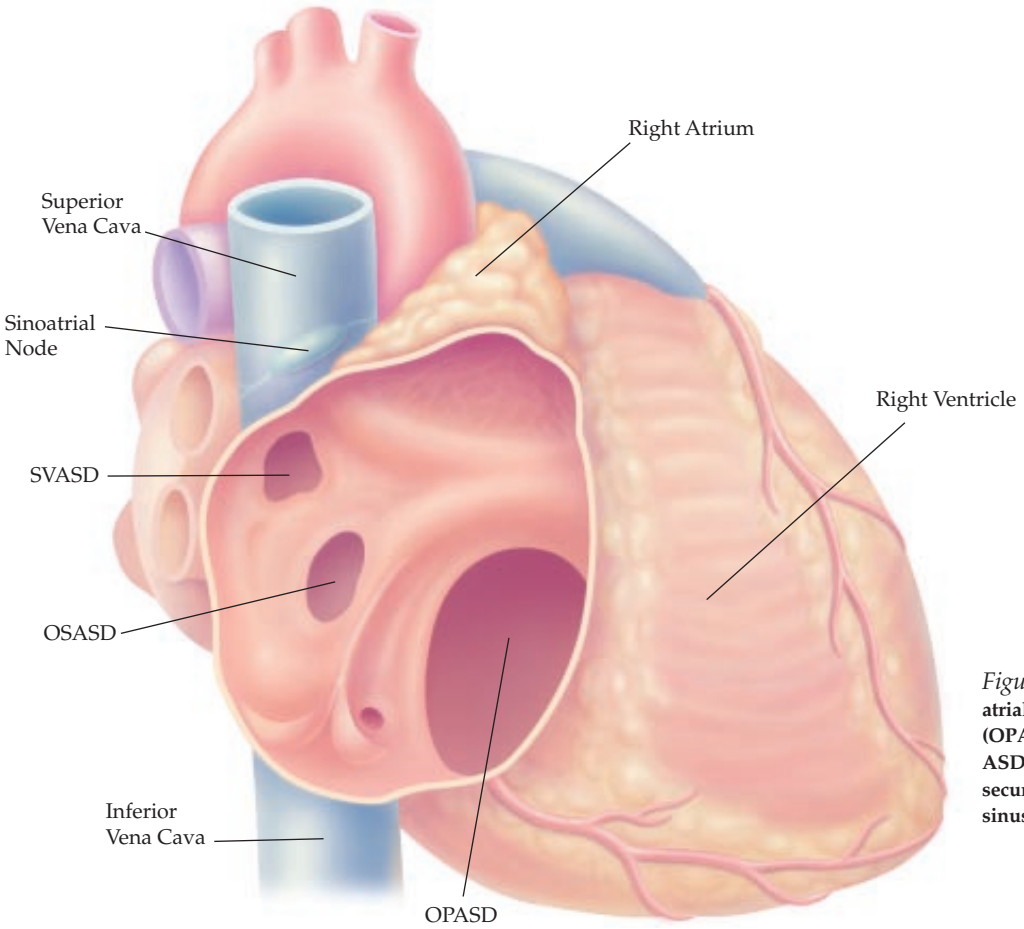

Figure 1 **Anatomy of atrial septal defects (ASDs). (OPASD—ostium primum ASD; OSASD—ostium secundum ASD; SVASD—sinus venosus ASD)**

Management

Large ASDs (defined as those with a pulmonary-to-systemic flow ratio [Qp:Qs] of over 1.5:1) should be closed to prevent the development of pulmonary hypertension and reduce the risk of paradoxical emboli. Direct surgical closure has been the method used, but devices are now available that permit catheterization-based closure of many defects.[5] Postclosure management includes periodic assessment for the development of atrial arrhythmias.[6] The need for endocarditis prophylaxis varies.

ATRIOVENTRICULAR SEPTAL DEFECTS

The septal leaflet of the tricuspid valve normally inserts into the septum slightly closer to the apex than does the septal leaflet of the mitral valve [*see Figure 2*]. Thus, the small portion of septal tissue superior to the tricuspid septal leaflet insertion separates the RA from the LV and so is called the atrioventricular septum. The term AVSD refers to a complex spectrum of disorders involving abnormalities of the atrioventricular septum and, frequently, the atrioventricular valves. Nomenclature for this spectrum of disorders has varied; synonymous terms include atrioventricular canal defect and endocardial cushion defect.

Pathophysiology

The spectrum of AVSDs ranges from a simple ostium primum ASD to a complete AVSD, which allows free communication among all four cardiac chambers. Variations of the anatomy of the anterior leaflet of the mitral valve and the septal leaflet of the tricuspid valve include a cleft or other abnormality in either or both of these leaflets; accessory chordae that attach in anomalous locations and alter function of the valve leaflets; or a common atrioventricular valve leaflet that bridges the septal defect. Physiologic consequences vary according to the extent of the anomaly; for example, the addition of a cleft mitral valve anterior leaflet adds varying degrees of mitral regurgitation (MR). Larger defects that also involve the ventricular septum, as well as complete AVSDs, can be associated with torrential left-to-right shunts or an admixture of venous and arterial blood.

Patients with an unrepaired complete AVSD are at risk for developing pulmonary hypertension. Eisenmenger syndrome is particularly common in AVSD patients who also have Down syndrome (trisomy 21).[7]

Clinical Presentation

Patients with isolated ostium primum ASDs may be asymptomatic until adulthood and then may present with fatigue, dyspnea, or symptoms related to atrial arrhythmias. Severe regurgitation of either atrioventricular valve can produce symptoms of heart failure or arrhythmias. Symptoms related to pulmonary hypertension occur in those patients who develop Eisenmenger syndrome.

Patients with only an ostium primum ASD will have clinical findings similar to those of patients with an ostium secundum ASD. The presence of a cleft in either atrioventricular valve will be associated with a pansystolic murmur. Finally, an additional pansystolic murmur can be found in patients with a complete AVSD.

Laboratory Tests

Electrocardiography Left axis deviation is present in the majority of patients. The combination of physical findings of

ASD along with left axis deviation on the ECG suggests the presence of an AVSD. RV conduction delay may be present as well.

Radiologic studies The chest x-ray shows cardiomegaly and pulmonary vascular engorgement because of the left-to-right shunt.

Echocardiography Echocardiography defines the specific anatomy and functional importance of the defects. Preoperative echocardiographic assessment includes estimation of the severity of atrioventricular valve regurgitation, the Qp:Qs ratio, and pulmonary arterial pressures. Postoperatively, echocardiography is used to identify and assess the significance of residual atrioventricular valve regurgitation or residual shunt.

Management

The rare patient who presents in adulthood with complete AVSD should be evaluated for pulmonary hypertension. If pulmonary pressures are normal or if pulmonary hypertension is not prohibitive (i.e., pulmonary vascular resistance is less than 50% of systemic vascular resistance), then surgical closure of the defect and repair of the atrioventricular valve anomalies should be undertaken. Postoperatively, patients are assessed for the adequacy of atrioventricular valve repair and are monitored for evidence of residual shunt. In patients with residual MR, management focuses on the need for and timing of reoperation, which may involve either repair or replacement of the mitral valve. The patient should also be followed for the development of atrial arrhythmias.

VENTRICULAR SEPTAL DEFECTS

VSDs are among the most common congenital cardiac disorders seen at birth but are less frequently seen as isolated lesions in adulthood. This is because most VSDs in infants either (1) are large and nonrestrictive (i.e., they permit equilibration of pressures between the ventricles) and therefore lead to heart failure, necessitating early surgical closure, or (2) are small and close spontaneously.

Classification systems for VSD vary but usually are referenced to the embryologic divisions of the ventricular septum into inlet, outlet, muscular, and membranous portions [*see Figure 3*]. The most common defects are perimembranous defects. Inlet VSDs, located more posteriorly, may be part of the spectrum of AVSDs (see above). Single or multiple defects may occur in the muscular septum (muscular VSD). Finally, outlet VSDs include subpulmonary defects, which may allow prolapse of an aortic cusp, leading to associated aortic regurgitation (AR).

Pathophysiology

Nonrestrictive VSDs permit equilibration of ventricular pressures between the RV and LV, whereas small defects produce a large pressure gradient across the defect, so right heart pressures remain normal. The magnitude of shunt flow across moderate or large VSDs depends on the relative resistances of the systemic versus the pulmonary vascular bed. Rarely, clinicians may encounter adult patients who have large, nonrestrictive defects in the absence of other lesions. Moderate pulmonic stenosis at either the valve or the subvalvular level may create increased resistance to right ventricular outflow sufficient to reduce the left-to-right shunt; consequently, patients with VSD and mild to moderate pulmonic stenosis may reach adulthood without experiencing symptoms. Adults with long-standing VSD and large shunts may develop Eisenmenger syndrome.

Clinical Presentation

With the exception of those patients who contract infective endocarditis or those with Eisenmenger syndrome, adults with VSD are asymptomatic.

The classic physical finding of a restrictive VSD is a harsh, fre-

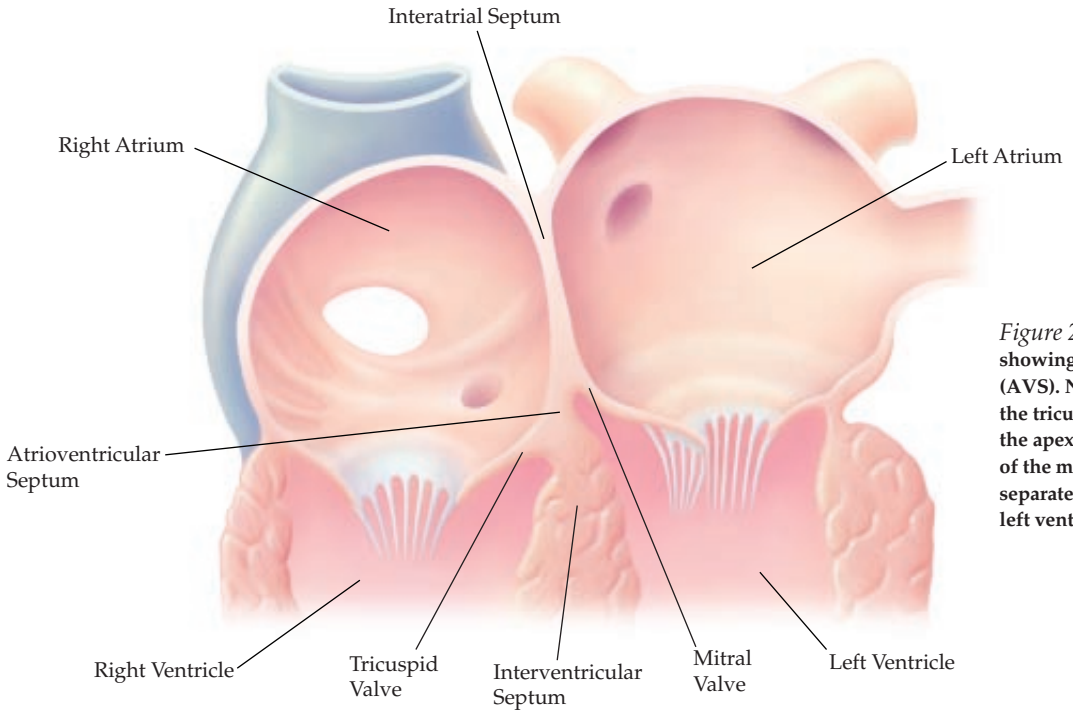

Figure 2 **Anatomic cross-section showing the atrioventricular septum (AVS). Note that the septal leaflet of the tricuspid valve inserts closer to the apex than does the septal leaflet of the mitral valve; thus, the AVS separates the right atrium from the left ventricle.**

quently palpable, pansystolic murmur heard best at the left lower sternal border. Patients who have large defects that allow equilibration of ventricular pressures may present with less impressive murmurs than patients with small defects; the reason is that with small defects, there is a large gradient between the LV and the RV, which results in severe turbulence across the defect. When aortic cusp prolapse occurs, the murmur of AR will be audible.

Laboratory Tests

Electrocardiography The ECG may be normal or show evidence of left ventricular hypertrophy (LVH) and a pattern of so-called diastolic overload, featuring prominent Q waves in left precordial leads V5 and V6 and in leads I and aV_L.

Radiologic studies The chest x-ray may be normal or show left ventricular enlargement and pulmonary arterial engorgement. Patients who have evidence of pulmonary hypertension should undergo right heart catheterization to determine the degree of pulmonary hypertension and the level of pulmonary resistance.

Echocardiography Echocardiography is the procedure of choice for identifying the location, size, and hemodynamic significance of a VSD; the interventricular gradient should be determined (to estimate RV pressure), and an assessment should be made of increased pulmonary blood flow.

Management

Patients with ventricular septal defects in which the Qp:Qs ratio is greater than 1.5:1 should be considered for surgical closure. Patients with pulmonary hypertension may undergo closure if pulmonary resistance is no more than about 50% of systemic resistance. Aortic cusp prolapse with resultant AR may diminish the shunt magnitude, but the presence of a prolapse constitutes an additional potential indication for closure.

Early VSD operative closures were performed through a right ventriculotomy, but now, many defects—particularly those in the perimembranous septum—are closed through a transatrial approach; such an approach leads to fewer problems with RV dysfunction and arrhythmias. Continual progress is being made in the deployment of transcatheter closure devices. Currently, however, surgical closure of VSD is still the most common approach. Postclosure management involves assessment for residual or recurrent VSD and atrial or ventricular arrhythmias, as well as assessment of RV function.

PATENT DUCTUS ARTERIOSUS

During fetal life, the ductus arteriosus connects the pulmonary artery to the aorta. Soon after birth, as a result of changes in circulating prostaglandin levels and arterial oxygen saturation, the ductus constricts; later, it closes permanently. Failure of the ductus to close leads to the condition termed patent ductus arteriosus (PDA).

Pathophysiology

The shunt from aorta to pulmonary artery increases pulmonary blood flow and return to the left heart. The size of the defect and the relative resistances of the pulmonary and systemic vascular beds determine the degree of shunting. Adults who have PDAs commonly present either with a small lesion without a large left-to-right shunt or with larger lesions and Eisenmenger syndrome.

Clinical Presentation

Except for patients with Eisenmenger syndrome, most adults with small to moderate PDAs will be asymptomatic, unless endarteritis supervenes.

The pathognomonic physical finding of PDA is the continuous murmur. A continuous murmur is one that is audible throughout systole and into diastole to any extent. The classic PDA murmur is machinelike and extends through systole and to variable degrees into diastole, peaking in intensity at the time of S_2. The runoff of blood into the pulmonary artery in diastole will produce a wide pulse pressure because of low aortic diastolic pressure.

Laboratory Tests

Electrocardiography The ECG in patients with PDA may be normal or may show evidence of LVH.

Radiologic studies If the shunt is small, the chest x-ray may be normal. Patients with larger shunts will have associated cardiomegaly and increased vascular markings. In adults, calcium may be noted within the wall of the ductus.

Echocardiography Echocardiography will identify the PDA and permit quantification of the Qp:Qs ratio.

Management

With the advent of reliable means of transcatheter closure of PDAs,[8] common practice is to recommend that most PDAs be closed. In rare cases, the ductus may need to be closed surgically if transcatheter closure is not successful. Postoperative management includes assessment for the need of a residual shunt, although this is uncommon. Patients who develop pulmonary hypertension are managed in the same way as those with Eisenmenger syndrome [*see* Eisenmenger Syndrome, *below*].

Acyanotic Disorders—Valvular Lesions

BICUSPID AORTIC VALVE AND OTHER CAUSES OF AORTIC STENOSIS

Abnormalities of the left ventricular outflow tract are common congenital cardiac disorders. In particular, as much as 2% of the population have congenitally bicuspid aortic valves. A bicuspid aortic valve may present as an incidental finding on physical examination or echocardiography done for other reasons; as significant aortic stenosis (AS) or AR; or when it results in infective endocarditis.

Pathophysiology

A stenotic bicuspid aortic valve will produce pressure overload of the LV, which leads to LVH and eventually to heart failure, angina pectoris, or sudden death from tachyarrhythmias. Similarly, the patient with an incompetent bicuspid aortic valve will exhibit LV dilatation, initially with normal systolic function; the condition will later progress to heart failure.

Clinical Presentation

On physical examination, the cardinal sign of a bicuspid aortic valve is an early systolic ejection click. If no significant hemodynamic abnormality is present, either no murmur or a soft ejection murmur may be heard; a very mild murmur of AR is not uncommon, even with hemodynamically insignificant bi-

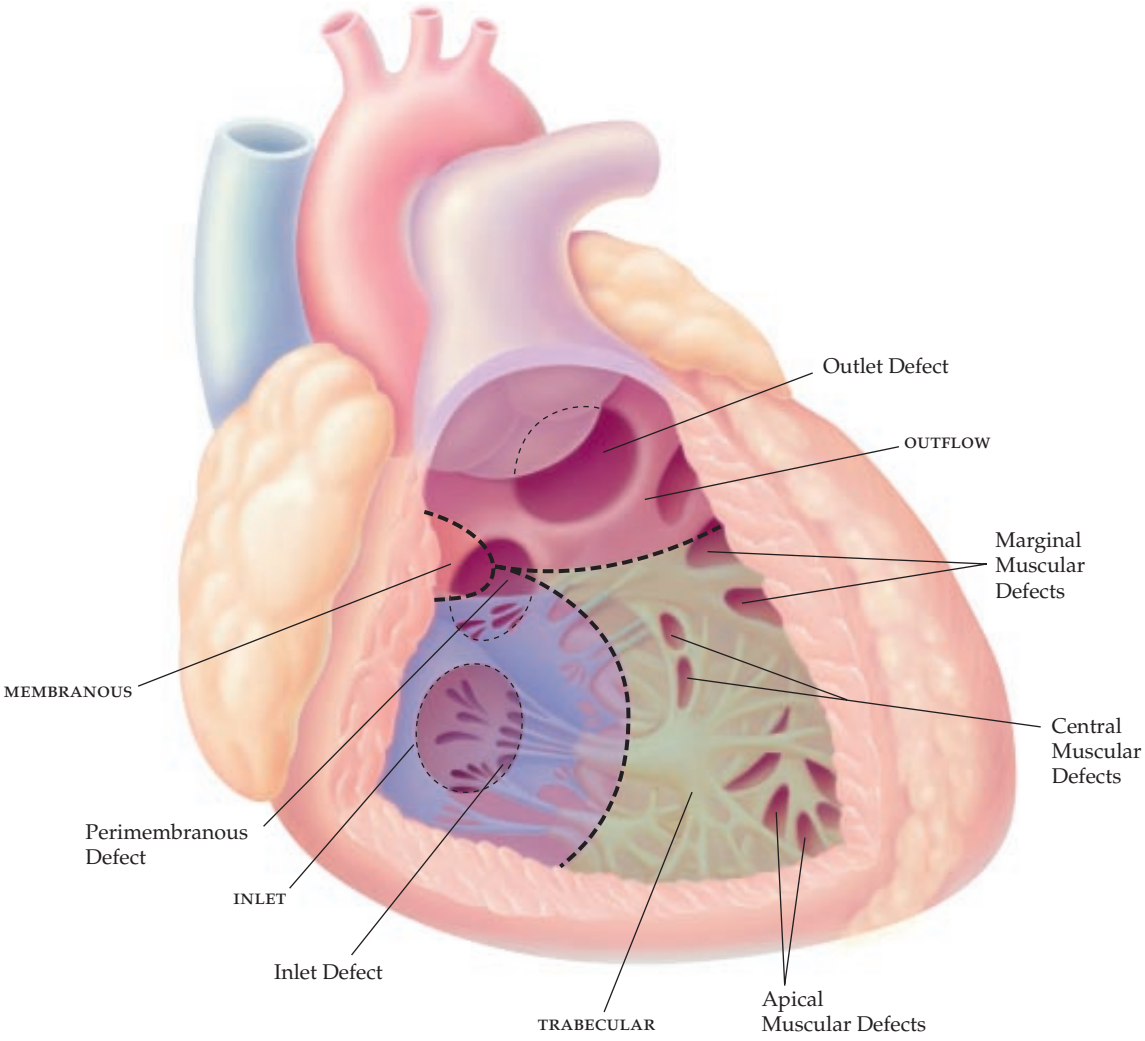

Figure 3 **Anatomic positions of ventricular septal defects. The major anatomic subdivisions of the ventricular septum are the membranous, outflow, inlet, and trabecular portions. Typical VSDs: outlet defect, perimembranous defect, marginal muscular defects, central muscular defects, inlet defect, apical muscular defects.**

cuspid aortic valves. More significant AS or AR will produce findings similar to those in patients with other disorders that cause these lesions.

Laboratory Tests

Electrocardiography The ECG will be normal unless hemodynamically significant stenosis or regurgitation is present, in which case it will show LVH.

Radiologic studies Chest x-ray findings in patients with hemodynamically significant bicuspid aortic valves are similar to those in patients with AS and AR from other etiologies. These may include LV dilatation in AR or in AS progressing to heart failure; the latter will also produce pulmonary congestion.

Echocardiography Both the presence of a bicuspid aortic valve and its hemodynamic significance can be determined by echocardiography. Serial studies are useful in following the progression of the lesion.

Management

All patients with bicuspid aortic valves—even those patients with no significant stenosis or regurgitation—should be given instructions regarding endocarditis prophylaxis. Patients with AR from a bicuspid valve who are asymptomatic and have normal systolic function are followed with echocardiograms and history and physical examinations at regular intervals. If they begin to show evidence of decreasing systolic function, symptoms of heart failure, or progressive dilation of the LV, surgical replacement of the aortic valve is indicated.

Surgical or balloon valvuloplasty (in younger patients) should be considered in a patient with AS who has heart failure, syncope, or chest discomfort. A variety of surgical procedures are available, including direct repair of the valve; replacement with a bioprosthesis or mechanical prosthesis; replacement of the valve and proximal aortic root with a cadaver homograft; and the Ross procedure, in which the abnormal bicuspid valve is removed surgically and replaced with the patient's native pulmonic valve, which in turn is replaced with a cadaver homograft. The Ross procedure eliminates the need for a prosthetic

valve in the aortic position. Postoperative management focuses on assessment for recurrent stenosis or progressive AR.

PULMONIC STENOSIS

Patients with pulmonic stenosis (PS) commonly have a malformed valve, with fusion of one or more of the commissures resulting in a dome-shaped valve. Most of these valves are thin and pliable. However, some patients have thickened valves, termed dysplastic.

Pathophysiology

The stenotic pulmonary valve imposes a pressure load on the ventricle, leading to right ventricular hypertrophy (RVH) and, in a subset of patients, RV failure. In patients with severely hypertrophic right ventricles, imbalance of myocardial oxygen supply and demand may lead to ischemia with attendant anginal chest discomfort and arrhythmias.

Clinical Presentation

Patients with PS of even a moderately severe degree may be asymptomatic for decades. Eventual symptoms may include chest discomfort reminiscent of angina pectoris from coronary artery disease, shortness of breath, fatigability, and symptoms of RV failure. Progression of disease and symptoms beyond adolescence is unusual.

The cardinal physical finding of PS is a systolic crescendo-decrescendo murmur of turbulence through the narrowed valve, preceded by a pulmonic ejection click. The behavior of the pulmonic ejection click during respiration may serve to differentiate it from the click of the bicuspid aortic valve. The pulmonic ejection click will exhibit a selective decrease in intensity with normal inspiration and may even disappear entirely with inspiration; in contrast, the bicuspid aortic valve click will exhibit no such selective decrease.

Laboratory Tests

All patients with suspected PS should have an ECG, a chest x-ray, and an echocardiogram.

Electrocardiography The ECG will be normal in patients with mild to moderate PS. Severe stenosis leads to RVH.

Radiologic studies In patients with mild to moderate degrees of PS, the chest x-ray may show no changes except mild poststenotic dilatation of the proximal pulmonary trunk.

Echocardiography Echocardiography is extremely accurate in identifying and diagnosing the severity of PS. It can also differentiate pliable from dysplastic pulmonary valves. Finally, the echocardiogram can assess RV systolic function.

Management

Early approaches to PS consisted of closed or open surgical valvotomy. In the past 20 years, the advent of reliable methods of balloon pulmonary valvuloplasty has brought a major change in the approach to these cases.[9] Particularly in patients with pliable-dome valves, the initial approach is to perform balloon valvuloplasty in cases of significant stenosis (defined by a right ventricular outflow tract gradient greater than 50 mm Hg). Some dysplastic valves are difficult to treat adequately by balloon valvuloplasty and require surgical repair or replacement. Postoperative management includes surveillance for recurrent stenosis or progressive regurgitation.

Acyanotic Disorders—Aortic Defects

COARCTATION OF THE AORTA

Coarctation of the aorta is a relatively common congenital heart defect that can be seen alone, in association with other defects (especially VSD), and in patients with Turner syndrome. A bicuspid aortic valve is a common associated lesion. Coarctation is a common cause of secondary hypertension and should be sought in all patients presenting with hypertension.

Pathophysiology

The essential pathology in coarctation of the aorta is a narrowing of the aortic lumen, usually in the vicinity of the ligamentum arteriosum, just distal to the take-off of the left subclavian artery. The narrowing of the aorta at the site of the coarctation divides the systemic circulation into a high-pressure zone proximal to the coarctation and a low-pressure zone distal to it. Hypertension may accelerate the development of atherosclerotic coronary artery disease and lead to stroke; stroke is a particular risk when aneurysms of the circle of Willis are present, as occurs with increased incidence in patients with coarctation.

Clinical Presentation

Although lower-extremity claudication may occur, even patients with significant coarctation of the aorta may be entirely asymptomatic. The cardinal feature on physical examination is the difference in pulses and blood pressures above versus below the coarctation. Palpation of the radial and femoral arteries in a normal patient will reveal simultaneous arrival or, perhaps, slightly earlier arrival of the pulse at the femoral artery. In coarctation of the aorta, the femoral pulse will occur later than the radial and is often lower in amplitude. Blood pressure should be evaluated in both arms and either leg when seeking coarctation of the aorta, because of variations in anatomy. When the coarctation is distal to the origin of the left subclavian artery, both arms will be in the high-pressure zone and both legs in the low-pressure zone. However, some coarctations are proximal to the left subclavian. Thus, the left arm and both legs will be in the low-pressure zone, and the diagnosis may be missed if only the left arm is used for measuring blood pressure. More rarely, there may be an anomalous origin of the right subclavian artery; the artery may arise directly from the aorta distal to the left subclavian instead of from the brachiocephalic (innominate) artery. In addition to differential blood pressures, physical examination may also reveal a murmur across the coarctation that can be best heard in the left infrascapular area.

Laboratory Tests

Electrocardiography The ECG in patients with coarctation will show varying degrees of LVH, depending on the severity of the narrowing.

Radiologic studies Dilatation of the aorta proximal and distal to the coarctation site may lead to a so-called 3 sign on chest x-ray. Rib notching is often present; this term refers to apparent effacement, or so-called scalloping, of the lower edges of ribs (usually the third through ninth ribs) because of large, high-flow intercostal collateral vessels that develop as a compensatory mechanism to bypass the narrowing at the coarctation site. Absence of rib notching does not rule out coarctation of the aorta, however.

MRI with MRA can be used effectively to identify coarctation and the collateral circulation. It is also useful for postrepair detection of aneurysms or restenosis at the site of repair.

Echocardiography Echocardiography is extremely helpful in identifying the site of the coarctation by direct visualization, as well as in measuring the pressure gradient across the coarctation site. Echocardiography can also identify bicuspid aortic valves, which frequently accompany coarctation of the aorta.

Management

Coarctation that is sufficient to produce hypertension should always be treated, either surgically or by balloon angioplasty with stent placement. The longest experience is with surgical excision of the coarctation and either end-to-end anastomosis or graft interposition. In recent years, balloon angioplasty has increasingly proved to be a viable alternative for both initial treatment of coarctation and for treatment of restenosis at the coarctation site that develops after repair or angioplasty.[10]

Both before and after correction of coarctation, patients are at risk for infective endarteritis in the vicinity of the coarctation or distal to it and should be treated with prophylactic antibiotics before procedures of risk.

Cyanotic Disorders

DEFINITION AND MECHANISMS

Central cyanosis is caused by an intracardiac shunt or an intrapulmonary right-to-left shunt. Cyanosis becomes evident when reduced (unoxygenated) capillary hemoglobin reaches about 5 g/dl, although this depends on the total hemoglobin concentration: cyanosis is more readily apparent in a patient with polycythemia and is less apparent in a patient with anemia. Mild cyanosis is difficult to detect. Generally, cyanosis does not become clinically apparent until the oxygen saturation falls below 85% (assuming a normal hemoglobin level). Patients with long-standing arterial desaturation will develop clubbing of the fingernails and toenails. Clubbing is characterized by thickening and widening of the nailbeds and loss of the angle between the nail and nail bed, producing a convex nail.

It is helpful to categorize cyanotic CHDs in terms of their effect on pulmonary blood flow. Defects producing decreased pulmonary blood flow include tetralogy of Fallot, tricuspid atresia, Ebstein anomaly, and pulmonary atresia. Defects associated with increased pulmonary blood flow include persistent truncus arteriosus, transposition of the great arteries with or without VSD or PDA, total anomalous venous return, a single or common ventricle, and hypoplastic left heart syndrome. Acyanotic patients with large left-to-right shunts may develop pulmonary vascular occlusive disease (Eisenmenger syndrome).

Adult patients with cyanotic CHD are at increased risk for hyperviscosity secondary to erythrocytosis. The erythrocytosis develops as a compensatory mechanism for red cell oxygen desaturation: a significantly increased red cell mass is necessary to deliver an adequate volume of oxygen to peripheral tissues, given the sometimes severe degree of desaturation. Venous and arterial thrombosis with secondary cerebrovascular accidents have been well documented in cyanotic CHD and have been attributed both to the increased red blood cell mass and to associated iron deficiency anemia, which also increases blood viscosity. This risk is increased in the presence of hypertension or atrial fibrillation and in patients with a history of phlebotomy and microcytosis, suggesting the need for a more conservative approach to phlebotomy and aggressive treatment of iron deficiency.

EISENMENGER SYNDROME

A serious complication of long-standing left-to-right shunts in the atria, ventricles, or great arteries is the development of severe, irreversible pulmonary hypertension, which is termed Eisenmenger syndrome.

Pathophysiology

Normally, the pulmonary vascular resistance is substantially lower than systemic vascular resistance; thus, large intracardiac or great artery communications tend to produce left-to-right shunting. As pulmonary vascular resistance rises, resistance to flow into the pulmonary circulation will eventually exceed that into the systemic circulation, and right-to-left shunting will occur. This will result in varying degrees of cyanosis as well as other physical findings of pulmonary hypertension. Unlike patients with polycythemia vera or polycythemia from chronic obstructive pulmonary disease, patients with Eisenmenger syndrome will often require hematocrits in the 60s, or even low 70s, to deliver sufficient oxygen to tissues to avoid ischemic symptoms.

Clinical Presentation

Patients with Eisenmenger syndrome may be asymptomatic except for cyanosis. Eventually, many patients will note decreased exercise tolerance and chest discomfort, often reminiscent of angina pectoris. If secondary erythrocytosis reaches severe levels, patients may develop symptoms of hyperviscosity, including visual disturbances, headaches, and other complaints.

Physical examination of a patient with Eisenmenger syndrome will reveal manifestations of pulmonary hypertension, including a loud pulmonary component of the second heart sound and the high-pitched diastolic murmur of high-pressure pulmonary regurgitation (the Graham Steell murmur). Additional findings include cyanosis, clubbing, and RV lift or heave.

Laboratory Tests

Electrocardiography The ECG shows right axis deviation and RVH, exhibited as tall R waves and ST-T abnormalities in V1 through V3.

Radiologic studies The chest x-ray will show enlarged central pulmonary arteries with peripheral arterial pruning. Cardiomegaly with specific chamber enlargement will reflect the underlying defect. Right-sided cardiac catheterization often is needed to assess pulmonary arterial pressure and resistance.

Echocardiography Echocardiography can identify and quantify the underlying cardiac shunt and provide an estimate of right heart pressures.

Management

Patients with Eisenmenger syndrome may live for decades after the diagnosis is made.[11] Alternatively, sudden death from ventricular arrhythmias may occur. Because pulmonary resistance is high and fixed in these patients, care needs to be taken to avoid situations that may lead to sudden decreases in systemic vascular resistance, which would exacerbate the right-to-left shunting, sometimes in a life-threatening manner. This would include avoidance of overly hot environments and de-

hydration; in addition, care should be taken during anesthesia or when using vasodilator drugs. Pregnancy is another state in which systemic vascular resistance falls; thus, pregnancy is extremely dangerous for a mother with pulmonary hypertension, as well as for her fetus. Iron deficiency should be treated if present. Only rarely will phlebotomy be required to relieve symptoms of hyperviscosity. A relatively recent therapeutic option for Eisenmenger syndrome is the use of prostacyclin[12] or endothelin-related drugs[13] to lower pulmonary vascular resistance. Heart-lung or lung transplantation has been successfully performed in some patients with Eisenmenger syndrome.[14]

TETRALOGY OF FALLOT

Pathophysiology

Tetralogy of Fallot is the most common form of cyanotic congenital heart disease. Classically, the syndrome includes pulmonary stenosis (subvalvar, valvar, supravalvar, or a combination of all of these), RVH, subaortic VSD, and dextropositioning of the aorta so that it overrides the interventricular septum. Associated anomalies include right aortic arch (25%), atrial septal defect (10%), and coronary artery anomalies (10%).[15] Approximately 15% of patients with tetralogy of Fallot have a deletion of chromosome 22q11 (CATCH 22 syndrome: cardiac anomalies, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, and 22q11 deletion).[16]

Surgical Repair in Childhood

Current surgical practice warrants early repair, usually in the first year of life. Without surgery, survival beyond 20 years of age is uncommon.

Surgical repair consists of patch closure of the VSD and alleviation of the RV outflow tract obstruction by one or more of the following methods: infundibular muscle resection, pulmonary valvotomy, outflow tract or transannular patch augmentation, and patch augmentation of the main or proximal branch pulmonary arteries. In some cases, it is necessary to place a conduit from the RV to the pulmonary artery. The conduit may be valved or nonvalved, and it may be bioprosthetic or a homograft.

When pulmonary blood flow is inadequate, surgical repair includes a shunt from the systemic circulation to the pulmonary artery to provide additional pulmonary flow. This may consist of a Blalock-Taussig shunt, a Potts shunt, or a Waterston shunt. The classic Blalock-Taussig shunt connects the subclavian artery to the pulmonary artery; the modified form comprises an interposed tube graft, usually of expanded polytetrafluoroethylene [Gore-Tex]. A Potts shunt connects the descending aorta to the left pulmonary artery. A Waterston shunt connects the ascending aorta to the right pulmonary artery [*see Figure 4*].

Clinical Presentation after Repair

In patients who have undergone surgical repair of tetralogy of Fallot, the examination focuses on residual defects. Not uncommonly, these patients have murmurs related to residual outflow tract obstruction and mild to severe pulmonary regurgitation (PR), which produces a to-and-fro murmur. The severity of RV outflow tract obstruction directly determines the presence and degree of cyanosis. Systolic ejection murmurs are inversely related to the severity of the obstruction: a short, soft murmur suggests severe obstruction with a large right-to-left ventricular level shunt and minimal forward flow in the pulmonary artery, whereas a long, harsh murmur suggests minimal obstruction.

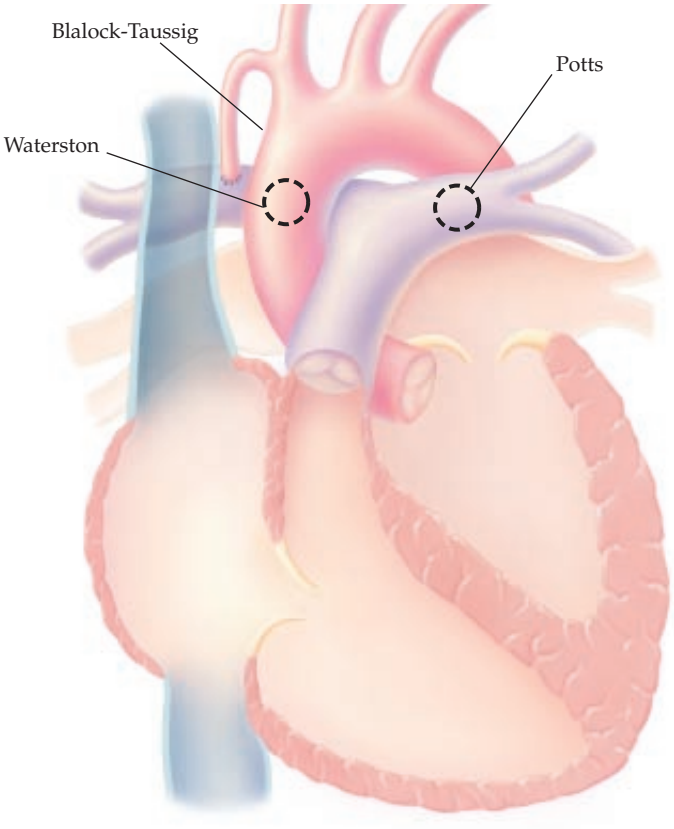

Figure 4 **Systemic artery–to–pulmonary artery shunts. The Blalock-Taussig shunt connects the subclavian artery to a pulmonary artery; the Waterston shunt connects the ascending aorta to the right pulmonary artery; and the Potts shunt connects the descending aorta to the left pulmonary artery.**

Patent shunts will produce a continuous murmur. The degree of cyanosis will depend on the adequacy of pulmonary blood flow provided by the shunt.

A residual VSD may be detected. With increasing RV volume overload, the patient may experience exercise intolerance, right heart failure, and arrhythmias.

Laboratory Data

Electrocardiography In patients who have undergone operative repair of tetralogy of Fallot, the ECG typically shows sinus rhythm, right axis deviation, and RVH; most of these patients also have right bundle branch block. Atrial and ventricular arrhythmias may be detected, especially on a 24-hour monitoring study.

Radiologic studies The findings on chest x-ray vary with the surgical history. A right aortic arch may be noted. The pulmonary artery segment is concave because of the variable degree of pulmonary artery hypoplasia, and the RVH results in an upturned apex; together, these produce the classic finding of a boot-shaped heart. Surgical intervention may result in significant pulmonary regurgitation that eventually will lead to volume overload of the heart, producing cardiomegaly. Over time, patch augmentation of the outflow tract may become aneurysmal, which may be indicated by an enlarged pulmonary artery

segment. Asymmetrical pulmonary blood flow suggests significant branch pulmonary artery obstruction and can be best quantitated by a pulmonary flow study. MRI with MRA is very useful to identify residual defects and assess ventricular function, especially in patients with poor acoustic windows and inadequate echocardiographic studies.

Echocardiography Echocardiography will establish the presence and severity of any residual defects, including progressive enlargement of the RV secondary to pulmonic regurgitation, a residual VSD, and continuous flow in a palliative shunt. Doppler studies will demonstrate the magnitude of the residual outflow tract gradient. The ascending aorta often is enlarged.

Management

Patients who have undergone repair of tetralogy of Fallot must be regularly monitored for progression of residual defects, particularly those with pulmonary regurgitation and conduit obstruction. Branch pulmonary artery stenosis may be approached with balloon angioplasty and stent placement. Repeat surgery should be considered in patients with a significant residual VSD; in patients whose RV pressure is greater than two thirds the systemic pressure because of residual obstruction; in patients with RV enlargement secondary to severe pulmonary regurgitation (which may mandate placement of a bioprosthetic valve, especially if there is associated tricuspid regurgitation [TR]); and in those with reduced exercise tolerance.[17] Reoperation in adults can be performed with low risk. Aortic valve or aortic root replacement is occasionally required because of progressive root dilatation and AR.[18] Ventricular arrhythmias, which are detected in 40% to 50% of patients, have been associated with older age at primary repair, RV volume overload, and QRS prolongation. Marked widening of the QRS to more than 180 msec and LV dysfunction have been identified as risk factors for sudden cardiac death. In such cases, consideration should be given to prophylactic placement of an implantable cardiac defibrillator.[19] Patients should be counseled to follow endocarditis prophylaxis during procedures that place them at risk.

DEXTROTRANSPOSITION OF THE GREAT ARTERIES

Pathophysiology

In the most common form of transposition of the great arteries (TGA), dextro-TGA (D-TGA), the aorta arises in an anterior position from the RV, and the pulmonary artery arises posteriorly from the LV. There is complete separation of the pulmonary and systemic circulations: systemic blood flow traverses the right heart and enters the aorta, whereas pulmonary blood flow traverses the left heart and enters the pulmonary artery. Most surviving patients have a patent ductus arteriosus and foramen ovale, permitting mixing of the two circulations. About one third have associated anomalies, including ASD and VSD. Left ventricular outflow tract obstruction is not uncommon. Unless intracardiac mixing is improved, survival beyond the first year is unusual.

Surgical Repair in Childhood

Initial treatment of D-TGA includes infusion of prostaglandin E to maintain patency of the ductus arteriosus and balloon septostomy (Rashkind procedure) to permit better mixing at the atrial level. Surgery initially consisted of redirecting the systemic venous return to the LV and the pulmonary venous return to the RV. These so-called atrial switch operations (Mustard or Senning procedures), which used a baffle within the atria, restored physiologic circulation but required the RV to function as the systemic ventricle. The arterial switch operation has replaced the atrial switch operation, at least in patients who have normal function of both semilunar valves. In the arterial switch operation, the pulmonary artery and aorta are first transected above the semilunar valves and coronary arteries, and then they are switched. The aorta is connected to the neoaortic valve (formerly the pulmonic valve) arising from the LV, and the pulmonary artery is connected to the neopulmonary valve (formerly the aortic valve) arising from the RV. The coronary arteries are relocated to the neoaorta.

Patients with D-TGA and a large VSD may undergo the Rastelli procedure. The pulmonary artery is divided and oversewn. Flow from the LV must pass through the septal defect and is directed by a baffle to the aortic valve. A conduit from the RV to the pulmonary artery allows egress from the ventricle to the pulmonary circulation.

Clinical Presentation after Repair

Physical findings relate to the presence of associated anomalies (i.e., murmurs of VSD, PS, or PDA). Similarly, the larger the septal defect, the less severe the cyanosis.

Laboratory Tests

Electrocardiography The ECG in patients with the atrial switch shows right axis deviation and RVH. In patients with the arterial switch, the ECG may be normal, provided coronary blood flow is not compromised.

Radiologic studies Patients who have had the atrial switch procedure generally have cardiomegaly from a dilated RV, and the pulmonary artery may show preferential flow to the right lung. Patients with the arterial switch repair are likely to have normal heart size.

Echocardiography Echocardiography is used to assess associated residual defects: depressed RV function, progressive TR, left ventricular outflow tract obstruction, residual VSD, or coronary artery perfusion abnormalities.

Management

The long-term outlook after the atrial switch is quite good, with actuarial survival of 80% at 28 years and 76% of survivors having no symptoms.[20] However, these patients must be monitored for progressive RV enlargement and TR leading to ventricular dysfunction. Although this complication occurs in only 3% of cases, such patients may require cardiac transplantation if medical therapy is ineffective. Atrial arrhythmias, including sick sinus syndrome, are common. The atrial baffle may cause either systemic or pulmonary venous obstruction, which is addressed either by reoperation or by balloon angioplasty and stent placement.

The long-term prognosis of patients with the arterial switch is less well known, but arrhythmias are thought to be less frequent and to occur secondary to imperfections in the operative procedure.[21] Patients should undergo nuclear medicine studies or stress testing to monitor for inadequate coronary perfusion secondary to coronary artery reimplantation abnormalities. Stenosis of the pulmonary artery (the most common complication) or stenosis at aortic anastomosis sites may occur. Complications of the Rastelli procedure include subaortic obstruction

(baffle or VSD obstruction), conduit stenosis (with or without regurgitation), baffle leak, and branch pulmonary artery stenosis. Significant residual defects require reoperation.[17]

THE UNIVENTRICULAR HEART

Pathophysiology

A functional single ventricle may result from hypoplastic left heart syndrome (aortic atresia, mitral atresia, or both), tricuspid atresia, pulmonary atresia with intact ventricular septum, or an unbalanced AVSD resulting in hypoplasia of either the RVor LV.

Surgical Repair in Childhood

The initial presentation of univentricular heart in childhood may include severe cyanosis associated with a marked decrease in pulmonary blood flow, mild cyanosis and heart failure associated with intracardiac admixture of circulations and excessive pulmonary blood flow, or nearly balanced systemic and pulmonary blood flows and mild cyanosis. Patients who survive to adulthood generally have undergone one or more palliative surgical procedures; these include the Norwood, Glenn, and Fontan procedures.

Norwood The Norwood operation establishes a single outlet from the single ventricle by anastomosing the hypoplastic ascending aorta to the main pulmonary artery, producing a so-called neoaorta and connecting the distal pulmonary artery to a systemic shunt, usually a modified Blalock-Taussig shunt [*see Figure 5a*]. Often, an atrial septectomy is required to allow complete mixing at the atrial level.

Glenn The bidirectional Glenn procedure involves anastomosis of the SVC to the pulmonary artery. It includes takedown of a previously placed shunt and repair of any branch pulmonary artery stenosis [*see Figure 5b*]. The term bidirectional refers to the fact that the right pulmonary artery remains in con-

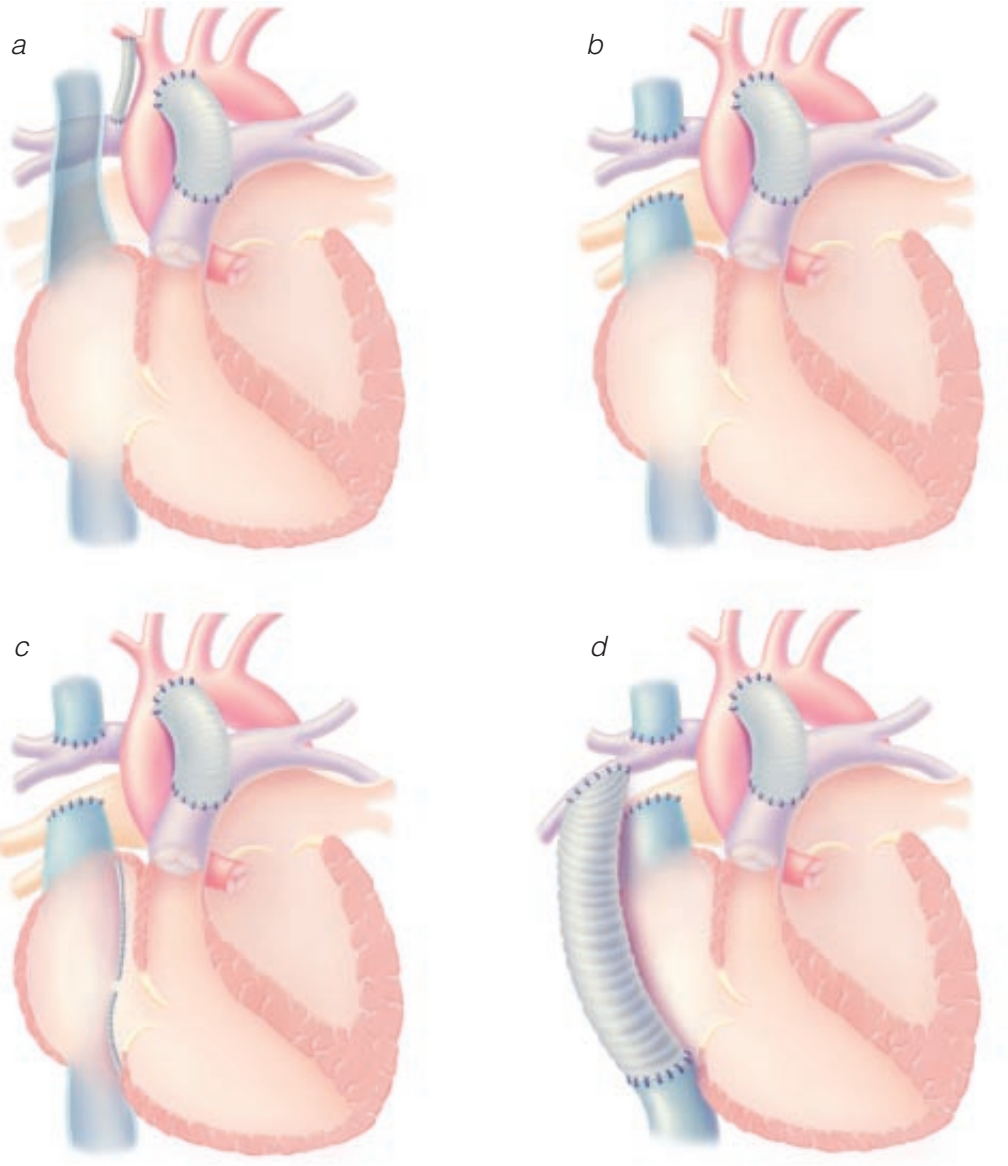

Figure 5 **Stages in the repair of functional single ventricles (see text for details). (*a*) Norwood; (*b*) bidirectional Glenn; (*c*) lateral tunnel; (*d*) extracardiac conduit.**

tinuity with the left pulmonary artery; this contrasts with the classic Glenn procedure, which involves anastomosis of the SVC to a right pulmonary artery that has been disconnected from the main and left pulmonary arteries. The bidirectional Glenn procedure is now done at 4 to 6 months of age.

Fontan The Fontan procedure is the final palliative procedure, providing direct connection of flow from the SVC and inferior vena cava (IVC) to the pulmonary circuit. Initially, this was a one-stage procedure that involved attaching the RA to the pulmonary artery or RV outflow tract and was performed in patients older than 4 years. Current practice is to stage the anastomosis of SVC and IVC to the pulmonary circuit, with the final stage, total cavopulmonary artery anastomosis, occurring at 2 to 3 years of age. The IVC is connected to the pulmonary artery either by a lateral tunnel placed in the RA to direct blood from the IVC to the proximal SVC stump, which is then attached to the pulmonary artery [*see Figure 5c*], or by an extracardiac conduit connecting the IVC to the pulmonary artery directly [*see Figure 5d*]. With any of these routes of flow, a small communication (fenestration) may be made between the caval blood flow conduit and the functional left atrium. Pulmonary blood flow is achieved by passive venous return without assistance of a ventricular pumping chamber. Any mild alteration of pulmonary pressure or resistance will impair adequacy of pulmonary blood flow.

Clinical Presentation after Repair

Clinical features are variable. Some patients may be well palliated, with near-normal oxygen saturation, acceptable activity levels, and negligible findings on cardiac examination. Others will demonstrate progressive heart failure as the single ventricle (especially if it is an anatomic RV) succumbs to the increased pressure and volume overload secondary to progressive atrioventricular valve regurgitation and myocardial dysfunction. Both atrial and ventricular arrhythmias are common. The sluggish pulmonary blood flow may predispose to in situ thrombosis and pulmonary embolism, which in turn will impede pulmonary blood flow by raising pulmonary arterial pressure.

Laboratory Tests

Electrocardiography ECG findings are quite variable and may include atrial or ventricular enlargement, axis deviation, conduction abnormalities, and arrhythmias.

Radiologic studies The chest x-ray may show progressive cardiomegaly. Pulmonary vascular markings may be unequal, indicating stenosis of one or more pulmonary artery branches. MRI with MRA may show areas of branch pulmonary artery stenosis and progressive changes in chamber size and ventricular function.

Echocardiography Echocardiographic studies are aimed at following the progression of atrioventricular valve regurgitation, ventricular enlargement, and dysfunction, as well as detecting so-called smoke or clots in the systemic venous–to–pulmonary artery circuit.

Management

After surgical correction, patients demonstrate significant limitations in exercise tolerance because they rely on passive pulmonary blood flow that does not increase maximally with exertion. Postoperative arrhythmias are common. Arrhythmias may need to be managed medically, because radiofrequency ablation techniques may be limited by access problems secondary to the extracardiac or lateral tunnel connections be-

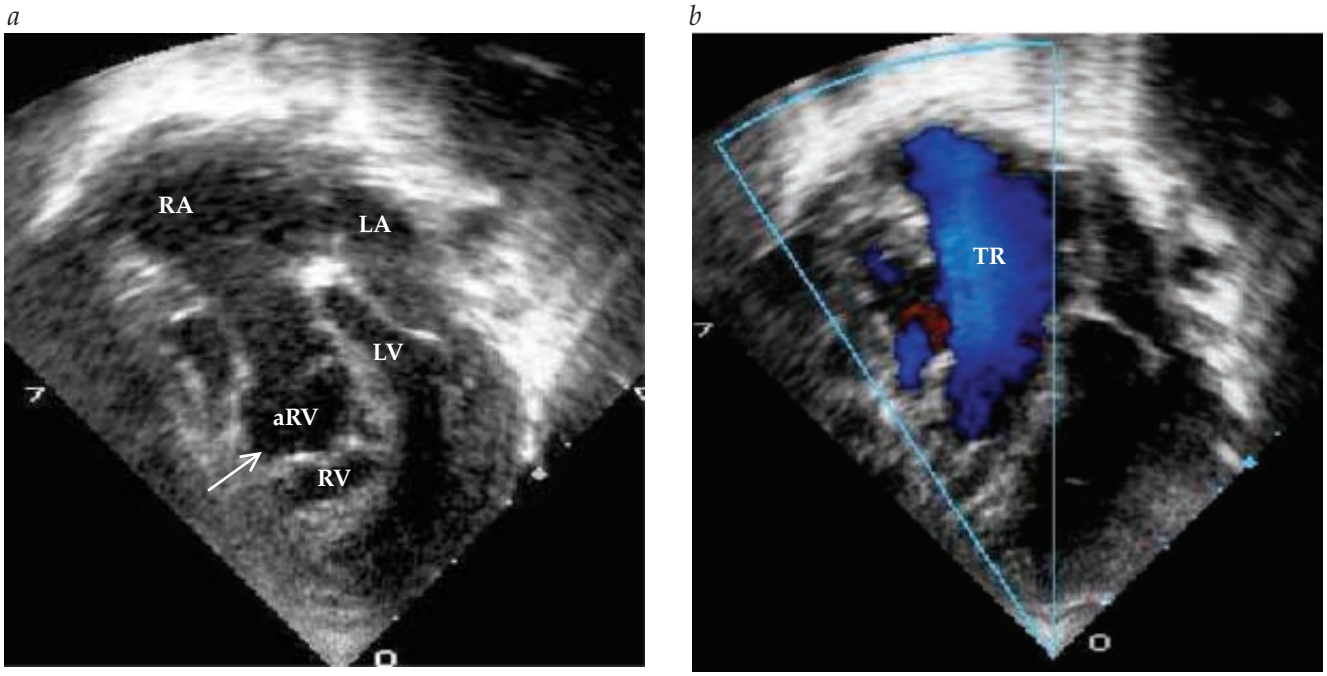

Figure 6 **Echocardiograms of a patient with Ebstein anomaly. (*a*) Apical four-chamber view. The arrow indicates apical displacement of tricuspid leaflet. (*b*) Color Doppler flow image demonstrating severe tricuspid regurgitation (TR), originating deep in the right ventricle from the displaced tricuspid valve leaflet. (ARV—atrialized right ventricle; LA—left atrium; LV—left ventricle; RA—right atrium; RV—right ventricle)**

tween the venous circulation and the pulmonary artery. The need for reoperation after the Fontan procedure is infrequent, with the most common indication being placement of a mechanical pacemaker. Protein-losing enteropathy (PLE) is a serious problem after the Fontan operation. Its cause is not known but probably relates to increased systemic venous and thoracic duct pressures. There may also be a local autoimmune or allergic component in the intestinal wall. PLE is characterized by peripheral edema, malabsorption, and a low serum protein level. Complications have become less frequent with staged surgery and provision of an atrial fenestration. Some older patients may benefit from conversion of classic Fontan to a total cavopulmonary artery anastomosis. Cardiac transplantation may be necessary for systemic ventricular failure or intractable PLE.[17]

EBSTEIN ANOMALY OF THE TRICUSPID VALVE

Pathophysiology

This uncommon anomaly of the tricuspid valve consists of adherence of the posterior and septal leaflets to the myocardium—causing a downward displacement of the functional annulus toward the RV apex—and enlargement of the anterior leaflet. The end result is an atrialization of the RV with resultant TR. In patients who present early in life, Ebstein anomaly is often found in association with other defects, including ASD and PS. Accessory pathways and clinical evidence of preexcitation are not uncommon, and arrhythmias are the most common presenting features in adults. There is an association with maternal lithium administration.

Clinical Presentation

Ebstein anomaly can become clinically evident at any age; the natural history of this lesion ranges from death in early life to adult survival without surgery, depending on the degree of regurgitation and whether significant arrhythmias are present. Cyanosis may occur, in neonates or adults, secondary to right-to-left shunting at the atrial level. Adult patients may complain of fatigue, shortness of breath, palpitations, or syncope. On auscultation, a murmur of TR is apparent and is often associated with a gallop rhythm, multiple systolic ejection sounds, and a widely split second sound.

Laboratory Tests

Electrocardiography ECG findings are quite variable. The PR interval may be normal; short, with preexcitation; or prolonged. The axis may be superior or rightward, with or without a right bundle branch block. There may be evidence of RA enlargement. Arrhythmias are detected in 43% of adolescents and adults.[22]

Radiologic studies The chest x-ray may show cardiomegaly with RA enlargement. Cardiac catheterization is not necessary unless there is concern regarding coronary artery disease or need for electrophysiologic assessment and possible radiofrequency ablation.

Echocardiography Echocardiography can confirm the diagnosis and the degree of the tricuspid valve displacement (which may vary from mild tethering of the septal leaflet to severe apical displacement) and characterize the severity of TR [*see Figure 6*]. The anterior leaflet is large and sail-like and may produce RV outflow obstruction. The atrial septum should be assessed for size of defect and magnitude of shunting.

Management

Surgery is recommended for patients with symptomatic heart failure and cardiomegaly, cyanosis, or arrhythmias; tricuspid valvuloplasty is preferred over valve replacement.[15] Surgery is not recommended for asymptomatic patients,[22] although some authors have advocated surgery if significant cardiomegaly is present, because this may be a better predictor of sudden death than functional status.[23]

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XVI PERIPHERAL ARTERIAL DISEASE

Mark A. Creager, m.d.

Peripheral arterial diseases comprise those disorders that compromise blood flow to the limbs. Causes of limb artery obstruction include atherosclerosis, thrombus, embolism, vasculitis, arterial entrapment, adventitial cysts, fibromuscular dysplasia, arterial dissection, trauma, and vasospasm.

Peripheral Atherosclerosis

The most freqently encountered cause of peripheral arterial disease is atherosclerosis. The pathology of atherosclerosis that affects the limbs is similar to that of atherosclerosis of the aorta, coronary arteries, and extracranial cerebral arteries. Of patients who present with symptoms of peripheral atherosclerosis, approximately 80% have femoropopliteal artery stenoses, 30% have lesions in the aorta or iliac arteries, and 40% have tibioperoneal artery stenoses. Most patients have multiple stenoses.

EPIDEMIOLOGY

The prevalence of peripheral atherosclerosis, both asymptomatic and symptomatic, increases with age, ranging from 3% in persons younger than 60 years to greater than 20% in persons 75 years of age and older.[1-3] An epidemiologic study in Germany found that the overall prevalence of peripheral arterial disease in patients older than 65 years was 20% in men and 17% in women.[4] A community-based survey in primary physicians' offices in the United States found that of patients who were between the ages of 50 and 69 years who had diabetes mellitus or smoked cigarettes or who were older than 70 years, 29% had peripheral arterial disease.[5]

The prevalence of claudication ranges from 1% to 5%.[1] The peak incidence of claudication occurs between the sixth and seventh decades and develops later in women than in men. Each year, approximately 2% to 4% of all patients with intermittent claudication develop critical limb ischemia.[6]

Long-term survival is reduced in patients with peripheral atherosclerosis. The risk of death in populations with peripheral atherosclerosis is increased twofold to fourfold. Most patients die as a consequence of myocardial infarction or stroke.[7] Patients with claudication have a 5-year survival rate of approximately 15% to 30%, and patients with critical limb ischemia have a 1-year survival rate of approximately 25%.[1,2,6-8] Overall, there is an inverse relationship between the severity of peripheral arterial disease and survival.

RISK FACTORS

The risk factors associated with the development of peripheral atherosclerosis are similar to those associated with coronary atherosclerosis. These include cigarette smoking, diabetes mellitus, dyslipidemia, hypertension, a family history of premature atherosclerosis, and hyperhomocysteinemia. The risk of developing intermittent claudication is twofold to fivefold higher in smokers than in nonsmokers.[9,10] Moreover, continued cigarette smoking greatly increases the risk of progression from stable claudication to severe limb ischemia and amputation. Diabetes mellitus is associated with a threefold to fourfold increase in the risk of peripheral arterial disease.[9,11] Peripheral atherosclerosis is often more severe and extensive in diabetic patients than in nondiabetic patients with atherosclerosis; in addition, the tibial and peroneal arteries are involved more frequently in diabetic patients than in nondiabetic patients. Prognosis is poor for patients with diabetes who have claudication: 30% to 40% develop critical limb ischemia over a 6-year period. The risk of amputation in diabetic patients is sevenfold to 15-fold higher than in nondiabetic patients with peripheral arterial disease.[2,12] Dyslipidemia, particularly hypercholesterolemia, is present in 40% of patients with peripheral atherosclerosis. The relative risk of peripheral arterial disease is 1.2 to 1.4 for each 40 to 50 mg/dl increase in total cholesterol.[10] Hypertriglyceridemia and an elevated plasma concentration of lipoprotein(a) each increase the risk of developing peripheral arterial disease. Hypertension increases the risk of claudication by at least twofold in men and by fourfold in women.[10] Hyperhomocysteinemia has emerged as an important risk factor for atherosclerosis and increases the risk of peripheral atherosclerosis by twofold to threefold.[13] Elevations in markers of inflammation, including levels of C-reactive protein and soluble intercellular adhesion molecule–1, are also independent predictors of the development of symptomatic peripheral arterial disease in otherwise healthy men.[14,15]

DIAGNOSIS

Clinical Presentation

The two principal symptoms of peripheral atherosclerosis are intermittent claudication and rest pain. However, many patients with peripheral arterial disease are asymptomatic, have symptoms that do not fit the typical pattern of intermittent claudication, or have symptoms from comorbid conditions (e.g., arthritis) that blur the presentation.[16]

Intermittent claudication is described as discomfort, pain, fatigue, or heaviness that is felt in the affected extremity during walking and resolves within a few minutes of resting. Intermittent claudication occurs when the metabolic demand of an exercising muscle exceeds supply. A hemodynamically significant stenosis prevents blood-flow augmentation during exercise. The increased pressure gradient that develops across the stenosis compromises perfusion pressure to the exercising muscle. As ischemia develops, autoregulatory mechanisms cause local vasodilatation and a further reduction in perfusion pressure, and extravascular forces created by the exercising muscle reduce perfusion pressure even further. The location of the symptom depends on the site of stenosis. Thigh, hip, or buttock claudication may develop in cases of proximal arterial occlusive disease involving the aorta or iliac arteries. Involvement of the femoral and popliteal arteries typically causes calf claudication. Tibial and peroneal artery stenoses may cause pedal claudication.

Rest pain occurs when the blood supply does not adequately meet the basic nutritional requirements of the tissues of the affected extremity. Pain typically occurs in the toes or foot. Initially, the pain is worse at night when the patient is lying in bed with the legs in a neutral position. Sitting up and dangling the leg may alleviate the discomfort, because this maneuver increases perfusion pressure via gravitational forces. Conversely, leg elevation worsens the pain. With persistent severe ischemia, skin breakdown occurs, leading to ulceration, necrosis, and gan-

Figure 1 **Photograph shows an ischemic right foot demonstrating dependent rubor.**

grene. Even minor trauma to an ischemic foot may produce a skin lesion that fails to heal.

The most reliable physical finding in patients with peripheral arterial disease is decreased or absent pulses. Examination of femoral, popliteal, posterior tibial, and dorsalis pedis pulses may indicate sites of stenosis. Bruits auscultated in the abdomen, pelvis, and inguinal areas also may indicate the presence of arterial stenosis. Foot pallor may be observed at rest, with leg elevation, or after exercise of the calf muscles. Signs of chronic limb ischemia include subcutaneous atrophy; hair loss; coolness; pallor; and cyanosis, dependent rubor, or both [*see Figure 1*]. Additional signs of critical limb ischemia include petechiae, fissures, ulceration, and gangrene. Ulcers often involve the tips of the toes or the heel of the foot and occur at sites of trauma or pressure caused by poor-fitting footwear. Arterial ulcers have pale bases and irregular borders and are usually quite painful.

Several classifications have been proposed to characterize the severity of limb ischemia in patients with peripheral arterial disease. The most widely recognized classification was developed by René Fontaine [*see Table 1*]. A contemporary classification scheme takes into consideration symptoms, physical findings, perfusion pressure, and exercise capacity; the classification scheme comprises four grades and seven categories [*see Table 2*].[17]

Table 1 Fontaine Classification of Chronic Limb Ischemia

Stage	*Symptoms*
I	Asymptomatic
II	Intermittent claudication
IIa	Pain-free; claudication walking > 200 m
IIb	Pain-free; claudication walking < 200 m
III	Rest pain and nocturnal pain
IV	Necrosis, gangrene

Table 2 Clinical Categories of Chronic Limb Ischemia[75]

Grade	*Category*	*Clinical Description*
I	0	Asymptomatic, not hemodynamically significant
	1	Mild claudication
	2	Moderate claudication
	3	Severe claudication
II	4	Ischemic rest pain
	5	Minor tissue loss; nonhealing ulcer; focal gangrene with diffuse pedal ischemia
III	6	Major tissue loss extending above transmetatarsal level; foot no longer salvageable

Noninvasive Diagnostic Tests

Several noninvasive diagnostic tests can be used to evaluate patients with peripheral arterial disease. Segmental blood pressure measurement of the extremity is a quantitative means to assess the presence and severity of arterial stenoses [*see Table 3*]. Pneumatic cuffs are positioned along the leg and are inflated to suprasystolic pressures. During cuff deflation, the onset of flow (i.e., systolic blood pressure) is assessed by use of a Doppler probe placed over the dorsalis pedis or the posterior tibial arteries. Normally, the systolic blood pressure in the leg is the same as that in the arm. However, because of reflected waves, systolic blood pressure in the leg may be slightly higher than that in the arm. The normal ankle:brachial systolic blood pressure ratio (i.e., the ankle:brachial index) is therefore 1.0 or slightly greater. Taking into consideration the variability in blood pressure measurements, an ankle:brachial index less than 0.95 is considered abnormal. Patients with leg claudication typically have an ankle:brachial index less than 0.8; in patients with ischemia at rest, the ankle:brachial index is frequently less than 0.4 [*see Table 3*].

Measurement of the ankle:brachial index can be performed in a medical office. It is a sensitive indicator of peripheral arterial disease; it is more closely associated with leg function in patients with peripheral arterial disease than is intermittent claudication or other leg symptoms.[18] Because atherosclerosis is a systemic problem, a decreased ankle:brachial index suggests that the burden of disease is increased throughout the body, including the coronary arteries; for that reason, the lower the ankle:brachial index, the higher the risk of a cardiovascular event.[19,20]

In patients with peripheral arterial disease, the pressure gradient across a stenosis increases during exercise, as vascular resistance in the exercising muscle decreases. The exercise-induced increase in systemic pressure (i.e., brachial artery pressure) is not accompanied by a comparable increase in ankle pressure. Thus, the ankle:brachial index will be lower immediately after the patient has exercised than when the patient is at rest.

Plethysmographic devices are used to record the change in limb artery volume that occurs with each pulse (pulse volume recordings). The pulse volume waveform comprises a systolic upstroke with a sharp peak, a dicrotic wave, and a downsloping component. Distal to the site of an arterial stenosis, the amplitude of the pulse volume waveform is diminished, and the dicrotic wave disappears. In the presence of severe ischemia, the waveform may be entirely absent [*see Figure 2*].

Doppler ultrasonography can identify vessels with stenotic lesions. A Doppler probe is positioned at various sites along the limb's arteries. The Doppler waveform has three components,

which correspond to three phases of blood flow: high-velocity antegrade flow during systole, transient flow reversal during early diastole, and low-velocity antegrade flow during late diastole. When stenosis is present, this triphasic waveform is altered distal to the stenosis: the amplitude is decreased, the rate of rise is delayed, and the reverse-flow component disappears. Duplex ultrasound scanning is a direct, noninvasive test that combines B-mode ultrasonography and pulsed Doppler ultrasonography to assess peripheral arterial stenoses. A B-mode scan identifies areas of intimal thickening, plaque formation, and calcification. Color Doppler imaging detects blood-flow abnormalities caused by arterial stenoses. An increase of greater than twofold in the systolic velocity is indicative of a hemodynamically significant stenosis, usually one that exceeds 50% of the artery diameter.

Transcutaneous oximetry, which measures the transcutaneous oxygen tension with oxygen-sensing electrodes placed at various sites on the legs, is used to assess the severity of skin ischemia in patients with peripheral arterial disease. Normally, the transcutaneous oxygen tension of the resting foot is approximately 60 mm Hg; it is often less than 40 mm Hg in patients with ischemia.

Angiography

Magnetic resonance angiography (MRA) and CT angiography can be used to evaluate the location and severity of peripheral atherosclerosis[21]; thus, these modalities can help determine whether a patient is a candidate for an endovascular intervention. In addition, they are free of the risks of conventional angiography. MRA is more widely used, although it is somewhat slower than CT angiography. The current generation of CT angiography machines can provide highly detailed images within minutes; however, CT angiography requires iodinated contrast and radiation exposure, which makes it less suitable for patients with renal insufficiency or contrast allergy.

In most patients, clinical evaluation and noninvasive testing are sufficient for confirming the diagnosis of peripheral arterial disease. Conventional catheter-based angiography is typically performed only when a diagnosis is in doubt or as a prelude to endovascular interventions or surgical reconstruction [*see Figure 3*]. Digital subtraction angiography is a computer-enhancing technique that is used to improve resolution; it is particularly useful in conjunction with the intra-arterial administration of radiographic contrast agent.

Table 3 Leg Segmental Pressure Measurements in Patient with Right Calf Claudication and Right Foot Pain*

	Right	*Left*
Brachial	158	158
Upper thigh	160	162
Lower thigh	94	154
Calf	62	116
Ankle	42	116
Ankle:brachial ratio	0.27	0.68

*Findings are consistent with femoropopliteal and tibioperoneal artery stenoses in the right leg. The right ankle:brachial ratio indicates ischemia. Systolic pressure gradients between the lower thigh and calf and between the calf and ankle in the left leg are consistent with distal femoropopliteal artery and tibioperoneal artery stenoses. The left ankle:brachial ratio is consistent with symptoms of claudication.

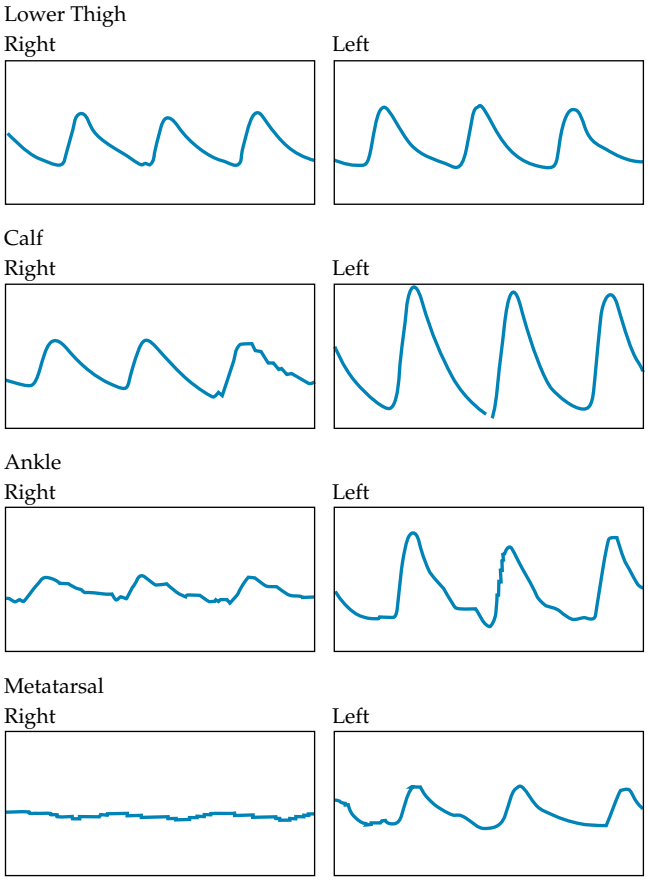

Figure 2 **Pulse volume recordings provide a qualitative assessment of blood flow to the extremity. In this example from a patient with right calf claudication and right foot pain, the pulse volume recordings are abnormal in the right calf, right ankle, and right metatarsal segments. In the right calf and ankle, the amplitude of the pulse is diminished and the rate of rise is delayed. No pulse volume can be recorded in the right metatarsal segment. The pulse volume recordings in the left leg are normal.**

TREATMENT

Risk Factor Modification and Antiplatelet Therapy

Risk factors for atherosclerosis should be identified and treated; this reduces the likelihood of progression of atherosclerosis and also helps to prevent adverse cardiovascular events in patients with peripheral arterial disease.[22,23] Patients who stop smoking cigarettes have a more favorable prognosis than those who continue to smoke. Aggressive lipid-lowering therapy reduces progression of peripheral atherosclerosis, but it has not been established that it prevents progression of symptoms from claudication to critical limb ischemia. Cholesterol-lowering therapy with statin drugs reduces adverse cardiovascular events in patients with atherosclerosis and may improve walking ability.[24-27]

Antihypertensive agents should be tailored to bring blood pressure into a normotensive range to reduce the risk of adverse events such as stroke, congestive heart failure, and renal insufficiency.[2,28] Occasionally, marked reduction of blood pressure may reduce perfusion pressure to an ischemic extremity and potentially aggravate symptoms. Angiotensin-converting enzyme inhibitors are effective antihypertensive drugs that may also reduce the risk of adverse cardiovascular events in patients with atherosclerosis, including those with peripheral arterial disease.[29]

Figure 3 **Arteriogram of a patient with critical ischemia of the right foot. The left panel shows a long, total occlusion of the right superficial femoral artery. The popliteal artery reconstitutes via collaterals. The right panel reveals evidence of anterior tibial, posterior tibial, and peroneal artery occlusions with poor runoff.**

Beta blockers do not worsen intermittent claudication but may cause reflex peripheral cutaneous vasoconstriction and exacerbate critical limb ischemia.[30] Beta blockers are indicated to reduce the risk of myocardial infarction and death in patients with coronary artery disease—a condition that frequently coexists with peripheral arterial disease.

Aggressive treatment of diabetes mellitus reduces microangiopathic complications such as retinopathy and nephropathy.[2,28,31] It is not known whether aggressive treatment of diabetes reduces progression of atherosclerosis or prevents critical limb ischemia or foot ulceration. B-complex vitamins, such as folic acid, cobalamin, and pyridoxine, may lower homocysteine levels, but it is not yet known whether such therapy reduces cardiovascular events or prevents progression of peripheral atherosclerosis.

There is little information regarding the efficacy of platelet inhibition in treating symptoms of peripheral arterial disease. In one study, primary prevention with aspirin was shown to reduce the need for surgical revascularization in patients with peripheral arterial disease.[32] Small angiography trials have suggested that platelet inhibitors reduce the risk of acute peripheral arterial occlusion.[33] These agents may prevent thrombosis after plaque rupture in the peripheral arteries, as they do in coronary arteries. Antiplatelet therapy has been shown to reduce the risk of adverse cardiac events such as nonfatal myocardial infarction and stroke and has been shown to reduce cardiovascular mortality in patients with atherosclerosis.[2,23,34] In one study, clopidogrel was more effective than aspirin in reducing the risk of adverse cardiovascular events, particularly in patients with peripheral arterial disease.[35]

Hygiene and Physical Therapy

Local measures are used to prevent skin ulceration and foot infection, particularly in patients with critical limb ischemia. The feet should be kept clean, and moisturizing cream should be applied to prevent drying and fissuring. The skin of the feet should be inspected frequently, and minor abrasions should be treated promptly. Stockings should be made of natural, absorbent fibers. Elastic hose are contraindicated because they restrict skin blood flow. Shoes should be carefully fitted to reduce the possibility of pressure-induced skin breakdown. In patients with critical limb ischemia, the limbs should be maintained in a dependent position to increase perfusion pressure. This can be achieved by angling the mattress so that the affected limb is below heart level. Cotton wicks placed between the toes absorb moisture and reduce friction. Sheepskin placed beneath the heels of the feet reduces pressure and necrosis. A warm environment is recommended to reduce vasoconstriction. Ulcerations and necrotic areas should be kept dry and covered with dry, nonadhesive material. Infections should be drained. Local antibiotics should be avoided. Pain should be treated with analgesics.

Supervised exercise training programs improve walking capacity in patients with peripheral arterial disease.[2,36] Among the most likely factors that account for the improvement are more efficient skeletal muscle metabolic function and changes in ergonomics.[37] Most studies have not found that exercise training improves blood flow to the exercising extremity, but investigations into the potential angiogenic effects of exercise are ongoing. Training programs should be individualized for each patient. Because supervised settings provide structure and guidance, patients have achieved the most success with supervised training. Programs typically involve treadmill exercise for approximately 1 hour three times a week for at least 3 months. Patients are encouraged to walk independently outside the supervised program.

Pharmacotherapy of Claudication and Critical Limb Ischemia

Drug therapy has generally not been successful in improving symptoms of claudication or reducing the complications of critical limb ischemia.[22] Although arterioles dilate in response to the metabolic demands of exercise, blood-flow augmentation is limited by critical stenoses. Thus, perfusion pressure distal to a stenosis falls further during exercise. Pharmacologic vasodilators may not reduce resistance to blood flow any more than endogenous vasodilators released during exercise. However, vasodilator drugs may increase blood flow to unaffected regions and thereby steal blood away from the ischemic limb.

Two drugs are approved by the Food and Drug Administration for the treatment of intermittent claudication: pentoxifylline and cilostazol. Pentoxifylline is a xanthine derivative with hemorrheologic properties. It has been reported to improve red cell flexibility and decrease blood viscosity. Pentoxifylline improved patients' exercise capacity in several but not all clinical trials.[30,38]

Cilostazol is a quinolinone derivative that inhibits phosphodiesterase III and thereby prevents the degradation of cyclic adenosine monophosphate. It has vasodilatory and platelet in-

hibitory properties, but its precise mechanism of action in patients with peripheral arterial disease is not known. Several trials have found that cilostazol leads to an increase in the distance walked before onset of claudication and also in the maximal walking distance in patients with peripheral arterial disease.[39-42]

Metal-chelating compounds, such as ethylenediaminetetraacetic acid (EDTA), are not useful in the treatment of patients with peripheral arterial disease.[43]

Several classes of drugs are currently undergoing investigation for use in the treatment of claudication, critical limb ischemia, or both. Some drug treatments are designed to increase the efficiency of substrate utilization, which enhances cellular energetics. L-Carnitine and its analogue, propionyl-L-carnitine, may decrease the ratio of acetyl coenzyme A (acetyl CoA) to CoA via the action of CoA:carnitine acetyltransferase and thereby stimulate glucose oxidation and energy production. Small placebo-controlled trials have found that treatment with L-carnitine or propionyl-L-carnitine improves exercise capacity in patients with intermittent claudication.[44,45]

In one study, L-arginine, the precursor of nitric oxide, improved endothelium-dependent vasodilatation and increased claudication distance after 3 weeks of intensive therapy.[46] Initial trials of prostaglandin E_1 (PGE_1) and prostacyclin (PGI_2) or their synthetic analogues suggested that these agents could increase the distance walked before onset of claudication, but subsequent definitive trials failed to show improvement in symptoms.[47,48] Angiogenic growth factors, such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), are undergoing intensive investigation for their potential efficacy in patients with peripheral arterial disease. These angiogenic factors may be delivered parenterally as recombinant proteins or through gene transfer using intra-arterial catheter techniques or intramuscular injection. Both VEGF and bFGF increase collateral blood vessel development and improve blood flow in experimental models of hindlimb ischemia. The efficacy of angiogenic growth factors in patients with intermittent claudication or critical limb ischemia is an active area of investigation. Several placebo-controlled trials in patients with claudication have been reported. In one trial, intra-arterial infusion of recombinant FGF-2 resulted in a significant increase in peak walking time at 90 days.[49] In another study, intramuscular administration of VEGF did not improve exercise performance.[50]

Autologous implantation of bone marrow mononuclear cells is a promising area of study. These cells have the potential to promote angiogenesis, because they can supply endothelial progenitor cells and they secrete angiogenic factors.[51]

Revascularization

Revascularization procedures are indicated for patients with disabling claudication, ischemic rest pain, or impending limb loss. Revascularization can be achieved by catheter-based endovascular interventions [*see Figure 4*] or surgical reconstruction.

Percutaneous transluminal angioplasty (PTA) of iliac arteries has an initial success rate of 90%.[52,53] Patency rates after 4 to 5 years are approximately 60% to 80% and are even higher with implantation of a stent.[54-56] The success rate of PTA of femoral and popliteal arteries is lower than that of PTA of iliac arteries. Patency rates at 1, 3, and 5 years are approximately 60%, 50%, and 45%, respectively.[54] The patency rate is better when PTA is performed for relief of claudication rather than for limb salvage and is also better in patients with good runoff (i.e., in patients with open distal vessels). Stents have not been shown to improve the patency rates of femoral and popliteal arteries over PTA alone. PTA of tibial and peroneal arteries is associated with poorer outcome than PTA of more proximal lesions and is usually performed in patients with critical limb ischemia who are considered at high risk for vascular surgery. Limb salvage rates of 1 to 2 years range from 50% to 75%. Thrombolytic therapy is not used routinely for the treatment of peripheral atherosclerosis but may be effective in restoring patency of native arteries and bypass grafts after acute arterial occlusion [*see* Acute Arterial Occlusion, *below*].

a *b*

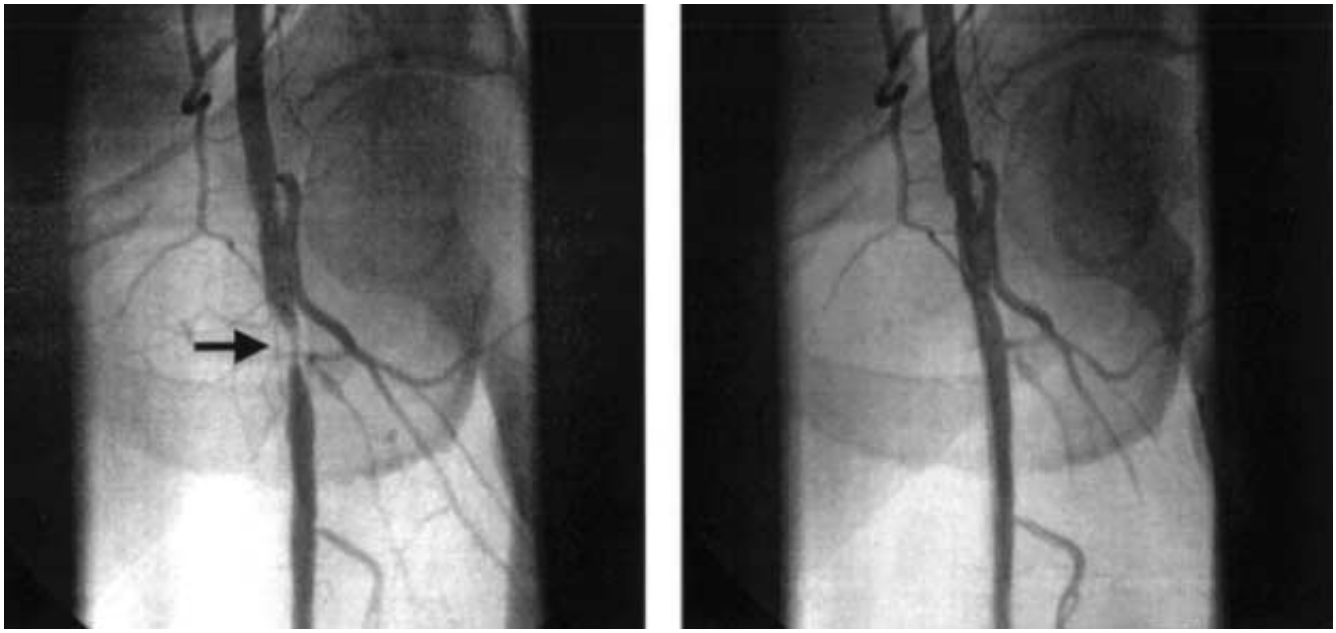

Figure 4 **Arteriograms of a patient with disabling claudication of the left leg. A focal stenosis (arrow) of the superficial femoral artery is apparent (*a*). After percutaneous transluminal angioplasty, patency is restored (*b*).**

The operative procedures used in vascular reconstruction depend on the location and severity of the arterial stenoses. Aortobifemoral bypass with a bifurcated Dacron or polytetrafluoroethylene prosthetic graft is the standard treatment for aortoiliac disease. Operative mortality ranges from 1% to 3% at centers with expertise in this technique. Long-term patency and relief of symptoms exceed 80% over 10 years.[57] Intra-abdominal aortoiliac reconstructive surgery is not feasible in patients whose comorbid conditions pose excessive surgical risk. Axillobifemoral bypass can circumvent the abdominal aorta and achieve revascularization of both legs. Femorofemoral bypass can be performed with the patient under regional anesthesia and is appropriate in cases of unilateral iliac artery obstruction.

Infrainguinal bypass procedures include femoral-popliteal and femoral-tibioperoneal reconstruction. Two techniques are generally used: the in situ saphenous vein bypass graft and the reversed autologous saphenous vein bypass graft. Femoral-popliteal reconstruction is most successful when the distal anastomosis is constructed proximal to the knee. The 5-year patency rate for all saphenous vein infrainguinal bypass grafts, including grafts that have undergone revision, is approximately 75% to 80%.[54,58] Patency rates are higher in claudicants than in patients with critical limb ischemia. Synthetic grafts made of polytetrafluoroethylene are used when veins are not available.[59] The patency of prosthetic grafts is inferior to those composed of veins, particularly because of early thrombotic occlusion. Synthetic grafts inserted below the knee have a very low patency rate and are typically not used for tibioperoneal reconstruction. Operative mortality for infrainguinal vascular reconstruction is 1% to 2%.[58] Antiplatelet agents should be administered to maintain graft patency after bypass grafts.[2,23,33]

Lumbar sympathectomy is used rarely to treat patients with critical limb ischemia. The pathophysiology of limb ischemia suggests that ischemic vessels are maximally vasodilated; thus, lumbar sympathectomy may not increase blood flow.

Amputation is a surgical alternative for patients with advanced limb ischemia in whom revascularization procedures are not possible or have failed. It is a final alternative for patients with unremitting rest pain or gangrene. Selection of the amputation level requires assessment of perfusion. Transphalangeal amputation causes minimal disability. Transmetatarsal amputation of the forefoot may affect balance, but patients are usually able to ambulate after rehabilitation. Patients who undergo below-the-knee amputation and subsequently use a prosthesis expend 10% to 40% more energy to walk on a horizontal surface than a person who has use of both legs. Patients who undergo amputations above the knee and use a prosthetic device expend 65% more energy to walk than a person who has use of both legs. Overall prognosis after major leg amputation is poor, usually because of coexisting coronary and cerebrovascular disease.

Acute Arterial Occlusion

Acute arterial occlusion is to be distinguished from the gradual development of limb artery obstruction caused by peripheral atherosclerosis. The causes of acute arterial occlusion include embolism, thrombosis, dissection, and trauma. The most common cause is arterial embolism. The majority of systemic emboli arise from cardiac sources, including atrial fibrillation, valvular heart disease, congestive heart failure, left ventricular aneurysm, acute myocardial infarction, and cardiac tumors (e.g., left atrial myxomas). Noncardiac sources of embolism include aneurysms of the aorta and aneurysms of the iliac, femoral, and popliteal arteries. A deep vein thrombus may enter the systemic circulation via an intracardiac shunt, resulting in what is termed paradoxical embolism. Thrombosis in situ may develop in peripheral atherosclerotic arteries at a site of plaque rupture and in bypass grafts. Thrombus may also develop in otherwise normal vessels of patients with procoagulant disorders such as hyperhomocysteinemia (including homocysteinuria), antiphospholipid antibody syndrome, and heparin-induced thrombocytopenia. Arterial thrombus formation is uncommon in patients with resistance to activated protein C and in patients deficient in protein C, protein S, or antithrombin. Aortic dissection and trauma may acutely occlude arteries by disrupting the integrity of the vessel lumen.

Acute arterial occlusion may cause severe limb ischemia, resulting in pain, paresthesia, and motor weakness distal to the site of occlusion. There is loss of peripheral pulses, cool skin, and pallor or cyanosis distal to the obstruction site. Noninvasive tests can provide additional evidence of peripheral arterial occlusion and may reveal the severity of ischemia, but definitive treatment should not be delayed. Arteriography is used to define the site of acute arterial occlusion and may distinguish thrombus in an atherosclerotic vessel from an arterial embolism. Once the diagnosis is made, anticoagulation with heparin should be initiated to prevent propagation of the thrombus.

Acute severe limb ischemia requires urgent revascularization. Catheter-directed intra-arterial thrombolysis with agents such as recombinant human tissue plasminogen activator may restore patency in acutely occluded arteries and bypass grafts. An embolectomy catheter can be used to remove arterial emboli. Surgical reconstruction to bypass the occlusion is considered if embolectomy is unsuccessful or not possible. The decision to utilize thrombolysis or surgery for acute arterial occlusion depends in part on the severity of ischemia and urgency of revascularization.[60,61]

Atheroembolism

Atherothrombotic debris from friable plaques in the aorta or other large arteries may dislodge and embolize to small distal limb arteries. Atheroembolism occurs spontaneously, although it occasionally occurs as a complication of arterial catheterization.[62] Violaceous discoloration, petechiae, and livedo reticularis appear when emboli occlude small vessels. Occlusion of digital vessels causes painful cyanotic toes (the blue toe syndrome), despite the presence of palpable pedal arteries [*see Figure 5*]. Embolic occlusion of intramuscular vessels causes pain and tenderness. Abnormal laboratory findings include an elevated eosinophil count and an increased erythrocyte sedimentation rate. Anemia, thrombocytopenia, and hypocomplementemia may also occur. Azotemia may occur if there is concurrent atheroembolism to the kidneys. Sites of shaggy atheroma may be identified by imaging the aorta with transesophageal echocardiography or MRA.[63] Confirmation of the diagnosis is made by skin or muscle biopsy. Tissue examination will reveal elongated needle-shaped clefts in small arteries that are associated with intimal thickening, perivascular fibrosis, inflammatory cells, and lipid-laden giant cells.

The risk of recurrence of atheroembolism is high. Platelet inhibitors have been used in this disorder, although it has not been established that these agents prevent recurrent atheroemboli. The role of warfarin is even less clear. Some investigators have

found that warfarin reduces the likelihood of atheroembolism in patients with mobile atheromas, whereas others have suggested that warfarin may contribute to the development of atheroemboli in persons with a predisposition to the disease.[64-66] Surgical bypass of occluded vessels usually is not possible, because the emboli typically lodge in small distal arteries. If a proximal source, such as an aneurysm, is identified, bypass surgery and removal of the source from the circulation may reduce the risk of recurrence. Risk-factor modification—in particular, lipid-lowering therapy—can serve to stabilize atheromatous plaques and may reduce the risk of cardiovascular events; it is not known whether lipid-lowering therapy can prevent atheroembolism.[66]

Popliteal Artery Entrapment

Popliteal artery entrapment is caused by a congenital anomaly in which the medial head of the gastrocnemius muscle compresses or displaces the popliteal artery. In young patients who present with symptoms of intermittent claudication or rest pain, popliteal artery entrapment should be considered a possible diagnosis. It occurs more frequently in men than in women and is unilateral in two thirds of cases.[67]

The diagnosis is made by measuring ankle pressures before and after exercising the calf muscle, because contraction of the gastrocnemius muscle compresses the popliteal artery. Duplex ultrasonography can demonstrate popliteal artery compression and cessation of blood flow during gastrocnemius contraction. Angiography is used to confirm the diagnosis by delineating the altered course of the popliteal artery and may reveal a popliteal artery thrombus and poststenotic dilatation.

Popliteal artery entrapment should be treated surgically, preferably by relieving compression of the popliteal artery. Occasionally, thrombectomy or bypass grafting is required.

Thromboangiitis Obliterans

Thromboangiitis obliterans is a vasculitis that is also known as Buerger disease.[68] In the United States, the prevalence is approximately 1 per 10,000 population. It occurs throughout the world but is most prevalent in Asia, portions of Eastern Europe, and Israel. Thromboangiitis obliterans affects men primarily but may also occur in women. Onset of the disease usually occurs before 45 years of age. The most important predisposing factor is tobacco use.

Figure 5 **Ischemia of the toes of the right foot caused by atheroemboli. There is fixed violaceous discoloration of several toes and the lateral aspect of the right foot.**

Thromboangiitis obliterans affects small and middle-sized arteries and veins in the extremities. Inflammatory cells, particularly polymorphonuclear leukocytes, infiltrate the intima, media, and adventitia; thrombi typically occlude the lumen. Leukocytes and multinucleated giant cells may be found within or surrounding the thrombus. The internal elastic lamina and media remain intact.

Involvement of limb arteries causes forearm, calf, or foot claudication. Severe ischemia of the hand and foot causes rest pain, ulcerations, and skin necrosis. Raynaud phenomenon, which is indicative of digital artery obstruction, occurs in approximately 45% of patients. Migratory superficial vein thrombosis develops in approximately 40% of patients.

There are no specific serologic laboratory tests to diagnose thromboangiitis obliterans; however, serologic tests are used to exclude other causes of vasculitis. Serum immunologic markers such as antinuclear antibodies, rheumatoid factor, and antiphospholipid antibodies should not be present, and acute-phase reactants are usually normal. The diagnosis can be supported by arteriography, which reveals interspersed affected and normal segments of blood vessels. Collateral vessels circumventing sites of occlusion are often present. Biopsy of affected vessels should reveal the typical pathologic findings described above but is rarely indicated.

The most effective treatment for patients with thromboangiitis obliterans is smoking cessation. The risk of progression to critical limb ischemia and amputation is greater in patients who continue to smoke. Surgical revascularization is not usually an option because of involvement of small distal vessels. There is no established pharmacologic intervention. The use of vasodilator prostaglandins may be beneficial in some patients. Intramuscular administration of naked plasmid DNA encoding the 165 amino acid isoform of human vascular endothelial growth factor [phVEGF (165)] was reported to heal ulcers and relieve pain in some patients with thromboangiitis obliterans.[69] The efficacy of platelet inhibitors, anticoagulants, and thrombolytic therapy has not been established.

Raynaud Phenomenon

Raynaud phenomenon is episodic vasospastic ischemia of the digits. It is characterized by digital blanching, cyanosis, and rubor after exposure to cold and rewarming and can also be induced by emotional stress. Although many patients describe a triphasic color response, most experience only one or two color changes. The digital discoloration is confined primarily to the fingers or toes. Occasionally, the tongue, tip of the nose, or earlobes are affected. Blanching represents the ischemic phase of the phenomenon, caused by digital vasospasm. Cyanosis results from deoxygenated blood in capillaries and venules. With rewarming and resolution of the digital vasospasm, a hyperemic phase ensues, causing the digits to appear red.[70]

Raynaud phenomenon is categorized as primary or secondary [*see Table 4*]. The primary form of Raynaud phenomenon is also called Raynaud disease. Diagnostic criteria for Raynaud disease include episodic digital ischemia, absence of arterial occlusion, bilateral distribution, absence of symptoms or signs of other diseases that also cause Raynaud phenomenon, and duration of symptoms for 2 years or longer. Most people with Raynaud disease develop symptoms before they reach 40 years of

Table 4 Secondary Causes of Raynaud Phenomenon

- Connective tissue diseases
  - Scleroderma
  - Systemic lupus erythematosus
  - Rheumatoid arthritis
  - Dermatomyositis
  - Mixed connective tissue disease
  - Sjögren syndrome
- Peripheral arterial occlusive diseases
  - Atherosclerosis
  - Thromboangiitis obliterans
  - Thromboembolism
  - Thoracic outlet syndrome
- Neurologic disorders
  - Carpal tunnel syndrome
  - Reflex sympathetic dystrophy
  - Stroke
  - Intervertebral disk disease
  - Spinal cord tumors
  - Syringomyelia
- Blood dyscrasias
  - Hyperviscosity syndromes
  - Myeloproliferative disorders
  - Cold agglutinin disease
  - Cryoglobulinemia
- Trauma
  - Thermal injury
    - Frostbite
  - Percussive injury
    - Exposure to vibrating tools
    - Hypothenar hammer syndrome
- Drugs
  - Antimetabolites
    - Vinblastine
    - Bleomycin
    - Cisplatin
  - Beta-adrenergic blockers
  - Ergot alkaloids
    - Ergotamine
    - Bromocriptine
  - Tricyclic antidepressants
    - Imipramine
  - Amphetamines
- Miscellaneous conditions
  - Primary pulmonary hypertension
  - Hypothyroidism

age. It can occur in young children. Raynaud disease affects women three to five times more frequently than men. The prevalence is lower in warm climates than in cold climates.

ETIOLOGY

The mechanisms postulated to cause Raynaud phenomenon include increased sympathetic nervous system activity, heightened digital vascular reactivity to vasoconstrictive stimuli, circulating vasoactive hormones, and decreased intravascular pressure. The sympathetic nervous system mediates the digital vasoconstrictive response to cold exposure and emotional stress, but sympathetic nervous system activity has been discounted as a primary causal mechanism. Some investigators have suggested that increased sensitivity, increased numbers of postsynaptic alpha$_2$-adrenergic receptors, or both enhance the vasoconstrictive reactivity to sympathetic stimulation.[71] In some cases of Raynaud phenomenon, endogenous vasoactive substances (e.g., angiotensin II, serotonin, and thromboxane A_2) and exogenous vasoconstrictors (e.g., ergot alkaloids and sympathomimetic drugs) may cause digital vasospasm. Many patients with Raynaud phenomenon have low blood pressure. Decreased digital vascular pressure caused by proximal arterial occlusive disease or by digital vascular obstruction may increase the likelihood of digital vasospasm when vasoconstrictive stimuli occur.

DIAGNOSIS

Noninvasive vascular tests that are occasionally used to evaluate patients with Raynaud phenomenon include digital pulse volume recordings and measurement of digital systolic blood pressure and digital blood flow. Nail-fold capillary microscopy is normal in patients with Raynaud disease, whereas deformed capillary loops and avascular areas are present in patients with connective tissue disorders or other conditions that cause digital vascular occlusion.[72] Determinations of the erythrocyte sedimentation rate and titers of antinuclear antibody, rheumatoid factor, cryoglobulins, and cold agglutinins are useful in excluding specific secondary causes of Raynaud phenomenon. Angiography is not necessary to diagnose Raynaud phenomenon but may be indicated in patients with persistent digital ischemia secondary to atherosclerosis, thromboembolism, or thromboangiitis obliterans to identify a cause that may be treated effectively with a revascularization procedure.

TREATMENT

Patients with Raynaud phenomenon should avoid unnecessary exposure to cold and should wear warm clothing. The hands, feet, trunk, and head should be kept warm to avoid reflex vasoconstriction. Pharmacologic intervention is indicated in patients who do not respond satisfactorily to conservative measures. Calcium channel blockers, such as nifedipine, and sympathetic nervous system inhibitors, such as prazosin and its longer-acting analogues, can be used to treat Raynaud phenomenon. Intravenous infusion of vasodilator prostaglandins, including PGE_1, PGI_2, and their analogues, has been reported to facilitate healing of digital ulcers in patients with scleroderma.[73] In patients with persistent severe digital ischemia, selective digital sympathectomy and microarteriolysis may facilitate ulcer healing and improve symptoms. Cervical and limb sympathectomy may also be considered in persons with severe Raynaud phenomenon, but long-term efficacy is not ensured.

Acrocyanosis

Raynaud phenomenon should be distinguished from acrocyanosis, a condition in which there is persistent bluish discoloration of the hands or feet.[74] Like Raynaud phenomenon, cyanotic discoloration intensifies during cold exposure, and rubor may appear with rewarming. Acrocyanosis affects both men and women; the age at onset is usually between 20 and 45 years. The prognosis of patients with idiopathic acrocyanosis is good, and loss of digital tissue is uncommon. Patients should avoid exposure to cold and should dress warmly. Pharmacologic intervention usually is not necessary. Alpha-adrenergic blocking agents and calcium channel blockers may be effective in some patients with acrocyanosis.

XVIII VENOUS THROMBOEMBOLISM

Clive Kearon, m.b., ph.d.
Jack Hirsh, m.d.

Venous thromboembolism, which involves venous thrombosis and pulmonary embolism, is a leading cause of morbidity and mortality in hospitalized patients and is being seen with increasing frequency in outpatients.[1,2] This increased incidence of venous thromboembolism in outpatients may be attributable to clinicians' heightened awareness of the importance of this condition and the comparatively recent development of reliable noninvasive tests for its diagnosis.

Risk Factors and Etiology

Most patients with venous thromboembolism have one or more clinical risk factors. The most common risk factors are recent surgery, trauma, and immobility, as well as serious illness, including chronic heart failure, stroke, malignancy, and inflammatory bowel disease.[3] The common risk factors in outpatients include hospital admission within the past 6 months, malignancy, presence of antiphospholipid antibody, and familial thrombophilia.[2,4,5] Less common risk factors are paroxysmal nocturnal hemoglobinuria, nephrotic syndrome, and polycythemia vera.

Classification

Although venous thrombosis can occur in any vein in the body, it usually involves superficial or deep veins of the legs. Thrombosis in a superficial vein of the leg is generally benign and self-limiting but can be serious if it extends from the long saphenous vein into the common femoral vein. Superficial thrombophlebitis is easily recognized by the presence of a tender vein surrounded by an area of erythema, heat, and edema. A thrombus can often be palpated in the affected vein. Superficial thrombophlebitis may be associated with deep vein thrombosis (DVT), which typically is clinically silent. Thrombosis involving the deep veins of the leg may be confined to calf veins or may extend into the popliteal or more proximal veins. Thrombi confined to calf veins are usually small and are rarely associated with pulmonary embolism. About 20% of calf vein thrombi, however, extend into the popliteal vein and beyond, where they can cause serious complications.[3,5,6] About 50% of patients with symptomatic proximal vein thrombosis also have clinically silent pulmonary embolism,[5,6] and about 70% of patients with symptomatic pulmonary embolism have DVT, which is usually clinically silent.[3,5,7]

Pulmonary embolism is the most serious and most feared complication of venous thrombosis, but the postthrombotic syndrome is responsible for greater morbidity. The postthrombotic syndrome occurs as a long-term complication in about 25% (and is severe in about 10%) of patients with symptomatic proximal vein thrombosis in the 8 years after the acute event, with most cases developing within 2 years afterward.[5,8,9] Clinically, the postthrombotic syndrome may mimic acute venous thrombosis but typically presents as chronic leg pain that is associated with edema and worsens at the end of the day. Some patients also have stasis pigmentation, induration, and skin ulceration; a smaller number of patients have venous claudication on walking, caused by persistent obstruction of the iliac veins.

Pathophysiology

Venous thrombi are composed predominantly of fibrin and red blood cells. They usually arise at sites of vessel damage or in the large venous sinuses of the calves or the valve cusp pockets in the deep veins of the calves. Thrombosis occurs when blood coagulation overwhelms the natural anticoagulant mechanisms and the fibrinolytic system. Coagulation is usually triggered when blood is exposed to tissue factor on the surface of activated monocytes that are attracted to sites of tissue damage or vascular trauma. Clinical risk factors that activate blood coagulation include extensive surgery, trauma, burns, malignant disease, myocardial infarction, cancer chemotherapy, and local hypoxia produced by venous stasis. Malignant cells contain a cysteine proteinase that activates factor X, which is a key clotting enzyme. Venous stasis and damage to the vessel wall increase the thrombogenic effect of blood coagulation. Venous stasis is produced by immobility, by obstruction or dilatation of veins, by increased venous pressure, and by increased blood viscosity. The critical role of stasis in the pathogenesis of venous thrombosis is exemplified by the observation that thrombosis occurs with equal frequency in the two legs in paraplegic patients but occurs with greater frequency in the paralyzed limb than in the nonparalyzed limb in stroke patients.[3]

Tissue damage also results in impaired fibrinolysis, which occurs through the release of inflammatory cytokines in response to the damage. These cytokines induce endothelial cell synthesis of plasminogen activator inhibitor–1 (PAI-1)[10]; in addition, they reduce the protective effect of the vascular endothelium by downregulating the endothelial-bound anticoagulant thrombomodulin.[3]

Increased central venous pressure, which produces venous stasis in the extremities, may explain the high incidence of venous thrombosis in patients with heart failure. Stasis resulting from venous dilatation occurs in elderly patients, in patients with varicose veins, and in women who are pregnant or using supplemental estrogen, perhaps contributing to the increased incidence of thrombosis in these persons. Venous obstruction contributes to the risk of venous thrombosis in patients with pelvic tumors. Increased blood viscosity, which also causes stasis, may explain the risk of thrombosis in patients with polycythemia vera, hypergammaglobulinemia, or chronic inflammatory disorders. Direct venous damage may lead to venous thrombosis in patients undergoing hip surgery, knee surgery, or varicose vein stripping and in patients with severe burns or trauma to the lower extremities.[3]

Blood coagulation is modulated by circulating inhibitors or by endothelial cell–bound inhibitors. The most important circulating inhibitors of coagulation are antithrombin, protein C, and protein S.[11,12] An inherited deficiency of one of these three proteins is found in about 20% of patients who have a family history of venous thrombosis and whose first episode of venous thrombosis occurs before 41 years of age.[13] Some types of congenital dysfibrinogenemias can also predispose patients to thrombosis, as can a congenital deficiency of plasminogen.[14] An inherited thrombophilic defect known as activated protein C (APC) resistance, or factor V Leiden, has now been established as the most common cause of inherited thrombophilia, occurring in about 5% of whites who do not have a family history of

venous thrombosis and in about 20% of patients with a first episode of venous thrombosis.[15,16] The second most common thrombophilic defect is a mutation (G20210A) in the 3′ untranslated region of the prothrombin gene that results in about a 25% increase in prothrombin levels.[15,17] This mutation is found in about 2% of whites who have no family history of venous thrombosis and in about 5% of patients with a first episode of venous thrombosis.[15] Elevated levels of clotting factors VIII[18] and XI[19] and of homocysteine[20] also predispose patients to thrombosis. The risk of thrombosis in patients with thrombophilic defects is increased through the use of estrogen-containing oral contraceptives.[15,21] Randomized trials have shown that the administration of estrogens in the doses used for postmenopausal hormone replacement therapy increase the risk of a first or recurrent thromboembolism about threefold.[22-24]

Natural History and Prognosis

Most venous thrombi produce no symptoms and are confined to the intramuscular and deep veins of the calf. Many calf vein thrombi undergo spontaneous lysis, but some extend into the popliteal and more proximal veins.[5] Complete lysis of proximal vein thrombosis is less common.[3,5,25] Most symptomatic pulmonary emboli and virtually all fatal emboli arise from thrombi in the proximal veins of the legs. Extensive venous thrombosis causes local valvular damage, which is thought to lead to the postthrombotic syndrome. Patients with a history of venous thrombosis are more likely to experience additional episodes, particularly if they are exposed to high-risk situations.[1]

Untreated or inadequately treated venous thrombosis is associated with a high rate of complications. About 25% of untreated calf vein thrombi extend into the popliteal vein, and about 50% of untreated proximal vein thrombi also undergo extension.[3,5,6,26] Patients with proximal vein thrombosis who are inadequately treated have a recurrence rate of about 40%,[26] and patients with symptomatic calf vein thrombosis who are treated with a 5-day course of intermittent intravenous heparin without continuation of oral anticoagulant therapy have a recurrence rate greater than 20% over the following 3 months.[27]

Complications can be decreased considerably by adequate anticoagulant therapy. Fewer than 3% of patients who have proximal vein thrombosis experience a clinically detectable recurrence during the initial period of treatment with high-dose heparin or low-molecular-weight heparin (LMWH), and fewer than 3% of patients experience recurrence during the subsequent 3 months of moderate-intensity oral anticoagulant therapy or moderate-dose subcutaneous heparin therapy.[28] After 3 months of anticoagulant therapy, patients have an annual recurrence rate of about 3% if their thrombosis developed after a reversible provocation, such as surgery; the recurrence rate is as high as 15% if the thrombosis is idiopathic or associated with ongoing conditions, such as prolonged immobilization or cancer.[16,29-34] The recurrence rate is significantly higher after a 4- or 6-week course of warfarin treatment, compared with a 3- or 6-month course.[29,31,32] Additional risk factors for recurrent venous thrombosis include proximal versus isolated distal thrombosis; hyperhomocysteinemia; elevated levels of factor VIII; an antiphospholipid antibody; homozygous factor V Leiden; and, probably, deficiency of protein C, protein S, or antithrombin.[33,35]

Table 1 Model for Determining Clinical Suspicion of Deep Vein Thrombosis[37]

Variables	*Points**
Active cancer (treatment ongoing or within previous 6 months or palliative)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for more than 3 days, or major surgery within the past 4 weeks	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Affected calf 3 cm greater than asymptomatic calf (measured 10 cm below tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Dilated superficial veins (nonvaricose)	1
Alternative diagnosis is at least as likely as that of deep vein thrombosis	-2
Total points	

*Pretest probability is calculated as follows: total points ≤ 0, low probability; 1 to 2, moderate probability; ≥ 3, high probability.

Diagnosis

VENOUS THROMBOSIS

Clinical Features

The clinical features of venous thrombosis, such as localized swelling, redness, tenderness, and distal edema, are nonspecific, and the diagnosis should always be confirmed by objective tests.[6,36]

About 75% of ambulatory patients with clinically suspected venous thrombosis have another cause for their symptoms. The conditions that are most likely to simulate venous thrombosis are ruptured Baker cyst, cellulitis, muscle tear, muscle cramp, muscle hematoma, external venous compression, superficial thrombophlebitis, and the postthrombotic syndrome. Of the patients who actually have venous thrombosis, about 85% have proximal vein thrombosis; for the rest, thrombosis is confined to the calf.[5,6]

Although clinical features cannot unequivocally confirm or exclude a diagnosis of venous thrombosis, careful review of the patient's history and of the signs and symptoms at presentation are useful in diagnosis [*see Table 1*].[37] Evidence suggests that patients can be classified as having a high, intermediate, or low probability of having venous thrombosis on the basis of (1) the presence or absence of risk factors (e.g., recent immobilization, hospitalization within the past 6 months, or malignancy), (2) whether the clinical manifestations at presentation are typical or atypical, and (3) whether there is an alternative explanation for the symptoms that is at least as likely as DVT.[35-38]

Laboratory Tests

Three objective tests have been well validated for the diagnosis of venous thrombosis: venography, impedance plethysmography (IPG), and venous ultrasonography.[6] Of these, venography and venous ultrasonography are most widely used. Magnetic resonance imaging appears to be an accurate test for the diagnosis of DVT[39] and may prove to be more accurate than ul-

Figure 1 **Filling defects in the left iliac vein, apparent in this venogram, reveal the presence of thrombi.**

trasonography for the diagnosis of isolated calf or pelvic vein thrombosis and of recurrence of DVT.

Venography Venography, which involves the injection of a radiocontrast agent into a distal vein, is the reference standard for the diagnosis of venous thrombosis [*see Figure 1*]. Venography detects both proximal vein thrombosis and calf vein thrombosis. However, it is technically difficult and expensive; can be painful; and requires injection of radiographic contrast, which can cause allergic reactions or renal impairment. For these reasons, venography has been replaced by venous ultrasonography for the diagnosis of most cases of suspected venous thrombosis.[6]

Venous ultrasonography Venous ultrasonography is the noninvasive method of choice for diagnosing venous thrombosis.[6] It is not painful and it is easier to perform than venography. The common femoral vein, superficial femoral vein, popliteal vein, and proximal deep calf veins are imaged in real time and compressed with the transducer probe. Inability to fully compress or obliterate the vein is diagnostic of venous thrombosis.[6] Duplex ultrasonography, which combines real-time imaging with pulsed Doppler and color-coded Doppler technology, facilitates the identification of veins.

Venous ultrasonography is highly accurate for the detection of proximal vein thrombosis in symptomatic patients, with reported sensitivity and specificity approaching 95%. The sensitivity for symptomatic calf vein thrombosis is approximately 70%. In asymptomatic patients who have had elective hip or knee replacement, the sensitivity of real-time or color Doppler ultrasonography for proximal DVT is only about 60%.[6]

Although venous ultrasonography fails to detect a substantial number of calf vein thrombi and small thrombi of the popliteal vein, this limitation is not critical. If the initial test result excludes proximal DVT, the test can be repeated in 7 days to detect the small number of calf vein thrombi that extend after the initial presentation.[6] If the test remains negative after 7 days, the risk that thrombus is present and will subsequently extend to the proximal veins is negligible, and it is safe to withhold treatment.[6,40]

Ultrasonography is accurate when its results are concordant with clinical assessment; its accuracy drops if the results of these two assessments do not agree.[38] Therefore, if the clinical suspicion for DVT is low and the ultrasound is abnormal, or if clinical suspicion is high and the ultrasound is normal, venography should be considered. In about one quarter of such cases, the results of venography differ from those of the ultrasound.[38] Because the prevalence of DVT is only about 2% (most of which is distal), a follow-up test is not necessary when the clinical suspicion of thrombosis is low and the result of an initial proximal venous ultrasound scan is normal [*see Table 2*].[6]

D-dimer blood testing D-dimer is formed when cross-linked fibrin in thrombi is broken down by plasmin; thus, elevated levels of D-dimer can be used to detect DVT and pulmonary embolism. A variety of D-dimer assays are available, and they vary markedly in their accuracy as diagnostic tests for venous thromboembolism.[41]

All D-dimer assays have low positive predictive value for DVT; an abnormal result is nonspecific and cannot be used to diagnose venous thrombosis. However, some D-dimer tests are sensitive for venous thrombosis, and a normal result can be used to exclude venous thromboembolism.[42] Management studies have shown that it is safe to withhold anticoagulant therapy and serial testing in patients who have a normal result on a moderately sensitive and specific D-dimer test in combination with at least one of three other findings: (1) a normal result on IPG (negative predictive value, 98.5%),[43] (2) a normal result on venous ultrasonography of the proximal veins (negative predictive value, 99.8%),[44] or (3) a low clinical suspicion for DVT[45] [*see Table 2*].

RECURRENT VENOUS THROMBOSIS

The diagnosis of acute recurrent DVT can be difficult.[6] A common approach is to perform venous ultrasonography. If the result is normal, the test should be repeated twice over the next 7 to 10 days. If the result is positive and the result of the previous test was negative, a recurrence is diagnosed. This diagnosis can also be made if venous ultrasonography shows convincing evidence of more extensive thrombosis than was seen on a previous examination. If findings on venous ultrasonography are equivocal, as compared with a previous scan, or a previous scan is not available for comparison, venography should be performed. If the venogram shows a new intraluminal filling defect or evidence of thrombus extension since a previous venogram, recurrent venous thrombosis is diagnosed. If no new defect is found, however, the diagnosis must be on the basis of clinical features [*see Table 2*].[6]

PULMONARY EMBOLISM

Clinical Features

Dyspnea is the most common symptom of pulmonary embolism. Chest pain is also common; it is usually pleuritic but can be substernal and compressive. Tachycardia is relatively common; hemoptysis is less frequent. Fewer than 25% of patients with symptomatic pulmonary embolism have clinical features of venous thrombosis.[46,47] However, the clinical features

Table 2 Test Results That Effectively Confirm or Exclude Deep Vein Thrombosis

Purpose	*Test*	*Significant Result*
Diagnostic for first DVT	Venography	Intraluminal filling defect
	Venous ultrasonography	Noncompressible proximal veins at two or more of the common femoral, popliteal, and calf trifurcation sites
Excludes first DVT	Venography	All deep veins seen, and no intraluminal filling defects
	D-dimer	Normal value on a test that has at least a moderately high sensitivity (≥ 85%) and specificity (≥ 70%) and (1) normal results on venous ultrasonography or IPG or (2) low clinical suspicion of DVT at presentation
	Venous ultrasonography or IPG	Normal and (1) low clinical suspicion for DVT at presentation, (2) normal D-dimer test at presentation, or (3) normal serial testing (venous ultrasonography at 7 days; IPG at 2 and 7 days)
Diagnostic for recurrent DVT	Venography	Intraluminal filling defect
	Venous ultrasonography	(1) A new noncompressible common femoral or popliteal vein segment or (2) a ≥ 4.0 mm increase in diameter of the common femoral or popliteal vein since a previous test*
	IPG	(1) Conversion of a normal test to abnormal* (2) An abnormal test 1 year after diagnosis*
Excludes recurrent DVT	Venography	All deep veins seen and no intraluminal filling defects
	Venous ultrasonography or IPG	Normal or ≤ 1 mm increase in diameter of the common femoral or popliteal veins on venous ultrasound since a previous test and continuing normal results (no progression of venous ultrasound) at 2 and 7 days
	D-dimer	Use of D-dimer to exclude recurrent DVT has not been well evaluated

*If other evidence is not consistent with recurrent DVT (e.g., venous ultrasonography or impedance plethysmography, clinical assessment, or D-dimer), venography should be considered.

IPG—impedance plethysmography

of pulmonary embolism, like those of venous thrombosis, are nonspecific, and in fewer than one third of symptomatic patients is the diagnosis confirmed by objective tests.[46,48]

In the past, clinical assessment of the probability of pulmonary embolism was not standardized; physicians made the assessment informally, on the basis of their experience and the results of initial routine tests (e.g., chest x-ray and electrocardiogram). Three groups have published explicit criteria for determining the clinical probability of pulmonary embolism. One group determined probability on the basis of symptoms and electrocardiography in conjunction with perfusion lung scanning,[49] whereas the other two studies used clinical features in conjunction with ventilation-perfusion lung scanning.[46,50] The model created by Wells and colleagues incorporates an assessment of symptoms and signs, the presence of an alternative diagnosis to account for the patient's condition, and the presence of risk factors for venous thromboembolism.[48,50] With this model, a patient's clinical probability of pulmonary embolism can be categorized as low (prevalence of 2%), moderate (prevalence of 19%), or high (prevalence of 60%) [*see Table 3*].[48]

Table 3 Model for Determining a Clinical Suspicion of Pulmonary Embolism[48]

Variables	*Points**
Clinical signs and symptoms of deep vein thrombosis (minimum leg swelling and pain with palpation of the deep veins)	3.0
An alternative diagnosis is less likely than pulmonary embolism	3.0
Heart rate > 100 beats/min	1.5
Immobilization or surgery in the previous 4 weeks	1.5
Previous deep vein thrombosis/pulmonary embolism	1.5
Hemoptysis	1.0
Malignancy (treatment ongoing or within previous 6 months or palliative)	1.0
Total points	

*Pretest probability is calculated as follows: total points < 2, low probability; 2 to 6, moderate probability; > 6, high probability.

Diagnostic Tests

Chest radiography and electrocardiography In patients with pulmonary embolism, chest x-rays show either normal or nonspecific findings. Chest radiography, however, is useful for exclusion of pneumothorax and other conditions that can simulate pulmonary embolism. The electrocardiogram also frequently shows normal or nonspecific findings, but it is valuable for excluding acute myocardial infarction. In the appropriate clinical setting, ECG evidence of right ventricular strain suggests pulmonary embolism.

Ventilation-perfusion lung scanning One of the main diagnostic tests for pulmonary embolism is ventilation-perfusion lung scanning.[7,45] The perfusion component of lung scanning involves the intravenous injection of isotopically labeled microaggregates of human albumin [*see Figure 2*]. These particles become trapped in the pulmonary capillary bed, so the distribution of the particles reflects blood flow in the lung; this pattern of distribution is recorded with an external photoscanner. Perfusion lung scanning is the pivotal test in the diagnostic process because a normal perfusion scan excludes a diagnosis of pulmonary em-

Figure 2 **Posterior, right posterior oblique, and left posterior oblique perfusion scans (top), which were developed by using radiopharmaceutical technetium-99m (^{99m}Tc) microspheres of albumin, show multiple perfusion defects, some relatively large, in both lungs. Three ventilation scans (bottom) made with the patient breathing krypton-81m (^{81m}Kr) were recorded simultaneously with the perfusion scans. The scans were interpreted as showing a marked ventilation-perfusion mismatch, highly suggestive of pulmonary emboli. This diagnosis was confirmed by pulmonary arteriography.**

bolism; an abnormal perfusion scan is nonspecific [*see Table 4*].[7,46]

For ventilation lung scanning, the patient inhales and exhales either radioactive gases or aerosols while a gamma camera records the distribution of radioactivity within the alveolar gas-exchange units. Ventilation imaging improves the specificity of perfusion scanning for the diagnosis of pulmonary embolism, particularly when the ventilation scan shows normal airflow at the site of a large or segmental perfusion defect.[7,46]

Unfortunately, only 40% of lung scans in patients with pulmonary embolism indicate a high probability of the disorder.[7,46] The remaining 60% are classified as non–high probability. Patients with non–high-probability findings on lung scanning require pulmonary angiography or objective tests for venous thrombosis. The latter are useful because approximately 70% of patients with proven pulmonary embolism have DVT of the legs.[46]

Table 4 Test Results that Effectively Confirm or Exclude Pulmonary Embolism[46]

Conclusion	*Test*	*Result*
Diagnostic for PE	Pulmonary angiography	Intraluminal filling defect
	Helical CT	Intraluminal filling defect in a lobar or main pulmonary artery
	Ventilation-perfusion scan	High-probability scan and moderate/high clinical probability
	Tests for DVT*	Evidence of acute DVT with nondiagnostic ventilation-perfusion scan or helical CT scan
	Pulmonary angiography	Normal
Excludes PE	Lung perfusion scan	Normal
	High-sensitivity D-dimer test†	Normal
	Moderate-sensitivity D-dimer test‡	Normal, plus low clinical suspicion of PE and normal alveolar dead space fraction on lung perfusion scan
	Combination of clinical assessment, ventilation-perfusion scan, ultrasonography of proximal leg veins, and D-dimer test‡	Low clinical suspicion, nondiagnostic scan, and negative D-dimer test
	Combination of clinical assessment, helical CT, ultrasonography of proximal leg veins, and D-dimer test‡	Low to moderate clinical suspicion and normal CT, ultrasonography, and D-dimer test results

*See Table 2.
†D-dimer assay with very high sensitivity (i.e., 98%) and at least moderate specificity (i.e., 40%).
‡D-dimer assay with at least moderately high sensitivity (i.e., 85%) and specificity (i.e., 70%).
DVT—deep vein thrombosis PE—pulmonary embolism

Figure 3 **Pulmonary arteriogram demonstrates nonfilling of pulmonary arterial branches in the right lung, an indication of massive occlusion.**

Pulmonary angiography Pulmonary angiography is the reference standard for establishing the presence or absence of pulmonary embolism [*see Figure 3*].[7,46] Unfortunately, it is invasive, technically difficult, and unavailable in most hospitals. If the test is performed adequately, a normal result excludes the diagnosis of pulmonary embolism; in a patient with a small perfusion defect, however, the diagnosis of a small pulmonary embolism cannot be excluded by pulmonary angiography unless the tertiary pulmonary arteries are visualized.

Pulmonary angiography can be complicated by arrhythmias, cardiac perforation, cardiac arrest, and hypersensitivity to the contrast medium. Complications occur in 3% to 4% of patients undergoing pulmonary angiography.

Computed tomography and magnetic resonance imaging Traditional CT scanning is not suitable for evaluating suspected pulmonary embolism because it is not feasible to opacify the pulmonary arteries with radiographic contrast for the time required to complete imaging (i.e., 3 minutes). Even if the pulmonary arteries could be opacified, motion artifact would interfere with image quality. These problems are overcome by helical CT (also known as spiral or continuous volume CT) because image acquisition can be completed within a single holding of the breath (e.g., 20 seconds).[46,51,52]

Current evidence suggests that helical CT has a sensitivity of about 70% for all pulmonary embolism and a specificity of about 90%. Accuracy varies according to the size of the largest pulmonary artery involved: sensitivity is about 90% for emboli in segmental or larger pulmonary arteries but only about 30% for isolated subsegmental emboli, which account for about 20% of symptomatic pulmonary emboli. Similarly, the positive predictive value of an abnormal helical CT decreases from about 100% with filling defects in main pulmonary arteries to 85% in lobar and about 60% in segmental arteries.[53] These observations suggest the following:

(1) An intraluminal filling defect in a lobar or larger pulmonary artery is likely to be associated with at least a 90% probability of embolism and, therefore, may be interpreted in the same way as a high-probability lung scan.
(2) A normal helical CT scan markedly reduces the probability of pulmonary embolism but does not exclude this diagnosis. It may be reasonable to interpret a normal spiral CT scan in the same way as a low-probability lung scan.
(3) Intraluminal defects that are confined to subsegmental pulmonary arteries are nondiagnostic and require further investigation (e.g., pulmonary angiography or lung scanning).
(4) Intraluminal filling defects that are confined to segmental pulmonary arteries should be considered nondiagnostic if clinical suspicion is low, if other diagnostic tests suggest the absence of pulmonary embolism (e.g., normal D-dimer level), or if helical CT findings are equivocal.

Musset and colleagues published a study evaluating helical CT, ultrasonography of the proximal veins, and clinical assessment for the management of 1,041 patients with suspected pulmonary embolism.[54] The main findings of this study are as follows: (1) a normal helical CT scan plus a normal ultrasound scan excluded pulmonary embolism in patients with a low or moderate clinical probability of the disorder; (2) helical CT was not sensitive enough to exclude pulmonary embolism on its own (16% of pulmonary embolism cases were diagnosed by an abnormal ultrasound scan with a normal helical CT scan); (3) isolated subsegmental filling defects were nondiagnostic for pulmonary embolism; and (4) 8% of helical CT examinations were nondiagnostic. The study provides and validates a helical CT-based algorithm for the diagnosis of pulmonary embolism.

MRI is less well evaluated than helical CT for the diagnosis of pulmonary embolism but appears to have a similar accuracy.[46] Both helical CT and MRI have the advantage of possibly suggesting an alternative pulmonary diagnosis. MRI does not expose the patient to radiation or radiographic contrast media, and the examination may be extended to look for concomitant DVT.

Compression ultrasonography and D-dimer assay Two noninvasive, relatively inexpensive, complementary approaches can be used to simplify the diagnosis of pulmonary embolism in patients with nondiagnostic lung scan findings. These approaches involve the use of compression ultrasonography and the D-dimer test. Because pulmonary emboli usually arise from mostly asymptomatic thrombi in the deep proximal leg veins, a positive compression ultrasound test result can serve as indirect evidence of pulmonary embolism. However, a positive compression ultrasound test result is found in only 5% to 10% of patients with nondiagnostic lung scans.[46,50,55] Furthermore, a negative compression ultrasound test result does not exclude a diagnosis of pulmonary embolism in these patients, possibly because either the original thrombus has embolized or the residual thrombus is too small to be detected by compression ultrasonography. A negative ultrasound test result can, however, eliminate the possibility of an associated large proximal vein thrombosis; in most patients with a negative ultrasound test result, treatment can be withheld while further investigations are performed [*see Table 4*].[46,50,55,56]

Two prospective studies—one utilizing plethysmography[57] and the other utilizing compression ultrasonography[50]—in patients with good cardiopulmonary reserve have reported that patients with non–high-probability lung scan results and a negative noninvasive test result for DVT can be safely managed with serial noninvasive testing for proximal vein thrombosis for 14 days. Both studies reported a very low rate (2%) of confirmed venous thromboembolism over a 6-month follow-up period, provided that the noninvasive test result remained negative.

About 90% of patients with a non–high-probability lung scan have a normal compression ultrasound test; of these, about 80% do not have pulmonary embolism. Therefore, the use of serial

ultrasonography in all patients with a non–high-probability lung scan result and a normal compression ultrasound test result would lead to the testing of a large number of patients to identify the very few at risk for recurrent pulmonary embolism. The noninvasive diagnostic process has been simplified by introducing two additional components: pretest probability [*see Table 3*] and D-dimer testing.

In pulmonary embolism, as in DVT, D-dimer testing is reliable only for excluding the diagnosis. In a prospective study of 1,177 patients with suspected pulmonary embolism, the negative predictive value of D-dimer testing (using the SimpliRED whole blood assay) was 99% in those patients with a low clinical likelihood of pulmonary embolism and a nondiagnostic lung scan.[58] Used alone, a rapid enzyme-linked immunosorbent assay (ELISA) for D-dimer has a high sensitivity (99%) and a low to moderate specificity (45%); it was found to rule out pulmonary embolism in 36% of consecutive patients with suspected embolism [*see Table 4*].[42]

Diagnostic Strategy

Algorithms A number of prospectively validated algorithms have been published that emphasize the use of different initial noninvasive tests in conjunction with ventilation-perfusion lung scanning. The noninvasive tests, as used in these algorithms, are as follows: structured clinical assessment and serial venous ultrasounds[50]; empirical clinical assessment, sensitive D-dimer assay, and venous ultrasound at presentation only[42]; and clinical assessment, moderately sensitive D-dimer assay, and serial venous ultrasounds[57] [*see Figure 4*]. Helical CT can be used rather than ventilation-perfusion scanning; Musset and colleagues have described and validated a diagnostic algorithm for pulmonary embolism that uses routine helical CT, ultrasonography of the proximal veins, and clinical assessment.[54]

Evaluation of patients with nondiagnostic, noninvasive tests Serial venous ultrasonography of the proximal veins (i.e., 1 and 2 weeks after the initial evaluation) is suitable for most patients in whom noninvasive tests are not diagnostic,[50,56] although pulmonary angiography is generally preferred for certain subgroups (see below). An alternative to pulmonary angiography is to perform bilateral venography before serial venous ultrasonography.

Pulmonary angiography is the preferred option in patients with a segmental intraluminal filling defect on helical CT. However, when clinical suspicion is high, this CT finding alone is likely to have a positive predictive value of 85% and could be considered diagnostic for pulmonary embolism. A subsegmental intraluminal filling defect on helical CT and high clinical probability of pulmonary embolism is also an indication for angiography, as is a high-probability ventilation-perfusion scan result and low clinical suspicion. Alternatively, helical CT scanning can be followed with ventilation-perfusion scanning, or vice versa, when the initial scan shows these findings; in such cases, the second test may be diagnostic for pulmonary embolism. If the second test is also nondiagnostic for pulmonary embolism, serial ultrasonography may be reconsidered.

Pulmonary angiography is also preferred when clinical manifestations are severe, posttest probability of pulmonary embolism is moderate, and pulmonary embolism needs to be excluded from the differential diagnosis. Finally, pulmonary angiography is indicated when serial testing is not feasible (e.g., because of impending surgery or geographic inaccessibility).

Prophylaxis and Treatment

PHARMACOLOGY OF ANTITHROMBOTIC AGENTS

Anticoagulants

A less intense anticoagulant effect is required for the prevention of venous thrombosis than is required for its treatment. The anticoagulants in clinical use are heparin, LMWH, and fondaparinux, which are administered subcutaneously or intravenously; and coumarin compounds, which are given orally. Thrombolytic agents are streptokinase, urokinase, and recombinant tissue plasminogen activator (rt-PA).

Heparin and LMWH Heparin is a highly sulfated glycosaminoglycan that produces its anticoagulant effect by binding to antithrombin, markedly accelerating the ability of the naturally occurring anticoagulant to inactivate thrombin, activated factor X (factor Xa), and activated factor IX (factor IXa).[59] At therapeutic concentrations, heparin has a half-life of about 60 minutes. Its clearance is dose dependent. Heparin has decreased bioavailability when administered subcutaneously in low doses but has approximately 90% bioavailability when administered in high therapeutic doses.

Heparin binds to a number of plasma proteins, a phenomenon that reduces the anticoagulant effect of heparin by limiting its accessibility to antithrombin. The concentration of heparin-binding proteins increases during illness, contributing to the variability in anticoagulant response in patients with thromboembolism.[59] Because of this variability, response to heparin should be monitored with the activated partial thromboplastin time (aPTT). The dose should be adjusted as necessary to achieve a therapeutic range, which for many aPTT reagents corresponds to an aPTT ratio of 1.5 to 2.5.[59]

LMWHs are effective in the prevention and treatment of venous thrombosis. They are derived from standard commercial-grade heparin by chemical depolymerization to yield fragments approximately one third the size of heparin.[60] Depolymerization of heparin results in a change in its anticoagulant profile, bioavailability, and pharmacokinetics and in a lower incidence of heparin-induced thrombocytopenia and of osteopenia.[59,60]

The plasma recoveries and pharmacokinetics of LMWHs differ from those of heparin because LMWHs bind much less avidly to heparin-binding proteins than does heparin. This property of LMWHs contributes to their superior bioavailability at low doses and their more predictable anticoagulant response. LMWHs also exhibit less binding to macrophages and endothelial cells than does heparin, a property that accounts for their longer plasma half-life, which is approximately 3 hours, and their dose-independent clearance. These potential advantages over heparin permit once-daily administration of LMWHs without laboratory monitoring. The advantages of LMWHs have been exploited to successfully treat patients with DVT out of hospital[61-63] and to treat patients with acute pulmonary embolism in hospital with once- or twice-daily subcutaneous dosing regimens.[47,63] The published research on LMWHs, which includes over 3,000 patients treated with either once-daily or twice-daily subcutaneous doses, has established this class of anticoagulants as safe, effective, and convenient for treating venous thrombosis and pulmonary embolism.[28]

Fondaparinux Fondaparinux is a new parenteral synthetic anticoagulant composed of the five saccharide units that make up the active site of heparin that binds antithrombin.[64] The fondaparinux-antithrombin complex inhibits factor Xa but has no

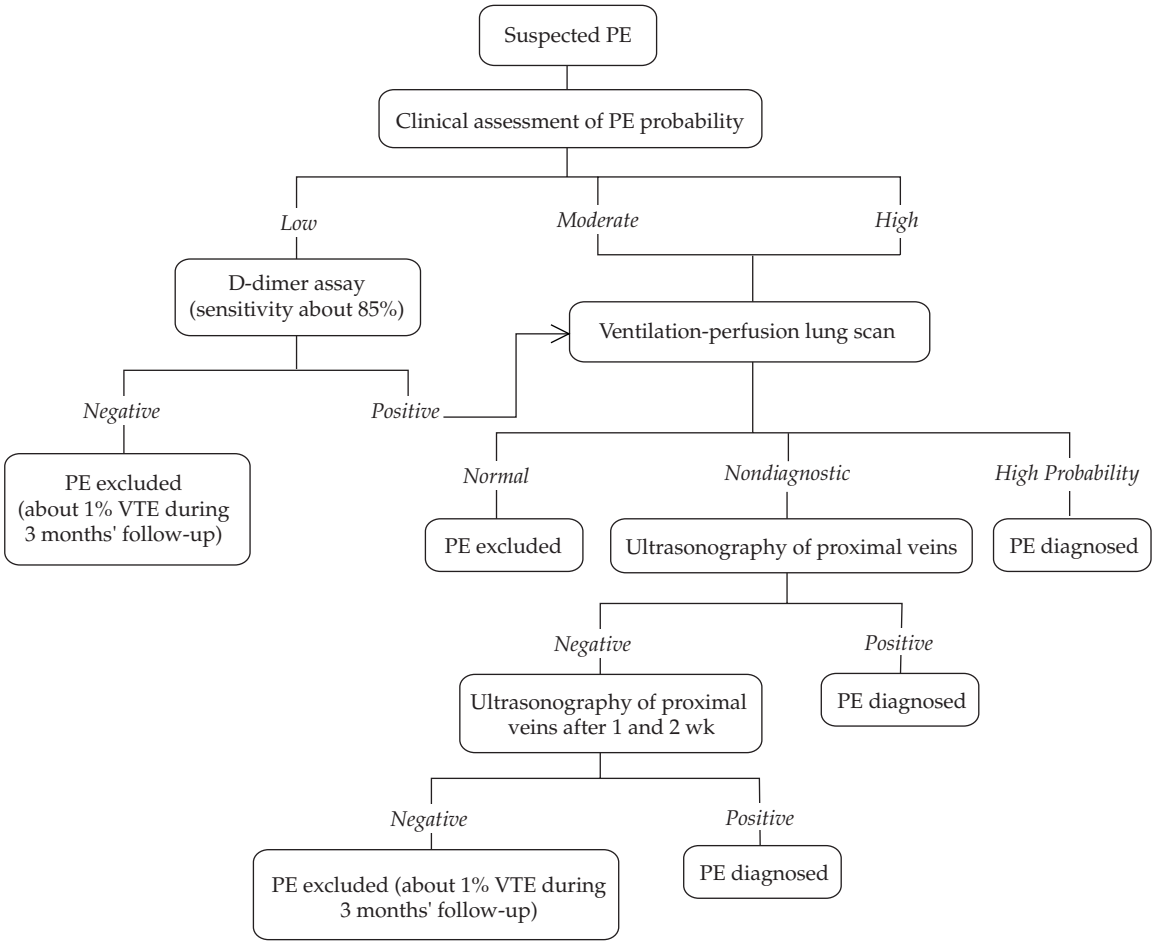

Figure 4 **Diagnostic approach to pulmonary embolism. Use of a very sensitive D-dimer assay can obviate clinical assessment: a negative result excludes pulmonary embolism regardless of the clinical assessment results; a positive test can be followed by a ventilation-perfusion scan. Similarly, a ventilation-perfusion scan can substitute for clinical assessment.**

If the clinical assessment indicates a low probability of pulmonary embolism and, in particular, if a D-dimer test is not done, pulmonary angiography or helical CT may be considered. If helical CT is used instead of ventilation-perfusion lung scanning, intraluminal filling defects in segmental or larger pulmonary arteries are generally diagnostic for pulmonary embolism, but all other findings are nondiagnostic, including normal results and intraluminal filling defects confined to the subsegmental pulmonary arteries. With nondiagnostic results, management is the same as with a nondiagnostic lung scan.

If ultrasonography is negative but overall assessment suggests a high probability of pulmonary embolism, symptoms are severe, or cardiopulmonary reserve is poor, then additional tests (e.g., helical CT or bilateral venography) may be considered. Venography should be considered if there is an increased risk of a false-positive ultrasound result (e.g., previous venous thromboembolism, equivocal ultrasound findings, preceding findings suggesting a low probability of pulmonary embolism). It is reasonable to not repeat ultrasound testing, or to do only one more ultrasound after 1 week, if preceding findings suggest a low probability of pulmonary embolism.

(PE—pulmonary embolism; VTE—venous thromboembolism)

direct activity against thrombin. Fondaparinux is rapidly absorbed and is 100% bioavailable when administered subcutaneously. It is not metabolized, is renally excreted, and has a dose-independent elimination half-life of 15 hours, which makes it suitable for once-daily administration. Fondaparinux is being evaluated for many indications, including prevention and treatment of DVT and pulmonary embolism.

Oral anticoagulants Oral anticoagulants are coumarin compounds, the most common being warfarin, that produce their anticoagulant effect through the production of hemostatically defective, vitamin K–dependent coagulant proteins (prothrombin, factor VII, factor IX, and factor X).[65]

The dose of warfarin must be monitored closely because the anticoagulant response varies widely among individuals. Laboratory monitoring is performed by measuring the prothrombin time (PT), a test responsive to depression of three of the four vitamin K–dependent clotting factors (prothrombin and factors VII and X). Commercial PT reagents vary markedly in their responsiveness to warfarin-induced reduction in clotting factors. This problem of variability in the responsiveness of PT reagents has been overcome by the introduction of the international normalized ratio (INR).[65]

The starting dose of warfarin has been 10 mg, with an average maintenance dose of about 5 mg. However, the dose required varies widely among individuals. Elderly patients, for example, have been shown, on average, to require lower doses. Evidence indicates that it might be safer to use a starting

dose of 5 mg of warfarin because, compared with 10 mg, the 5 mg starting dose does not result in a delay in achieving a therapeutic INR and is associated with a lower incidence of supratherapeutic INR values during the first 5 days of treatment.[66] Warfarin therapy is difficult to manage in some patients because of unexpected fluctuations in dose response, which may reflect changes in diet, inaccuracy in PT testing, undisclosed drug use, poor compliance, or surreptitious self-medication. Certain over-the-counter and prescription drugs can augment or inhibit the anticoagulant effect of coumarin compounds or prolong hemostasis by interfering with platelet function [*see Table 5*].

Patients receiving coumarin compounds are also sensitive to fluctuating levels of dietary vitamin K, which is obtained predominantly from leafy green vegetables. The effect of coumarins can be potentiated in sick patients with poor vitamin K intake, particularly if they are treated with antibiotics and intravenous feeding without vitamin K supplementation, and in states of fat malabsorption.

Direct thrombin inhibitors Direct thrombin inhibitors include hirudin, bivalirudin, argatroban, melagatran, and ximelagatran.[67] Whereas the first four of these compounds must be administered parenterally, ximelagatran is absorbed from the gastrointestinal tract and exhibits no known food or drug interactions. Once absorbed, ximelagatran is converted to melagatran, a partial mimetic of fibrinopeptide A, which blocks the active site of thrombin. Ximelagatran is primarily eliminated by the kidneys and has a half-life of about 3 hours, mandating twice-daily administration. It is being evaluated for many indications, including primary prevention and acute and long-term treatment of venous thromboembolism.

Table 5 Drug and Food Interactions with Warfarin by Level of Supporting Evidence* and Direction of Interaction[92]

	Antibiotics	*Cardiac*	*Anti-inflammatory*	*Central Nervous System*	*Gastrointestinal*	*Miscellaneous*
Potentiation Level 1	Trimethoprim-sulfamethoxazole, erythromycin, isoniazid, fluconazole, metronidazole, miconazole, clarithromycin, amoxicillin	Amiodarone, clofibrate, propafenone, propranolol, sulfinpyrazone†	Phenylbutazone,† piroxicam High-dose intravenous methylprednisolone Acetaminophen	Alcohol (with liver disease)	Cimetidine,‡ omeprazole	—
Level 2	Ciprofloxacin, itraconazole, tetracycline, norfloxacin	Aspirin, quinidine, simvastatin	Aspirin, dextropropoxyphene	Chloral hydrate, disulfiram, phenytoin	—	Anabolic steroids, influenza vaccine, tamoxifen
Level 3	Nalidixic acid, ofloxacin	Disopyramide, lovastatin, metolazone	Topical salicylates, sulindac, tolmetin	—	—	Fluorouracil, ifosfamide
Level 4	Cefamandole, cefazolin, sulfisoxazole, doxycycline	Gemfibrozil, heparin	Indomethacin	—	—	—
Inhibition Level 1	Griseofulvin,* nafcillin, rifampin	Cholestyramine	—	Barbiturates, carbamazepine, chlordiazepoxide	Sucralfate	Foods with a high vitamin K content, enteral nutritional support, large amounts of avocado Ticlopidine
Level 2	Dicloxacillin	—	—	—	—	—
Level 3	—	—	Azathioprine	Trazodone	—	Azathioprine, cyclosporine, etretinate, large amounts of broccoli
No effect Level 1	Enoxacin	Atenolol, bumetanide, felodipine, metoprolol, moricizine	Diflunisal, ketorolac, naproxen	Alcohol, fluoxetine, nitrazepam	Antacids, famotidine, nizatidine, psyllium, ranitidine‡	—
Level 2	Ketoconazole	—	Ibuprofen, ketoprofen	—	—	—
Level 4	Vancomycin	Diltiazem	—	—	—	Tobacco

*Level 1 evidence indicates that the likelihood of an association is very strong; level 2 evidence suggests that a true association is likely; level 3 evidence suggests that a true association is probable; and level 4 evidence suggests that a true association is possible.
†Supporting level 1 evidence was obtained from both patients and volunteers.
‡In a small number of volunteers, an inhibitory drug interaction occurred.

Thrombolytic Agents

Pharmacologic thrombolysis is produced by plasminogen activators—including streptokinase, rt-PA, and urokinase—which convert the proenzyme plasminogen to the fibrinolytic enzyme plasmin.[68]

Streptokinase Streptokinase is a protein produced by β-hemolytic streptococci. In contrast to other plasminogen activators, streptokinase is not an enzyme and does not convert plasminogen directly to plasmin by proteolytic cleavage. Instead, streptokinase binds noncovalently to plasminogen, converting it to a plasminogen-activator complex that acts on other plasminogen molecules to generate plasmin. Streptokinase has a plasma half-life of 30 minutes.

Because streptokinase is a bacterial product, it stimulates antibody production and can prompt allergic reactions. Antistreptococcal antibodies, present in variable titers in most patients before streptokinase treatment, induce an amnestic response that makes repeated treatment with streptokinase difficult or impossible for a period of months or years after an initial course of treatment. Laboratory monitoring of streptokinase can be limited to thrombin time, which is used as a marker for an effective lytic state. If the thrombin time is not prolonged within the first few hours of commencing treatment, resistance to streptokinase resulting from a high titer of antistreptococcal antibodies should be suspected and the dose of streptokinase should be increased.

Urokinase Synthesized by endothelial and mononuclear cells, urokinase is a direct activator of plasminogen. Like streptokinase, urokinase is non–fibrin specific. It has a plasma half-life of 10 minutes.

rt-PA rt-PA, which is fibrin specific, is synthesized by endothelial cells as a single-chain polypeptide. Proteolytic cleavage converts the single-chain form into a two-chain species. Both forms are enzymatically active. rt-PA has a plasma half-life of approximately 5 minutes.

Complications of Antithrombotic Agents

Bleeding is the main complication of antithrombotic therapy.[69] With all antithrombotic agents, the risk of bleeding is influenced by the dose and by patient-related factors, the most important being recent surgery or trauma. Other patient characteristics that increase the risk of bleeding are older age, recent stroke, generalized hemostatic defect, a history of gastrointestinal hemorrhage, and serious comorbid conditions.

Bleeding is more common and more serious with thrombolytic drugs than with anticoagulants. The risk of bleeding with thrombolytic therapy is just as great with rt-PA as with streptokinase and urokinase, which, unlike rt-PA, lack fibrin specificity. With heparin, the incidence of bleeding is influenced by dosage and by means of administration, being higher with intermittent intravenous therapy than with continuous intravenous therapy.[69] Bleeding rates are similar for heparin and LMWH.[28]

Bleeding associated with coumarin anticoagulants is influenced by the intensity of anticoagulant therapy. Such bleeding is reduced to about one third if the targeted INR range is lowered from between 3.0 and 4.5 to between 2.0 and 3.0. Both heparin-induced bleeding and warfarin-induced bleeding are increased by concomitant use of aspirin, which impairs platelet function and produces gastric erosions. When the INR is less than 3.0, coumarin-associated bleeding frequently has an obvious underlying cause or is from an occult gastrointestinal or renal lesion.

Nonhemorrhagic side effects of thrombolytic therapy are limited mainly to allergic reactions to streptokinase. Nonhemorrhagic side effects of heparin include the following: (1) urticaria at sites of subcutaneous injection; (2) thrombocytopenia, which occurs in 2% to 4% of patients treated with high-dose heparin and is complicated by arterial or venous thrombosis in about 0.2% of treated patients [*see 5:XIV Thrombotic Disorders*]; (3) osteoporosis, which occurs with prolonged high-dose heparin use; and, rarely, (4) alopecia, adrenal insufficiency, and skin necrosis. The incidence of thrombocytopenia is lower with LMWHs than with heparin. Similarly, there is evidence that the risk of osteopenia is lower with LMWH than with heparin.[59]

The most important nonhemorrhagic side effect of coumarin anticoagulants is skin necrosis, an uncommon complication usually observed on the third to eighth day of therapy. Skin necrosis is caused by extensive thrombosis of the venules and capillaries within the subcutaneous fat. An association has been reported between coumarin-induced skin necrosis and protein C deficiency—and, less commonly, protein S deficiency—but this complication can occur in patients without these deficiencies.

PRIMARY PROPHYLAXIS

The most effective way of reducing the mortality associated with pulmonary embolism and the morbidity associated with the postthrombotic syndrome is to institute primary prophylaxis in patients at risk for venous thromboembolism. On the basis of well-defined clinical criteria, patients can be classified as being at low, moderate, or high risk for venous thromboembolism, and the choice of prophylaxis should be tailored to the patient's risk [*see Table 6*]. In the absence of prophylaxis, the frequency of fatal postoperative pulmonary embolism ranges from 0.1% to 0.4% in patients undergoing elective general surgery and from 1% to 5% in patients undergoing elective hip or knee surgery, emergency hip surgery, major trauma, or spinal cord injury. Prophylaxis is cost-effective for most high-risk groups.[70]

Prophylaxis is achieved either by modulating activation of blood coagulation or by preventing venous stasis by using the following proven approaches: low-dose subcutaneous heparin, intermittent pneumatic compression of the legs, coumarin anticoagulants, adjusted doses of subcutaneous heparin, graduated compression stockings, LMWHs, or fondaparinux.[64,70] Antiplatelet agents, such as aspirin, also prevent venous thromboembolism but less effectively than the previously stated methods.[70,71]

Low-dose heparin is given subcutaneously at a dose of 5,000 units 2 hours before surgery and 5,000 U every 8 or 12 hours after surgery. In patients undergoing major orthopedic surgical procedures, low-dose heparin is less effective than warfarin, adjusted-dose heparin, or LMWHs. Intermittent pneumatic compression of the legs enhances blood flow in the deep veins and increases blood fibrinolytic activity. This method of prophylaxis is free of clinically important side effects and is particularly useful in patients who have a high risk of serious bleeding. It is the method of choice for preventing venous thrombosis in patients undergoing neurosurgery, it is effective in patients undergoing major knee surgery, and it is as effective as low-dose heparin in patients undergoing abdominal surgery.

Table 6 Risk Categories for Venous Thromboembolism and Recommendations for Prophylaxis

	High Risk	*Moderate Risk*
Calf vein thrombosis	30%–50%	10%–30%
Proximal vein thrombosis	10%–20%	2%–8%
Fatal pulmonary embolism	1%–5%	0.2%–0.7%
Recommended prophylaxis	Low-molecular-weight heparin, oral anticoagulants, adjusted-dose heparin, or fondaparinux	Low-dose heparin, external pneumatic compression, or graduated compression stockings

Graduated compression stockings reduce venous stasis and prevent postoperative venous thrombosis in general surgical patients and in medical or surgical patients with neurologic disorders, including paralysis of the lower limbs.[70] In surgical patients, the combined use of graduated compression stockings and low-dose heparin is significantly more effective than use of low-dose heparin alone. Graduated compression stockings are relatively inexpensive and should be considered in all high-risk surgical patients, even if other forms of prophylaxis are used.

Moderate-dose warfarin (INR = 2.0 to 3.0) is effective for preventing postoperative venous thromboembolism in patients in all risk categories.[70] Warfarin therapy can be started preoperatively, at the time of surgery, or in the early postoperative period. Although the anticoagulant effect is not achieved until the third or fourth postoperative day, warfarin treatment started at the time of surgery or in the early postoperative period is effective in patients at very high risk, including patients with hip fractures and those who undergo joint replacement. Prophylaxis with warfarin is less convenient than that with low-dose heparin or LMWHs, however, because careful laboratory monitoring is necessary.

LMWH is a safe and effective form of prophylaxis in high-risk patients undergoing elective hip surgery, major general surgery, or major knee surgery, as well as in patients who have experienced hip fracture, spinal injury, or stroke. LMWH is more effective than standard low-dose heparin in general surgical patients, patients undergoing elective hip surgery, and patients with stroke or spinal injury.

In patients who undergo hip or major knee surgery, LMWH is more effective than warfarin but is associated with more frequent bleeding; both of these differences may be caused by a more rapid onset of anticoagulation with postoperatively initiated LMWH than with warfarin. It is uncertain whether the superior efficacy of LMWH over warfarin in the prevention of venographically detectable venous thrombosis is mirrored by fewer symptomatic episodes of venous thromboembolism with LMWH.[70,72]

Fondaparinux was shown to reduce the frequency of venographically-detected DVT by 50% but to cause a small increase in bleeding compared with LMWH in a series of large trials in orthopedic surgical patients.[64]

Indications for Prophylaxis

General surgery and medicine Low-dose-heparin prophylaxis is the method of choice for moderate-risk general surgical and medical patients. It reduces the risk of venous thromboembolism by 50% to 70% and is simple, inexpensive, convenient, and safe.[70] If anticoagulants are contraindicated because of an unusually high risk of bleeding, graduated compression stockings, intermittent pneumatic compression of the legs, or both should be used.

Major orthopedic surgery LMWH, fondaparinux, or oral anticoagulants provide effective prophylaxis for venous thrombosis in patients who have undergone hip surgery. Aspirin has also been shown to reduce the frequency of symptomatic venous thromboembolism and fatal pulmonary embolism after hip fracture.[71] The relative efficacy and safety of aspirin versus LMWH, fondaparinux, or oral anticoagulants in patients who have a hip fracture or have undergone hip or knee arthroplasty is uncertain. However, because studies have shown that aspirin is much less effective than LMWH or oral anticoagulants at preventing venographically detectable venous thrombosis, aspirin is not recommended as the sole agent for postoperative prophylaxis.[70]

LMWH, warfarin, fondaparinux, and intermittent pneumatic compression are effective in preventing venous thrombosis in patients undergoing major knee surgery.

Extended prophylaxis with LWMH or warfarin for an additional 3 weeks after hospital discharge should be considered after major orthopedic surgery. Extended prophylaxis is strongly recommended for high-risk patients (e.g., those with previous venous thromboembolism or active cancer).[70,73]

Genitourinary surgery, neurosurgery, and ocular surgery Intermittent pneumatic compression, with or without graduated compression stockings, is effective prophylaxis for venous thrombosis and does not increase the risk of bleeding.

TREATMENT

The objectives of treating patients with venous thromboembolism are to prevent pulmonary embolism, the postthrombotic syndrome, thromboembolic pulmonary hypertension, and recurrent venous thromboembolism and to alleviate the discomfort of the acute event.

Superficial venous thrombosis usually can be treated conservatively with anti-inflammatory drugs. In patients with DVT, anticoagulants can effectively reduce morbidity and mortality from pulmonary embolism.[7] Vena caval interruption, which is usually achieved with an inferior vena caval filter, is also effective but is more complicated, expensive, and invasive and is associated with a doubling of the frequency of recurrent DVT during long-term follow-up.[74] For these reasons, it is in general used only if anticoagulant therapy has failed or is contraindicated because of the risk of serious hemorrhage.[7]

Thrombolytic therapy with streptokinase, urokinase, or rt-PA is more effective than heparin in achieving early lysis of venous thromboembolism and is better than heparin for preventing death in patients with massive pulmonary embolism associated with shock.[75] Thrombolytic therapy is therefore the treatment of choice for patients with life-threatening pulmonary embolism.

Thromboendarterectomy is effective treatment in selected cases of chronic thromboembolic pulmonary hypertension involving proximal pulmonary arterial obstruction.[76] Urgent pulmonary embolectomy is rarely indicated.

In one study, the routine early use of graduated compression

stockings for 2 years reduced the incidence of the postthrombotic syndrome by about 50%.[9] Consequently, use of graduated compression stockings is recommended for 2 years after proximal DVT, particularly if thrombosis was extensive or associated with marked leg swelling, and if the patient finds the stockings comfortable.

Administration and Dosage Guidelines

Anticoagulant therapy Anticoagulants are the mainstay of treatment for most patients with venous thromboembolism. In the past, the treatment of choice was heparin administered by continuous intravenous infusion or subcutaneous injection, in doses sufficient to produce an adequate anticoagulant response. It is now believed that LMWH administered by subcutaneous injection without laboratory monitoring is as effective and safe as heparin.[28]

The anticoagulant effect of intravenous heparin or LMWH is immediate. With subcutaneous injection, the anticoagulant effect of both anticoagulants is delayed for about an hour; peak levels occur at 2 to 3 hours. The anticoagulant effect of subcutaneous heparin is maintained for about 12 hours with therapeutic doses. LMWH is effective when administered subcutaneously once daily.[28]

Heparin therapy is usually monitored by the aPTT and less frequently by heparin assays, which measure the ability of heparin to accelerate the inactivation of factor Xa or thrombin by antithrombin. The anticoagulant effect should be monitored carefully (e.g., every 6 hours until the aPTT is in the therapeutic range, and then daily). The dosage should be adjusted as necessary to achieve an adequate anticoagulant effect because there is a greater risk of recurrent venous thromboembolism if the anticoagulant effect is suboptimal.[7] The therapeutic range of aPTT is equivalent to a heparin level between 0.35 and 7.0 U/ml as measured by an anti–factor Xa assay.[77] For many aPTT reagents, this range is an aPTT ratio of 1.8 to 2.5 times the mean of the normal laboratory control value.[59,77]

LMWH is administered subcutaneously on a weight-adjusted basis at a dosage of either 100 anti-Xa U/kg every 12 hours or 150 to 200 anti-Xa units once daily.[60] Monitoring is not required.

Treatment with heparin or LMWH is usually continued for 5 to 6 days; warfarin therapy is started on the first or second day, overlapping the heparin therapy (or LMWH) for 4 or 5 days, and is continued until an INR of 2.0 is maintained for at least 24 hours.[59] For patients with major pulmonary embolism or extensive DVT, heparin should be given for at least 7 days. A 4- to 5-day period of overlap is necessary because the antithrombotic effects of oral anticoagulants are delayed. The initial course of heparin should be followed by warfarin for at least 3 months.[34] Less intense warfarin therapy (INR = 2.0 to 3.0) is just as effective as the high-intensity regimen (INR = 3.0 to 4.5) and produces significantly less bleeding.[65] Adjusted-dose subcutaneous heparin or intermediate-dose LMWH can also be used in the outpatient setting,[34] but they are more expensive and less convenient than warfarin.

Duration of anticoagulant therapy During the past decade, a series of well-designed studies has helped to define the optimal duration of anticoagulation. The findings of these studies can be summarized as follows:

- Shortening the duration of anticoagulation from 3 or 6 months to 4 or 6 weeks results in a doubling of the frequency of the recurrence of venous thromboembolism during 1 to 2 years of follow-up.[29,31,32]
- Patients with venous thromboembolism that was provoked by a transient risk factor have a risk of recurrence about one third lower than those with unprovoked venous thromboembolism or a persistent risk factor.[8,29,31-34]
- Three months of anticoagulation may not be adequate treatment for an unprovoked (so-called idiopathic) episode of venous thromboembolism; subsequent risk of early recurrence has varied from 5% to 25% per patient-year.[8,29,31-34,78]
- After 6 months of anticoagulation, recurrent DVT is at least as likely to affect the contralateral leg, which suggests that these recurrences result from systemic rather than local factors (including inadequate treatment).[79]
- There is a persistently elevated risk of recurrent venous thromboembolism after a first episode; this risk appears to be 5% to 12% per year after 6 or more months of treatment of an unprovoked episode.[8,30,31,78]
- Oral anticoagulants targeted at an INR of about 2.5 are very effective (risk reduction of 90% or greater) at preventing recurrent unprovoked venous thromboembolism after the first 3 months of treatment.[16,80]
- Time-limited extensions of anticoagulant therapy beyond 3 or 6 months (e.g., to 12 or 24 months) may delay but not ultimately reduce the risk of recurrent venous thromboembolism.[30,34,78]
- Indefinite anticoagulation (i.e., anticoagulation therapy that is not time-limited) is an option for patients who have experienced their first unprovoked venous thromboembolism and who are at low risk for bleeding.[34]
- A second episode of venous thromboembolism does not necessarily indicate a high risk of recurrence or the need for indefinite anticoagulation.[34]
- Risk of bleeding during anticoagulation therapy differs markedly among patients, depending on the prevalence of risk factors (e.g., advanced age, previous bleeding or stroke, renal failure, anemia, antiplatelet therapy, malignancy, or poor anticoagulant control).[34,69]
- Risk of recurrence is lower (about half) after an isolated calf (distal) DVT; in such patients, a shorter duration of treatment is appropriate.[30,31]
- Risk of recurrence is higher with antiphospholipid antibodies (anticardiolipin antibodies or lupus anticoagulants), homozygous factor V Leiden, cancer, and, probably, antithrombin deficiency; the presence of any of these factors argues for a longer duration of treatment.[15,34]
- Heterozygous factor V Leiden and the G20210A prothrombin gene mutations do not appear to be clinically important risk factors for recurrence.[34]
- Other clotting abnormalities (e.g., elevated levels of clotting factors VIII, IX, and XI and homocysteine, and deficiencies of protein C and protein S) may be risk factors for recurrence; they have uncertain implications for duration of treatment.[34]
- Recurrent venous thromboembolism after an initial pulmonary embolism tends to be in the form of another pulmonary embolism (about 60% of cases), whereas recurrent venous thromboembolism after an initial DVT tends to be another DVT (about 80% of cases).[81] Consequently, the chance of dying of recurrent venous thromboembolism after anticoagulants are stopped appears to be at least twice as high after a pulmonary embolism as after a DVT; the difference in prognosis may favor indefinite treatment of selected patients after a first unprovoked pulmonary embolism.[34]

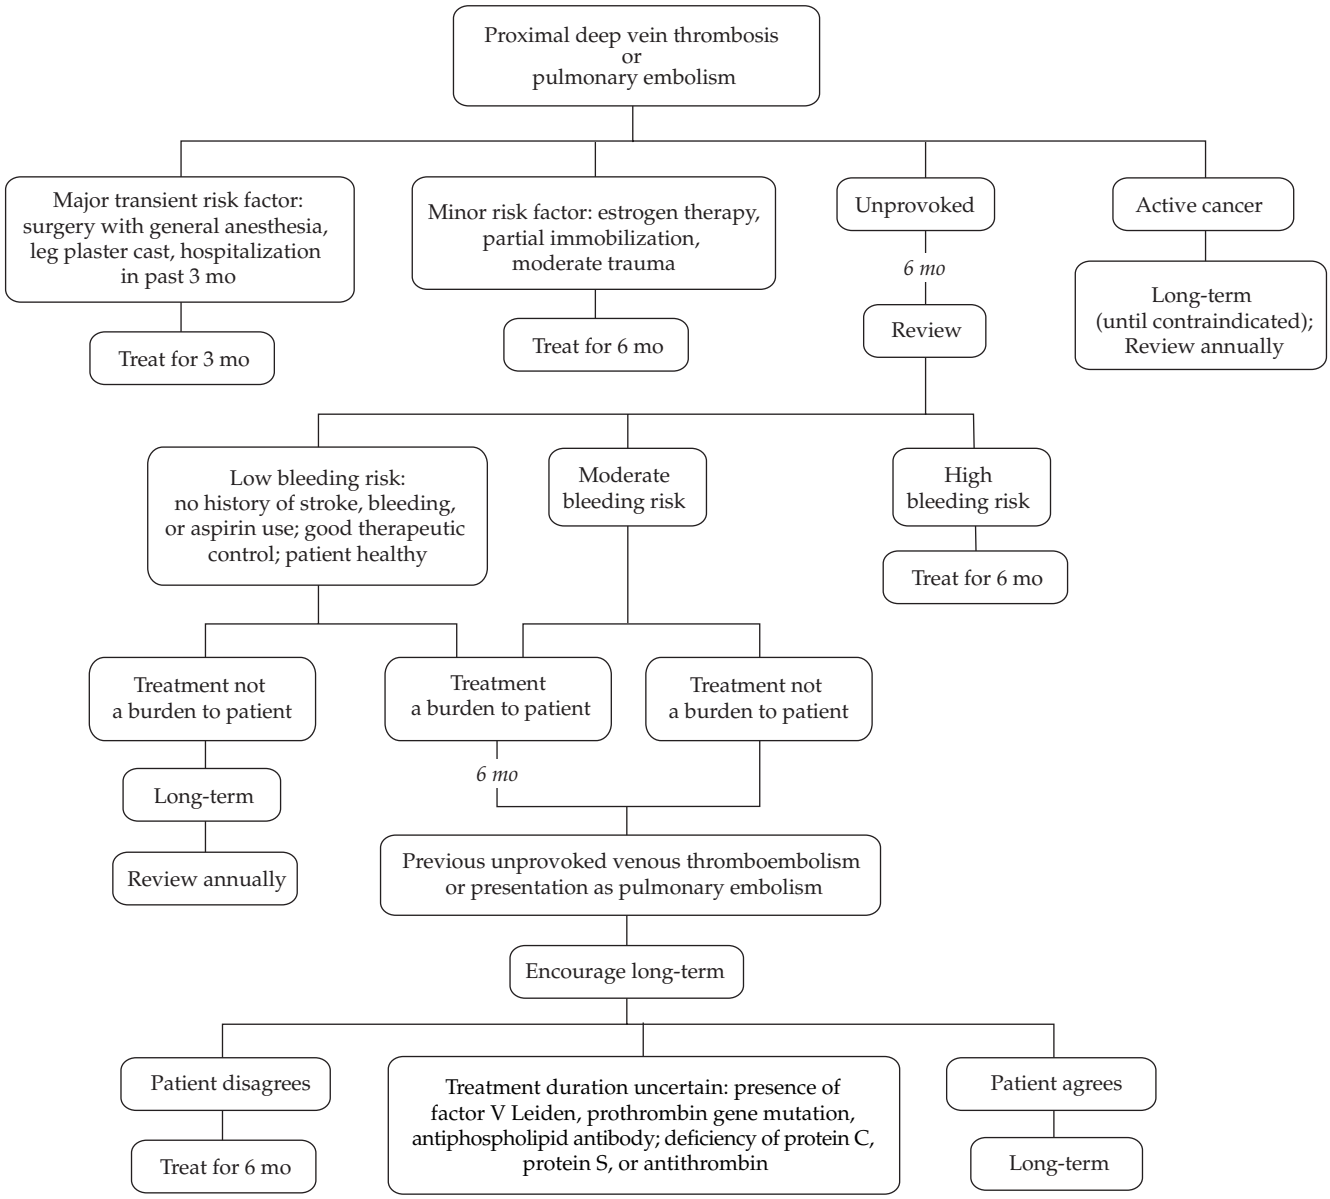

Figure 5 **Algorithm for selecting the duration of anticoagulation for venous thromboembolism.**

These findings permit the construction of an algorithm for selecting duration of anticoagulation for venous thromboembolism [*see Figure 5*]. Whether anticoagulant therapy (INR = 2.0 to 3.0) is recommended for 3 months, 6 months, or an indefinite period (with annual review) depends primarily on the presence of a provoking risk factor for venous thromboembolism (i.e., major or minor transient risk factor, no risk factor, or cancer), risk factors for bleeding, and patient preference (i.e., burden associated with treatment). Secondary factors are whether the patient has had a previous unprovoked venous thromboembolism, whether the venous thromboembolism presented as DVT or as pulmonary embolism, and whether the patient has biochemical risk factors for recurrent venous thromboembolism.

Thrombolytic therapy Thrombolytic therapy produces complete early lysis of acute venous thrombi in 30% to 40% of cases and partial lysis in an additional 30%; in contrast, complete early lysis of venous thrombi occurs in fewer than 10% of patients treated with heparin.[7,25,82] The risk of major bleeding, however, is about three times greater with thrombolytic therapy than with heparin.[25] The risk of hemorrhage increases with the duration of thrombolytic infusion. Hemorrhage often occurs at a site of previous surgery or trauma. Intracranial hemorrhage occurs in 1% to 2% of patients with pulmonary embolism who are treated with thrombolytic agents, which is a rate about five to 10 times higher than that seen in patients with pulmonary embolism who are treated with heparin.[83] Some evidence suggests that thrombolytic therapy with streptokinase reduces the incidence of postthrombotic syndrome,[25,82] but data from properly designed trials are lacking. The potential role of thrombolytic therapy in preventing late sequelae of pulmonary embolism is unknown.

Indications for Treatment

Anticoagulant therapy Most patients with proximal vein thrombosis, calf vein thrombosis, or symptomatic pulmonary

embolism should be treated first with high-dose heparin or LMWH and then with moderate-intensity oral anticoagulant therapy (INR = 2.0 to 3.0) for at least 3 to 6 months (see above).

Long-term anticoagulant therapy should be considered for patients with malignancy; recurrent unprovoked episodes of venous thromboembolism; unprovoked venous thromboembolism and homozygous factor V Leiden; deficiency of protein C, protein S, or antithrombin; an antiphospholipid antibody; or pulmonary embolism.[34] Risk of bleeding and patient preference also strongly influence the decision to use long-term therapy [*see Figure 5*].

Thrombolytic therapy Thrombolytic therapy is indicated in patients who have major pulmonary embolism with hemodynamic compromise (see above). A regimen of 100 mg of rt-PA administered over 2 hours is probably the method of choice because this regimen produces greater lysis at 2 hours than a 24-hour course of conventional urokinase[84] and, compared with heparin, produces more rapid clinical improvement in pulmonary vascular resistance and right ventricular function.[85,86]

The use of thrombolytic therapy in patients who have venous thrombosis is more controversial. Although there is no rigorous supporting evidence for it and it is not part of our clinical practice, regional or systemic thrombolysis may be considered in patients who have large proximal venous thrombi—particularly if the thrombi are confined to the iliac and femoral veins—provided that there are no contraindications.

Absolute contraindications to thrombolytic therapy include active internal bleeding, stroke within the past 3 months, and intracranial disease. Relative contraindications include major surgery within the past 10 days, recent organ biopsy, recent puncture of a noncompressible vessel, recent gastrointestinal bleeding, liver or renal disease, severe arterial hypertension, and severe diabetic retinopathy.

Surgical treatment Pulmonary endarterectomy may be beneficial in selected patients with thromboembolic pulmonary hypertension, which is estimated to occur in about 5% of patients who have undergone treatment of pulmonary embolism.[76] Urgent pulmonary embolectomy is reserved for patients with a saddle embolism lodged in the main pulmonary artery, those with massive embolism whose blood pressure cannot be maintained despite administration of thrombolytic therapy and vasopressor agents, or those in whom there is an absolute contraindication to thrombolytic therapy.[7]

Venous Thromboembolism in Pregnancy

The management of venous thromboembolism during pregnancy is complicated because clinical diagnosis is unreliable, some of the objective diagnostic tests are potentially risky to the fetus, and treatment may cause teratogenicity or fetal bleeding.[87,88]

DIAGNOSIS

In pregnant patients suspected of having venous thrombosis, venous ultrasonography should be used as the initial test.[6,88] If the result is abnormal, a diagnosis of proximal DVT is made and the patient is treated with anticoagulants. If venous ultrasound results are normal, we employ IPG or color Doppler to exclude an isolated iliac vein thrombosis. If both tests are normal, either a limited venogram can be performed to exclude isolated calf vein thrombosis, or serial compression ultrasonography can be performed on two occasions over the next 14 days.[6] MRI may also be considered.

The diagnostic approach to pulmonary embolism in pregnancy is similar to that used in nonpregnant patients. Lung scanning and pulmonary angiography can be performed, but the techniques should be modified to reduce exposure of the fetus to radiation.[88] Although there is little radiation exposure from ventilation-perfusion scanning, exposure can be reduced further without a serious loss of resolution by administering 50% of the standard dose of radioactive particles for perfusion lung scanning and by limiting ventilation scanning to patients with an abnormal perfusion scan. Fetal radiation exposure from pulmonary angiography can be reduced by using the brachial route for contrast injection and by shielding the abdomen with a lead-lined apron.

TREATMENT

The treatment of venous thromboembolism is much more complicated in pregnant patients because oral anticoagulants cross the placenta and, if administered during the first trimester, can cause warfarin embryopathy, which is characterized by nasal hypoplasia and skeletal abnormalities.[87,88] Warfarin administered during the second and third trimesters can cause dorsal midline dysplasia, abnormalities of the ventricular system, and optic atrophy.

Heparin does not cross the placenta and is much safer than oral anticoagulants during pregnancy. Although there have been reports associating heparin therapy during pregnancy with a high incidence of stillbirth or prematurity, most of these complications occurred in mothers receiving heparin for disorders that are known to be associated with a high rate of fetal loss. Other studies have shown that heparin is safe for the fetus but, when used on a long-term basis during pregnancy, can produce osteoporosis in the mother. The incidence of heparin-induced osteopenia diagnosed by dual-photon absorption x-ray or by conventional x-ray may be as high as 30%, but overt fractures are uncommon, occurring in fewer than 5% of patients. Heparin-induced bleeding is not a common problem during pregnancy, provided that heparin therapy is monitored carefully. The anticoagulant response to heparin can be prolonged if the drug is administered in high doses just before parturition, so there is the potential for local bleeding during and immediately after delivery.[87,88]

In pregnant patients with acute venous thromboembolism, continuous intravenous heparin or twice-daily LMWH should be administered for 4 to 7 days, followed by subcutaneous heparin or LMWH given in adjusted therapeutic doses for the remainder of the pregnancy.[89] The injection site should be rotated over the fatty tissue of the lower abdomen and thighs; the site should be compressed for 5 minutes after injection to prevent local bruising. An unwanted anticoagulant effect during delivery can be avoided by discontinuing subcutaneous heparin therapy 24 hours before elective induction of labor.[87,88]

If there is no evidence of excessive postpartum bleeding, heparin therapy can be resumed within 12 hours of delivery and continued until oral anticoagulation is established. The intensity of heparin therapy will depend on the amount of time that has passed since the diagnosis of venous thromboembolism was made: if the diagnosis was made less than 1 month ago, therapeutic doses may be used (with stepwise increases in subcutaneous or intravenous doses over 24 hours); if the diagnosis was made more than 1 month ago, prophylactic or intermediate doses of heparin may be used. Warfarin is started at the

same time as heparin and is continued for a minimum of 6 weeks and preferably until patients have received a minimum of 3 months of anticoagulation. Warfarin does not enter breast milk and therefore can be administered to nursing mothers.[87,88]
