Thrombosis of the subclavian or axillary veins may be idiopathic or may occur as a complication of local vascular damage.[90] It is now most frequently seen as a complication of chronic indwelling catheter use, but it also occurs as a complication after mastectomy and local radiotherapy for breast cancer. Idiopathic subclavian or axillary vein thrombosis often occurs in young muscular individuals and may be preceded by repetitive, strenuous activity involving the affected arm. Some of these persons have a fixed stenosis of the subclavian vein that is thought to be caused by external compression of the vein as it courses behind the clavicle. Occasionally, subclavian or axillary vein thrombosis can occur in patients with congenital deficiency of antithrombin, protein C, or protein S or in patients with antiphospholipid antibodies. Thrombosis of the axillary or subclavian vein or the superior vena cava is a rare complication of an implantable perivenous endocardial pacing system.

Subclavian or axillary thrombosis causes pain, edema, and cyanosis of the arm. In rare cases, the thrombosis extends into the superior vena cava and causes edema and cyanosis of the face and neck. Definitive diagnosis is made by venography or venous ultrasonography.[91] Subclavian or axillary vein thrombosis is usually treated with anticoagulants. Regional or systemic thrombolytic therapy may be considered in young patients without contraindications, because a substantial number of these patients experience aching and swelling when they exert the affected arm.

Mesenteric Vein

An uncommon disorder, mesenteric vein thrombosis usually occurs in the sixth or seventh decade of life. It generally involves segments of the small bowel, leading to hemorrhagic infarction. Affected patients often have associated disorders, such as inflammatory bowel disease, malignancy, portal hypertension, or familial thrombophilia or polycythemia vera, or they may have a history of recent abdominal surgery. In about 20% of cases, no underlying cause is found.

The clinical manifestations of mesenteric vein thrombosis include intermittent abdominal pain, abdominal distention, vomiting, diarrhea, and melena. Diagnosis of mesenteric vein thrombosis is often difficult, but the finding of blood-stained ascitic fluid on abdominal paracentesis or peritoneoscopic evidence of hemorrhagic bowel infarction is characteristic of the disorder. Management includes supportive care and surgical resection, followed by anticoagulant therapy. Mortality is about 20%, and up to 20% of patients experience recurrence.

Renal Vein

Renal vein thrombosis can be idiopathic or a complication of the nephrotic syndrome. Patients may be asymptomatic or may present with abdominal, back, or flank pain and tenderness. Pulmonary embolism is a relatively common complication of renal vein thrombosis. Anticoagulant therapy results in a gradual improvement in renal function, but patients may have long-standing proteinuria. Thrombolytic agents have been used, but the data are inadequate for critical appraisal of this form of treatment.

THROMBOPHILIA

The term thrombophilia denotes any increased tendency to thrombosis, whether inherited or acquired. Thrombophilia is discussed in detail elsewhere [*see 5:XIV Thrombotic Disorders*].

I CUTANEOUS MANIFESTATIONS OF SYSTEMIC DISEASES

Mark Lebwohl, m.d.

The cutaneous manifestations of systemic diseases are so numerous and varied that a single chapter could not cover them all, even in a cursory way. Instead, this chapter reviews key cutaneous manifestations of systemic diseases that should be recognized by most physicians, and it highlights recent developments in the diagnosis and management of such disorders. For fuller discussions of specific diseases, including their cutaneous manifestations, readers are referred to the chapters devoted to these conditions.

In many of the disorders presented in this chapter, workup and therapy of the underlying systemic condition are essential to a favorable outcome. A finding of cutaneous sarcoidosis, for example, should prompt a search for systemic sarcoidosis. In other conditions—for example, recessive dystrophic epidermolysis bullosa—treatment of the skin disorder is key to the management of the systemic disease.

Cardiopulmonary and Vascular Diseases

SARCOIDOSIS

The cutaneous manifestations of sarcoidosis are as varied as its systemic manifestations [*see 14:V Chronic Diffuse Infiltrative Lung Disease*]. Papules around the eyes or nose are most characteristic. The term lupus pernio refers to noncaseating granulomas that result in translucent, violaceous plaques of the ears, cheeks, and nose [*see Figure 1*]. Involvement of underlying bone can occur. Diagnosis is made by skin biopsy. Treatment with intralesional corticosteroids is traditional, and oral antimalarials and methotrexate have been used with success. More recently, infliximab has been successfully used for the treatment of sarcoidosis.[1] Other tumor necrosis factor–α (TNF-α) blockers such as etanercept have been used to successfully treat arthritis and skin lesions associated with sarcoidosis.[2] Infliximab has also been used to treat lupus pernio.[3]

There has been an increase in the use of interferon for the treatment of hepatitis C and multiple sclerosis, and a number of reports of sarcoidosis have been attributed to this treatment. Infliximab therapy has been found to effect a response in these cases.[4]

In some patients with sarcoidosis, erythema nodosum, characterized by deep, tender erythematous nodules, occurs on the lower extremities. Lupus pernio is associated with a more chronic course of sarcoidosis, whereas erythema nodosum indicates a more acute and benign disease.[5]

GRANULOMATOUS VASCULITIS

Wegener Granulomatosis

Wegener granulomatosis is associated with both distinctive and nonspecific mucocutaneous signs. Palpable purpura is one of the most common skin findings, but ulcers, papules, nodules, and bullae have also been described. In addition to upper and lower pulmonary symptoms [*see 14:IV Focal and Multifocal Lung Disease*], saddle-nose deformity, nasal ulcerations, and septal perforation should suggest the diagnosis of Wegener granulomatosis. Definitive diagnosis is made by demonstrating a necrotizing granulomatous vasculitis in a patient with upper and lower respiratory tract disease and glomerulonephritis. Cytoplasmic antineutrophil cytoplasmic autoantibodies (c-ANCA) are often present. Standard therapy is with cyclophosphamide and corticosteroids. TNF-α blockers have proved to be effective for some patients with refractory Wegener granulomatosis.[6]

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare, destructive, angiocentric disorder that results from Epstein-Barr virus–associated B cell lymphoproliferative disease.[7] This condition can be associated with skin lesions. Typically, patients develop erythematous papules or nodules that may or may not ulcerate.[8] This disorder is clinically distinguishable from Wegener granulomatosis by the absence of upper respiratory tract involvement. Diagnosis is established by demonstrating a granulomatous necrotizing infiltrate with atypical lymphoid cells around blood vessels. Lymphomatoid granulomatosis is usually fatal; however, rituximab has been used successfully to treat this condition.[9]

Churg-Strauss Syndrome

Churg-Strauss syndrome, or allergic granulomatous angiitis, most commonly presents as asthma and eosinophilia; however, related skin lesions develop in up to 40% of patients. Symmetrical, palpable purpura and petechiae of the lower extremities are the most common findings; these lesions show a leukocytoclastic vasculitis on skin biopsy. Cutaneous nodules caused by extravascular necrotizing granulomas and papules of the elbows also occur.[10] One of the clues to the diagnosis of this disorder is the presence of perinuclear antineutrophil cytoplasmic antibodies (p-ANCA).[11]

Figure 1 **Characteristic facial lesions of sarcoidosis, called lupus pernio, are shown.**

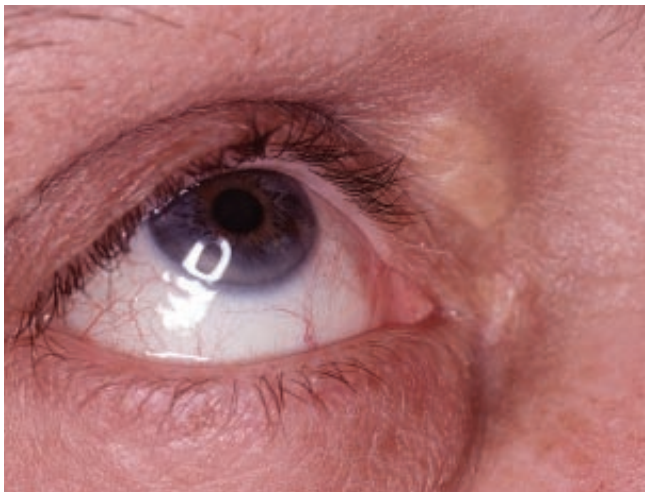

Figure 2 **Xanthelasma and arcus senilis are shown in a patient with hypercholesterolemia.**

HYPERLIPOPROTEINEMIA

Xanthomas are cutaneous manifestations of hyperlipoproteinemias. Several types of xanthomas occur with different lipid abnormalities. Xanthelasmas of the eyelids [*see Figure 2*] are the most common manifestations of familial hypercholesterolemia; however, in at least half the people who have eyelid lesions, plasma lipid levels are normal. Planar xanthomas are flat yellow plaques that can involve the palms, soles, neck, and chest. They can occur in patients with primary biliary cirrhosis or multiple myeloma. Tuberous xanthomas are large yellow or red nodules that appear on the extensor surfaces of joints, such as on the elbows and hands, but are not attached to underlying tendons. They can occur in patients with elevated triglyceride or cholesterol levels. In contrast, tendinous xanthomas, which can appear in patients with familial hypercholesterolemia, are fixed to underlying tendons of the elbows, ankles, knees, and hands. Eruptive xanthomas occur when plasma triglyceride levels suddenly become elevated. Skin lesions consist of small yellow papules that often resolve with lowering of triglyceride levels.

KAWASAKI DISEASE

Kawasaki disease, also called mucocutaneous lymph node syndrome [*see 15:VIII Systemic Vasculitis Syndromes*], is a disorder in children that can be complicated by coronary artery occlusion and myocardial infarction, coronary artery aneurysms, ECG abnormalities, cardiac arrhythmias, or myocarditis.[12] It has been suggested that a toxin secreted by *Staphylococcus aureus* is responsible for this disease, but proof of the precise cause remains elusive.[13] Diagnosis is based on clinical criteria that include fever, conjunctivitis, lymphadenopathy, and rash. In addition to a generalized erythematous eruption, abnormalities of the oral mucosa, as well as swelling and erythema of the hands and feet, may develop. Striking desquamation of the palms and soles ultimately occurs. Perianal and scrotal erythema and scaling are common as well. Thrombocytosis is a late finding, with platelet counts increasing to more than one million over 2 weeks after the onset of the disease. Approximately 15% to 25% of untreated children develop coronary artery aneurysms that may lead to sudden death.[14] Treatment with intravenous immunoglobulin reduces the frequency of coronary artery abnormalities.[15]

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum (PXE) is an autosomal recessively inherited disorder of elastic tissue caused by mutations in the ABCC6 transporter protein.[16] PXE is associated with a wide array of systemic manifestations. Angioid streaks, the ocular hallmark of PXE, are breaks in the Bruch membrane. Retinal bleeding and vision loss commonly occur. Calcification of the internal elastic laminae of arteries can result in bleeding or occlusion of these vessels. As a result, patients develop intermittent claudication on walking and occlusive coronary artery disease at an early age. Cardiac valvular abnormalities have also been described.[17] Skin lesions consist of yellow xanthomalike macules, papules, or redundant folds of skin in flexural areas, particularly the neck and axillae [*see Figure 3*]. Some patients may have systemic manifestations of PXE without clinically apparent skin lesions.[18] Diagnosis is established by biopsy of scar or normal-appearing flexural skin.[19] There is no therapy for the skin lesions associated with PXE.

RHEUMATIC FEVER

The two cutaneous manifestations of rheumatic fever are erythema marginatum and subcutaneous nodules. Erythema marginatum is a transient faint annular erythematous rash that often develops over joints [*see Figure 4*]. The subcutaneous nodules that appear with rheumatic fever are nontender, freely movable nodules measuring approximately 1 cm in diameter; they occur on the extensor surfaces of elbows, hands, or feet.

YELLOW NAIL SYNDROME

Yellow nail syndrome is caused by an abnormality of lymphatics [*see Figure 5*]. Affected patients develop lymphedema, usually of the legs, and pleural effusions. Pulmonary symptoms such as recurrent bronchitis are also common. Diagnosis is made by finding evidence of abnormal lymphatic function associated with yellow nails without other causes of nail pathology. Increased microvascular permeability with leakage of proteins may play a role in the development of the yellow nail syndrome.[20]

Endocrinologic Diseases

DIABETES MELLITUS

There are numerous cutaneous manifestations of diabetes mellitus [*see 9:VI Diabetes Mellitus*]. Acanthosis nigricans can occur in patients with diabetes and other endocrinopathies, such as Cushing syndrome, acromegaly, polycystic ovary syndrome, and thyroid disease. Insulin resistance is an underlying factor in several of the aforementioned endocrinopathies; it also may play a role in the development of acanthosis nigricans. Skin lesions consist of brown velvety patches in intertriginous areas, especially the neck and axillae [*see Figure 6*], and occur more commonly in obese patients with diabetes.[21] Acanthosis nigricans has also been associated with internal malignancies, particularly gastric adenocarcinoma or other gastrointestinal adenocarcinomas.

Necrobiosis lipoidica is a specific cutaneous manifestation of diabetes. Lesions consist of chronic atrophic patches with enlarging erythematous borders. The legs are most commonly affected. The centers of the lesions appear yellow because of subcutaneous fat that is visible through the atrophic dermis and epidermis. Occasionally, the lesions ulcerate. Necrobiosis lipoidica is often associated with diabetic nephropathy or retinopathy.[22]

Scleredema, another manifestation of diabetes, consists of induration of the skin of the back and posterior neck in obese pa-

Figure 3 **Xanthomalike papules are characteristic of pseudoxanthoma elasticum. The neck and axillae are the most common sites of involvement.**

Figure 4 **Transient annular erythematous rashes (erythema marginatum) typically occur in patients with rheumatic fever.**

Figure 5 **Yellow nails are a sign of underlying disease of the lymphatics in patients with yellow nail syndrome.**

Figure 6 **Acanthosis nigricans, a dark velvety acanthosis that can occur in patients with diabetes mellitus and other endocrine disorders, often appears on the neck.**

tients with type 2 (non–insulin-dependent) diabetes. Scleredema may improve if diabetes is controlled.[23] Less commonly, scleredema occurs in nondiabetic patients after streptococcal pharyngitis; in such patients, the disease is self-limited, resolving within 2 years of onset. High-dose corticosteroids,[24] radiation,[25] and ultraviolet-A1 irradiation (UVA1)[26] have all been used to treat scleredema.

Diabetic bullae, neuropathic ulcers, and so-called waxy skin and stiff joints occur in patients with diabetes. In the last condition mentioned, scleroderma-like induration of the skin over the dorsal aspect of the hands prevents full flexion or extension of the proximal interphalangeal joints.

Diabetic patients are prone to a number of infections, including erythrasma, a corynebacterial infection resulting in asymptomatic reddish-brown patches in intertriginous sites, especially the groin and axillae. Patients are also prone to staphylococcal infections and frequently develop furuncles and carbuncles. Candidal infections are another risk, particularly when blood glucose levels are poorly controlled.

GRAVES DISEASE

Graves disease consists of a triad of exophthalmos, hyperthyroidism, and pretibial myxedema [*see 3:I Thyroid*]. Pretibial myxedema presents as skin-colored nodules and plaques that extend from the pretibial area down to the dorsa of the feet. Lesions often develop after treatment of hyperthyroidism, although they can occur at any stage in the evolution of Graves disease.

Onycholysis, the separation of the nail plate from the nail bed, occurs in many patients with hyperthyroidism. Other autoimmune skin diseases, such as vitiligo and alopecia areata, are increased in patients with Graves disease. Manifestations of thyroid disease include the stigmata of hypothyroidism. Patients can develop alopecia; specifically, they can lose the lateral third of the eyebrows. Edematous thickening of the lips, tongue, and nose occur as well.

Gastrointestinal Diseases

Patients with any of a number of gastrointestinal diseases may present with cutaneous manifestations; similarly, patients

Figure 7 **Aphthous stomatitis is a common finding in patients with ulcerative colitis.**

Figure 8 **Pyoderma gangrenosum is characterized by ulcers that begin with craterlike holes draining pus.**

Figure 9 **The patient's nose and cheeks are covered with small papules called trichilemmomas, which represent the cutaneous hallmark of Cowden disease.**

with certain cutaneous diseases can develop gastrointestinal complications.

CARCINOID SYNDROME

The carcinoid syndrome is characterized by episodic flushing that can be associated with abdominal pain, diarrhea, and wheezing. Ninety percent of carcinoid tumors originate in the gastrointestinal tract; however, bronchial carcinoids occur occasionally. Less common cutaneous manifestations of carcinoid tumors include sclerodermatous changes. Cutaneous metastases present as deep nodules; hyperkeratosis may occur; and the patient may experience pigmentation changes similar to those seen in pellagra.

INFLAMMATORY BOWEL DISEASE

There are several specific and nonspecific cutaneous manifestations of inflammatory bowel disease [*see 4:IV Inflammatory Bowel Diseases*]. In both Crohn disease and ulcerative colitis, disease can progress to a hypercoagulable stage, causing venous and arterial thromboses that can lead to loss of digits and limbs. Aphthous stomatitis is another nonspecific manifestation of inflammatory bowel disease [*see Figure 7*]. In patients with Crohn disease, the lesions may appear as noncaseating granulomas, whereas in patients with ulcerative colitis, they may be indistinguishable from canker sores.

Pyoderma gangrenosum occurs in patients with Crohn disease and ulcerative colitis and has also been reported in patients with chronic active hepatitis, rheumatoid arthritis, and a number of myeloproliferative disorders. The lesions are distinguishable from other ulcers by the presence of craterlike holes, pustules, and purulent drainage [*see Figure 8*]. Pyoderma gangrenosum may occur at sites of trauma. Treatment with intralesionally injected or systemic corticosteroids may be required. Immunosuppressive agents such as cyclosporine have proved to be dramatically effective; in refractory cases, thalidomide has been shown to be beneficial.[27] Infliximab has proved to be highly effective in the treatment of refractory pyoderma gangrenosum.[28]

Erythema nodosum is a septal panniculitis that is associated with a number of conditions, including Crohn disease, ulcerative colitis, Behçet syndrome, sarcoidosis, infection, and the ingestion of estrogens and other drugs. Other manifestations of Crohn disease include inguinal abscesses and sinuses and anal fistulas.

Figure 10 **The primary lesions of herpetiformis are vesicles that quickly break to form crusts and erosions.**

METASTATIC CROHN DISEASE

The term metastatic Crohn disease refers to histologically proven noncaseating granulomas that are remote from the gastrointestinal tract in patients with Crohn disease. The clinical presentation can be quite variable, and the diagnosis of this disorder is frequently missed. In some cases, patients present with marked swelling of the scrotum or vulva.

CUTANEOUS CONDITIONS WITH GASTROINTESTINAL COMPLICATIONS

Cowden Disease

Cowden disease is an autosomal dominant disorder in which gastrointestinal polyps develop along with numerous skin lesions. This disease has been attributed to mutations of the tumor suppressor gene *PTEN*.[29] Wartlike papules known as trichilemmomas occur, particularly around the nose, mouth, and ears but

also on the hands and feet [*see Figure 9*]. Small papules can also develop on the gingival mucosa, creating a cobblestone appearance. Hemangiomas and lipomas can occur.[30] A distinctive nodule of the scalp known as Cowden fibroma has been described. Up to 50% of women with Cowden disease develop breast cancer, a finding that has been associated independently with the *PTEN* mutation.[31] Thyroid carcinomas, thyroid adenomas, and thyroid goiters can occur as well.

Dermatitis Herpetiformis

Dermatitis herpetiformis is an immunobullous disease that is associated with a gluten-sensitive enteropathy [*see 2:IX Vesiculobullous Diseases*]. Skin lesions begin as vesicles that are so pruritic that they are quickly broken by scratching, leaving only excoriations and crusts [*see Figure 10*]. Like patients with celiac disease who are not on a gluten-free diet, patients with dermatitis herpetiformis have an increased risk of gastrointestinal lymphoma.[32]

Peutz-Jegher Syndrome

In Peutz-Jegher syndrome, patients develop hamartomatous polyps of the small intestine that are associated with pigmented macules of the lips and oral mucosa [*see 2:X Malignant Cutaneous Tumors*]. Also, pigmented macules can develop on the palms, fingers, soles, and toes and in areas around the mouth, nose, and rectum. The disease is inherited as an autosomal dominant trait, and a significant proportion of cases are associated with mutations in the serine/threonine protein kinase I1/LKB1 (*STKI1/LKB1*) gene, although mutations in this gene do not account for all cases.[33]

Recessive Dystrophic Epidermolysis Bullosa

Recessive dystrophic epidermolysis bullosa is a congenital bullous disease with recurrent blistering and scarring, particularly on the hands and feet [*see 2:IX Vesiculobullous Diseases*]. The scarring results in pseudosyndactyly, giving rise to mitten-like hands. Ingestion of coarse food can result in mucosal bullae of the esophagus, which heal with scarring and stricture formation. Dysphagia is a frequent complaint. Scarring of the esophagus can lead to squamous cell carcinoma, which is a leading cause of death in this disorder.[34] Gastroenterologists and dermatologists must play key roles in the management of these patients. Liquid and pureed diets and appropriate skin care are essential to the survival of patients with this debilitating disorder. Prenatal diagnosis can be made by sampling DNA from the chorionic villus.[35] All forms of dystrophic epidermolysis bullosa have been attributed to mutations in the type VII collagen gene.[36] Recently, through the use of a self-inactivating minimal lentivirus-based vector, the type VII collagen gene has been delivered and type VII collagen expressed in immunodeficient mice, suggesting the possibility that, in the future, gene therapy may be available to successfully treat this devastating disorder.[37]

Hematologic Diseases

AMYLOIDOSIS

There are several forms of local and systemic amyloidosis [*see 12:XV Chronic Lymphoid Leukemias and Plasma Cell Disorders*]. In a form associated with multiple myeloma, amyloid fibrils consisting of immunoglobulin light chains are deposited in the skin. Shiny translucent papules develop, particularly on the eyelids. Because of amyloid deposits in blood vessels, spontaneous bleeding occurs. Minimal trauma results in petechiae and purpura. Macroglossia also occurs in some patients with myeloma-associated amyloidosis and in some with primary systemic amyloidosis. The systemic manifestations of myeloma-associated and primary systemic amyloidosis are quite varied. Hepatomegaly develops in 50% of patients. Amyloid can affect the heart, resulting in heart failure or myocardial infarction. Survival of patients who undergo heart transplantations for cardiac amyloidosis is lower than survival after cardiac transplantation for other indications.[38] Amyloidosis of the gastrointestinal tract can result in malabsorption and protein-losing enteropathy. Treatment with thalidomide (up to 400 mg daily) and intermittent dexamethasone is rapidly effective in some patients, but side effects are frequent.[39]

MASTOCYTOSIS

Mastocytosis is caused by the infiltration of mast cells into the skin and other organs [*see 4:XI Diseases Producing Malabsorption and Maldigestion*]. Urticaria pigmentosa refers to the skin lesions that occur in most patients with mastocytosis. Reddish-brown macules and papules resembling nevi are characteristic [*see Figure 11*]. Stroking of individual lesions results in urticarial wheals—a phenomenon known as the Darier sign. Pruritus, flushing, abdominal pain, nausea, vomiting, and diarrhea are common complaints.

Most patients with mastocytosis have an indolent form of the disease, even when mast cells have infiltrated the bone marrow.[40] Malignant or aggressive systemic mast cell disease can involve the spleen, liver, and lymph nodes in addition to the skin and bone marrow. Histologically, infiltrates contain atypical nonmetachromatic mast cells that are monoclonal in some patients.[41] Children with urticaria pigmentosa usually have a better prognosis than adults with the disease.[42]

The diagnosis of mastocytosis is made by the demonstration of mast cells on skin biopsy. Because mast cells easily degranulate, making them difficult to identify, biopsies should be performed with a minimum of tissue manipulation.

PORPHYRIAS

The porphyrias result from defective hemoglobin synthesis, leading to excess porphyrins in the blood and in body tissues [*see 9:V The Porphyrias*].

Figure 11 **Multiple brown macules resembling nevi occur in patients with urticaria pigmentosa.**

Congenital Erythropoietic Porphyria

Congenital erythropoietic porphyria is a rare autosomal recessive disorder that has been attributed to mutations in the gene for uroporphyrinogen III synthase.[43] This condition is characterized by severe photosensitivity. Vesicles and bullae develop after sun exposure; these lesions heal with scar formation. Erythrodontia (red-stained teeth) is a characteristic feature [*see Figure 12*]. Digit, ear, and nose loss is common in patients who manage to survive to adulthood [*see Figure 13*]. Hypertrichosis is another frequent complication. Formation of gallstones, splenomegaly, and hemolytic anemia are also associated with this condition.

Porphyria Cutanea Tarda

Porphyria cutanea tarda is characterized by photosensitivity, vesicle formation (especially on the dorsa of the hands) [*see Figure 14*], and hypertrichosis. The condition may be associated with ingestion of alcohol or medications such as estrogens. Diagnosis of the porphyrias can be established by elevated urinary porphyrin levels. Examination of the urine with a Wood lamp will often reveal pink-red fluorescence attributable to the high level of urinary porphyrins. Porphyria cutanea tarda can be associated with hepatitis C. Phlebotomy is effective therapy.

Figure 12 **A reddish pigmentation (erythrodontia) occurs when porphyrins are deposited in the teeth in congenital erythropoietic porphyria.**

Figure 13 **Skin changes in congenital erythropoietic porphyria can be severe; scarring and loss of digits are common in older patients.**

Immunodeficiency Diseases

AIDS

AIDS may result in cutaneous infections and neoplasms that are often dramatic in their extent and severity. This section focuses on selected cutaneous manifestations of infections and other diseases associated with AIDS. (For a more comprehensive discussion of disorders associated with HIV infection, see *7:XXXIII HIV and AIDS* and other chapters devoted to specific conditions.)

Opportunistic Infections

Viral infections Banal viral infections, such as molluscum contagiosum, that are ordinarily self-limited and easily curable have become widespread, chronic, and enormous problems in patients with AIDS. These umbilicated white papules, ordinarily only a few millimeters in diameter, can reach diameters of 1 to 2 cm in patients with AIDS. Similarly, condyloma acuminatum, caused by human papillomavirus (HPV) infection, is often difficult to treat in patients with AIDS.

Herpes simplex virus infections become chronic and erosive, forming large, nonhealing ulcers [*see 7:XXVI Herpesvirus Infections*]. Acyclovir-resistant strains of herpes simplex virus have been reported in some patients with AIDS[44]; these patients require other antiviral agents, such as foscarnet. Mutations in thymidine kinase and DNA polymerase genes of herpes simplex viruses can render them resistant to acyclovir and foscarnet.[45] Topical cidofovir gel has been reported to be beneficial for herpes infections in patients infected with HIV.[46]

Herpes zoster infections are a common sign of HIV infection. In the non–HIV-infected host, herpes zoster is characterized by grouped vesicles in a dermatomal distribution. The eruption is self-limited, resolving within 1 to 2 weeks. In contrast, herpes zoster infection can develop into a disseminated vesicular eruption in patients with AIDS; and in some AIDS patients, chronic herpetic lesions develop and last for months.

Fungal infections Fungal infections are common in patients with HIV infection. Monilial infections include oral thrush and candidiasis of the groin. Several fungal infections that rarely cause widespread infection in patients with normal immune systems (e.g., cryptococcosis, histoplasmosis, aspergillosis, and sporotrichosis) have emerged as serious pathogens in patients with AIDS.

Bacterial infections Bacterial infections are more frequent and severe in patients with AIDS than in patients with normal immune systems. Bacillary angiomatosis, caused by *Bartonella henselae,* presents as purple papules and nodules that can be mistaken for Kaposi sarcoma (see below). Chronic fever and chills can occur, as can bone lesions. Epidemiologic evidence suggests that cats may be the source of human infection.[47] Diag-

nosis by serologic testing has been commonly used, but in the future, polymerase chain reaction may offer a rapid and convenient way of establishing this diagnosis.[48] The condition resolves upon treatment with oral antibiotics [*see 7:XI Infections Due to Brucella, Francisella, Yersinia pestis, and Bartonella*].

Scabies and other pruritic eruptions Scabies, a severely pruritic eruption, has a predilection for the buttocks, the genitals, the periumbilical area, and the webs between the fingers. Norwegian scabies, a thickly crusted psoriasislike form of the parasitic disease, has been described in patients with Down syndrome and in other immunosuppressed persons. In recent years, Norwegian scabies has been reported most commonly in patients with AIDS. The scales of Norwegian scabies contain thousands of mites that are easily seen with the microscope. Burrows form linear lesions up to 1 cm long. The causative mite, *Sarcoptes scabiei,* can be identified by microscopic examination of scrapings from the burrows.

Eosinophilic pustular folliculitis and papular eruption of AIDS are pruritic rashes that affect patients with HIV infection. It has been suggested that pruritic papular eruption in patients with HIV infection may represent a reaction to arthropod bites.[49]

Figure 14 **Crusting and scarring follow the appearance of vesicles and bullae in porphyria cutanea tarda.**

Figure 15 **Kaposi sarcoma is the most common malignancy of AIDS patients. It often presents as purple patches, plaques, or papules. Purple macules on the foot can be seen in patients with classic Kaposi sarcoma but are seen here in a patient with AIDS-related Kaposi sarcoma.**

Both eosinophilic pustular folliculitis and papular eruption of AIDS are characterized by severe itching, and skin-colored papules and excoriations are common in both. Patients with eosinophilic pustular folliculitis can develop pustules and erythematous papules. Both conditions respond to treatment with ultraviolet B.

Kaposi Sarcoma

Kaposi sarcoma, a slowly progressive vascular neoplasm, was originally described in elderly Italian and Jewish men [*see 2:X Malignant Cutaneous Tumors*]. Subsequently, a more rapidly progressive form of the disorder was described in immunosuppressed patients with lymphomas and in kidney transplant patients on immunosuppressive drugs. An aggressive form has been described in patients with AIDS [*see Figure 15*]. Classic Kaposi sarcoma typically affects the lower extremities and only gradually progresses to other sites. In contrast, AIDS-related Kaposi sarcoma can occur on any surface of the body, including mucous membranes. Human herpesvirus type 8 has been implicated in both classic and AIDS-related Kaposi sarcoma.[50] Treatments include radiation therapy, cryotherapy, and intralesional injection with vinblastine; systemic chemotherapy can also be effective. In patients with AIDS, Kaposi sarcoma is best treated with antiretroviral regimens.

Oral Hairy Leukoplakia

Oral hairy leukoplakia, another condition that has been described in HIV-infected patients, consists of linear white papules on the lateral surfaces of the tongue that result in the so-called hairy appearance. Oral hairy leukoplakia can be distinguished from oral thrush in that the lesions cannot be rubbed off, as they can be in thrush.

Thanks to the development of effective antiretroviral therapy, the frequency of opportunistic infections in patients with HIV infection has diminished markedly.

OTHER IMMUNODEFICIENT STATES

Other inherited or acquired immunodeficiency states share a number of clinical features. Susceptibility to monilial infections or bacterial infections is increased in disorders such as chronic granulomatous disease and chemotherapy-induced neutropenia. Oral ulcers similarly occur in cyclic neutropenia and in chemotherapy-induced immunosuppression.

Some immunosuppressive drugs have characteristic cutaneous effects. Corticosteroids, when used long-term, cause vascular fragility, resulting in steroid purpura. They can also cause cutaneous atrophy, formation of striae, and acneiform eruptions. Cyclosporine is associated with hypertrichosis. Aphthous stomatitis is a characteristic effect of numerous immunosuppressive drugs, particularly agents that suppress bone marrow function. Chronic immunosuppression can lead to the development of lymphoma and nonmelanoma skin cancer. Avoidance of excessive exposure to sunlight may prevent development of the latter.

Infectious Diseases

Cutaneous manifestations can be major features of a number of systemic infections; for example, patients with overwhelming septicemia can develop disseminated intravascular coagulation (DIC), which results in cutaneous infarcts and hemorrhage into the skin. Key cutaneous features of selected systemic infections follow.

INFECTIVE ENDOCARDITIS

The cutaneous manifestations of infective endocarditis include petechiae, splinter hemorrhages (linear red streaks under the nail), Osler nodes (tender purpuric nodules on the finger pads and toes), and Janeway lesions (nontender purpuric macules of the palms and soles). Skin lesions are caused by either septic emboli or vasculitis. Treatment of the underlying infection results in resolution of the cutaneous manifestations [*see 7:XVIII Infective Endocarditis*].

STAPHYLOCOCCAL TOXIC-SHOCK SYNDROME

Staphylococcal toxic-shock syndrome was first recognized in menstruating women who used superabsorbent tampons [*see 7:I Infections Due to Gram-Positive Cocci*]. It is caused by an exotoxin produced by certain strains of *S. aureus*.[51] Staphylococcal infections in bone, soft tissue, and other sites have been implicated. Patients develop diffuse sunburnlike erythema, with swelling of the hands and feet, followed by desquamation of the palms and soles. Erythema of mucous membranes, fever, and hypotension also occur. Gastrointestinal symptoms, impaired renal function, elevated liver function values, thrombocytopenia, and myositis can develop.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Staphylococcal scalded skin syndrome (SSSS) is caused by a circulating exfoliative toxin produced by *S. aureus* phage group 11. Generalized bulla formation with large areas of desquamation is characteristic of the disorder. Along with tenderness, erythema, and exfoliation of skin, patients have fever. The source of the staphylococcal infection is not always apparent; occasionally, the infection arises in a wound or in an occult abscess. Because the staphylococcal infection is usually remote from the affected skin, culture of the skin does not grow *S. aureus*.

SSSS must be differentiated from toxic epidermal necrolysis. Toxic epidermal necrolysis commonly affects adults and involves mucous membranes; SSSS usually affects children and spares mucous membranes. In addition, toxic epidermal necrolysis can last for several weeks and has a high mortality, whereas SSSS lasts a few days and usually has a good outcome. Histologically, SSSS shows bulla formation in the upper epidermis, and the bulla cavity contains free-floating, normal-appearing, acantholytic cells. In toxic epidermal necrolysis, bulla formation occurs at the basal layer of the epidermis, and the epidermal cells are necrotic. Treatment with antibiotics effective against *S. aureus* eliminates the underlying cause of SSSS.

NECROTIZING FASCIITIS

Necrotizing fasciitis is caused by a mixed anaerobic infection of an ulcer or a surgical or traumatic wound. The affected skin is erythematous, warm, and tender and develops hemorrhagic bullae that rupture to form rapidly enlarging areas of gangrene that extend down to the fascia. Surgical debridement is essential for this life-threatening infection.[52]

MENINGOCOCCEMIA

Acute meningococcemia can occur either in epidemics or in isolated cases [*see 7:III Infections Due to Neisseria*]. Fever, headache, and a hemorrhagic rash develop. If untreated, patients develop DIC, with extensive hemorrhage, hypotension, and ultimately death. The causative organism, *Neisseria meningitidis*, is usually identified in cerebrospinal fluid but can also be identified by smear or cultures of skin lesions or by blood cultures.

Figure 16 **Several weeks after primary infection with Lyme disease, hematogenous dissemination of spirochetes results in multiple patches of erythema chronicum migrans.**

Treatment with antibiotics and supportive care are essential aspects of therapy.

SCARLET FEVER

Scarlet fever begins with pharyngitis caused by group A *Streptococcus* [*see 7:I Infections Due to Gram-Positive Cocci*]. A generalized rash develops 1 to 2 days after onset of the pharyngitis. The rash is characterized by pinpoint erythematous papules that may be easier to palpate than to see. Other characteristic lesions include a white strawberry tongue and linear petechial macules occurring in body folds (Pastia lines). As the rash fades, desquamation of the palms and soles appears. Treatment with penicillin results in rapid resolution of all symptoms.

VIBRIO INFECTION

Vibrio vulnificus infection arises from minor trauma sustained while swimming in lakes or the ocean or while cleaning seafood. Cellulitis occurs, with lymphangitis and bacteremia. In patients with hepatic cirrhosis, infection can occur after eating raw oysters. These patients develop hemorrhagic bullae, with leukopenia and DIC.[53] Treatment with antibiotics is necessary; management of complications may require intensive supportive care.

LYME DISEASE

Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is transmitted primarily by the tick *Ixodes scapularis* [*see 7:XVII Infections Due to Rickettsia, Ehrlichia, and Coxiella*]. The characteristic skin lesion, erythema chronicum migrans, begins as an erythematous macule or papule at the site of the tick bite. Over days and weeks, the erythematous lesion expands to form a red ring, often with central clearing. If left untreated, lesions last weeks or months. Hematogenous dissemination of spirochetes occurs after several weeks, resulting in multiple annular patches of erythema chronicum migrans [*see Figure 16*]. Systemic complications include an acute arthritis involving one or a few large joints a few weeks after the onset of symptoms. A chronic erosive arthritis develops in approximately 10% of patients. Neurologic symptoms, including Bell palsy, can occur, as can cardiac complications, including heart failure and cardiac conduction abnormalities.

Lyme disease can be prevented by the removal of ticks within 18 hours of attachment. Once symptoms have developed, oral

antibiotics are effective at destroying *B. burgdorferi*. A vaccine containing a genetically engineered protein from the surface of the bacteria was found to prevent infection in most vaccinated people[54]; however, for a number of reasons, including lack of demand, the vaccine has been discontinued.[55]

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF) is a tick-borne illness caused by *Rickettsia rickettsii* [*see 7:XVII Infections Due to Rickettsia, Ehrlichia, and Coxiella*]. It is characterized by the sudden onset of fevers, chills, and headache. Approximately 4 days later, a characteristic erythematous rash develops on the wrists and ankles and becomes purpuric. The rash then spreads centrally to involve the extremities, trunk, and face.

Because the mortality of RMSF is high, patients should be treated immediately with intravenous chloramphenicol or tetracycline if RMSF is suspected. Diagnosis can then be established by skin biopsy: immunofluorescence with antibodies against *R. rickettsii* shows the organism in the walls of cutaneous blood vessels. Serologic tests, such as the Weil-Felix reaction, can confirm the diagnosis after the acute phase of the illness.

Neurologic Diseases

BASAL CELL NEVUS SYNDROME

The basal cell nevus syndrome is an autosomal dominant disorder attributed to mutational inactivation of the *PTCH* gene[56] in which patients develop basal cell carcinomas at an early age [*see 2:X Malignant Cutaneous Tumors*]. Multiple skeletal abnormalities are associated with the syndrome, and affected individuals may also develop jaw cysts. Lamellar calcification of the falx cerebri occurs, as well as other neurologic abnormalities, including medulloblastomas.

EPIDERMAL NEVUS SYNDROME

The epidermal nevus syndrome is characterized by systemic manifestations, such as seizures, mental retardation, blindness, and skeletal abnormalities in association with large epidermal nevi. The nevi consist of long pigmented streaks that are linear or whirled and involve large areas of the body [*see Figure 17*].

INCONTINENTIA PIGMENTI

Incontinentia pigmenti is an inherited syndrome that affects the skin and nervous system. Mutations in the *NEMO* gene, an essential component of the nuclear factor–κB signaling cascade, account for 85% of cases.[57] The inheritance pattern is X-linked dominant and is lethal in male fetuses. The first skin manifestations begin within weeks after birth, occasionally occurring in utero, and consist of linear patterns of vesiculobullous lesions. Within weeks, these lesions evolve into verrucous papules and, eventually, into pigmented whirls. Apart from neurologic symptoms, patients may have ocular abnormalities, scarring alopecia, and skeletal malformations.

Hypomelanosis of Ito

Hypomelanosis of Ito, also called incontinentia pigmenti achromians, consists of whirls of hypopigmentation that are associated with neurologic symptoms in 50% of patients. Skin lesions are present at birth or develop in early childhood. In addition to seizures and mental retardation, skeletal and ocular abnormalities occur.

NEUROFIBROMATOSIS

Neurofibromatosis is a common autosomal dominant disorder involving the skin and nervous system [*see 2:XI Benign Cutaneous Tumors*]. Skin lesions include cutaneous neurofibromas, which are soft, skin-colored nodules that are often pedunculated [*see Figure 18*]. Café au lait macules are flat, evenly pigmented patches up to several centimeters in diameter. Six or more café au lait macules greater than 1.5 cm in diameter are found in most patients with neurofibromatosis type 1 (also called von Recklinghausen disease). Plexiform neuromas are larger, deeper tumors that are associated with hypertrophy of bony and soft tissues. In a small proportion of tumors, neurofibrosarcomas will arise. On skin biopsy, café au lait macules are found to contain macromelanosomes—giant granules of pigment in melanocytes and keratinocytes. Axillary and inguinal freckling also appear as pigmented macules that resemble small café au lait spots in intertriginous sites. Lisch nodules—pigmented iris hamartomas—are also found in most patients with neurofibromatosis.

Several variants of neurofibromatosis exist, including segmental neurofibromatosis, in which patients develop a segmental distribution of café au lait spots and cutaneous neurofibromas, and neurofibromatosis type 2, which consists of acoustic neuromas, schwannomas, and meningiomas without Lisch nodules and with fewer café au lait macules than appear in type 1. Patients with neurofibromatosis type 2 may have some cutaneous neurofibromas as well. Neurofibromatosis types 1 and 2 are caused by different genetic defects. Neurofibromatosis type 1 is caused by mutations in the *NF1* gene for neurofibromin on chromosome 17.[58] Neurofibromatosis type 2 has been attributed to inactivating mutations in the *NF2* tumor suppressor gene whose product, merlin, plays a number of roles in tumorigenesis.[59]

SNEDDON SYNDROME

Sneddon syndrome is a disease of the skin and nervous system caused by occlusion of small to medium-sized arteries in persons younger than 45 years. The skin lesions resemble livedo reticularis and have been called livedo racemosa. Transient ischemic attacks or strokes are common. Definitive diagnosis is made by demonstrating characteristic vascular changes on skin biopsy of patients with associated neurologic findings.

TUBEROUS SCLEROSIS

Tuberous sclerosis is an autosomal dominant disease that affects the skin and nervous system. Mutations that inactivate the *TSC1* or *TSC2* tumor suppressor genes affect the respective gene products, hamartin and tuberin, leading to tuberous sclerosis.[60] Affected patients can develop seizures, mental retardation, and brain lesions called tubers, which can be seen on CT scans. Adenoma sebaceum, the most characteristic cutaneous manifestation of tuberous sclerosis, consists of skin-colored papules of the face [*see Figure 19a*]. Other skin lesions are hypopigmented macules referred to as ash-leaf macules [*see Figure 19b*], smaller hypopigmented lesions called confetti macules, periungual and subungual fibromas (skin-colored nodules that arise around the fingers and toenails) [*see Figure 19c*], and the shagreen patch (a skin-colored plaque made of thick dermal connective tissue).

Renal Diseases

FABRY DISEASE

Fabry disease is caused by an abnormality of α-galactosidase

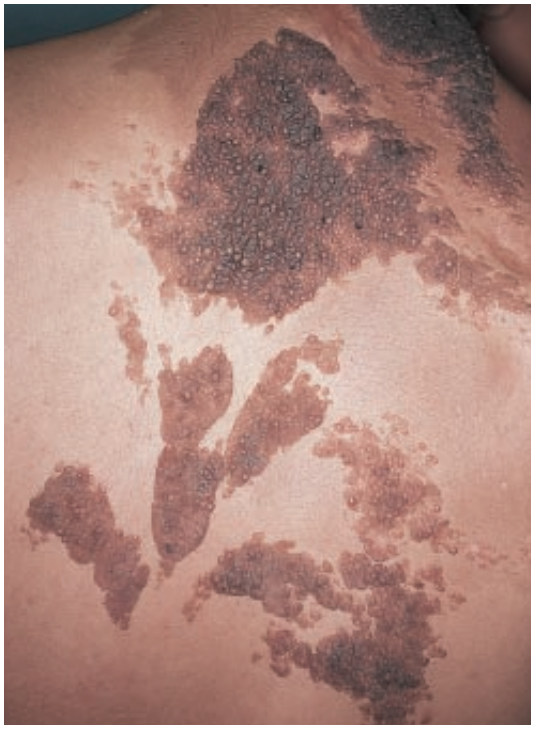

Figure 17 **The epidermal nevus syndrome is characterized by linear or whirled streaks of pigmentation that involve large areas of the body.**

Figure 18 **Axillary freckling, café au lait spots, and neurofibromas are evident in a patient with neurofibromatosis type 1.**

A, resulting in deposition of glycosphingolipids in body tissues. The disorder is inherited as an X-linked recessive trait. A variety of different mutations in the gene for α-galactosidase A have been found in unrelated families with Fabry disease.[61] Affected males often complain of severe pain in the extremities, with burning of the palms and soles. Episodes of pain are transient, but patients complain of persistent paresthesias in the hands and feet.

Skin lesions consist of angiokeratomas, which are pinpoint red or purple papules that resemble cherry hemangiomas [*see Figure 20*]. Angiokeratomas are most commonly found in the periumbilical area but can also occur on the palms, soles, trunk, extremities, and mucous membranes. In adults, glycosphingolipids become deposited in blood vessels and organs, affecting the heart, heart valves, coronary arteries, and kidneys. Replacement therapy with recombinant human α-galactosidase A can improve cutaneous, gastrointestinal, neurologic, and psychiatric symptoms; it has been shown to be safe and can eliminate substrate storage of glycosphingolipids, but questions remain regarding optimal dosing.[62]

POLYARTERITIS NODOSA

Polyarteritis nodosa is an inflammatory condition that affects muscular arteries [*see 15:VIII Systemic Vasculitis Syndromes*]. Aneurysms form in many arteries, including those leading to the kidneys and subcutaneous tissue. Diagnosis of the systemic form of polyarteritis can be made by demonstrating aneurysms of the renal arteries on renal arteriograms.

A localized cutaneous form of polyarteritis nodosa most commonly presents as painful nodules of the lower extremi-

Figure 19 **Several of the characteristic cutaneous findings of tuberous sclerosis are shown: adenoma sebaceum (*a*); ash-leaf macule (*b*); and periungual fibromas (*c*).**

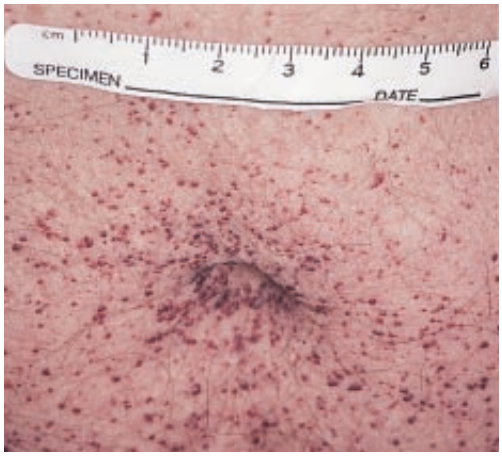

Figure 20 **Angiokeratomas are particularly common in the periumbilical area of patients with Fabry disease.**

ties.[63] In mild cases, patients may only have livedo reticularis; but in severe cases, skin lesions can ulcerate. A polyneuropathy may be associated with the disorder. Patients with classic polyarteritis and microaneurysms have an increased incidence of hepatitis B antigenemia; in contrast to patients with other vasculitides, they usually do not have antineutrophil cytoplasmic antibodies.[64]

PERFORATING DISORDERS

Perforating disorders include several conditions characterized by extrusion of dermal material through the epidermis. These lesions often develop in association with renal failure and diabetes mellitus.[65] Skin lesions are characterized by hyperkeratotic papules with central white craters that histologically can be shown to contain dermal material. Reactive perforating collagenosis, perforating folliculitis, and Kyrle disease are all examples of perforating disorders associated with renal failure.

CALCIPHYLAXIS

Calciphylaxis, also known as calcific uremic arteriolopathy, is a condition of patients with renal failure in which localized areas of skin become necrotic as a result of vascular calcification. Calciphylaxis begins with painful purpuric patches that may be reticulated, resembling livedo reticularis. These patches progress to indurated plaques that may ulcerate, becoming necrotic [*see Figure 21*]. Calciphylaxis often eventuates in amputation or death. Parathyroidectomy may result in healing of affected skin without amputation.[66]

Rheumatologic Diseases

DERMATOMYOSITIS

The best-known cutaneous manifestations of dermatomyositis, an inflammatory disorder of muscle and skin, are Gottron papules and heliotrope erythema. Gottron papules are erythematous scaling macules and papules that occur on the dorsa of the knuckles [*see Figure 22*]. Heliotrope erythema consists of periorbital erythema and edema. Scalp lesions, which can be associated with alopecia, have been described.[67] The lesions are often misdiagnosed as seborrheic dermatitis or psoriasis.

The association between dermatomyositis and malignancy has been established[68,69]; one epidemiologic study indicates patients with dermatomyositis are at particular risk for ovarian and lung cancer.[69]

Classifications of dermatomyositis include a juvenile variant characterized by calcification of skin or muscle. A vasculitic form in children is complicated by cutaneous infarcts and ulceration and by gastrointestinal vasculitis with abdominal pain, bleeding, or perforation. The vasculitic form carries a poor prognosis, with many of the patients dying of this disease.

SCLERODERMA AND SCLERODERMA-LIKE DISEASES

The sclerodermas include a number of distinct syndromes sharing a common feature, induration of the skin [*see 15:V Scleroderma and Related Diseases*].

Progressive Systemic Sclerosis and CREST Syndrome

Progressive systemic sclerosis, also known as systemic scleroderma, is a frequently fatal disease in which patients present with Raynaud phenomenon and sclerodactyly (induration of the skin of the digits) [*see Figure 23*]. Cutaneous induration can become widespread. Involvement of the face can lead to a characteristic appearance with pursed lips and bound-down skin of the nose that creates a beaklike appearance. Patients with antibodies to Scl-70 have a poor prognosis, often succumbing to renal disease and malignant hypertension. Pulmonary fibrosis can

Figure 21 **Calcification of arteries in patients with renal failure results in calciphylaxis. Affected skin forms a black, necrotic eschar.**

Figure 22 **Erythematous scaling papules on the dorsal aspects of the knuckles (Gottron papules) are a sign of dermatomyositis.**

Figure 23 **Sclerodactyly with a nonhealing digital ulcer commonly occurs in progressive systemic sclerosis.**

occur. Patients with anticentromere antibodies have a more slowly progressive variant of scleroderma known as the CREST syndrome, which is characterized by cutaneous calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia. With time, pulmonary hypertension and right-sided heart failure develop.

Morphea

Morphea, also called localized scleroderma, is characterized by sharply demarcated patches of indurated skin that can become generalized. It is distinguished from progressive systemic sclerosis by the absence of Raynaud phenomenon, sclerodactyly, or the systemic complications of scleroderma. There have been innovations in the treatment of both progressive systemic sclerosis and morphea. Exposure to psoralen and longwave ultraviolet light (PUVA) has been reported to improve progressive systemic sclerosis and morphea dramatically,[70] and exposure to UVA1 (the longer UVA spectrum, from 340 to 400 nm) has been reported to benefit patients with localized scleroderma.[71] Anecdotal evidence suggests that topical calcipotriene is an effective treatment for morphea.[72] Further studies must be done to confirm the efficacy of these treatments. Anecdotal reports have indicated that minocycline may benefit patients with progressive systemic sclerosis, but controlled trials are needed.[73]

Graft versus Host Disease

As organ transplantation becomes more common, another scleroderma-like illness, graft versus host disease, increases in frequency, particularly after bone marrow transplantation [*see 5:X Transfusion Therapy and 5:XI Hematopoietic Stem Cell Transplantation*]. There are two stages of graft versus host disease. The first, acute graft versus host disease, develops 10 to 40 days after transplantation and consists of an erythematous macular and papular rash that is often associated with fever, hepatomegaly, lymphadenopathy, or gastrointestinal symptoms. Chronic graft versus host disease usually develops 3 months after transplantation but can occur later; it consists of purple papules resembling lichen planus [*see Figure 24*]. Sclerodermatous skin changes with telangiectasia, reticulated hyperpigmentation, and alopecia are most characteristic. Both cyclosporine and PUVA have proved to be useful in the prevention and treatment of graft versus host disease.[74,75] Infliximab has been used very successfully to treat acute graft versus host disease.[76]

Eosinophilic Fasciitis

Scleroderma-like hardening of the skin also occurs in eosinophilic fasciitis. Puckering of the skin on the extremities typically develops and is associated with pain. In contrast to progressive systemic sclerosis, Raynaud phenomenon does not occur. Definitive diagnosis requires biopsy of skin and fascia overlying the affected muscle. In some cases of eosinophilic fasciitis, hematologic abnormalities develop, including aplastic anemia, thrombocytopenia, Hodgkin disease, and leukemias.[77]

SYSTEMIC LUPUS ERYTHEMATOSUS

There are many cutaneous manifestations of systemic lupus erythematosus (SLE), including nonspecific manifestations such as Raynaud phenomenon, photosensitivity, alopecia, and mucosal ulcers. More specific cutaneous manifestations of SLE include so-called discoid lupus (characterized by round scarred skin lesions with central hypopigmentation and a rim of hyperpigmentation) and malar erythema [*see 15:IV Systemic Lupus Erythematosus*]. As we learn more about lupus, the spectrum of skin diseases associated with this disorder continues to expand. Subacute cutaneous lupus, a variant characterized serologically by anti-Ro and anti-La antibodies, is associated with annular or psoriasiform skin lesions [*see Figure 25*].

Anticardiolipin Antibody Syndrome

The anticardiolipin antibody syndrome, which can occur in patients with SLE, has been described in patients who suffer re-

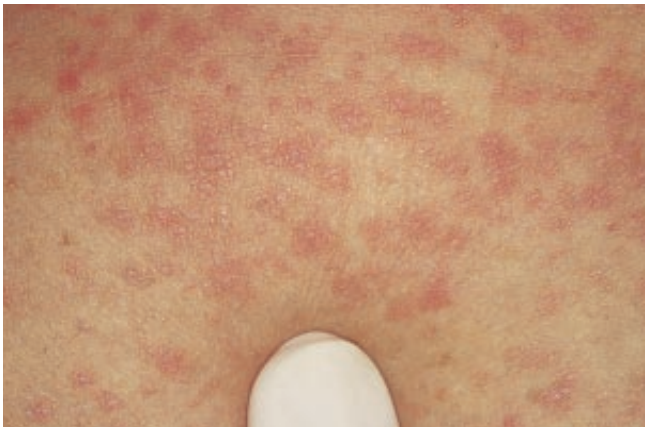

Figure 24 **Flat-topped papules are seen in this chronic lichenoid graft versus host reaction.**

Figure 25 **Annular scaling erythematous patches are characteristic of subacute cutaneous lupus erythematosus.**

peated episodes of phlebitis, arterial thromboses, and repeated miscarriages. Cutaneous infarcts are common manifestations, and livedo reticularis can occur. Patients may have false positive serologies for syphilis and have a circulating lupus anticoagulant. Circulating antiphospholipid antibodies are the serologic hallmark of this syndrome; however, many asymptomatic persons have antiphospholipid antibodies,[78] and antiphospholipid antibody tests can have false negative results. In some patients, a battery of tests may be needed to establish diagnosis; the dilute Russell viper venom time, an assay for circulating lupus anticoagulant, has been found to be among the more sensitive tests.[79]

Livedo Vasculitis

Livedo vasculitis, another disorder that has been associated with lupus, is characterized by painful recurrent ulcers over the lower legs and ankles. The ulcers heal, leaving white sclerotic scars. Affected patients often have livedo reticularis. This condition, also known as atrophie blanche, has been attributed to thrombotic processes rather than immune complex deposition or leukocytoclastic vasculitis.[80]

Neonatal Lupus

Neonatal lupus is a distinct syndrome of annular, erythematous macules and papules occurring on the face of newborn infants. The disorder has been attributed to transplacental passage of anti-Ro and occasionally anti-La antibodies. Mothers are often asymptomatic, but some may have lupus or Sjögren syndrome. Congenital heart block is the most serious complication of this disorder.[81]

The author has served as an investigator, consultant, or speaker for the following companies: Abbott Laboratories, Inc., Allergen, Inc., Amgen, Inc., Biogen, Inc., Centocor, Inc., Connetics Corporation, Fujisawa Healthcare, Inc., Galderma Laboratories, L.P., Genentech, Inc., Leo Pharmaceuticals, and Warner-Chilcott Pharmaceuticals.

The FDA has not approved the following drugs for specific uses described in this chapter: infliximab and TNF-α blockers for the treatment of sarcoidosis and Wegener granulomatosis; rituximab for the treatment of lymphomatoid granulomatosis; and calcipotriene for the treatment of morphea.

II PAPULOSQUAMOUS DISORDERS

Elizabeth A. Abel, m.d.

Papulosquamous disorders comprise a group of dermatoses that have distinct morphologic features.[1] The characteristic primary lesion of these disorders is a papule, usually erythematous, that has a variable amount of scaling on the surface. Plaques or patches form through coalescence of the primary lesions. Some common papulosquamous dermatoses are pityriasis rosea, lichen planus, seborrheic dermatitis, tinea corporis, pityriasis rubra pilaris, psoriasis [*see 2:III Psoriasis*], and parapsoriasis. Drug eruptions, tinea corporis, and secondary syphilis may also have a papulosquamous morphology. Some papulosquamous disorders may be a cutaneous manifestation of AIDS.[2]

Pityriasis Rosea

Pityriasis rosea is a relatively common, self-limited, exanthematous disease characterized by oval papulosquamous lesions on the trunk and proximal areas of the extremities. Pityriasis rosea typically appears during the spring and fall in temperate climates[3]; its incidence is highest in persons between 10 and 35 years of age.[4]

A population-based 10-year epidemiologic survey identified 939 patients with pityriasis rosea, about one third of whom had antecedent acute infection or atopy.[5] It also showed that peak incidence occurred at 20 to 24 years of age, that the incidence was higher in colder months, and that recurrences were rare. Occurrences among household contacts are uncommon. This study also noted that the incidence of disease had appeared to decline.

etiology

A viral etiology has been suggested for pityriasis rosea on the basis of immunologic and histologic data. The superficial dermis contains aggregates of $CD4^+$ helper T cells in perivascular locations and increased numbers of Langerhans cells. It has been postulated that IgM antibodies to keratinocytes cause the secondary form of the eruption. An association between human herpesvirus type 7 (HHV-7) and pityriasis rosea was initially reported in 1997.[6] Studies using polymerase chain reaction and immunohistochemical analyses of tissue samples to detect HHV-7 DNA sequences and antigens have provided inconclusive evidence of a causal relationship between HHV-7 and pityriasis rosea. In a retrospective study of 13 patients and 14 control subjects, the prevalence of HHV-7 was lower in lesional skin of patients with pityriasis rosea than in control subjects.[7] A subsequent seroepidemiologic study of HHV-6 and HHV-7 was conducted in 44 patients with pityriasis rosea and in 25 patients with other skin eruptions. Although in this study several patients with pityriasis rosea had antibody titers consistent with active infection, the overall prevalence of HHV-6 and HHV-7 was no greater in patients with pityriasis rosea than in control subjects.[8] A meta-analysis reviewed the data from 13 studies and found insufficient evidence to support a causal relationship between HHV-7 infection and pityriasis rosea.[9] A viral etiology of pityriasis rosea thus remains elusive. Certain drugs that cause a pityriasis rosea–like eruption have been implicated in the etiology of this disorder. These drugs include the antihypertensive agent captopril, metronidazole, isotretinoin (13-*cis*-retinoic acid), penicillamine, arsenic, gold, bismuth, barbiturates, and clonidine.[4]

diagnosis

The primary lesion, called a herald patch, appears first as a slightly raised, salmon-colored oval patch with a fine, wrinkled scale resembling cigarette paper. Typically, 7 to 10 days after the appearance of the herald patch, there occurs a bilaterally symmetrical eruption of smaller lesions; this secondary eruption occurs mainly on the trunk and upper extremities [*see Figure 1*]. Secondary lesions tend to follow cleavage lines (Langer lines) in a so-called fir tree distribution. A V-shaped formation on the upper chest and upper back, a circumferential pattern around the shoulders and hips, and a transverse pattern on the lower anterior trunk and lower back are seen in most patients.[10] The lesions are occasionally pruritic. The secondary rash is frequently more helpful in making a diagnosis than the initial herald patch, which is often misdiagnosed.[10] Atypical manifestations occur in 20% of persons affected. Such manifestations include a purpuric form of pityriasis rosea that resembles vasculitis, as well as papular, vesicular, pustular, and urticarial forms. An inverse variant of pityriasis rosea, more common in children than in adults, is characterized by lesions on the face and extremities, with relatively few lesions appearing on the trunk.[4]

differential diagnosis

Because lesions of pityriasis rosea may closely resemble those of secondary syphilis, a serologic test for syphilis may be indicated. Lesions may also resemble tinea corporis or tinea versicolor and should be examined by fungal scrapings and potassium hydroxide (KOH) wet mounts. A careful drug history must be obtained to exclude the possibility of a drug eruption.

treatment

Pityriasis rosea lesions resolve spontaneously after 6 to 8 weeks. The patient should be reassured that the disorder is benign and self-limited; such reassurance, together with educating the pa-

Figure 1 **Pityriasis rosea commonly presents as a single, large salmon-colored plaque called a herald patch (arrow). Appearance of the isolated lesion is followed in a week to 10 days by a bilaterally symmetrical papulosquamous eruption, mainly on the trunk and upper extremities.**

Figure 2 **Violaceous, flat-topped, polygonal papules are typical of lichen planus. A common location is the flexor aspect of the wrists and forearms.**

tient about the disease, is the most important aspect of treatment. Lesions are variably pruritic. Symptoms should be treated with bland emollients or systemic antipruritics. Sun exposure may accelerate clearing. Irradiation with ultraviolet B (UVB) sunlamps is beneficial in decreasing the severity of disease, especially when treatment is initiated within the first week of the eruption. One study found that 10 erythemogenic exposures of UVB substantially decreased the extent of pityriasis rosea, although it neither altered the duration of the disorder nor improved the itching.[11] Other evidence suggests that UVB therapy may hasten resolution of the rash but may cause hyperpigmentation.[12]

In a double-blind, placebo-controlled study in India, oral erythromycin administered in divided doses for 14 days was effective in treating patients with pityriasis rosea.[13] In this cohort, upper respiratory tract infections preceded the skin eruption in 68.8% of the 90 patients. A complete response, with complete resolution of skin lesions occurring within 2 weeks, was reported in 33% of the treatment group, as compared with 0% in the placebo group. The duration of disease was comparable for the two groups of patients. Although not all patients with pityriasis rosea benefit from erythromycin therapy, a trial of erythromycin is a safe treatment approach.

Lichen Planus

Lichen planus is a localized or generalized eruption with violaceous, flat-topped, polygonal papules and little or no observable scaling [*see Figure 2*]. It is often localized to the oral mucosa; 25% of patients with oral lichen planus have skin involvement as well.[14] The incidence is highest in young to middle-aged persons. Lichen planus usually appears in the fifth or sixth decade and affects women more often than men.

ETIOLOGY

The etiology of lichen planus is unknown. An alteration in basal keratinocytes that induces humoral and cell-mediated immune responses has been postulated as a mechanism. Skin and mucous membrane lesions resembling lichen planus have been observed in patients with graft versus host disease (GVHD) [*see 2:VI Cutaneous Adverse Drug Reactions*]. Lichen planus has also been associated with other immune-mediated diseases, including ulcerative colitis, bullous pemphigoid, myasthenia gravis with thymoma, primary biliary cirrhosis, and chronic active hepatitis.[15]

There is an increased prevalence of viral hepatitis, especially hepatitis C, in patients with lichen planus. In a multicenter study of 303 sequential patients with lichen planus, the prevalence of hepatitis C virus (HCV) was 19.1%, compared with 3.2% in control subjects.[16] The role of HCV in the pathogenesis of lichen planus is not clearly understood; some investigators suggest that the cause of lichen planus may be related to the pattern of immune dysregulation induced by HCV.[17] There are a number of reports of lichen planus occurring after administration of different types of hepatitis B vaccine.[18] This is a rare occurrence, considering the widespread use of this vaccine; several cases have been reported from France and Italy, and one case has been reported from the Middle East. An immunologic mechanism has been postulated as the cause. The latency period ranges from several days to 3 months after any one of the three usual injections of vaccine.

A variety of drugs have been reported to cause lichenoid reactions in the skin, usually sparing the mucous membranes. Such drugs include beta blockers, methyldopa, penicillamine, quinidine, and quinine. Other drugs that have been implicated but for which causal evidence is insufficient include angiotensin-converting enzyme inhibitors, sulfonylurea agents, carbamazepine, gold, and lithium.[19] In one study, the administration of penicillamine for primary biliary cirrhosis was followed by the development of lichen planus in 17 of 24 patients[20]; in addition, after treatment with penicillamine, the skin eruption became worse in three of seven patients with biliary cirrhosis and preexisting lichen planus. Nonsteroidal anti-inflammatory drugs have been documented to cause a lichenoid drug eruption; these drugs include naproxen, indomethacin, diflunisal, ibuprofen, acetylsalicylic acid, and salsalate.[21] Although the latency period is highly variable, symptoms usually develop within a few months after drug initiation and resolve within weeks to months after discontinuance of the offending agent.

DIAGNOSIS

Lichen planus appears as flat-topped, shiny, violaceous papules, often with a fine, reticulated scale on the surface. Common sites of involvement include the skin, nails, mucous membranes, vulva, and penis. Wickham striae—white, lacy patterns on the papule surface—are apparent on magnification with a hand lens.[22] The occurrence of papules along a scratch line, as in linear lichen planus, is referred to as the Koebner phenomenon [*see Figure 3*]. In the hypertrophic form of the disease, papules coalesce to form thick plaques or nodules that are often found on the lower extremities. Pruritus may be severe, particularly in the generalized or hypertrophic forms of the disease. Common sites of involvement are the flexor surfaces of the wrists, the sacrum, the

mucous membranes of the mouth, the medial thighs, and the genitalia. Mucous membrane lesions show a white, reticulated mosaic pattern [*see Figure 4*]. A severe erosive form of lichen planus can involve the oral mucous membranes. In rare cases, lesions occur in the esophagus, causing esophageal stricture and dysphagia.[23]

A follicular form known as lichen planopilaris may result in scarring alopecia. Variants of lichen planus with distinct morphologic features include actinic, annular, bullous, hypertrophic, linear, ulcerative, and zosteriform forms. The nails may also be involved [*see 2:XIV Diseases of the Nail*]. The clinical features of some forms of lichen planus may resemble those of lupus erythematosus.[22]

Skin biopsy confirms the clinical diagnosis of lichen planus. Typically, the epidermis shows hyperkeratosis, a prominent granular layer, liquefaction degeneration of the basal cell layer, and an intense upper dermal inflammatory infiltrate. Immunoperoxidase studies using monoclonal antibodies to cell surface antigens have shown that most cells in the infiltrate are of the helper-inducer T cell subset. Colloid bodies (Civatte bodies) coated with immunoglobulin are frequently seen in the dermal papillae. On ultrastructural examination, numerous Langerhans cells can be observed at the dermoepidermal junction.

TREATMENT

Limited data exist for making evidence-based recommendations regarding treatment of lichen planus.[24,25] Definitive clinical trials have not been performed, and information on the efficacy of treatments is derived from small trials and anecdotal evidence.

Body Lesions

Emollients, topical glucocorticoids, a short course of systemic corticosteroids, and systemic antipruritics have been used to treat cutaneous lichen planus. Most experts recommend medium- to high-potency topical corticosteroids as first-line treatment for localized cutaneous lichen planus. Oral corticosteroids may be used for generalized cutaneous lichen planus. As an alternative to systemic corticosteroids, systemic retinoids, such as acitretin, are beneficial in some patients with cutaneous forms of lichen planus.[26] Azathioprine has been used for its steroid-sparing effect in erosive and generalized lichen planus.[27]

Other therapies that have been reported to have efficacy in the treatment of cutaneous lichen planus include phototherapy (psoralen plus ultraviolet A [PUVA]), cyclosporine, and hydroxychloroquine.[24] In a trial of oral psoralen photochemotherapy for widespread recalcitrant lichen planus, clinical remission occurred in six of seven patients and correlated with the disappearance of the upper dermal infiltrate.[28] Oral cyclosporine has also been effective, but potential renal toxicity and hypertension limit its long-term use.[22] Recombinant interferon alfa–2b, administered subcutaneously every other day, was successful in the treatment of generalized lichen planus in three patients with no evidence of hepatitis, further supporting the cell-mediated immunologic etiology of this disease.[29]

Mouth Lesions

For lichen planus that is localized to the oral mucosa, a high-potency corticosteroid such as clobetasol in a vehicle that is adherent to the mucosal surface (Orabase) is helpful.[24,29] Intralesional injections of corticosteroids may be used to treat localized, recalcitrant lesions. Use of miconazole gel in combination with chlorhexidine mouth rinses is effective for prophylaxis against oral candidiasis.[30] Topical isotretinoin gel is an effective alternative to corticosteroids, although relapses often occur after discontinuance of this medication.[31] In a double-blind, placebo-controlled study of 22 patients with biopsy-proven oral lichen planus, an 8-week course of 0.1% isotretinoin gel was found to be effective.[31] Cyclosporine mouth rinses have been helpful for some patients. A 6-month course of hydroxychloroquine, 200 to 400 mg daily, was successful in nine of 10 patients with oral lichen planus; ulcers healed and pain decreased after 1 to 2 months.[32] Topical tacrolimus, a macrolide that suppresses T cell activation, was used to treat erosive mucosal lichen planus in 19 patients whose conditions were resistant to conventional treatment. Therapeutic levels of tacrolimus were demonstrated in eight patients, and areas of ulceration showed a mean decrease of 73.3% over the 8-week study period; however, 13 of 17 patients suffered a relapse after cessation of therapy.[33] Topical pimecrolimus cream is being evaluated as a treatment for oral erosive lichen planus.[34] The role of these agents in the treatment of lichen planus must be further investigated, particularly in view of the alert by the Food and Drug Administration issued in 2005 regarding a possible link between use of topical tacrolimus and pimecrolimus and cases of lymphoma and skin cancer.

Genital and Perianal Lesions

Mild, nonerosive disease can be controlled with topical corticosteroids; erosive disease, although more difficult to treat, may

Figure 3 **The Koebner phenomenon—the appearance of lesions along a scratch line—may be seen in patients with lichen planus.**

Figure 4 **Lichen planus of the mucous membrane assumes a white, reticulated mosaic pattern, as seen above on the buccal mucosa.**

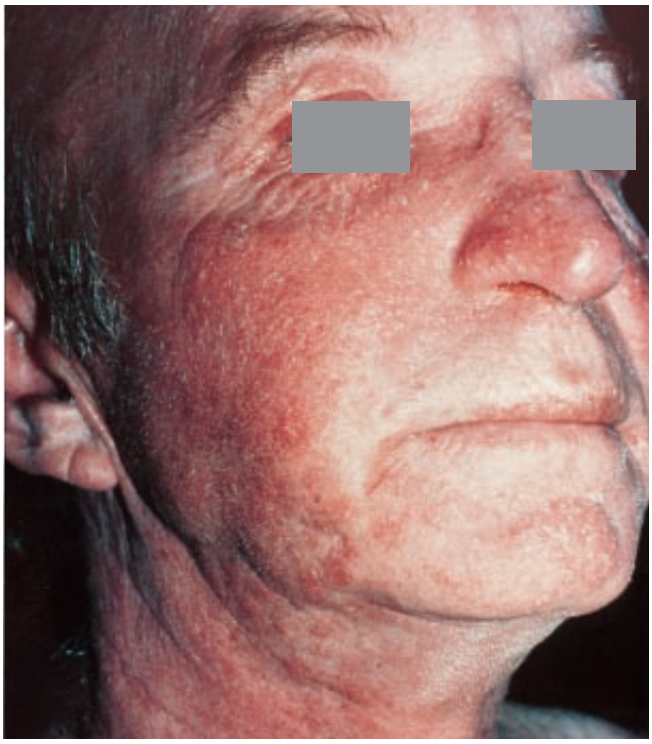

Figure 5 **Seborrheic dermatitis seen on the face of this patient involves sites of sebaceous gland activity.**

be treated with topical corticosteroids in combination with other topical or systemic medications.[35] Topical tacrolimus[36,37] and topical pimecrolimus[38] may be useful in the treatment of recalcitrant cases that have failed to respond to other therapies.

PROGNOSIS

Patients who experience an acute outbreak of lichen planus have a good prognosis; in most cases, the papules clear within several months to a year. The chronic form, however, may last for 10 years or longer. In a study following the long-term course of lichen planus in 214 patients for 8 to 12 years, lichen planus cleared in two thirds of the patients within 1 year. The recurrence rate was 49%, which was higher than recurrence rates reported in previous studies; the authors attributed the high rate of recurrence to treatment with potent topical corticosteroids.[39]

Seborrheic Dermatitis

Seborrheic dermatitis is a papulosquamous condition that is often associated with excessive oiliness or seborrhea, dandruff, and well-defined red, scaly patches on the face, trunk, and intertriginous areas.[40] Some cases may progress to a severe exfoliative erythroderma. Seborrheic dermatitis is a common skin disorder that occurs in otherwise healthy adults. It is increasingly prevalent in middle-aged and elderly persons. Seborrheic dermatitis does not occur before puberty except during infancy (usually between 2 and 12 weeks of age), at which time transplacentally derived maternal hormones are present. The prognosis in adults is one of lifelong recurrence, with each episode lasting weeks to months.

ETIOLOGY

The cause of seborrheic dermatitis is unknown. An occasional association with neurologic abnormalities, especially parkinsonism, has been observed. Genetic predisposition, emotional stress, diet, hormones, and climatic factors may also influence this disorder. It is thought that an association exists between the yeast-like organism *Pityrosporum* and seborrheic dermatitis. Seborrheic dermatitis may, in part, be the result of an abnormal or inflammatory immune response to this yeast, or it may be caused by an epidermal hyperproliferation of this organism.[41]

Patients with classic seborrheic dermatitis may have normal or reduced rates of sebum excretion; therefore, seborrhea is not essential for the development of this disorder.[42] However, seborrhea may play a role in the seborrheic dermatitis present in certain patients, such as those with parkinsonism. Reduction of seborrhea with improvement of the dermatitis has been observed after a favorable neurologic response to levodopa treatment for parkinsonism.

DIAGNOSIS

The scale associated with seborrheic dermatitis may be yellowish and either dry or greasy. Sites of predilection are the areas of sebaceous gland activity [*see Figure 5*], such as the scalp, eyebrows, eyelids, forehead, nasolabial folds, and presternal or interscapular regions. Blepharitis involves granular inflammation of the lid margin, with scaling and shedding of debris into the eye, which may cause conjunctivitis. Seborrheic dermatitis is the most common cause of otitis externa. When the scalp is involved, lesions often extend along the frontal hairline, forming a band of erythema. The postauricular area is a common site of involvement. Lesions of the trunk may consist of erythematous follicular papules covered by greasy scales, which may coalesce to form large plaques or circinate patches. Seborrheic dermatitis can be seen in areas of male pattern baldness, but it is not a cause of hair loss unless there has been a severe intervening secondary infection resulting in a scarring alopecia.

DIFFERENTIAL DIAGNOSIS

Seborrheic dermatitis should be considered in the differential diagnosis of chronic eczematous dermatitis and in that of papulosquamous disorders, particularly psoriasis. The clinical features of seborrheic dermatitis limited to the scalp and face may resemble those associated with psoriasis, giving rise to the term sebopsoriasis. Histologic features range from psoriasiform changes of acanthosis and parakeratosis to the spongiosis of eczema. Seborrheic dermatitis of the face may resemble the facial lesions found in lupus erythematosus or other photosensitivity dermatoses. Lesions on the trunk may be confused with tinea versicolor, but the latter is easily excluded by skin scraping and KOH preparation or Wood light examination. Atopic dermatitis and psoriasis, especially when partially treated, are also included in the differential diagnosis.

SEBORRHEIC DERMATITIS ASSOCIATED WITH AIDS

Severe seborrheic dermatitis can be one of the most common and earliest manifestations of AIDS. From 30% to 80% of patients with AIDS have seborrheic dermatitis, compared with 3% to 5% of HIV-negative young adults.[43] Lesions may be explosive in onset and are often resistant to therapy. Clinical features include a predominantly inflammatory papular eruption on the face, with a tendency to spare the scalp, in contrast to the mild erythema and scaling of the scalp typical of seborrheic dermatitis in persons without AIDS. Truncal involvement in seborrheic areas is common in AIDS patients, and the lesions may resemble psoriasis. Although the cause of the association of seborrheic dermatitis

with AIDS is unknown, immunologic dysfunction may lead to an overgrowth of the yeast *P. orbiculare* in seborrheic areas.

Skin biopsy specimens from AIDS patients with seborrheic dermatitis have distinct histologic features, including keratinocyte necrosis, leukoexocytosis, a superficial perivascular infiltrate of plasma cells, and, frequently, neutrophils.[44]

TREATMENT

The condition on the scalp usually responds well to frequent—as often as daily—shampooing with a preparation containing 3% to 5% sulfur and 2% to 3% salicylic acid. Good response has also been reported with use of ciclopirox 1% shampoo once or twice weekly.[45] For the face and nonhairy areas, a mild cream containing precipitated 3% sulfur and 3% salicylic acid is effective. Involved areas also respond well to low-potency topical glucocorticoids, such as 1% hydrocortisone cream or desonide cream. Caution, however, must be exercised in the use of high-potency fluorinated steroid preparations, especially on the face and in skin folds; prolonged application may lead to chronic skin changes, such as atrophy and telangiectasia. Wet dressings followed by a topical antibiotic preparation are helpful in treating intertriginous areas, in which maceration and superficial secondary infection may occur.

Topical antifungal agents have been used in the treatment of seborrheic dermatitis. In addition to their antifungal properties, certain azoles (e.g., bifonazole, itraconazole, and ketoconazole) have demonstrated anti-inflammatory activity, which may be beneficial in alleviating symptoms.[46] In one study, 575 patients with seborrheic dermatitis underwent twice-weekly treatments with 2% ketoconazole shampoo; an excellent response was seen in 88% of the patients.[47] Continued prophylactic treatment once weekly over 6 months was helpful in preventing relapse of the disorder in a significant number of patients.

In a trial of 38 patients with seborrheic dermatitis, 1% metronidazole gel was found to be effective. Improvement was noted after 2 weeks, and marked improvement or complete clearing was noted at 8 weeks[48]; however, in a randomized, controlled trial, metronidazole 0.75% gel and placebo were found to have similar efficacy.[49] In a small randomized, open-label clinical trial, pimecrolimus 1% cream and betamethasone 1% cream were both found to be effective in reducing symptoms of seborrheic dermatitis, but relapses were observed more frequently with betamethasone.[50] A multicenter, randomized, controlled trial found oral terbinafine (an antimycotic allylamine compound) to be effective in patients with moderate to severe seborrheic dermatitis.[51]

Seborrheic blepharitis may be treated by applying baby shampoo with a cotton-tipped applicator to debride scales. If topical corticosteroids are required, the patient should be referred to an ophthalmologist to monitor potential side effects to the eye, such as increased intraocular pressure, glaucoma, cataracts, and activation of latent herpes infection.[1]

Treatment of HIV-associated seborrheic dermatitis is similar to that of seborrheic dermatitis in general, although HIV-associated seborrheic dermatitis is apt to be recalcitrant, requiring intensive, prolonged therapy. Treatment of the underlying HIV infection may lead to improvement of the associated seborrheic dermatitis.

Pityriasis Rubra Pilaris

Pityriasis rubra pilaris is a relatively uncommon chronic inflammatory dermatosis that is considered to be a disorder of keratinization. The age distribution is bimodal, occurring either in childhood or in the fifth decade; the clinical course is variable. An autosomal dominant inheritance has been postulated for the juvenile form of the disease.[52] Patients with the classic adult form of the disease have the best prognosis; resolution usually occurs over a 3-year period.

Figure 6 **Islands of spared skin within a background of diffuse erythema are present on the legs of this patient with pityriasis rubra pilaris.**

DIAGNOSIS

Typically, pityriasis rubra pilaris initially manifests itself as a seborrheic dermatitis–like eruption that occurs on sun-exposed areas of the body; this eruption is followed by the development of follicular papules that coalesce into psoriasiform patches on the trunk and extremities, with progression to erythroderma. Generalized involvement is characterized by yellow-orange erythema with desquamation. Diffuse areas of involvement generally show islands of spared skin [*see Figure 6*]. Additional features are palmoplantar hyperkeratosis [*see Figure 7*] and prominent follicular plugging over the dorsal aspects of the fingers. Pruritus is usually mild or absent. A pityriasis rubra pilaris–like eruption with follicular hyperkeratosis is a little known but distinctive cutaneous manifestation of dermatomyositis.[53]

TREATMENT

The response of patients with pityriasis rubra pilaris to conventional antipsoriatic therapies, such as topical corticosteroids, tars, and oral methotrexate, is often unsatisfactory; some patients, however, have shown a favorable response to topical calcipotriene (known outside the United States as calcipotriol).[54] UVB phototherapy may exacerbate the disease.[55] High-dose vitamin A in excess of 200,000 IU daily has been used but can cause liver or central nervous system toxicity. An oral retinoid such as acitretin or isotretinoin is indicated for the treatment of pityriasis rubra pilaris in men and postmenopausal women. In an early study in-

Figure 7 **Plantar hyperkeratosis and confluent erythematous follicular papules typical of pityriasis rubra pilaris are seen on the ankle and foot of this patient.**

volving 45 patients with pityriasis rubra pilaris, isotretinoin produced definite improvement in 50% of the patients after 4 weeks of therapy.[56] Remission of up to 6 months was sustained in some patients after the drug was withdrawn. Long-term use of this drug in patients with keratinizing disorders has been associated with irreversible skeletal toxicity. Because teratogenicity is a concern, women of childbearing age must use effective birth control with either agent.

In a study of patients with pediatric pityriasis rubra pilaris, isotretinoin achieved the best response among a range of therapies including steroids, systemic retinoids, and methotrexate; five of six patients treated with isotretinoin showed 90% to 100% clearing of lesions within 6 months of initiation of treatment.[57] Cyclosporine, 5 mg/kg/day, was effective in the treatment of three adult patients with pityriasis rubra pilaris, with a favorable response being noted within 2 to 4 weeks of initiation of therapy; however, relapse occurred when the dose was decreased to 1.2 mg/kg/day.[58]

Numerous reports have suggested that infliximab, a monoclonal antibody that binds to tumor necrosis factor–α, may be useful in the treatment of cutaneous inflammatory diseases, such as pityriasis rubra pilaris.[59] The drug is currently approved by the FDA for the treatment of rheumatoid arthritis and Crohn disease; further investigation is required to determine its efficacy for cutaneous dermatoses.

Parapsoriasis

Parapsoriasis encompasses a variety of relatively uncommon chronic inflammatory dermatoses of unknown etiology that are resistant to conventional treatment. Despite the designation parapsoriasis, the clinical appearance of the noninfiltrated scaly patches or plaques is distinct from that of psoriatic lesions. Classification of these disorders is controversial and is further complicated by the use of several terms to denote a single entity and by the use of various systems of nomenclature. A proposed standard nomenclature divides parapsoriasis into two distinct subgroups: pityriasis lichenoides, which may be acute or chronic, and small- and large-plaque parapsoriasis.[60]

PITYRIASIS LICHENOIDES

Diagnosis

The acute form of pityriasis lichenoides, also known as pityriasis lichenoides et varioliformis acuta (PLEVA) or Mucha-Habermann disease, is characterized by the abrupt onset of a generalized eruption of reddish-brown maculopapules that evolve during a period of weeks to months. Lesions are typically present at all stages of evolution and may be vesicular, hemorrhagic, crusted, or necrotic [*see Figure 8*]. Healing with varioliform scarring is common. Nonspecific histologic features include intraepidermal lymphocytes and erythrocytes, dermal hemorrhage, and a lymphocytic vasculitis.[61] Skin lesions of PLEVA may resemble those of lymphomatoid papulosis, which has immunohistologic features of a $CD30^+$ cutaneous T cell lymphoma.[62] Lymphomatoid papulosis occurs as a chronic, recurrent, self-healing papulonodular eruption; an association with mycosis fungoides has been observed in some patients. T cell clonality has been documented by PCR in 20 patients with PLEVA; similar findings have been made in patients with lymphomatoid papulosis.[63] Investigators have suggested that PLEVA is a lymphoproliferative process rather than an inflammatory reaction to various trigger factors, such as infectious agents. One case report demonstrated that pityriasis lichenoides lesions evolved concomitantly with a known Epstein-Barr virus (EBV)–mediated disease (i.e., acute infectious mononucleosis), suggesting that pityriasis lichenoides may be caused by EBV infection.[64]

A chronic form of pityriasis lichenoides, pityriasis lichenoides chronica, shows milder skin changes without necrosis. Lesions evolve during a period of weeks and may recur over many years.

Treatment

Treatment of both acute and chronic forms of pityriasis lichenoides is generally unsatisfactory. Topical corticosteroids, tars, and systemically administered methotrexate have all been tried, with variable success. Ultraviolet radiation from sunlamps[65] and oral psoralen photochemotherapy[66] may have a beneficial effect on the course of disease. High-dose tetracycline, 2 g/day for 1 month or more,[67] and minocycline, 100 mg once or twice daily, have also

Figure 8 **Hemorrhagic brown-crusted varioliform papules are present on the lower legs of this patient with the acute form of pityriasis lichenoides.**

Figure 9 **The digitate variant of small-plaque parapsoriasis is seen in this patient.**

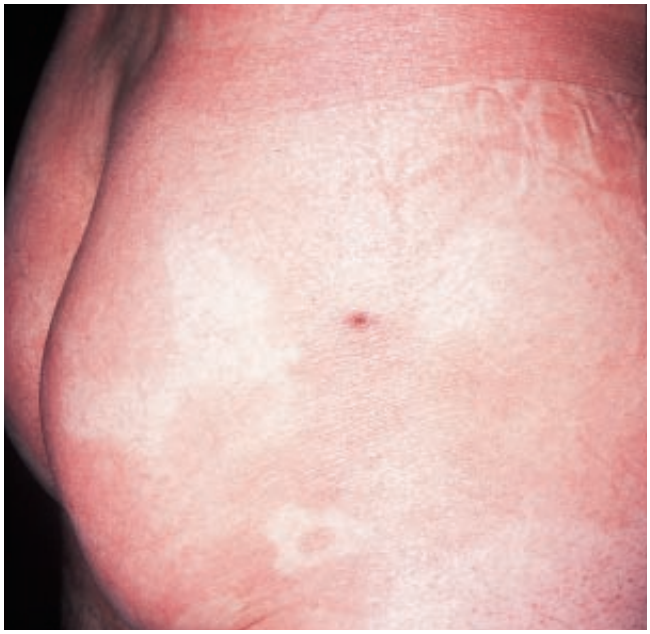

Figure 10 **Large-plaque parapsoriasis as seen on the buttocks of this patient may eventuate in cutaneous T cell lymphoma.**

been shown to be effective treatments. A rare type of Mucha-Habermann disease known as Degos disease (also called malignant atrophic papulosis), characterized by fever and hemorrhagic and papulonecrotic lesions, responds rapidly to the administration of methotrexate [*see 15:VIII Systemic Vasculitis Syndromes*].[68]

SMALL- AND LARGE-PLAQUE PARAPSORIASIS

Diagnosis

Small-plaque parapsoriasis consists of slightly scaly, thin, oval erythematous plaques of less than 5 cm in diameter, commonly located on the trunk and proximal extremities. The variant—digitate dermatosis—shows elongated lesions falling along lines of skin cleavage. The two diseases follow similar chronic, benign courses [*see Figure 9*].

Clinically, large-plaque parapsoriasis consists of slightly thickened, red-brown, scaly plaques that are more than 10 cm in diameter and have ill-defined borders; such lesions are present mainly on the proximal extremities and the buttocks and on the breasts of women [*see Figure 10*]. Frequently, there is a component of poikiloderma, which includes mottled hyperpigmentation and hypopigmentation, atrophy, and telangiectasia. Early lesions may show a nonspecific histology; late lesions show atypical lymphocytes within the epidermis.

It is important to differentiate large-plaque parapsoriasis from the small-plaque form because about 10% of cases of large-plaque parapsoriasis result in a cutaneous T cell lymphoma (mycosis fungoides).[60] Large-plaque lesions may be present for many years before malignant transformation is recognized histologically. The malignant change is suggested clinically by increased pruritus and progressive induration of lesions. The retiform variant may show prominent poikiloderma with atrophy and has a greater potential for malignant transformation.[69] Studies of T cell subsets using monoclonal antibodies to membrane markers have shown a variable predominance of helper T cells in the cutaneous infiltrates in atrophic parapsoriasis; such findings suggest a similarity to lesions of mycosis fungoides, although epidermotropism is absent.[70] Patients with this form of the disease should be evaluated with repeated biopsies of untreated lesions. Once a definitive diagnosis of mycosis fungoides has been established, specific treatment of this disease may be instituted.

Treatment

Treatment of large- and small-plaque parapsoriasis is similar to that of pityriasis lichenoides chronica [*see* Pityriasis Lichenoides, *above*].

Erythroderma

Papulosquamous and psoriasiform eczematous dermatitis may progress to generalized skin involvement with erythema and scaling, known as exfoliative erythroderma. Other causes of eryth-

Figure 11 **Erythroderma, which appears as total skin erythema and scaling, can occur as a result of papulosquamous and eczematous disorders caused by a variety of diseases. Cutaneous T cell lymphoma, as seen in this patient with Sézary syndrome, can result in erythroderma.**

roderma include drug eruption, contact dermatitis, and pityriasis rubra pilaris. Eyrthroderma is a rare skin disorder that occurs more often as an exacerbation of a preexisting skin disorder; less commonly, it is idiopathic. There are no accurate studies on the incidence of erythroderma. On the basis of a survey of all dermatologists in the Netherlands, however, the annual incidence was estimated to be one to two patients per 100,000 inhabitants.[71]

DIAGNOSIS

Most cases of exfoliative erythroderma are associated with exacerbation of an underlying dermatosis, such as psoriasis, pityriasis rubra pilaris, seborrheic dermatitis, drug eruptions, atopic dermatitis, or contact dermatitis.[72] Some patients have idiopathic erythroderma, also called red man syndrome.[69] Common associated skin findings include palmoplantar keratoderma, alopecia, and nail dystrophy. Skin biopsy usually shows nonspecific inflammation. Lymph node biopsy may reveal dermatopathic lymphadenopathy. In some patients, idiopathic erythroderma may progress to cutaneous T cell lymphoma (e.g., erythrodermic mycosis fungoides and Sézary syndrome) [*see Figure 11*] [*see 2:X Malignant Cutaneous Tumors*].

Systemic symptoms associated with erythroderma include fever and chills, dehydration from transepidermal water loss, and high-output cardiac failure.

TREATMENT

Nonspecific treatment includes restoration of fluid and electrolyte balance and supportive measures such as administration of antipruritics, application of cool compresses and mild topical corticosteroids, and bed rest. Antibiotics may be required for treatment of secondary bacterial infection. Generally, more aggressive topical and systemic therapies are avoided until the inflammation subsides. More specific treatment depends on the underlying diagnosis and cause of the erythroderma. For example, in patients with erythroderma that is secondary to Sézary syndrome, treatment would be directed toward the underlying cutaneous T cell lymphoma [*see 2:X Malignant Cutaneous Tumors*]. For erythroderma caused by a drug eruption, the offending drug must be discontinued. Systemic agents such as acitretin and methotrexate may be used to treat psoriatic erythroderma [*see 2:III Psoriasis*]. Drug-induced erythroderma may have the best prognosis.[72]

The author has served as advisor or consultant to Abbott Laboratories, Amgen, Inc., Biogen Idec, Inc., and Genentech, Inc.

III PSORIASIS

Elizabeth A. Abel, m.d.
Mark Lebwohl, m.d.

Psoriasis is an immune-mediated inflammatory cutaneous disorder characterized by chronic, scaling, erythematous patches and plaques of skin. It can begin at any age and can vary in severity. Psoriasis can manifest itself in several different forms, including pustular and erythrodermic forms. In addition to involving the skin, psoriasis frequently involves the nails, and some patients may experience inflammation of the joints (psoriatic arthritis). Because of its highly visible nature, psoriasis can compromise both the personal and the working lives of its victims.

Breakthroughs in the treatment of psoriasis have led to a better understanding of its pathogenesis. This chapter reviews current knowledge of the genetics, pathogenesis, and treatment of psoriasis.

Epidemiology

The estimated prevalence of psoriasis ranges from 0.5% to 4.6% worldwide. The reasons for the geographic variation in prevalence are unknown, but climate and genetics may play a role. Psoriasis is uncommon in blacks in tropical zones, but it is more often seen in blacks in temperate zones. It occurs commonly in Japanese persons but rarely in persons native to North and South America. In the United States, studies have variously reported that 4.5 million adults[1] or 7 million adults and children[2] have psoriasis.

Psoriasis can occur at any age, with some cases being reported at birth and others being reported in patients older than 100 years. In Farber and Nall's pioneer study of 5,600 patients, the average age of onset of psoriasis was 27.8 years; in 35% of patients, onset occurred before 20 years of age, and in 10%, onset occurred before 10 years of age.[3] Psoriasis occurs with equal frequency in men and women, but in Farber and Nall's study, onset occurred later in men. In populations in which there is a high prevalence of psoriasis, onset tends to occur at an earlier age. In the Faroe Islands, for example, the prevalence is 3%, and the average age of onset is 12.5 years. The average age of onset is 23 years in the United States. In persons with earlier age of onset, psoriasis is more likely to be severe, with involvement of a large area of skin surface.

Pathogenesis

Psoriasis was once thought to be caused by an abnormality in epidermal cell kinetics; it is now thought that an abnormality in the immune system triggers epidermal proliferation. The role of activated lymphocytes in the development of psoriasis was first proved through investigations of DAB389 interleukin-2 (IL-2), a fusion protein consisting of molecules of IL-2 fused to diphtheria toxin. This fusion protein binds to high-affinity IL-2 receptors on activated T cells, destroying those cells. In a study of DAB389 IL-2 treatment in 10 patients, four patients showed dramatic clinical improvement and four others showed moderate improvement.[4] Unfortunately, the side effects of DAB389 IL-2 have precluded its approval for the treatment of psoriasis.[5]

The skin of patients with lesional psoriasis has higher numbers of antigen-presenting cells that can activate T cells. For T cell activation to occur, antigen-presenting cells must deliver at least two signals to resting T cells. The first signal occurs when major histocompatibility complex (MHC) class II molecules of the antigen-presenting cells present antigens to the T cells. A second costimulatory signal must be delivered through the interaction of ligands on the surface of the antigen-presenting cells with receptors on the surface of T cells. Examples of this process include the interaction of B7 molecules with CD28 on the surface of resting T cells and the interaction of lymphocyte function–associated antigen 3 (LFA-3) with CD2 or intercellular adhesion molecule–1 (ICAM-1) with LFA-1 on the surface of T cells.[6,7] Blockade of any of these steps results in clearing of psoriasis.[8,9] Upon activation, T cells release Th1 (T helper type 1) cytokines, IL-2, and interferon gamma, which together induce proliferation of keratinocytes and further stimulation of T cells. Inflammatory cytokines such as tumor necrosis factor–α (TNF-α) are found in psoriatic skin lesions and joints, and treatment with TNF-α blockers results in clearing of psoriasis and of psoriatic arthritis.[10]

Etiology

Genetic Factors

Several lines of evidence suggest that psoriasis has a genetic etiology. One third of persons affected have a positive family history. Studies have found a higher concordance rate in monozygotic twins than in dizygotic twins or siblings (70% versus 23%).[11]

Current evidence suggests genetic heterogeneity. Both autosomal dominant inheritance with incomplete penetrance and polygenic or multifactorial inheritance have been described. The most important psoriasis susceptibility gene appears to be *PSORS1*, which has been mapped to the region on chromosome 6p21 that codes for the MHC; seven other *PSORS* genes have been found on other chromosomes.[12] Psoriasis is also associated with a single-nucleotide polymorphism on chromosome 17q25 that impairs binding of a runt-related protein (RUNX1).[13]

Contributing Factors

The course and severity of psoriasis can be affected by a number of endogenous and exogenous factors, including stress, climate, concurrent infections, and medications.

Psychological Stress

Many patients believe that anxiety or psychological stress has an adverse effect on the course of their psoriasis. The etiologic significance of stress in psoriasis is difficult to evaluate, however, because of the subjective nature of the evidence used in many of the investigations into this question.[14] In a prospective study, a multivariate statistical method revealed a positive correlation between severity of psoriasis symptoms and psychological stress related to adverse life events.[15] Psoriasis itself can be a source of stress: the effects of psoriasis on physical and mental function have been compared with the effects of cancer, heart disease, diabetes, and depression.[16]

Climate

It has long been known that psoriasis improves when patients are exposed to sunny climates and to regions of lower latitude. In northern latitudes, exacerbation of psoriasis commonly occurs during the fall and winter.

Infection

Viral or bacterial infections, especially streptococcal pharyngitis or tonsillitis, may precipitate the onset or exacerbation of psoriasis.[17] Guttate psoriasis, in particular, is often attributed to a previous streptococcal infection. Attempts to reverse psoriasis by treatment with oral antibiotics have not proved effective in double-blind trials.[18] Nevertheless, some investigators advocate antibiotic therapy for psoriasis.[19]

Infection with HIV has also been associated with psoriasis. In some patients with HIV infection, preexisting psoriasis becomes exacerbated; in other patients, psoriasis develops within a few years after HIV infection. Often, HIV-infected patients present with symptoms similar to those of Reiter syndrome.[20]

Drugs

Numerous drugs can worsen psoriasis.[21] Antimalarial agents such as chloroquine can cause exfoliative erythroderma or pustular psoriasis. Up to 31% of patients experience new onset or worsening of psoriasis as a result of antimalarial therapy. Lithium and beta blockers such as propranolol may precipitate the onset of psoriasis or cause exacerbations of psoriasis.[22] Some nonsteroidal anti-inflammatory drugs (NSAIDs) also exacerbate psoriasis, although this effect is sufficiently minor to allow NSAIDs to be used in the treatment of psoriatic arthritis.[23] Flares of pustular psoriasis may be precipitated by withdrawal from systemic corticosteroids or withdrawal from high-potency topical corticosteroids. Interferon therapy has been associated with development or exacerbation of psoriasis, presumably because of the Th1 effects of this therapy.[24]

Other Factors

Trauma to the clinically uninvolved skin of patients with psoriasis can cause a lesion to appear at the exact site of injury; this phenomenon is known as the Köbner response. Cuts, abrasions, injections, burns resulting from phototherapy, and other forms of trauma can elicit this reaction.

Smoking may be an exacerbating factor in psoriasis.[25] Alcohol use has also been implicated in the exacerbation of psoriasis.[26]

Surveys have suggested that diet plays a role in the development of psoriasis, and attempts have been made to affect the clinical course of psoriasis through modification of diet.[27] Double-blind studies, however, have failed to show that diet has either a beneficial or a detrimental effect on the severity of psoriasis.

Diagnosis

The diagnosis of psoriasis is usually made on clinical grounds. If unusual features are present, biopsy of affected skin can be done to confirm the diagnosis.

CLINICAL VARIANTS

Nearly 90% of patients with psoriasis have plaque type, a form that is characterized by sharply demarcated, erythematous, scaling plaques. The elbows [*see Figure 1*], knees, and scalp [*see Figure 2*] are the most commonly affected sites. The intergluteal cleft [*see Figure 3*], palms [*see Figure 4*], soles [*see Figure 5*], and genitals are also commonly affected, but psoriasis can involve any part of the body. Lesions frequently occur in a symmetrical pattern of distribution.

Many patients have only one or a few lesions that persist for years and that occasionally resolve after exposure to sunlight. Other patients can be covered with plaques that become confluent, affecting nearly 100% of the body surface area. Nail involvement is common, particularly in patients with severe disease.

The second most common form of psoriasis, guttate psoriasis, affects fewer than 10% of patients and is characterized by the development of small, scaling, erythematous papules on the trunk and the extremities [*see Figure 6*]. This form of psoriasis often follows streptococcal infection. Patients with plaque-type psoriasis can develop guttate psoriasis. Conversely, patients with guttate psoriasis frequently develop plaque-type psoriasis. Occasionally, guttate lesions enlarge and become confluent, resulting in the formation of plaques.

Figure 1 **Involvement of the elbows is characteristic of plaque psoriasis.**

Figure 2 **The scalp is affected in the majority of patients with plaque psoriasis.**

Figure 3 **The intergluteal cleft is a common site of involvement in patients with plaque psoriasis.**

Figure 4 **Psoriasis of the palms is shown in this patient.**

Figure 5 **Sharply demarcated, erythematous, scaling plaques on the feet are apparent in this patient with psoriasis of the soles.**

Erythrodermic psoriasis is a severe form of psoriasis that often affects the entire cutaneous surface. Patients present with an exfoliative erythroderma in which the skin is very red and inflamed and is constantly scaling [*see Figure 7*]. Patients are acutely ill, their skin having lost all protective function. Loss of temperature control, loss of fluids and nutrients through the impaired skin, and susceptibility to infection make this a potentially life-threatening condition.

Erythrodermic psoriasis can develop de novo or evolve from typical plaque-type or guttate psoriasis. Erythrodermic psoriasis can occur after withdrawal of systemic corticosteroids, after phototherapy burns, as a result of antimalarial treatment, as a result of a drug-induced hypersensitivity reaction, or for no apparent reason. Cutaneous T cell lymphoma may also present as erythroderma and needs to be differentiated from erythrodermic psoriasis.

Pustular psoriasis, another severe form of the disease, can occur in patients with preexisting psoriasis or can arise de novo. Pustular psoriasis can be generalized (von Zumbusch type) or localized to the palms and soles [*see Figure 8*]. In either case, the condition is severe and debilitating. In generalized

Figure 6 **Guttate psoriasis is characterized by small scaly papules and plaques.**

Figure 7 **Erythrodermic psoriasis is characterized by generalized erythema and desquamation.**

Figure 8 **Pustular psoriasis can be localized to the palms and soles or generalized.**

Figure 9 **Involvement of the nails is common in psoriasis.**

pustular psoriasis, the body is covered with sterile pustules. As with erythrodermic psoriasis, the protective functions of the skin are lost, and patients may succumb to infection or hypovolemia and electrolyte imbalance caused by loss of fluid through the skin. Although fever and leukocytosis are common features in pustular psoriasis, the possibility of infection should not be overlooked; patients with pustular psoriasis have died of staphylococcal sepsis.[28]

As with erythrodermic psoriasis, pustular psoriasis is most commonly precipitated by withdrawal of systemic corticosteroids. However, it can also result from therapy with antimalarial drugs or lithium, and it can develop spontaneously.

Nail Psoriasis

Nail changes can be of immeasurable value when the diagnosis is in doubt [*see Figure 9*]. In one study, 55% of patients with psoriasis experienced such changes.[29] The most common change consists of the appearance of tiny pits, as might be made with an ice pick, which often occur in groups. This characteristic pitting of the nails is highly specific for psoriasis, although a few isolated pits may be seen in healthy nails or as a result of past trauma. Yellowish discoloration is common in psoriatic toenails and may appear in fingernails as well. Onycholysis, or distal separation of the nail plate from its bed, frequently occurs.

Other changes include subungual hyperkeratosis—an accumulation of keratinous debris under the nail—as well as transverse and longitudinal ridging. These findings, however, are much less specific because they also occur secondary to dermatitis, fungal infection, vascular insufficiency, and other conditions. Occasionally, a patient shows typical psoriatic nail changes without any other cutaneous signs at initial examination; all such patients are probably psoriatic and may eventually manifest psoriatic lesions.

Psoriatic Arthritis

Psoriatic arthritis has been estimated to occur in 7% to 42% of patients with psoriasis.[30] Joint inflammation in psoriatic arthritis is chronic, with occasional remissions.[31] There are five classic subtypes. The most common presentation is an oligoarthritis in which one or a few joints are affected. This form accounts for approximately 70% of cases of psoriatic arthritis. Skin lesions of psoriasis usually precede articular disease by 5 to 10 years, but joint inflammation develops before skin lesions in some patients. If a diagnosis of psoriatic arthritis is suspected, the physician should carefully examine the scalp, nails, intergluteal cleft, external ear canal, and genital region for psoriasis lesions.

The second most common type of psoriatic arthritis is virtually identical to rheumatoid arthritis. This form is characterized by symmetrical involvement of the joints with ulnar deviation and typical deformities, such as swan-neck deformity and boutonnière deformity. The only distinguishing features are the presence of psoriasis and the absence of circulating rheumatoid factor.

Arthritis mutilans is a rare, severely destructive form of psoriatic arthritis in which the interphalangeal joints of the hands and feet are destroyed, resulting in deformed digits. Ankylosing spondylitis accounts for 5% of cases of psoriatic arthritis. As in other forms of ankylosing spondylitis, the genetic marker HLA-B27 is usually present.

Distal interphalangeal joint involvement is the most characteristic form of psoriatic arthritis. It is usually associated with nail involvement.

HISTOPATHOLOGY

The classic microscopic features of a psoriatic plaque include the following:

- A markedly thickened stratum corneum, with layered zones of parakeratosis (retention of nuclei).
- A moderately to markedly hyperplastic epidermis, with broadening of rete projections and elongation to a uniform depth in the dermis.
- Increased mitotic activity in the lower epidermis.
- Epidermal thinning over the dermal papillae.
- A scant amount of inflammatory infiltrate from mononuclear cells in the superficial dermis.
- Intracorneal or subcorneal collections of polymorphonuclear leukocytes (Munro microabscesses)

Differential Diagnosis

The differential diagnosis of psoriasis includes other scaling dermatoses [*see 2:II Papulosquamous Disorders*]. Such dermatoses include the following:

- Seborrheic dermatitis that involves the scalp, nasolabial folds, and retroauricular folds.
- Pityriasis rosea, which begins with a herald patch and is self-limited.

- Lichen simplex chronicus, which is caused by repeated rubbing or scratching.
- Parapsoriasis, which is characterized by atrophy, telangiectasia, and pigmentary abnormalities.
- Pityriasis rubra pilaris, which is characterized by psoriasiform patches that often begin in sun-exposed areas.
- Other conditions (e.g., discoid eczema or secondary syphilis) that can be differentiated by clinical and pathologic criteria.

Treatment

More treatments are available for psoriasis than perhaps for any other dermatologic disease. New topical therapies, new systemic therapies, and new forms of phototherapy have been introduced, and additional treatments are in development. Biologic therapies that target specific molecules are likely to change the treatment of psoriasis in the future. Topical therapy will continue to be used by most patients, however.

TOPICAL THERAPY

The 1990s saw the development of many new therapies for psoriasis.[32] Topical therapy is the mainstay of treatment for most patients, particularly those with mild disease. Topical corticosteroids are the most commonly prescribed class of medication, but they are now often used together with topical calcipotriene, a vitamin D_3 analogue, or topical tazarotene, a retinoid; both calcipotriene and tazarotene have approval by the Food and Drug Administration for the treatment of psoriasis.[33] Tar and salicylic acid are available by prescription and as over-the-counter products. Use of anthralin has declined as effective nonsteroidal agents have become available.

Emollients are an important part of any topical regimen for psoriasis. Application of petrolatum alone may be sufficient therapy for some patients. More elegant creams and lotions are helpful but are somewhat less effective than greasy ointments. Tar and salicylic acid shampoos are valuable in the treatment of patients with scalp involvement. These preparations are available without prescription.

Corticosteroids

Topical corticosteroids are indicated for limited plaques of psoriasis. Because of their ease of use and their wide availability, topical corticosteroids are the most commonly prescribed medication for treatment of psoriasis. They have anti-inflammatory, antiproliferative, and antipruritic effects. Corticosteroids are more potent when they are applied under occlusion, which increases their percutaneous penetration. Unfortunately, occlusion also increases side effects.

Topical steroids have been ranked in seven categories in decreasing order of potency, with potency determined by a vasoconstriction assay [*see Table 1*]. Superpotent corticosteroids are in group I, and weak over-the-counter topical corticosteroids are in group VII.[34]

Side effects The most commonly encountered side effects of topical corticosteroids are local cutaneous reactions. Development of cutaneous atrophy, telangiectasia, and irreversible striae are the most common side effects. Perioral dermatitis, which is characterized by erythematous papules and pustules on the face, is caused by chronic use of topical corticosteroids. Tachyphylaxis, with habituation to topical corticosteroids and loss of response to them, is noted by most patients. Flare or rebound of psoriasis upon sudden withdrawal of topical corticosteroids can occur. Finally, suppression of the hypothalamic-pituitary-adrenal axis can occur, especially with use of superpotent topical corticosteroids, the widespread application of corticosteroids, occlusion, or chronic use. Because of concern over side effects, the package inserts for some superpotent corticosteroids suggest that use be limited to 2 weeks' duration. A number of regimens have been developed in which, after the initial weeks of continuous treatment with superpotent topical corticosteroids, psoriasis plaques are subsequently treated only on weekends.[35]

Vitamin D Analogues

Calcipotriene The first topical vitamin D analogue to receive FDA approval for use in the United States, calcipotriene has rapidly gained acceptance, despite the fact that it is not as effective as superpotent topical corticosteroids. Calcipotriene is available in ointment and cream form and as a solution. The primary reason for its success is its freedom from any corticosteroid side effects—namely, cutaneous atrophy, telangiectasia, striae, or suppression of the hypothalamic-pituitary-adrenal axis. Calcipotriene is comparable in efficacy to a group II corticosteroid. It is applied twice daily.

Calcipotriene has been used very successfully in combination with several other medications. It is most effective when used in combination with a superpotent topical corticosteroid. A regimen of calcipotriene ointment and halobetasol propionate ointment, each applied once daily, has been found to be more effective than monotherapy with either calcipotriene twice daily or halobetasol propionate twice daily.[36] Up to 90% of patients achieve marked improvement within 2 weeks of combination therapy with once-daily calcipotriene and once-daily halobetasol propionate ointment. For long-term maintenance of remission, a regimen has been developed in which halobetasol propionate is applied only on weekends and calcipotriene is applied on weekdays.[37] Using this regimen, 76% of patients achieved marked improvement for at least 6 months; this level of improvement was achieved in only 40% of patients receiving halobetasol propionate ointment on weekends only. Calcipotriene has also been shown to improve the response to ultraviolet B light (UVB)[38] and to psoralen plus ultraviolet A light (PUVA).[39]

Caution must be used when combining calcipotriene ointment with other medications, because it is easily inactivated. Salicylic acid, for example, completely inactivates calcipotriene on contact. Several other topical medications, including topical corticosteroids, can inactivate calcipotriene. In contrast, halobetasol propionate ointment is compatible with calcipotriene even when one medication is applied on top of the other.[40] UVA has been shown to inactivate calcipotriene,[41] so calcipotriene should be applied after PUVA therapy, not before. Use of calcipotriene should be limited to a maximum of 120 g a week because of isolated reports of hypercalcemia.[42]

A combination product containing calcipotriene and betamethasone dipropionate is now available in Europe and Canada. It appears to be more effective than the individual medications applied separately.[43]

Other vitamin D analogues Several new vitamin D analogues are under investigation in the United States or are in use elsewhere. Tacalcitol and maxacalcitol are promising medications for the treatment of psoriasis. The only common side effect

Table 1 Ranking of Topical Steroids for Psoriasis in Order of High to Low Potency

Group	*Generic Name*	*Trade Name*	*Strength (%)*
I	Betamethasone dipropionate in optimized vehicle	Diprolene ointment	0.05
	Clobetasol propionate	Temovate cream, ointment	0.05
	Diflorasone diacetate	Psorcon ointment	0.05
II	Amcinonide	Cyclocort ointment	0.1
	Betamethasone dipropionate, augmented	Diprolene AF cream	0.05

is irritation, which occurs in up to 20% of patients, most often on the face and in intertriginous areas. Topical calcitriol has FDA approval for the treatment of psoriasis in several countries around the world[44]; it may be less irritating than calcipotriene in intertriginous sites.

Tazarotene

Tazarotene is a retinoid that has been developed for the treatment of psoriasis. It is available in 0.05% and 0.1% gels and in cream formulations. Tazarotene is comparable in efficacy to a group II corticosteroid cream. Patients receiving tazarotene 0.1% gel experience longer periods of remission after discontinuance of therapy than patients receiving corticosteroids.

Tazarotene has several advantages over the corticosteroids. First, it is not associated with cutaneous atrophy, telangiectasia, or the development of striae. In fact, tazarotene, like other retinoids, may actually prevent corticosteroid atrophy. Tazarotene has been shown to enhance the efficacy of UVB phototherapy.[45] It does, however, increase the ability of ultraviolet light to induce erythema.[46] Doses of UVB and UVA should therefore be reduced in patients who are also receiving tazarotene.

Side effects The main side effect of tazarotene is local irritation, which has caused many patients to discontinue its use. The combination of tazarotene and a topical corticosteroid reduces irritation and enhances the efficacy of both agents.

Tars

Tar has been used since the 19th century to treat psoriasis. Crude coal tar, a complex mixture of thousands of hydrocarbon compounds, affects psoriatic epidermal cells through enzyme inhibition and antimitotic action.[47] Crude coal tar is messy to apply, has a strong odor, and stains skin and clothing. It is applied in conjunction with UVB phototherapy in the Goeckerman regimen [see Phototherapy, below]. More refined tar preparations, which are cosmetically acceptable, are available by prescription and over the counter in the form of gels, creams, bath oils, shampoos, and solutions (liquor carbonis detergens). Tar is often used in combination therapies and as maintenance therapy after psoriasis plaques have resolved.

Anthralin

Anthralin (dithranol) has been used to treat psoriasis since

1916.[48] It is an extremely effective topical agent for psoriasis, probably because it inhibits enzyme metabolism and reduces epidermal mitotic turnover.[48]

Indications Because of the staining and irritation associated with the use of anthralin, this agent is usually prescribed for patients who do not respond to other topical therapies.

Formulations and regimens A modified Ingram regimen combines the daily application of anthralin in a stiff paste with tar baths and with exposure to ultraviolet light. This therapy involves application of progressively higher concentrations of anthralin for 6 to 8 hours at a time; it was introduced in the United States for hospitalized psoriatic patients[44] and for ambulatory patients in a psoriasis day care center.[49]

Modified anthralin formulations have been used to minimize the staining from anthralin, to decrease irritation, and to promote home use of the medication. Short-contact therapy consists of the application of anthralin to localized plaques for 30 minutes to 2 hours, after which time the anthralin must be thoroughly removed to minimize irritation of the surrounding skin.[50] Anthralin in a cream base, which can be removed by washing with water, is suitable for home use; it is available in 1% and 0.5% concentrations, for application to localized lesions on the skin and the scalp.

A formulation of 1% anthralin cream, composed of microencapsulated lipid crystals that release anthralin for absorption at skin temperature, is available. When used as short-contact therapy, this preparation carries a low risk of staining and irritation.[51]

Anthralin is most effective therapeutically when it is compounded in the form of a hard paste containing paraffin; this form is most commonly used in ambulatory psoriasis treatment centers. Anthralin ointment is less effective than anthralin paste, and anthralin cream is even less effective. With regard to patient compliance, this order is reversed. The end point of treatment is resolution of plaques to a macular state; this is usually associated with residual postinflammatory hyperpigmentation and temporary staining from anthralin. Resolution of symptoms usually occurs within 2 to 3 weeks after a modified Ingram regimen; remissions last for weeks to months.

Side effects Staining of skin, clothing, and the home is common with anthralin, as is irritation at the site of application.

SUNLIGHT

Ultraviolet radiation has a beneficial effect on psoriasis. Sunbathing for 2 to 4 weeks lessens the morbidity associated with the disorder, and climatotherapy at the Dead Sea is an effective alternative therapy for psoriasis for those who can travel to that part of the world. Because of its unique geographic location, 300 m below sea level, patients are exposed to naturally filtered ultraviolet light, which results in significant improvement or complete resolution of symptoms in 83% of patients over several weeks.[52] The sunlight at the Dead Sea accounts for most of the response, with little additional improvement resulting from bathing in the Dead Sea. Not surprisingly, patients treated at the Dead Sea have higher rates of nonmelanoma skin cancer.[53]

PHOTOTHERAPY

Phototherapy with UVB is an important therapeutic option for patients with extensive psoriasis. UVB irradiation can be used alone, but it has traditionally been combined with topical application of tar. Daily in-hospital application of crude coal tar and exposure to ultraviolet light (the Goeckerman regimen) can lead to a resolution of symptoms in widespread psoriasis within 3 or 4 weeks and can effect remissions that last for weeks to months.

In a reevaluation of the Goeckerman regimen, application of a 1% tar preparation was found to be as effective as a 6% preparation. Furthermore, application of the tar preparation for 2 hours before irradiation was equivalent to longer periods of application.[54] Contraindications to the use of the Goeckerman regimen include the presence of severely excoriated or inflamed psoriasis, erythrodermic and pustular forms of the disease, folliculitis, and a history of photosensitivity.

Newer regimens, which are more convenient and aesthetically acceptable, combine UVB with emollients. The emollient or vehicle decreases reflectance of the psoriatic scale, thereby increasing light transmission. According to a report by Lowe and colleagues, results with emollients are equivalent to those with tar, when used in regimens that utilize UVB in doses sufficient to cause erythema (erythemogenic); however, tar may have an additive effect when combined with a less aggressive regimen of suberythemogenic UVB.[55]

In a comparison study, outpatient UVB phototherapy was administered three times weekly, along with the application of either a tar oil or an emollient twice a day. This approach led to clearing of psoriatic lesions in 78% of patients [*see Figure 10*]. No difference in response was observed between the tar oil and the emollient.[56] Although the Lowe study had shown an additive effect for tar combined with UVB irradiation when patients were evaluated after 3 to 4 weeks (before their lesions had cleared),[57] this comparison study showed no such advantage in patients who were evaluated at the time of lesion clearing. Remission lasted longer in patients who received maintenance UVB phototherapy twice weekly for 1 to 2 months and then once weekly for up to 4 months than in patients who stopped receiving UVB phototherapy after the initial clearing.

Narrow-Band UVB

Narrow-band UVB, which comprises wavelengths of approximately 311 nm (as opposed to the 295 to 320 nm range of broad-band UVB), is a newer approach that is more effective than broad-band UVB.[58] Like other forms of phototherapy, narrow-band UVB works through local effects; therefore, covered areas, such as the scalp, do not respond.[59]

PHOTOCHEMOTHERAPY

Photochemotherapy with PUVA is indicated for patients with extensive, disabling psoriasis that has failed to respond to conventional forms of therapy, including conventional or narrow-band UVB phototherapy. PUVA therapy entails the administration of the photosensitizing drug methoxsalen (8-methoxypsoralen)—in an oral dose or by soaking in a tub containing methoxsalen or applying topical methoxsalen—followed by exposure of the patient to high-intensity longwave ultraviolet light in a walk-in irradiation chamber. The initial UVA dose (in joules/cm^2) is based on the patient's skin type and calculated in accordance with established protocols.[60]

Although its therapeutic effect is local, PUVA is a systemic treatment in which photoactivated methoxsalen binds to epidermal DNA, forming monofunctional and bifunctional adducts. It has been postulated that the resulting interference with epider-

Figure 10 **Psoriasis in a child before (*a*) and after (*b*) phototherapy.**

mal mitosis is one of the mechanisms of action of PUVA therapy for psoriasis, although effects on immune function in the skin play an important role.

The efficacy of oral PUVA therapy has been established by several multicenter clinical trials.[61] A course of PUVA therapy administered two or three times weekly resulted in significant clearing of psoriasis lesions in approximately 90% of patients within a mean of 25 total treatments. After the initial course, a tapering maintenance regimen is instituted, and PUVA therapy is eventually discontinued. In most patients, psoriasis recurs months to years after PUVA is discontinued, indicating that this therapy is palliative rather than curative.

Side Effects

Acute side effects caused by phototoxicity, such as erythema and blistering, are dose related and can therefore be controlled. Pruritus, usually associated with dryness of the skin, is fairly common and can be alleviated by the use of emollients and oral antihistamines. Nausea may follow ingestion of methoxsalen. Of greater concern are the potential long-term side effects, particularly carcinogenicity. Although the FDA has approved the use of PUVA to treat psoriasis, patients must be closely monitored for long-term side effects. A multicenter study of more than 1,300 PUVA-treated patients in the United States who were evaluated after 1 to 3 years of follow-up revealed a significant increase in the number of squamous cell carcinomas (SCCs) in those patients with a history of exposure to ionizing radiation or a history of skin cancer.[62] A higher-than-expected ratio of SCCs to basal cell epitheliomas and an excess of SCCs in areas of the body that were not exposed to the sun were significant findings of the study. A 5.7-year follow-up study of the original cohort group revealed a dose-dependent increase in the risk of SCC.[63] There was only a slight increase in the risk of basal cell carcinoma in these patients. The risk of SCC was almost 13-fold higher in patients who had received high cumulative doses of PUVA than in patients who received low-dose therapy.

A follow-up study of the surviving members of that cohort, at least 15 years after original treatment, again assessed the risk of skin cancers. Of great concern was a small but statistically significant increase in the incidence of malignant melanoma.[64] Because that increase did not become apparent until after a period of at least 15 years, there is great concern that high rates of melanoma will occur in patients who began PUVA therapy years ago. Fortunately, this has not happened thus far.

Studies in animals suggest that PUVA may have ocular side effects. Methoxsalen has been detected in the lenses of rats after they have ingested the drug; subsequent exposure to UVA enhances such ultraviolet-induced changes as cataracts.[65] The risk of ocular toxicity and possible retinal damage is of particular concern in young persons, whose lenses transmit more UVA than the more opaque lenses of older persons, and in aphakic persons, in whom lenses are absent.[66] The use of UVA-opaque goggles during PUVA treatment sessions is extremely important. Glasses that block UVA must be worn from the time that methoxsalen is administered throughout the rest of the day. Some investigators advise protection of the eyes the day after therapy. Thus far, studies of patients treated with PUVA have not revealed an increase in the incidence of cataracts.

SYSTEMIC THERAPY

Methotrexate

Short-term use of the antimetabolite methotrexate can be an extremely effective treatment for psoriasis. Methotrexate is indicated for patients who do not respond adequately to phototherapy and for patients with psoriatic arthritis.

The source of methotrexate's efficacy against psoriasis was once thought to be its antimitotic effect on proliferating keratinocytes. However, tissue culture studies have suggested that activated lymphoid cells in the lymph nodes, blood, and skin are a likely target of methotrexate; proliferating macrophages and T cells are 100 times more sensitive to methotrexate than are prolif-

erating epithelial cells.[67] These findings may be relevant to the mechanism of action of methotrexate in other immunologically based disorders, including psoriatic arthritis, rheumatoid arthritis, and Crohn disease.

Dosage Methotrexate is best given in a single weekly oral dose of up to 30 mg or in three divided doses at 12-hour intervals during a 24-hour period (e.g., at 8:00 A.M., at 8:00 P.M., and again at 8:00 A.M.).

Hepatoxicity and liver biopsy The use of liver biopsy has been advocated for monitoring patients with psoriasis who are receiving methotrexate. This recommendation is controversial, however; critics point out that liver biopsies are not routinely performed in patients with rheumatoid arthritis who are undergoing treatment with methotrexate.[68] Nevertheless, a review of the literature clearly shows that patients with psoriasis who are treated with methotrexate are more likely to develop hepatic fibrosis, possibly because of their underlying disease or because of the concomitant treatments they are given.

Current guidelines call for the use of liver biopsy in patients with psoriasis who have received a cumulative dose of 1 to 1.5 g of methotrexate and who do not have a history of liver disease or alcoholism. Biopsy should be performed early in the course of treatment in patients with a history of hepatitis C, alcoholism, or other liver disease. Other risk factors for hepatotoxicity are obesity, diabetes, and abnormalities on liver function testing.

Pathologic liver changes caused by methotrexate therapy have been graded as follows: grade I, normal liver histology or mild fatty infiltration; grade II, moderate to severe fatty infiltration with portal tract inflammation and necrosis; grade IIIA, mild fibrosis; grade IIIB, moderate to severe fibrosis; and grade IV, cirrhosis. Methotrexate should be discontinued in patients with grade IIIB or IV pathologic liver changes. The importance of strict adherence to current guidelines for the administration of methotrexate is emphasized by the occurrence of methotrexate-induced cirrhosis necessitating liver transplantation in three patients with long-term psoriasis who did not undergo serial liver biopsies.[69]

Other side effects In addition to hepatotoxicity, other side effects of methotrexate therapy include bone marrow suppression, nausea, diarrhea, and stomatitis. Methotrexate is teratogenic and can cause reversible oligospermia. Pneumonitis can occur early in the course of treatment if methotrexate is administered in oncologic doses. Evaluation by tests of liver function, renal function, and blood elements must be made before and throughout the course of methotrexate therapy.

Certain drugs increase the toxicity of methotrexate by reducing renal tubular secretion; these drugs include salicylates, sulfonamides, probenecid, and penicillins. Other drugs increase toxicity by displacing methotrexate from its binding sites on plasma proteins; these drugs include salicylates, probenecid, barbiturates, and phenytoin. Many of the NSAIDs and trimethoprim-sulfamethoxazole enhance methotrexate toxicity.[68] Cases of pancytopenia after low-dose methotrexate therapy underscore the hazards of using this drug in patients with renal insufficiency or in patients who are concomitantly receiving drugs that increase methotrexate toxicity.[70]

Contraindications to treatment with methotrexate and indications for stopping treatment should be heeded. Constant medical supervision is necessary, and therapy must be stopped at once if toxicity develops.

Acitretin

Indications and dosage Acitretin, an oral retinoid, has FDA approval for the treatment of plaque psoriasis. It is highly effective in the treatment of pustular psoriasis and can be very effective as monotherapy for erythrodermic psoriasis. For plaque-type and guttate psoriasis, however, acitretin is most useful in combination with other treatments, particularly UVB and PUVA phototherapy.[71,72] Acitretin is initiated 1 to 2 weeks before UVB or PUVA therapy is started. With combination treatment, symptoms resolve much more quickly. Doses of only 10 to 25 mg daily are effective, thus minimizing retinoid side effects.[71,72] When used as monotherapy, acitretin is prescribed in doses of 25 mg daily, which can be increased to 50 mg a day or higher.

Side effects Acitretin side effects are dose related and are common with doses above 25 mg daily. Hair loss, cheilitis, desquamation of the palms and soles, sun sensitivity, and periungual pyogenic granulomas are among the mucocutaneous side effects. Hyperlipidemia is common but is easily controlled with lipid-lowering agents. Elevations in liver enzyme levels can occur, and enzyme levels must be monitored. Serial liver biopsies have not demonstrated hepatic fibrosis in patients treated with oral retinoids.[73]

Acitretin poses a significant risk of teratogenicity. Characteristic retinoid birth defects occur in a high proportion of fetuses exposed to even small amounts of the drug in utero. Acitretin is eliminated from the body much more quickly than its prodrug etretinate. In the presence of alcohol, however, acitretin is converted back to etretinate,[74] raising concerns that women of childbearing age who take acitretin and who later become pregnant would then be at risk for exposing their fetus to acitretin's teratogenic effects. The FDA therefore requires that acitretin not be given to women planning a pregnancy within 3 years.

Long-term side effects of oral retinoids include calcification of ligaments and tendons and osteoporosis.[75,76] The long-term safety of etretinate, acitretin's prodrug, was examined in a 5-year prospective study of 956 patients with psoriasis. The investigators concluded that with appropriate patient selection and monitoring, there was no substantially increased risk of side effects related to cardiovascular disease, cancer, diabetes, cataracts, and inflammatory bowel disease. Although joint symptoms improved in some patients, more patients had joint problems associated with etretinate. Etretinate also caused short-term changes in liver enzyme levels in some patients and, in rare cases, caused acute hepatitis. The long-term risk of liver disease and cirrhosis with etretinate, however, was less than that associated with comparable periods of methotrexate.[77]

Cyclosporine

Cyclosporine in a microemulsion formulation was approved by the FDA for the treatment of psoriasis after extensive worldwide experience. In dosages of 2.5 to 5 mg/kg/day, cyclosporine is highly effective for psoriasis. Even at such doses, however, it may be associated with significant side effects, which have limited its use in patients with severe or refractory disease.

Indications and dosage Cyclosporine is indicated for patients in whom phototherapy or methotrexate therapy has failed. The microemulsion formulation of cyclosporine is better ab-

sorbed than earlier formulations. It is available in gel capsules of 25 and 100 mg and is most commonly taken in divided doses twice daily. At dosages of 5 mg/kg/day, a response is usually seen within 4 weeks, and some patients respond as quickly as 1 week. It should be noted that in the United States, the package insert for cyclosporine recommends an upper dosage limit of 4 mg/kg/day, although worldwide experience regarding the efficacy and safety of this drug has established an upper limit of 5 mg/kg/day.[78] In the United States, the maximum FDA-approved duration of treatment of cyclosporine is 1 year.

Side effects Cyclosporine is associated with a number of side effects that are easily managed; other side effects are of greater concern. Hypertrichosis, tremors, paresthesias, headache, gingival hyperplasia, joint pain, and fatigue can occur. Elevations in serum lipid levels and minor elevations in liver enzyme levels are also common. Hypomagnesemia may require magnesium supplementation. The most serious common side effects are hypertension and nephrotoxicity. Hypertension can be managed by lowering the dose or by instituting treatment with calcium channel blockers such as amlodipine besylate. There is some evidence that in normotensive patients receiving cyclosporine, amlodipine therapy may prevent some of the nephrotoxicity that has been associated with this potent psoriasis treatment.[79]

Renal interstitial fibrosis and renal tubular atrophy are common in patients on long-term therapy with cyclosporine.[80,81] Consequently, serum creatinine levels must be monitored on a regular basis. If the serum creatinine level rises more than 30% above baseline (or more than 25%, according to the United States package insert), the dosage may have to be reduced.[78]

Organ transplant patients taking cyclosporine, as well as other immunosuppressive drugs, to prevent rejection have experienced an increase in lymphoproliferative diseases and skin cancers.[82,83] It is hoped that the lower doses and intermittent usage of cyclosporine in psoriasis patients will not be associated with an increase in malignancies, but caution must be exercised. In one study, no increase in lymphoproliferative disorders was found in rheumatoid arthritis patients who were treated with cyclosporine for a short period (median, 1.6 years), compared with a parallel group of rheumatoid patients who were not treated with cyclosporine.[84] Nevertheless, caution must be used with this powerful new psoriasis treatment.

Tacrolimus

Although tacrolimus does not have FDA approval for use in psoriasis, it is a potent immunosuppressive agent that may be substituted for cyclosporine in patients who cannot tolerate the hypertrichosis associated with this agent. Tacrolimus has proved to be effective in the treatment of psoriasis. In a double-blind trial, 50 patients with severe recalcitrant psoriasis were given either oral tacrolimus or placebo.[85] In the tacrolimus group, starting dosages were 0.5 mg/kg/day, and the dosages could be increased to 0.10 mg/kg at week 3 or 6 if patient response was judged to be insufficient. After 9 weeks of treatment, patients receiving tacrolimus had an 84% reduction in Psoriasis Area and Severity Index (PASI) scores.

As with cyclosporine, there are concerns about hypertension, nephrotoxicity, and immunosuppressive effects with tacrolimus. This drug is not associated with hypertrichosis or gingival hyperplasia. Tacrolimus has not been studied as extensively as cyclosporine for the treatment of psoriasis, and further investigations are warranted for this very effective antipsoriatic agent.

Hydroxyurea

Hydroxyurea may be considered for the treatment of psoriasis in patients with hepatic disease, because hepatotoxicity is uncommon with this agent.[86] Response is slower and less complete than with methotrexate, however, and resistance to hydroxyurea may develop more frequently. Hydroxyurea is administered orally at a dosage of 1 to 2 g/day. Careful monitoring of blood counts is necessary during therapy.

Sulfasalazine

Sulfasalazine does not have FDA approval for the treatment of psoriasis but is highly effective in selected patients. It is typically given in dosages of 3 to 4 g daily. In one study, over 25% of patients given sulfasalazine stopped the treatment because of side effects (cutaneous eruptions or nausea). In clinical practice, results have been less promising than in studies.[87]

Combination Therapy

Combinations of various psoriasis treatments have proved to be superior in efficacy to monotherapy. Acitretin is routinely used with UVB and PUVA, a combination that allows the use of smaller doses and minimizes toxicities of both retinoid therapy and phototherapy.[71,72] The combination of methotrexate and acitretin has been used successfully despite some concern that both drugs are hepatotoxic.[88] Careful monitoring of liver enzyme levels is essential. Methotrexate and cyclosporine can be used together, and their concurrent administration in small doses can result in greater efficacy and less toxicity than that which can be achieved with higher doses of either agent used alone.[89] Methotrexate has also been used very successfully in combination with UVB[90] and PUVA,[91] although there is some concern that methotrexate may potentiate the carcinogenic effect of PUVA.[92] Because cyclosporine has been associated with skin cancers, it is not routinely used in combination with PUVA. It can be used in combination with retinoids and mycophenolate mofetil.

Other Systemic Therapies

Mycophenolate mofetil, a drug that has FDA approval for the prevention of organ transplant rejection, is highly effective for some patients with psoriasis.[93] Mycophenolate mofetil is the prodrug of mycophenolic acid, a medication that was tested for psoriasis in the 1970s.[94] Although mycophenolic acid was found to be highly effective in the treatment of psoriasis, the manufacturers did not pursue FDA approval for that indication because of its side effects, which included gastrointestinal toxicity and an immunosuppressive effect that resulted in herpes zoster infections in more than 10% of treated patients.

6-Thioguanine is another anticancer chemotherapeutic agent that is highly effective for psoriasis. Unfortunately, it has been associated with bone marrow suppression in approximately 50% of patients.[95] Bone marrow toxicity from 6-thioguanine can be reduced by administering the drug two to three times a week rather than daily.[96]

Biologic Therapies

The ability to create molecules that target specific steps in the pathogenesis of psoriasis has led to the development of biologic agents that can treat psoriasis without the nephrotoxicity associated with cyclosporine and without the bone marrow and liver toxicities associated with methotrexate. Biologic agents are immunosuppressive, and their long-term toxicity is not known. As

with other immunosuppressive agents, there is concern about the potential to predispose patients to infections or malignancies. Several biologic agents have FDA approval for use in psoriasis—namely, alefacept, efalizumab, and etanercept. Others have been approved for use in other diseases but are undergoing clinical trials for use in psoriasis—namely, adalimumab and infliximab. Still other agents, such as onercept, a TNF-α blocking agent, and anti–IL-12, are at earlier stages of development.

Alefacept Alefacept is a fusion protein consisting of LFA-3 fused to the Fc portion of human IgG1. The LFA-3 portion of the molecule attaches to its naturally occurring receptor, CD2, on the surface of a resting T cell, thereby blocking T cell activation. The Fc portion of the molecule attaches to Fc receptors on natural killer cells and macrophages, resulting in apoptosis of the bound T cell.[97]

Alefacept originally received FDA approval as intravenous and intramuscular formulations, but it is now available only in the intramuscular form. Alefacept is administered weekly for 12 weeks in a dose of 15 mg. In one study, by 14 weeks after the start of therapy, 21% of patients achieved PASI 75 (75% reduction in disease from baseline) and 42% of patients achieved PASI 50 (50% reduction in disease from baseline). Improvement typically progresses after the completion of treatment, with maximal disease reduction 8 weeks after a second course of therapy; in one study, 33% of patients achieved PASI 75 and 57% achieved PASI 50 by this point.[98] The most striking benefit of alefacept therapy is the long duration of remission achieved in a subgroup of patients. In patients who achieved PASI 75, the median time to recurrence of psoriasis (as defined by maintenance of PASI 50) was 7 months after a single 12-week course of therapy and more than a year after two courses of therapy.[99]

Drawbacks of alefacept therapy include the high cost of the drug and the need for weekly $CD4^+$ T cell counts because the drug tends to reduce the number of these cells. The onset of action of alefacept is slow, with many patients achieving maximal response weeks after completing the 12-week course. Moreover, only a proportion of patients achieve a satisfactory response.

Efalizumab Efalizumab is a humanized monoclonal antibody directed against the CD11a portion of LFA-1. Efalizumab blocks the interaction between LFA-1 and ICAM-1, an interaction that is responsible for T cell activation and trafficking of T cells into inflamed skin. After a conditioning dose of 0.7 mg/kg the first week, patients self-administer subcutaneous injections of efalizumab at a dose of 1 mg/kg weekly. In double-blind, placebo-controlled trials, 22% to 39% of patients treated with weekly efalizumab for 12 weeks achieved PASI 75,[100-102] and nearly 60% of patients achieved PASI 50. With longer therapy, higher proportions of patients achieve greater degrees of improvement. Like the other biologic agents, efalizumab does not cause the nephrotoxicity associated with cyclosporine or the bone marrow or liver toxicity associated with methotrexate. The drug is fairly expensive, however, and flulike symptoms may develop after the first or second injection; a serious concern is the development of psoriasis rebound (defined as a worsening of psoriasis over baseline), which occurs in up to 15% of patients. To avoid psoriasis rebound, efalizumab should not be stopped abruptly but, rather, slowly converted to alternative therapies.

Etanercept Etanercept is a recombinant fusion protein that includes the p75 TNF receptor that binds to TNF-α, blocking its interaction with cell surface receptors. Etanercept originally received FDA approval for a dosage of 25 mg administered subcutaneously by the patient at home twice weekly for the treatment of psoriatic arthritis. Subsequently, etanercept received approval for the treatment of psoriasis at a dosage of 50 mg administered subcutaneously twice weekly for 3 months and then once weekly. In a double-blind, placebo-controlled, four-arm trial comparing placebo with three dosage regimens, analysis after 12 weeks of treatment showed that PASI 75 was achieved in 14% of patients who received 25 mg once a week, in 34% who received 25 mg twice a week, and in 49% who received 50 mg twice a week. Response rates were even higher at 24 weeks of therapy.[103]

The drawbacks of etanercept include its cost and the need to self-inject the medication on a long-term basis. Injection-site reactions, although common, are almost always minor and seldom require any treatment other than temporarily using a different site for injections. There is evidence that TNF-α blockers can cause an exacerbation of multiple sclerosis, so the drug should be avoided in patients with a personal or family history of demyelinating disease. Some controversy exists as to whether TNF-α blockers exacerbate chronic heart failure, and there is concern that the immunosuppressive effects of TNF-α blockers may contribute to an increase in the development of lymphoproliferative diseases.[104] Antinuclear antibodies also develop in etanercept-treated patients, but they are of questionable physiologic significance.

Infliximab Infliximab is a chimeric monoclonal antibody directed against TNF-α. In the short term (12 weeks), it is the most effective treatment for psoriasis, but it does not yet have FDA approval for this indication. It is administered by slow intravenous infusion at baseline, at weeks 2 and 6, and then every 8 weeks thereafter. In a double-blind, placebo-controlled trial evaluating patients at week 10, after only three infusions, 82% of patients achieved PASI 75.[105] Moreover, 55% of patients maintained PASI 50 or higher during 6 months of follow-up.

Like the other TNF-α blockers, infliximab is associated with worsening of chronic heart failure, multiple sclerosis, and lymphoproliferative diseases. In addition, infusion reactions develop in a significant proportion of patients; these appear to be related to the development of human antichimeric antibodies. Although infusion reactions are mild in the majority of patients, they can be severe, resulting in chest pain and hypotension. Pretreating patients with antibiotics is beneficial. TNF-α blocking plays a significant role in the control of mycobacterial infection, and an increase in reactivation of latent tuberculosis has been observed in patients treated with infliximab. Consequently, patients should undergo tuberculosis testing before starting on this medication.[106]

Adalimumab Adalimumab is a fully human monoclonal antibody against TNF-α. It has FDA approval for the treatment of rheumatoid arthritis and has been successfully tested for psoriasis.[107] Like the other biologics, adalimumab is not toxic to kidneys, liver, or bone marrow; however, also like the other biologic agents, it is quite expensive. The same concerns about heart failure, multiple sclerosis, and lymphoproliferative diseases that exist with etanercept and infliximab are also described in adalimumab's package insert. In a three-arm, placebo-controlled trial, PASI 75 was achieved by 53% of patients who received adalimumab every other week and by 80% of pa-

tients who received it weekly. An even greater number of patients achieved PASI 50. Adalimumab, 40 mg, is given by subcutaneous injection.

Prognosis

Psoriasis is usually lifelong, but the severity of the disease may vary, with periodic exacerbations and relative remissions in some patients. Although pustular psoriasis and erythrodermic psoriasis can be life-threatening, even stable plaque psoriasis can have a negative impact on overall health, possibly because of comorbid conditions such as psoriatic arthritis or obesity or because of complications of therapy.

Severe exacerbation of psoriasis taxes the ingenuity of even the most skilled clinician. Fortunately, because of the wide range of psoriasis therapies now available, clinicians are able to successfully treat almost all patients with psoriasis. The goal of therapy must be to minimize toxicity while achieving satisfactory improvement both in physical signs and symptoms and in patients' quality of life.

IV ECZEMATOUS DISORDERS, ATOPIC DERMATITIS, AND ICHTHYOSES

Seth R. Stevens, m.d.

Eczematous Disorders

Eczematous dermatitis, or eczema, is a skin disease that is characterized by erythematous vesicular, weeping, and crusting patches. Although the term eczema is often used as a diagnosis, it can in fact be used appropriately to describe lesions seen in several diseases. Itching is a characteristic symptom, and epidermal intercellular edema (spongiosis) is a characteristic histopathologic finding of eczematous conditions. The term eczema is also commonly used to describe atopic dermatitis [*see* Atopic Dermatitis, *below*].

CONTACT DERMATITIS

Contact dermatitis, a paradigmatic example of an eczematous disorder, is common and well studied [*see 2:V Contact Dermatitis and Related Disorders*]. Contact dermatitis can be either allergic or irritant in etiology. Allergic contact dermatitis differs from other eczematous disorders in that determination of the offending contactant is an important part of the evaluation. If the patient's history does not provide the answer, the body site of the lesion may (e.g., head involvement in allergy to paraphenylenediamine in hair dye). Patch testing may be required to confirm the diagnosis.[1]

The manifestations of irritant contact dermatitis are similar to those of allergic contact dermatitis[2]; in the irritant form, however, the mechanism is not immunologic. Given sufficient concentration and duration of contact, offending agents will induce irritation in anyone's skin. Detergents, acids, alkalis, solvents, formaldehyde, and fiberglass are common causes.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is another common eczematous condition [*see 2:II Papulosquamous Disorders*]. Clinically, seborrheic dermatitis may exist without vesicle formation. Lesional morphology is usually a greasy scale on erythematous patches; however, the scale may be dry and the patches may have an orange hue. Scalp, eyebrows, mustache area, nasolabial folds, and chest are typical areas of involvement. Psoriasis may be part of the differential diagnosis. Treatment is with shampoos containing selenium sulfide, zinc pyrithione, tar, or ketoconazole; emollients; and mild (nonfluorinated) topical steroids. Antimicrobial therapy directed at the commensal yeast *Pityrosporum ovale* can be effective, although a causative role of the organism remains unproved.

OTHER ECZEMATOUS DERMATITIDES

Two other eczematous dermatitides are nummular eczema and dyshidrotic eczema (pompholyx). Nummular eczema describes well-demarcated, coin-shaped eczematous patches that are usually 2 to 4 cm (rarely more than 10 cm) in diameter. The lesions are quite pruritic and require potent topical steroids, antihistamines, and, occasionally, intralesional or systemic corticosteroids for treatment. Dyshidrotic eczema presents as a vesicular eruption of the hands and feet, accompanied on rare occasions by hyperhidrosis. Typically, 1 to 2 mm vesicles appear on the sides of fingers, although more extensive involvement can occur. Treatment is with compresses and soaks, antipruritics, topical steroids, and, in severe recalcitrant cases, systemic corticosteroids. Photochemotherapy with topical psoralen and ultraviolet A irradiation (PUVA) may also be effective.

Atopic Dermatitis

Atopic dermatitis (AD) is a common chronic inflammatory dermatosis that generally begins in infancy. The term atopy was coined in the early 1920s to describe the associated triad of asthma, allergic rhinitis, and dermatitis.[3] Children with AD are at increased high risk of developing asthma and allergic rhinitis, and the risk is further increased for patients with a family history of atopy.[4] The role of reaginic antibodies and allergies in the etiology of AD is controversial; in 80% of patients with AD, however, serum immunoglobulin IgE is elevated, sometimes markedly.

ETIOLOGY AND PATHOGENESIS

The expression of AD is a complex integration of environmental and genetic factors. The lifetime prevalence is estimated to be 30% of the population,[5-7] possibly because of increasing contact with causative agents in the environment. Epidemiologic data suggest a genetic influence—25% of dizygotic twins and 75% of monozygotic twins are concordant for AD.[8] The condition develops in 60% of children who have one affected parent and in 80% of children with two affected parents.[9] The defect is likely carried in the immune system, because both antigen-specific IgE reactivity and AD have been transplanted from an AD-affected bone marrow donor to a previously unaffected recipient.[10] Candidate genes continue to be investigated.[11]

AD can be quickly exacerbated by environmental trigger factors.[12] Wool, lanolin, and harsh detergents are particularly irritating. Emotional stress can also lead to flares, which are characterized by increased itch, erythema, vesiculation, and excoriation, as well as expanded area of involvement. The role of airborne and foodborne allergens is difficult to assess. Although patients with AD frequently have circulating dust mite antigen-specific IgE and Th2 $CD4^+$ T cells,[13] hyposensitization infrequently results in improvement. Contact urticaria to food occurs in AD,[14] but generalized exacerbation after eating is rare. In the absence of a strong supporting history, elimination diets are rarely effective in treating AD. A role has been frequently suggested for cow's milk in inducing AD; however, studies examining the association of AD and early feeding with cow's milk have shown varying results.[15,16] Meta-analyses indicate that exclusive breast-feeding during the first 3 months of life is associated with lower incidence rates of atopic dermatitis during childhood in children with a family history of atopy.[17]

Gut microflora may be a natural source of immune modulation that prevents atopic dermatitis. In a double-blind, randomized, placebo-controlled trial, a probiotic containing a strain of *Lactobacillus* was administered prenatally to mothers who had at least one first-degree relative with atopy and 6 months postnatally to their infants; the frequency of AD in the group receiving *Lactobacillus* was half that of the placebo group.[18] These findings

suggest that impairment of the intestinal mucosal barrier may be involved in the pathogenesis of AD, and strengthening of the mucosal barrier with probiotic bacteria may help prevent AD in high-risk infants. Although intriguing, these results await confirmation.

Mechanisms have been proposed to explain a link between *Staphylococcus aureus* and exacerbations of AD,[19] including effects of cell wall constituents to increase expression of IgE, IgE receptor, and enterotoxin B, a superantigen that activates T cells in an antigen-independent fashion.[20]

The apparent paradox of reduced cell-mediated immunity[21,22] and hyperimmunoglobulinemia E seen in AD is addressed by the so-called Th1/Th2 model of helper T cells. In this model of the murine immune system, $CD4^+$ T cells are divided into two mutually exclusive classes on the basis of cytokine secretion: Th1 cells, which secrete cytokines that promote cell-mediated immunity (e.g., interleukin-2 [IL-2], interferon gamma), and Th2 cells, which secrete cytokines that promote humoral immunity and eosinophil function (e.g., IL-4 and IL-5). Atopy, including AD, has been seen as the paradigmatic condition of a so-called Th1-deficient state. Refinements have shown a heterogeneity of responses within different AD lesions, however. The current model is that blood and acute lesions of AD patients are more often dominated by Th2 cells, whereas chronic lesions are more often dominated by Th1 cells.[23]

Table 1 Diagnostic Criteria for Atopic Dermatitis[14]

- Major criteria
  - Personal or family history of atopy (atopic dermatitis, allergic rhinitis, allergic conjunctivitis, allergic blepharitis, or asthma)
  - Characteristic morphology and distribution of lesions
  - Pruritus
  - Chronic or chronically recurring dermatosis
- Minor features
  - Hyperimmunoglobulinemia E
  - Food intolerance
  - Intolerance to wool and lipid solvents
  - Recurrent skin infections
  - Xerosis
  - Sweat-induced pruritus
  - White (not red) dermatographism
  - Ichthyosis
  - Chronically scaling scalp
  - Accentuation of hair follicles
  - Recurrent conjunctivitis
  - Anterior subcapsular cataracts and keratoconus
  - Morgan line, or Dennie sign (single or double creases in the lower eyelids)
  - Periorbital darkening (allergic shiner)
  - Pityriasis alba (hypopigmented, scaling patches, typically on the cheeks)
  - Cheilitis
  - Anterior neck folds
  - Keratosis pilaris (perifollicular papules with keratotic plugs, typically on the arms and thighs)
  - Nipple eczema
  - Hyperlinear palms (increased folds, typically on the thenar or hypothenar eminence)
  - Recurrent hand and foot dermatitis
  - Exacerbation of symptoms by environmental or emotional factors

Hyperstimulatory dendritic antigen-presenting cells (Langerhans cells) are present in patients with AD.[24] One proposed mechanism for the augmented function of Langerhans cells in AD is the binding of antigen-specific IgE and antigen to the IgE receptors on Langerhans cells as a means of antigen focusing.[25] Another antigen-presenting cell, the monocyte, also manifests altered function in AD. Cyclic adenosine monophosphate (cAMP) phosphodiesterase has increased activity in monocytes of patients with AD—leading to hyperproduction of prostaglandin E_2, among other effects. Increased cAMP phosphodiesterase in AD may explain aberrant adrenergic responses, and the increased prostaglandin E_2 leads to diminished interferon-gamma production. Additionally, monocytes secrete IL-10 in AD, which further augments the so-called Th2 responses.[26] Altered cyclic nucleotide metabolism leads to excessive release of histamine by basophils and, potentially, to mast cell degranulation. High levels of cAMP phosphodiesterase are found in the umbilical cord blood of infants of AD-affected parents.[27] This finding may indicate an early, if not primary, defect in the disease that may become the basis of a diagnostic laboratory test.

Because IL-5 is a critical eosinophil growth factor and activating cytokine, blood eosinophilia may be expected to occur in a Th2 disease such as AD[28]; tissue eosinophilia, however, is variable. Cutaneous endothelial cells are also activated in AD, leading to increased expression of adhesion molecules and recruitment of leukocytes into the skin (i.e., dermatitis).

DIAGNOSIS

AD remains a clinical diagnosis. Major diagnostic criteria are (1) personal or family history of atopy (AD, allergic rhinitis, allergic conjunctivitis, allergic blepharitis, or asthma); (2) characteristic morphology and distribution of lesions; (3) pruritus; and (4) chronic or chronically recurring dermatosis. Several minor features can be added [*see Table 1*].[14] Pruritus is a consistent feature of AD. The lack of itching or of another major diagnostic criterion should prompt consideration of alternative diagnoses [*see* Differential Diagnosis, *below*]. Cutaneous signs can vary, depending on the age of the lesions.

Acute lesions of AD are eczematous—erythematous, scaling, and papulovesicular. Weeping and crusted lesions may develop [*see Figure 1*]. Scratching results acutely in linear excoriations, presenting as erosions or a hemorrhagic crust. In extremely severe cases, exfoliative dermatitis (erythroderma) may occur, with generalized redness, scaling, weeping, and crusting. There may be accompanying systemic toxicity, sepsis, lymphadenopathy, altered thermoregulation (either hyperthermia or hypothermia), and high-output cardiac failure. Erythroderma is a potentially life-threatening condition.

Chronic lesions tend not to be eczematous (thus, atopic eczema is not an ideal synonym for AD). Instead, lichenified plaques [*see Figure 2*] or nodules predominate. Lichenification denotes areas of thickened skin divided by deep linear furrows. Lichenified plaques result from repeated rubbing or scratching and thus often occur in areas of predilection, such as the popliteal and antecubital fossae. As is typical of lesions in AD, lichenification is poorly demarcated. There may be accompanying acute signs. Lichenified lesions are very difficult to treat; once established, they may persist for months even with adequate therapy and avoidance of rubbing or scratching.

Clinical expression of AD also varies with the age of the patient. The infantile stage of AD occurs up to approximately 2 years of age. Of all cases of AD, approximately 90% arise before

the fifth year and 60% in the first year of life; onset before 2 months of age is unusual, however.[8] During infancy, ill-defined, erythematous scaling patches and confluent, edematous papules and vesicles are typical. These lesions may become crusted and exudative. Intense pruritus leads to scratching, which induces linear excoriations and, with time, lichenification. Before the infant begins to crawl, the scalp and face are most often involved [*see Figure 3*], although lesions may be seen anywhere. After the child begins crawling, the extensor surfaces—particularly the knees—become involved. Involvement of fingers can be severe if the child sucks them frequently. Intense pruritus can lead to sleep disturbances of child and parents. Other features may arise [*see Table 1*]. Perifollicular accentuation and papules are commonly seen at any point in the life of an atopic patient, particularly in persons of Asian or African ancestry.

During childhood, the clinical features evolve into those seen in adults. Lesions tend to become less eczematous and drier, with increasing flexural and neck involvement. Scaling, fissured, and crusted hands may become especially troublesome. Infraorbital folds (sometimes called Morgan lines or the Dennie sign) and pityriasis alba can appear. Chronic or chronically relapsing pruritic, erythematous, papulovesicular eruptions that progress to scaling, lichenified dermatitis in a flexural distribution typify adult AD. Extensive areas of skin may be involved, including the face, chest, neck, flanks, and hands. Areas of dyspigmentation may result from repeated skin trauma. Approximately 10% to 15% of childhood AD persists after puberty.[8]

AD that begins after 20 years of age has been termed adult-onset atopic dermatitis.[29] This condition should be considered in patients with characteristic features of AD.

There are many associated features of AD. Asthma and allergic rhinitis, the major and minor criteria, respectively, have already been mentioned. Another important association, cutaneous infection, is related to diminished cutaneous cell-mediated immunity and defective chemotaxis. *S. aureus* is usually found on AD skin, and its density correlates with lesion severity.[30] Although such observations have implicated *S. aureus* as a cause of AD,[19,31] it is also clear that reduction in AD lesions reduces bacterial colonization.[32] Regardless, the high bacterial counts in lesional skin and the relative ease of their reduction suggest the desirability of extra efforts (e.g., use of topical steroids) to reduce the presence of *S. aureus* before elective procedures are performed through involved skin. Frank infection also occurs more commonly in AD, which results in pustules and oozing, crusted lesions.

Cutaneous fungal and viral infections also occur frequently and with increased severity in patients with AD. Eczema herpeticum, an extensive eruption of 2 to 3 mm vesicles, pustules, and punched-out erosions caused by herpes simplex virus, may coalesce into extensive areas of eroded skin. Frequently, the condition is most severe on the face (where it often arises from a herpetic lesion) and diminishes as it progresses to the trunk and extremities. Secondary bacterial infection is common. Lymphadenopathy, fever, and malaise may develop. Antiviral and antibiotic therapy can be lifesaving and should be started empirically upon presentation. Tzanck test, viral culture, and direct fluorescent antibody detection of viral antigens can confirm the diagnosis.

Molluscum contagiosum and common warts are also problematic in patients with AD, as are dermatophyte infections. Because of similar appearance, foot eczema must be distinguished from tinea pedis by potassium hydroxide preparation or fungal culture.

Figure 1 **Extensive, severe, weeping, crusted acute eczematous patches on the face of this infant are characteristic of patients in this age group.**

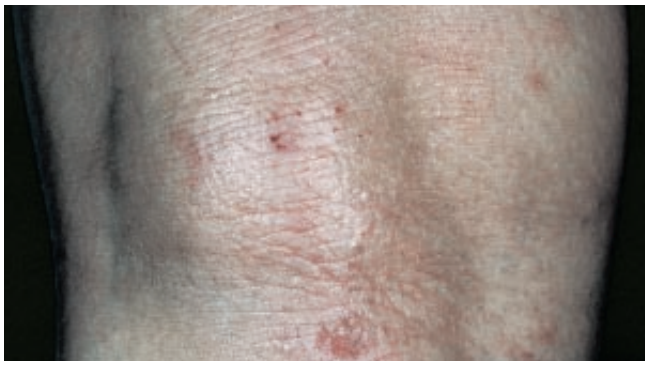

Figure 2 **Lichenified patches appear after chronic rubbing of eczematous patches. These lesions are characteristic of chronic allergic contact dermatitis and atopic dermatitis.**

Numerous ocular complications of AD exist.[33] These include anterior subcapsular cataracts, retinal detachment, keratoconus, blepharitis, conjunctivitis, and iritis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of AD includes the eczematous conditions and ichthyoses described in this chapter and other immunologic, metabolic, neoplastic, and rheumatologic disorders [*see Table 2*]. Because 80% to 85% of patients with occupational hand dermatitis have AD, the possibility of coexisting AD and contact dermatitis needs to be considered. Another important element of the differential diagnosis is cutaneous T cell lymphoma. Cutaneous T cell lymphoma can arise clinically as scaling, erythematous patches or exfoliative erythroderma. The classic distribution—near axillae, buttocks, and groin—is distinct from that of AD, and patches are frequently well demarcated. There is often sufficient clinical overlap between the two conditions, however, to necessitate further investigation, including histology, immunophenotyping, and gene-rearrangement analysis of T cell receptors. Cutaneous T cell lymphoma can arise in patients with AD, and the lack of conclusive clinical or laboratory tests for either disease can make distinction difficult. Reassessment from time to time in such cases is recommended.[34]

Reduction of Trigger Factors

Reduction of trigger factors (e.g., harsh chemicals, detergents, and wool) and avoidance of occupations that require contact with trigger factors (e.g., hairdressing, nursing, and construction) can be helpful.[35] Appropriate behaviors should be taught to patients and parents early during life, when habits are more easily formed.[36,37]

Bland Emollients

The use of mild, nonalkali soaps and frequent use of emollients are important elements in the long-term management of AD. Because moisture evaporating off the skin can trigger flares, bathing is sometimes discouraged. A better approach is the prompt application of an emollient such as petrolatum (finishing within 3 minutes of the end of the bath), which can serve to seal the moisture from the bath. Lotions and creams containing high amounts of water are usually inadequate, however, and can actually worsen AD. Products containing hydroxy acids, phenol, or urea can reduce dryness and scaling, but these can sting inflamed skin and should therefore be used with caution. Because of a specific reduction of ceramides in AD, a lotion that provides excess ceramides relative to other lipids has been shown to have a therapeutic advantage in AD.[38] Bubble baths and scented salts and oils can be irritating. Scalp care should include a bland shampoo. Topical tar products, such as shampoos and bath solutions, and topical creams and lotions containing 5% to 10% liquor carbonis detergens can help. Baths, soaks, and compresses with Burow solution can ameliorate crusted, infected, eczematous patches. Cotton clothing, washed to remove finishing (which often releases formaldehyde), is preferable to wool or synthetics.

Corticosteroids

Topical corticosteroids are another mainstay of therapy. Application immediately after bathing improves cutaneous penetration. Lowering the risk of side effects with less potent preparations must be balanced against gaining control of a flare quickly with more potent preparations. Long-term use of inadequately potent topical corticosteroids may pose a greater risk of adverse effects than brief use of more potent agents followed by a rapid taper to bland emollients. Because steroid-induced cutaneous atrophy is a greater risk on the face, in intertriginous areas (e.g., groin, axillae, and inframammary folds), and under diapers, less potent steroids (e.g., hydrocortisone and desonide) should be used in these areas, and they should be used with particular caution. For the remainder of the body, midpotency preparations, such as 0.1% triamcinolone acetonide, are helpful. More potent ointments, such as fluocinonide and desoximetasone, are useful for lichenified plaques. Flurandrenolide tape is useful for nodular prurigo (so-called picker's nodules) because it also physically protects the area from manipulation. For the scalp, solutions are preferred.

Systemic corticosteroids (e.g., prednisone, 20 to 80 mg/day orally) may be useful to treat severe, acute flares. Because of the risks of gastrointestinal, endocrine, skeletal, central nervous system, and cardiovascular complications, however, they should not be used more than twice yearly.

Table 2 Differential Diagnosis of Atopic Dermatitis

Type	*Disorders*
Dermatitides	Allergic contact dermatitis Dermatitis herpetiformis Irritant contact dermatitis (may be concomitant with atopic dermatitis) Nummular eczema Seborrheic dermatitis
Ichthyoses	Ichthyosis vulgaris
Immunologic disorders	Graft versus host disease HIV-associated dermatosis Hyperimmunoglobulinemia E syndrome Wiskott-Aldrich syndrome
Infectious diseases	Scabies Dermatophytosis
Metabolic disorders	Zinc deficiency Various inborn errors of metabolism
Neoplastic disorders	Cutaneous T cell lymphoma
Rheumatologic disorders	Dermatomyositis

Calcineurin Inhibitors

The steroid-free topical calcineurin inhibitors, tacrolimus ointment and pimecrolimus cream, are effective alternatives to topical corticosteroids. These agents do not cause the skin atrophy associated with prolonged use of topical corticosteroids and, therefore, are useful for treating skin on the face and neck.

The macrolide antibiotic tacrolimus (formerly FK506) has been found to be effective in treating moderate to severe atopic dermatitis. The efficacy of tacrolimus has been shown in several randomized, controlled trials.[39-41] The most common adverse side effects are skin burning, flulike symptoms, skin erythema, and headache.[41] Topical tacrolimus is available in 0.1% and 0.03% concentrations. In children with moderate and severe AD, treatment with tacrolimus ointment (0.03%) was shown to be superior to conventional 1% hydrocortisone acetate.[42]

The ascomycin derivative pimecrolimus (ASM 981) cream is a cell-selective cytokine inhibitor that was specifically developed for treatment of inflammatory skin diseases. Its mechanism of action is similar to that of topical tacrolimus. Two independent randomized, multicenter studies found pimecrolimus to be effective in infants and children with AD.[43] Another randomized, multicenter study found that pimecrolimus was effective in preventing AD flares, which reduced the need for topical corticosteroids.[44] In adults, pimecrolimus was found to be effective and well tolerated, and it reduced the incidence of AD flare.[45]

A meta-analysis of 16 trials involving more than 5,300 patients showed success rates of tacrolimus and pimecrolimus to be statistically similar; however, tacrolimus success rates were numerically higher than those of pimecrolimus, and tacrolimus was used in patients with more severe disease.[46] The efficacy of these drugs must be balanced against a potential cancer risk. The Food and Drug Administration recently issued a warning that these drugs should be used only as directed and only after other eczema treatments have failed to work.[47]

Other Therapies

Antihistamines can sometimes be helpful in breaking the itch-scratch cycle in AD. Sedating antihistamines, such as hydroxyzine and diphenhydramine, are particularly useful—especially

when itching prevents sleep[48]; however, the sedative properties of antihistamines may limit their use in AD. Cetirizine, a sedating antihistamine, appears to be well tolerated in infants. A multinational, randomized, placebo-controlled trial examined the effects of long-term treatment with cetirizine on infants with AD; the drug proved to be safe, and it reduced the need for topical corticosteroids in patients with more severe disease.[49] Nonsedating antihistamines such as fexofenadine and loratadine are less useful. Doxepin, a tricyclic antidepressant known to have antihistaminic effects, can be beneficial when applied topically in a 5% cream.[50]

Virtually every phototherapy regimen has been reported to ameliorate AD. Some patients cannot tolerate the heat generated by the equipment, however—particularly that used in UVB irradiation. In addition to UVB, the following can be beneficial: UVA, longwave UVA1, narrow-band UVB, UVA-UVB, and PUVA. Extracorporeal photochemotherapy (photopheresis) is reported to be effective therapy for recalcitrant disease.[51] Phototherapies are expensive, and prolonged use of PUVA has been linked to an increased risk of melanoma.[52] Although some patients may benefit from natural sunlight, the risk of sunburn and induction of malignancy by ultraviolet light must be considered.

Antimicrobials are obviously important for patients with infection. Less clear is whether antimicrobial agents can directly treat AD by reducing bacterial products thought to exacerbate the condition. Antistaphylococcal therapy has been advocated for use in patients with AD; however, a double-blind, placebo-controlled study of flucloxacillin did not show improvement in AD despite reduced bacterial counts.[53] Ketoconazole, likewise, has been used; its success, however, may be the result of anti-inflammatory, rather than antifungal, effects.

More advanced therapeutic options exist for severe, recalcitrant AD. The altered expression of cytokines in AD [*see* Etiology and Pathogenesis, *above*] has led investigators to explore the use of interferon gamma. Clinical trials have demonstrated that for some patients, daily subcutaneous administration of interferon gamma is effective in reducing both signs and symptoms of AD[54,55] and that long-term treatment can maintain the benefit.[56] However, moderate results and high costs make interferon gamma less viable as a treatment option.

Oral cyclosporine (2.5 to 5 mg/kg/day orally),[57,58] methotrexate (15 to 25 mg/wk orally), and azathioprine (100 to 200 mg/day orally) can be used in severe,[59] recalcitrant disease provided that patients are monitored for adverse effects specific to those agents.

Traditional Chinese herbal medicine has been found to be effective in the treatment of AD, both in children[60] and in adults,[61] although the efficacy of this treatment remains controversial.[62] The mechanisms of action of these preparations are unclear. A small, randomized, placebo-controlled study found topical treatment with St. John's wort to be significantly superior to placebo in patients with moderate AD.[63] Although evening primrose oil has for many years been proposed to be effective in AD, a well-controlled study failed to show any benefit to patients taking either evening primrose oil or a combination of evening primrose oil and fish oil, as compared with those receiving placebo.[64] Patients should be cautioned that herbal remedies are not risk free and may carry a potential for hepatotoxicity, cardiomyopathy, and other adverse effects; such remedies should be monitored, as should any other treatment. To avoid potential adverse drug reactions, physicians should identify any herbal remedies used by patients.[65]

Topical vitamin B_{12} was found to be significantly superior to placebo in reducing the extent and severity of AD in a randomized, multicenter phase III study[66]; however, larger trials are needed to establish the efficacy of this therapy. The cAMP phosphodiesterase inhibitor cipamfylline in cream form has been shown to be more effective than placebo but significantly less effective than hydrocortisone cream in the treatment of AD.[67] The importance of well-controlled studies to assess efficacy of treatments must be stressed because AD patients on the placebo arms of most controlled studies tend to show benefit, sometimes marked.

Ichthyoses

The ichthyoses are a group of diseases of cornification that are characterized by excessive scaling.[68] Etiologies of the ichthyoses are diverse, including genetic defects of structural proteins and enzymes, as well as acquired forms. Only the major clinical variants will be discussed here.

MAJOR VARIANTS

Ichthyosis Vulgaris

Ichthyosis vulgaris, the most common form of ichthyosis, is found in approximately one in 300 births. This autosomal dominant condition presents as dry skin with fine scaling. The extensor surfaces of extremities are the most commonly affected areas. Ichthyosis vulgaris can occur concomitantly with keratosis pilaris and can also be associated with AD. Age at onset is typically between 3 months and 12 months. Implicated etiologic factors include reduced filaggrin (filament-aggregating protein) and its precursor profilaggrin, whose normal functions are to allow for aggregation of keratin filaments and to serve as sources of compounds that hydrate the skin. The clinical severity of ichthyosis vulgaris correlates with the degree of reduction in filaggrin and profilaggrin. Another possible etiologic factor is the reduced activity of proteases that normally lead to dissociation of keratinocytes.[69]

X-Linked Ichthyosis

Recessive X-linked ichthyosis occurs in approximately one in 2,000 to one in 6,000 male infants. Although collodion membrane may be present at birth, the skin is usually normal, with fine scaling beginning at 1 to 3 weeks of life. Typically, the scales are thick and dark, giving the skin a dirty appearance. Extensor distribution—combined with involvement of the sides of the neck and preauricular skin and sparing the flexural areas—is typical. Steroid sulfatase deficiency is an etiologic factor, causing an increase in cholesterol sulfate and a decrease in cholesterol in the stratum corneum.[70] The accumulated cholesterol sulfate may inhibit proteolysis—a process similar to the inhibition seen in ichthyosis vulgaris. Prenatal diagnosis is available, and gene therapy may be on the horizon.

Lamellar Ichthyosis

Lamellar ichthyosis occurs in one in 300,000 births. It is inherited in an autosomal recessive pattern. Collodion membrane may be present at birth but is then shed, revealing characteristic large, platelike scales. Erythroderma may be present, albeit difficult to discern because of the thickness of the scales. Ectropion is present in most patients and can give rise to ophthalmic complications. Lamellar ichthyosis is often caused by mutations in the gene encoding the enzyme transglutaminase 1.[71]

Figure 3 **Erythroderma (total body erythema) and extensive scaling are seen in this infant with congenital ichthyosiform erythroderma.**

Congenital Ichthyosiform Erythroderma

Formerly, congenital ichthyosiform erythroderma [*see Figure 3*] was considered to be a variant of lamellar ichthyosis. Both are inherited as autosomal recessive traits, and collodion membrane may be present at birth in both conditions. Ectropion, eclabion (eversion of the lip), and erythroderma can also occur. Like patients with lamellar ichthyosis, patients with congenital ichthyosiform erythroderma may have platelike scales on the lower extremities, but scales are fine and white on other parts of the body. Also in contrast to lamellar ichthyosis, X-linked ichthyosis, and ichthyosis vulgaris—whose lesions are scaly because of an abnormal ability to desquamate (so-called retention hyperkeratoses)—the lesions of congenital ichthyosiform erythroderma are scaly because of increased production of keratinocytes (so-called hyperproliferative ichthyosis).

Epidermolytic Hyperkeratosis

Epidermolytic hyperkeratosis (formerly called bullous congenital ichthyosiform erythroderma) is autosomal dominant in inheritance. The combinations of large blisters and erythema with denuded skin that appear at birth may be confused with epidermolysis bullosa, staphylococcal scalded skin syndrome, or toxic epidermal necrolysis. Several months to 1 year after birth, the blisters become less prominent, and thick, verrucous plaques comprising rows of hyperkeratotic ridges develop. Flexural skin is usually involved, but the disease can be more extensive. Bacterial colonization leads to a clinically significant foul odor. Abnormal keratin gene expression is the etiologic basis of this condition.[71]

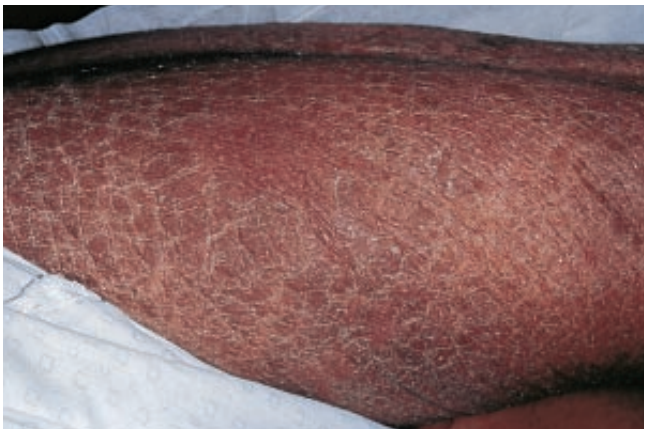

Figure 4 **This patient developed marked scaling (acquired ichthyosis) over a 6-month period. Investigation revealed non-Hodgkin lymphoma.**

Acquired Ichthyosis

Acquired ichthyoses have been associated with numerous systemic diseases and medications. Although the onset of scaling is commonly a manifestation of dryness or ichthyosis vulgaris, patients with unusual manifestations or with severe or recalcitrant disease warrant further investigation. Endocrinopathies (e.g., thyroid disease), autoimmune diseases, infectious diseases (e.g., HIV), and malignancies such as lymphomas [*see Figure 4*] and other carcinomas have been associated with the onset of ichthyosiform dermatosis.

TREATMENT

The standard therapy for the ichthyoses is emollients (e.g., petrolatum) and keratolytics (e.g., lactic acid with or without propylene glycol).[72] Lactic acid should be used cautiously in neonates to avoid causing excess absorption. Oral retinoids (which require lipid monitoring) can be helpful, particularly in the management of X-linked ichthyosis, congenital ichthyosiform erythroderma, and lamellar ichthyosis. Epidermolytic hyperkeratosis is the most difficult of these conditions to treat because of the risk of blistering induced by therapeutic agents. Antimicrobial agents can be useful to reduce the odor caused by bacterial colonization.

V CONTACT DERMATITIS AND RELATED DISORDERS

James S. Taylor, m.d.

Contact dermatitis is an acute or chronic skin inflammation resulting from interaction with a chemical, biologic, or physical agent.[1] It is one of the most common conditions seen by physicians, accounting for more than 6.5 million physician visits a year and 95% of all reported occupational skin diseases.[2] Substances that produce contact dermatitis after a single exposure or multiple exposures may be irritant or allergenic. Direct tissue damage results from contact with irritants. Tissue damage by allergic substances is mediated through immunologic mechanisms. Eczema or dermatitis is the most common clinical expression of this induced inflammation. Of the more than 85,000 chemicals in our environment, most can be irritants, depending on the circumstances of exposure.[1] More than 3,700 substances have been identified as contact allergens.[3] The potential for these substances to cause contact dermatitis varies greatly, and the severity of the dermatitis ranges from a mild, short-lived condition to a severe, persistent, job-threatening, and possibly life-threatening disease.

Major Types of Contact Dermatitis

irritant contact dermatitis

Irritants cause as much as 80% of cases of contact dermatitis, act by direct nonimmunologic chemical or physical action on the skin, and are divided into marginal and acute types. Marginal irritants are the most common. Repeated daily exposures to low-grade irritants such as soap, detergents, surfactants, organic solvents, and oils may not cause clinical changes for days or months. Dryness of the skin with a glazed, parched appearance are often the initial signs; erythema, hyperkeratosis, and fissuring may supervene.

In contrast, acute irritants cause a more immediate reaction. Some irritants, such as strong acids and alkalis, aromatic amines, phosphorus, and metallic salts, produce a marked observable effect within minutes.[4,5] Others, such as hydrofluoric acid, ethylene oxide, podophyllin, and anthralin, produce a reaction within 8 to 24 hours after exposure.[4] Acute irritant contact dermatitis (ICD) is usually easily diagnosed by the patient history and often results from occupational accidents. The clinical appearance varies depending on the irritant and ranges from burns and deep-red ulcerations with sharp circumspection of the dermatitis, sometimes with a gravitational, dripping effect, to a vesicular dermatitis that is indistinguishable from acute allergic contact dermatitis.

Almost any substance can be an irritant, depending on the conditions of exposure [*see Figure 1*]. The nature of the irritant (i.e., its pH, solubility, physical state, and concentration), the duration of contact, and the nature of the vehicle affect disease severity. Host factors that predispose to ICD include preexisting dermatitis, skin dryness, sweating, and decreased thickness or breaks in the stratum corneum; environmental factors include high temperature, low humidity, friction, and pressure.

ICD provoked by work materials is believed to be a frequent cause of occupational skin disease. In one large population-based study, the highest annual incidence rates of ICD were reported for hairdressers (46.9 per 10,000 workers per year), bakers (23.5 per 10,000 workers per year), and pastry cooks (16.9 per 10,000 workers per year).[6] The causative factors of ICD are complex and usually involve exposure to a combination of irritants. The sentinel event for irritant hand eczema in hairdressers is dermatitis developing in moist areas that are difficult to rinse and dry, such as under rings and in the web spaces of the fingers.[7] Dermatitis may spread to the dorsum of the hand, where the skin is thinner and less resistant than on the palms.

No universally accepted test exists for diagnosing ICD, which is often diagnosed by excluding allergic contact dermatitis (ACD). Because of the clinical similarities between allergic and irritant contact dermatitis, it is important that patients who are thought to have either disorder undergo patch testing, the results of which are positive with ACD and negative with ICD.

ICD may become chronic if it is not treated early [*see* Treatment of Irritant and Allergic Contact Dermatitis, *below*]. Even when the skin appears to be healed, its protective capacity remains impaired for weeks or months. Additionally, ICD impairs the barrier function of the skin, allowing penetration of potential contact allergens. Individuals who had childhood atopic eczema are more likely than others to develop ICD of the hands when their jobs involve wet work.

allergic contact dermatitis

Allergic contact dermatitis is a type 4, T cell–mediated, delayed hypersensitivity reaction in the skin. The disorder affects

Figure 1 **Wearing a plastic bib resulted in irritant dermatitis in an 18-month-old child.**

Table 1 Body Sites Often Affected by 10 Common Contact Allergens

Allergen	*Common Uses*	*Localization Site*
Nickel	Costume jewelry	Earlobes, neck, fingers, wrists, abdomen
Neomycin	Topical antibiotics (dermatologic; ophthalmologic; ear, nose, throat)	Face, neck, trunk, extremities
Balsam of Peru	Fragrances, cosmetics, medications, flavorings	Face, trunk, extremities, perianal area
Fragrance mix	Toothpaste, fragrances, toiletries, cosmetics	Same as for balsam of Peru
Thimerosal	Topical antiseptic, contact lens solutions, eye cosmetics, nasal sprays	Eyelids, face, neck (relevance hard to prove)
Gold	Jewelry	Eyelids, earlobes, wrists, fingers
Formaldehyde	Cosmetics (preservative), shampoos, nail enamel	Eyelids, face, neck, trunk (especially intertriginous areas)
Quaternium-15	Cosmetics (preservative), shampoos, soaps, lotions	Face, trunk, extremities, hands
Cobalt	Metal-plated objects, jewelry	Earlobes, neck, fingers, wrists
Bacitracin	Topical antibiotics (dermatologic; ophthalmologic; ear, nose, throat)	Face, neck, trunk, extremities

only certain sensitized individuals, typically after two or more exposures, and accounts for about 20% of contact dermatitis cases.

Predisposing Factors

Immunologic status Predisposing factors to ACD include the patient's immunologic status, which in turn is influenced by genetics, age, gender, and the presence of systemic disease. Patients with AIDS, severe combined immunodeficiency, advanced lymphoma or other malignancy, sarcoidosis, lepromatous leprosy, cachexia, and atopic dermatitis may have impaired cell-mediated immunity or anergy.[8] However, contact allergy should not be excluded in these individuals, especially those with atopic eczema. In experimental models, agents that affect the immune system, such as ultraviolet light (ultraviolet B or psoralen and ultraviolet A [PUVA]), glucocorticoids, cyclosporine, and various other drugs, may downregulate ACD.[8] Administration of systemic corticosteroids below certain dosages (e.g., prednisone, 20 mg or less daily), however, does not inhibit strong patch-test reactions.[9]

In patients with occupational dermatitis, a form of natural hyporeactivity termed hardening may occur with diminished but continued exposure to chemical irritants. The process is inducible and is not localized.[10] This acquired state of unresponsiveness, when describing adaptation to allergens, is called tolerance.[8]

Environment The chemical environment in which we live defines opportunities for exposure to various allergens. A patient's age, gender, occupation, avocation, habits, and nationality are among the factors that determine the environment and thus the chemicals to which an individual is exposed. The most common source of contact allergy in the United States is *Toxicodendron*, a plant genus that includes poison ivy, poison oak, and poison sumac. In addition to *Toxicodendron*, 10 sources of contact allergens are commonly encountered in North America [*see Table 1*],[11] and numerous other allergens are known to cause contact reactions.[3]

Other cutaneous disorders Skin that is infected, inflamed, burned, or eczematous predisposes a patient to ACD. Patients with stasis, hand and foot eczema, or chronic actinic dermatitis are at high risk for ACD. ACD occasionally occurs with other skin disorders, including seborrheic dermatitis, psoriasis, prurigo nodularis, and benign familial pemphigus (Hailey-Hailey disease).[12] Noneczematous contact reactions have also been reported: purpuric reactions caused by black rubber; lichen planus–like eruptions caused by color-film developers, gold, and other dental metals (oral mucosa); and granulomas caused by beryllium and zirconium.[12]

Pathogenesis

Some inflammatory immune reactions in ACD are the same as those in ICD—specifically, the two disorders have similar cytokine activity (tumor necrosis factor–α and interferon gamma) and accessory molecule activity (HLA-DR and intercellular adhesion molecule–1) producing the cascade of inflammation. However, there is no memory T cell function in ICD,[13] and the extent of reaction is directly related to the amount of irritant and duration of exposure.[14] In contrast, even small amounts of an allergen can trigger the T cell reaction in ACD. Minor variations in an allergen's physical and chemical properties may affect its ability to induce sensitization.[8] Most environmental allergens are haptens–that is, they are small (< 500 daltons) molecules that penetrate the skin and undergo in vivo conjugation with tissue, or carrier, protein. Once the complex forms, the carrier protein is no longer recognized by the immune system as self. ACD represents a delayed-type hypersensitivity reaction to this complex.

During the sensitization phase, which usually takes a minimum of 5 to 21 days, an individual acquires a specific hypersensitivity to a particular contact allergen. Sensitization not only can evoke a type 4 delayed hypersensitivity response (mediated by lymphocytes) but also can produce a type 1 immediate hypersensitivity reaction (mediated by circulating antibodies).

On reexposure to an allergen, a hapten-carrier complex capable of eliciting a specific reaction re-forms. The reaction time—the time required for a previously sensitized individual to mani-

fest a clinical dermatitis after reexposure to the antigen—is usually 12 to 48 hours but may range from 8 to 120 hours.

A spontaneous flare may occur within 10 to 21 days without reexposure, possibly because enough allergen remains at the site to cause a reaction once the sensitization phase has occurred.

Cross-sensitization occurs when a patient who is allergic to one chemical also reacts to structurally related chemicals. Examples include *Toxicodendron* antigens (poison ivy, oak and sumac Japanese lacquer, mango, and cashew nutshell oil), aromatic amines (*p*-phenylenediamine, procaine, benzocaine, and *p*-aminobenzoic acid), and perfumes or flavors (balsam of Peru, benzoin, cinnamates, and vanilla). This phenomenon may explain persistence or reactivation of dermatitis when such exposures are unknown.[8,12,15]

Diagnosis

Diagnosis of ACD is based on the patient history; on the appearance, periodicity, and localization of the eruption; and on the clinical course. The history is especially important in cases of chronic dermatitis and putative occupational contact dermatitis. The history alone may be accurate only 50% of the time, on average, ranging from 80% accuracy for nickel to 50% accuracy for moderately common allergens to about 10% accuracy for less common allergens. Even with causes that are considered obvious, the specific allergen may not be known, and ACD that is caused by other chemicals may also be present. Skillful history taking is required to differentiate ACD from contact urticaria and ICD, with differentiation being especially difficult in chronic cases [*see Table 2*].[16] Also important is detailed questioning of the patient about all topical medications (over-the-counter and prescription), systemic medication, cosmetics, other lotions and creams, occupation, hobbies, travel, and clothing. A history of hypersensitivity to one or more of the major contact allergens (e.g., nickel, rubber, topical medications, and cosmetics [fragrances, preservatives, and dyes]) or obvious occupational or avocational exposures to certain substances or chemicals (e.g., chrome, epoxy, acrylics, latex gloves, clothing, first-aid creams, preservatives, and plants) may point to the diagnosis of ACD in an otherwise unexplained eruption.[16]

Clinical features In the acute stage, papules, oozing vesicles, and crusting lesions that are surrounded by inflammation predominate. These clinical features may occur anywhere, but they are best visualized on the palms, sides of the fingers, periungual areas, and soles of the feet. Frequently occurring or persistent episodes of ACD often become chronic; lesions associated with chronic ACD may appear thickened and exhibit lichenification, scaling, and fissuring [*see Figures 2 and 3*]. Post-inflammatory hyperpigmentation or hypopigmentation may occur. In the subacute stage of ACD, features characteristic of both acute and chronic ACD may be present. All forms of contact dermatitis frequently cause pruritus. The onset of ACD is often subtle. A low-grade, subacute to chronic eczema may appear as primarily a scaly or chapped eruption, especially on the face or on the dorsa of the hands.[12,16]

The distribution of dermatitis is often the single most important clue to the diagnosis of ACD. The area of most intense dermatitis usually corresponds to the site of most intense contact with the allergen. Exceptions occur, such as nail-polish allergy, which typically appears on ectopic sites, especially the eyelids, face, and neck. In addition to the transfer of allergens to distant sites, volatile airborne chemicals may cause dermatitis on exposed body areas. Regional differences in susceptibility to contact allergens exist. Thinner eyelid and genital skin is more susceptible to both allergic and irritant contact dermatitis. Because head hair is often protective of the scalp, allergic reactions to hair cosmetics frequently involve the upper face, eyelids, postauricular area, and neck. Other areas of the body have higher or lower

Table 2 Common Misconceptions about ACD[49]

Fallacy	*Truth*
Rash quickly follows contact	Rash is often delayed 1 to 2 days and may not appear for 1 wk after contact
Allergy develops only to new substances	Allergy can develop years after contact; an induction period may last virtually a lifetime
Allergy is dose-dependent	Allergy is not, within a wide range, dose-dependent
If changes in medications or cosmetics do not lead to clearing of the rash, those products are not the cause	Many products contain the same or cross-reacting allergens; also, the composition of the product may be altered without a change in the trade name of the product
Contact allergy occurs only at the site of exposure to the offending agent	Contact allergy can spread by direct or indirect contact, airborne exposure, connubial contact, or autoeczematization
Expensive products are not allergenic	Allergy is not related to cost
Negative prick or scratch test or RAST excludes ACD	Only patch testing is diagnostic of ACD
ACD is always bilateral if allergen exposure is bilateral	Shoe and glove allergy are often bilateral but may be unilateral
ACD is of the same intensity at all areas of exposure	Body sites may differ in responsiveness to allergens; ACD may be patchy (e.g., hand dermatitis from gloves)
ACD does not affect the palms and soles	ACD may occur on the palms and soles (e.g., from gloves, topical medicaments, shoes)

ACD—allergic contact dermatitis RAST—radioallergosorbent test

Figure 2 **Exposure to poison oak produced this acute *Toxicodendron* dermatitis with erythema, edema, and linear vesicles and bullae.**

Figure 3 **Chronic eczematous dermatitis, with scaling, lichenification, and hyperpigmentation, was caused by an allergy to leather components in a hatband.**

exposures to various allergens; these exposures are not always clear and are reflected in unusual distributions of dermatitis. Allergens in lotions and creams applied all over the body sometimes produce reactions in skin folds and intertriginous areas, where the chemicals tend to concentrate. Recognition of ACD on the basis of the physical examination alone may be only partially accurate. Linear vesicular streaks are commonly seen in poison ivy, poison oak, and poison sumac dermatitis, but contact with other plants can give a similar picture. Contact with liquids may also produce linear vesicles. Failure to examine the entire skin surface may result in misdiagnosis. Eczema on the trunk and arms may in fact represent autoeczematization from contact or stasis dermatitis of the legs. Significant regional variations are associated with contact dermatitis, and knowledge of substances that cause dermatitis of specific body sites facilitates the diagnosis. Three such areas are the hands, face and neck, and feet [*see Figures 4 through 7*].

If the history and clinical presentation reveal one or more risk factors for ACD, a patch test is indicated [*see Table 3* and Patch Test, *below*]. The differential diagnosis of ACD is extensive, and a list of key points can be useful in establishing an accurate diagnosis [*see Table 4*].

Histopathology Biopsies are of limited help in diagnosing contact dermatitis. Microscopic findings vary according to the stage of the process: acute, subacute, or chronic. The hallmark of eczema is spongiosis, or intercellular edema, associated with spongiotic vesicles. Intracellular edema may cause reticular degeneration of the epidermis with multilocular bullae formation. Most types of eczema show similar pathologic changes and cannot be distinguished with certainty.[17]

Patch test The patch test is the only useful and reliable method—the gold standard—for the diagnosis of ACD. The proper performance and interpretation of this bioassay require

Figure 4 **Acute contact dermatitis caused by wearing sandals typically involves the dorsal surface of the feet.**

Figure 5 **Hairdresser with acute allergic contact dermatitis of the hands, caused by glyceryl thioglycolate.**

Figure 6 **Ectopic allergic contact dermatitis of the eyelids from tosylamide formaldehyde resin in nail polish.**

considerable experience. Because the procedure is subject to patient variability and observer error, the technique has been standardized by the North American Contact Dermatitis Group. First, the allergen is diluted in petrolatum or water to a concentration that does not produce active sensitization or irritation. A widely used patch-test system consists of strips of paper tape, onto which are fixed aluminum disks 8 mm in diameter (Finn Chambers on Scanpor tape). A small amount of allergen is placed within these disks, covering slightly more than one half of its diameter [*see Figure 8*]. Currently, the only commercially available patch-test system in the United States is the thin-layer rapid-use epicutaneous (T.R.U.E.) test. The T.R.U.E. test contains 23 preloaded allergens that are crystallized, micronized, or emulsified into gels that are affixed to paper tape.

With both systems, the tests are applied to the upper back or midback, which must be free of dermatitis. The patches are left in place and kept dry. When removed at 48 hours, the first reading is performed after 20 to 30 minutes, which allows time for pressure erythema to resolve. It is important to perform a second reading between 4 and 7 days after the patches are initially applied; otherwise, almost 20% of positive reactions will be missed. Neomycin, formaldehyde and formaldehyde-releasing preservatives, and tixocortol pivolate are often late reactors. Results at both readings are graded according to intensity of the reaction covering at least 50% of the patch-test site on a scale of 0 to 3+, as follows:

0 = no reaction
? (doubtful) = weak erythema only
1+ = erythema and edema
2+ = erythema, edema, and papules
3+ = vesicles or bullae

Both false positive and false negative reactions can result. Thus, patch testing is best done by physicians who are familiar with the intricacies of the procedure and who have been trained to advise patients about allergen substitution, relevance of the test, and prognosis. Reading test results and interpreting relevance are as important as performing the test. Any reaction must be evaluated with regard to the individual patient. Thus,

a

b

c

Figure 7 **Allergic contact dermatitis of the hands (*a*) and neck (*b*), with a positive patch test to rosin (colophony) (c).**

Table 3 Criteria* for Determining Which Patients with Putative ACD Should Be Patch Tested[49]

Presence of a specific type of eczema that places patient at higher risk for ACD (stasis, hand, foot, or chronic)
Patient is in a high-risk occupation
Health care worker
Cosmetologist (hairdresser)
Rubber compounder
Plastics processor
Chemical worker
Printer
Machinist
Woodworker
Specific allergen or substance is suspected
Patient has a highly suggestive history or distribution of dermatitis
Dermatitis flares or does not respond to treatment
Patient has previously undiagnosed dermatoses and erythroderma
Patient has putative occupational dermatitis
Special situation applies, such as photosensitivity or systemic contact dermatitis

*Test is ordered if any one of the risk factors is present.

when an allergen is found to be positive, it cannot always be assumed to be the cause of ACD.[8,12,15] The relevance of positive reactions to present or past episodes of ACD ranges from a low of 7.2% for thimerosal to 93.4% for dimethylol-dimethylhydantoin (DMDM hydantoin) and diazolidinyl urea [*see Table 5*]. Thus, relevance is determined by correlating the patch-test results with chemicals, products, and processes encountered in the environment. Occasionally, when patients are allergic to chemicals in products they use, the allergen may be present in only minimal amounts and may not be responsible for the dermatitis.[8] In these cases, repeat open application testing (ROAT), in which the patient applies the commercial product to normal skin twice daily for several days, can be helpful. ROAT is typically used with products that are left on rather than washed off after application.

In the United States, patch testing for ACD is often initially performed using the T.R.U.E. test; however, because there are over 3,700 environmental contact allergens and this test screens for only 23 allergens, testing with additional chemicals is imperative for a thorough evaluation. In one study, the T.R.U.E. test series of 23 allergens would have completely identified all allergens in only 25.5% of patients and clinically relevant allergens in 28% of patients.[18] Additional substances can be obtained from chemical suppliers and prepared by a compounding pharmacist in appropriate concentrations, as detailed in a standard text, for testing with the Finn Chamber system. As an alternative, many centers in the United States use individual patch-test chemicals or series (e.g., corticosteroid, plastics and glues, acrylic, dental, machinist, hairdresser) that are available in Europe but have not been approved in the United States.[11,19]

Reproducibility and validity of patch testing In a study in which 383 patients received simultaneous duplicate patch tests on opposite sides of the upper back, 8% of patients had completely discordant results: positive on one side of the back and negative on the other.[20] The intensity of the reactions was not disclosed, and clinical relevance of this problem was considered small. The most reproducible positive patch tests were for fragrance mix, nickel, and balsam of Peru. Formaldehyde and lanolin were the least reproducible positive reactors, both of which may be weak irritants.[20] The sensitivity, specificity, and validity of a standard screening series has been estimated at about 70%,[21] indicating that about 30% of these patch-test results were not valid. The patients whose screening results were negative later had positive results to other allergens. It was assumed that the earlier screening results had been false negative. A study of 500 consecutive patients who received identical patch testing reported discordant results in 5% of patients; the investigators concluded that patch testing is a reasonably reproducible procedure as long as methodological error is minimized.[22]

The positive predictive value of a diagnosis of ACD is a function of the prevalence of ACD in the population and a function of the sensitivity and specificity of the patch test.[23] A large dose-response study that tested the impact of seasonal variation on the irritant susceptibility of skin identified a stronger reaction to irritants in winter.[24]

Table 4 Key Points in the Diagnosis of ACD

Key Points	*Examples*
ACD may be identical to another disease	Tinea pedis misdiagnosed as ACD; a positive potassium hydroxide preparation made the diagnosis
	Psoriasis of the soles misdiagnosed as ACD caused by shoes; patch tests were negative
	Factitial eczema of the dorsal hand misdiagnosed as ACD; cured with an Unna Boot occlusive dressing
	ACD caused by fragrances and preservatives; misdiagnosed for 5 yr as lupus erythematosus
	ACD caused by hair tonic; misdiagnosed as seborrheic dermatitis
	ACD caused by sunscreen; misdiagnosed as sunburn
ACD may be concurrent with another disorder	ACD caused by neomycin; misdiagnosed as worsening atopic eczema
	Chronic actinic dermatitis of the face can be present with ACD caused by a fragrance
	Morphea of the leg can be present with ACD caused by a topical corticosteroid cream
ACD may be caused by an occult exposure to an allergen	Keys in pants pocket caused ACD of the lateral thigh in a man allergic to nickel
	ACD caused by the preservative imidazolidinyl urea, present in a sunscreen with a label that listed only the active ingredients
	Chronic hand eczema from ACD caused by red dye in window curtains
Diagnosis of ACD may be elusive because of inadequate or deceptive history	Patient allergic to neomycin had periorbital contact eczema caused by an ophthalmic ointment that contained tobramycin, which was not recognized as a cross-reacting allergen
	Chronic eczema worsened by use of a topical cream (doxepin) identified only from a pharmacy prescription list
Initial patch testing may not provide accurate diagnosis	Occupational contact dermatitis of the hands attributed to a false positive irritant-patch-test reaction to a cleanser
	Occupational contact dermatitis of the hands with a false negative patch-test reaction to latex surgical gloves; further patch testing indicated an allergy to thiurams, which were present as accelerators in the gloves

a

b

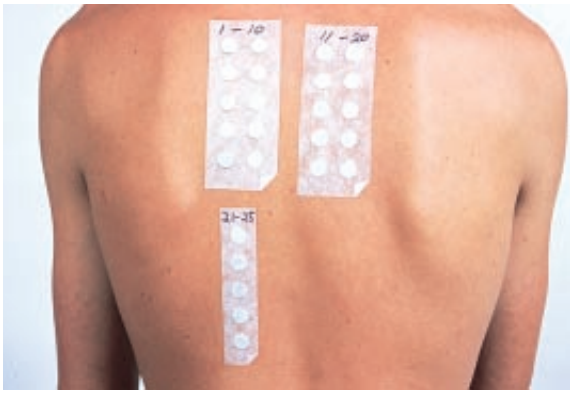

Figure 8 **Patch-test allergens to be tested, usually in petrolatum and occasionally aqueous, are placed on Finn Chambers on Scanpor tape (*a*) for application to the patient's back (*b*) for 48 hours. See patch testing in text and Figure 7c for a positive patch test.**

TREATMENT OF IRRITANT AND ALLERGIC CONTACT DERMATITIS

Most cases of contact dermatitis can be effectively treated and controlled once the offending irritant or allergen is identified and eliminated. Identifying hidden sources of allergens is important, and patients who have positive patch-test results are given exposure lists identifying various names of allergens, cross-reacting substances, lists of potential products and processes containing the allergen, and nonsensitizing substitutes. Standard texts should be consulted for detailed information[12,17]; the Internet is also a source of information on treatment of contact dermatitis [*see Sidebar* Internet Resources on Contact Dermatitis]. Examples of allergen alternatives include topical erythromycin or mupirocin ointments as substitutes for neomycin.[25] Neomycin may cross-react with gentamicin and tobramycin. Bacitracin should generally be avoided for neomycin-sensitive patients because of coreactivity.

Reasons for persistence of ACD include unidentified sources of allergens or irritants at home or at work, exposure to cross-reacting allergens, presence of underlying endogenous (e.g., atopic) eczema, and adverse reactions to therapy [*see* Topical-Medication Allergy, *below*].

Reduction of Trigger Factors

In the case of hand dermatitis, practical management must include protective measures, topical corticosteroids, and lubrication. The use of vinyl gloves with cotton liners to avoid the accumulation of moisture that often occurs during activities involving exposure to household or other irritants and foods (e.g., peeling or chopping fruits or vegetables) may be helpful. However, it is important to verify that gloves are safe to use in the workplace around machinery before recommending them. Protective devices themselves may introduce new allergic or irritant hazards in the form of rubber in gloves and solvents in waterless cleansers. Barrier creams are generally the last resort and are probably best for workers who do not have dermatitis.[26] Hand alcohol may be a superior disinfectant to soap and water in occupations that require extensive wet-work exposure.[27] A barrier agent containing quaternium-18 bentonite has been shown to be effective with exposure to a specific allergen, such as poison ivy.[28] Principles of treatment of atopic dermatitis may also be applied to treatment of contact dermatitis [*see 2:IV Eczematous Disorders, Atopic Dermatitis, and Ichthyoses*].

Topical Therapy

Treatment of contact dermatitis depends on the severity of the dermatitis. When acute serous oozing is present, cool, wet compresses should be applied for 15 minutes two or three times a day. Isotonic saline or Domeboro powder dissolved in tap water to make a 1:40 dilution (aluminum acetate) may be used. A soft cloth, such as Kerlex gauze or a towel, is immersed in the solution. The cloth is wrung slightly and applied to the affected area of the skin. The solution should not be poured directly on the dressing. Lukewarm to cool water baths or sitz baths are antipruritic and anti-inflammatory; they also aid in cleansing and removing crusts and medications. Oatmeal in the form of Aveeno Oilated Bath Treatment (colloidal powdered oatmeal with oils) may be added to the bath for its antipruritic and drying effects.

In acute vesicular dermatitis such as that caused by poison ivy, treatment with compresses and baths should be followed by the application of a topical corticosteroid spray (either triamcinolone acetonide [Kenalog aerosol] or betamethasone dipropionate [Diprosone aerosol]). A spray of 2 or 3 seconds' duration on each affected area supplies sufficient coverage, providing the container is held 6 in. from the skin. In cases in which the dermatitis is extensive or less vesicular, one of the many topical corticosteroid creams may be used. Corticosteroid creams range in potency from extremely potent (e.g., clobetasol propionate [Temovate]), to potent (e.g., betamethasone dipropionate [Diprosone topical cream]), to midstrength formulations. In addition, a lotion of camphor, menthol, and hydrocortisone (Sarnol-HC) is soothing, drying, and antipruritic. Pramoxine, a topical anesthetic in a lotion base (Prax), may also relieve pruritus.

In the subacute and chronic stages of contact dermatitis, an emollient lotion (Eucerin) or ointment (Aquaphor) may be applied to moist skin after bathing for lubrication. Oil-in-water emulsions that contain perfluoropolyethers have been shown to significantly inhibit ICD caused by a wide variety of hydrophilic and lipophilic irritants.[29] A potent or midstrength topical glucocorticosteroid cream or ointment is often used in the treatment of subacute and chronic contact dermatitis. Hydrocortisone 1% is only occasionally effective. Fluorinated corticosteroids should be used with discretion; frequent and prolonged use of these agents in skin-fold areas may cause atrophy, telangiectasia, or striae, and their use on the face may cause steroid rosacea. For patients with chronic dermatitis, crude coal tar preparations may be used to control eczema. Topical PUVA treatment may be effective for contact dermatitis of the palms and soles.[30]

Systemic Therapy

Intense itching may be relieved with sedating antihistamines such as diphenhydramine hydrochloride (Benadryl), hydroxyzine hydrochloride (Atarax), and doxepin hydrochloride (Sinequan), administered at night. Most cases of ICD and ACD are effectively managed without the use of systemic corticosteroids. However, short courses of systemic corticosteroids are indicated for patients with severe vesiculobullous eruptions of the hands and feet or the face [*see Figure 9*] or with severe disseminated ACD, such as poison ivy. Strategies to reduce the side effects of corticosteroid use are especially important in patients who have diabetes, hypertension, glaucoma, latent or active tuberculosis (as indicated by a positive skin-test reaction to purified protein derivative), and diseases that could be affected by steroid therapy. Attempts at desensitization have generally been unsuccessful.[8] Secondary infection sometimes arises as a complication of ICD and ACD; in such cases, systemic antibiotics may be indicated.[29]

Specific Etiologic Forms of Contact Dermatitis

TOPICAL-MEDICATION ALLERGY

Reactions to topically applied medications include allergic and irritant contact dermatitis, photosensitivity, airborne contact dermatitis, and contact urticaria and anaphylaxis. ACD is the most common skin reaction to topically applied drugs. The three most important contact allergens are topical antibiotics, anesthetics, and antihistamines. Neomycin and bacitracin are among the most frequently prescribed medications and are common causes of ACD.[15] Mupirocin ointment infrequently causes ACD.[25] Benzocaine, the most common topical anesthetic allergen, is still widely used in topical agents, and there have been a number of reports of contact allergy to topical doxepin.[31,32]

ACD from topical corticosteroids is most often caused by the steroid itself rather than the vehicle. Studies indicate that in patients screened for contact dermatitis, the prevalence of allergy to one or more corticosteroids ranges from 0.55% to 5.98%.[33,34] Patch testing for allergy to the corticosteroid markers tixocortol pivolate and budesonide detects a great majority of cases of ACD caused by topical corticosteroids.[34] Further patch or ROAT testing using commercial preparations from the major cross-reacting classes may identify additional allergenic steroids or, alternatively, nonreacting steroids. Delayed readings are important at 5 to 7 days, because without a late reading, up to 30% of cases of contact allergy to corticosteroid markers can be missed.[34] Allergy to inhaled corticosteroids may present as perinasal or perioral itching or dermatitis, mimicking impetigo and herpes simplex or worsening asthma or allergic rhinitis. In such cases, prior sensitization by the cutaneous route is the usual occurrence, although allergy occasionally develops in response to corticosteroid inhalation.[35]

Topical-drug allergy is particularly common in patients with other forms of dermatitis, especially stasis dermatitis [*see Figure 10*]. In patients with stasis dermatitis, allergy to topical drugs often presents as a nonhealing dermatitis, which can mask the underlying cause of the eruption. A detailed history is important and should include the patient's use of nonprescription preparations, topical agents meant for animal use, medicated bandages, borrowed medications, transdermal devices, and herbal medicines. Patch testing with the standard screening tray and the patient's topical medications is invaluable in diagnosing ACD caused by topical medications.

Figure 9 **For this patient with allergic contact dermatitis with marked facial edema, a short course of therapy with systemic corticosteroids is indicated.**

SYSTEMIC CONTACT DERMATITIS

Systemic contact dermatitis occurs in individuals with contact allergy to a hapten when they are exposed systemically to the hapten via the oral, subcutaneous, transcutaneous, intravenous, inhalational, intra-articular, or intravesicular route. The disorder has been caused by a number of medications, metals, and other allergens, including food components, but occurs infrequently compared with allergic and irritant contact dermatitis. Systemic contact dermatitis presents with the following clinically characteristic features[36,37]:

1. Flare-up of previous dermatitis or of prior positive-patch-test sites.
2. Skin disorders in previously unaffected skin, such as vesicular hand eczema, dermatitis in the elbow and knee flexures, nonspecific maculopapular eruption, vasculitis with palpable purpura, and the so-called baboon syndrome. This syndrome includes a pink–to–dark-violet eruption that is well demarcated on the buttocks and the genital area and is V-shaped on the inner thighs. It may occupy the whole area or only part of it.
3. General symptoms of headache, malaise, arthralgia, diarrhea, and vomiting.

Systemic contact dermatitis may start a few hours or 1 to 2 days after experimental provocation, suggesting that more than one type of immunologic reaction is involved. Documentation rests on patch testing and investigational oral-challenge studies. Well-controlled oral-challenge studies in sensitized individuals have been performed with medications but are more difficult to perform with ubiquitous contact allergens, such as metals and natural flavors. A relatively high dose of hapten is usually needed. Other variables include route of administration, bioavailability, individual sensitivity to the allergen, and interaction with amino acids and other allergens.[36] These variables can have dramatic effects on test results. For example, when 12 leg-ulcer patients with neomycin allergy were challenged with an oral dose of the hapten, 10 reacted.[37] However, of 29 patients with confirmed localized ACD caused by transdermal clonidine, only one had a skin reaction to oral clonidine.[38]

CLOTHING AND TEXTILE DERMATITIS

ACD from clothing is usually not caused by the fibers but rather by the dyes used to color the garments or by formalin finish resins added to make them wrinkle-resistant, shrinkproof, or wash-and-wear. Disperse blue dyes (especially blue 106 and blue 124) are highly valuable screening agents for diagnosing an important cause of textile dermatitis.[39] In a study in which 4,913 patients were patch tested using 65 allergens, disperse blue dye resulted in positive reactions in 3% of the study population [*see Table 5*].[11]

The distribution of dermatitis corresponds to areas where garments fit snugly, such as the upper and inner anterior thighs, popliteal fossae, buttocks, and waistband areas. Other areas include, in men, the parts of the neck that come in contact with stiff collars and, in women, the anterior or posterior axillary folds, vulva, and suprapubic area. Diagnosis is confirmed by patch testing with disperse dyes (especially blue 106 and blue 124) and formaldehyde-releasing fabric-finish resins (e.g., dimethyloldihydroxyethyleneurea and ethyleneurea melamine formaldehyde). Patch testing with the clothing (particularly acetate and polyester liners) of patients with dye allergy may yield positive results.[40]

Textile-dye dermatitis can be managed in the following ways[41]:

1. Avoiding clothes with the offending dye (especially 100% acetate or 100% polyester liners).
2. Avoiding nylon hose (especially beige tones) and tight synthetic spandex/Lycra exercise clothing.
3. Wearing 100% natural fabrics (i.e., cotton, linen, silk, wool) or 100% silk long-sleeved undershirts and slip pants.
4. Wearing loose-fitting clothing that has been washed (three times) before wearing.[42]

Many of these principles also apply to managing fabric-finish allergy, especially avoiding wrinkle-resistant, shrinkproof, and wash-and-wear clothing.

Figure 10 **Patients with stasis dermatitis are at high risk for allergic contact dermatitis, especially from topical medications. Bacitracin was the cause in this case.**

OCCUPATIONAL CONTACT DERMATITIS

Contact dermatitis, particularly of the hands, is one of the most common types of occupational skin disorders. Special issues associated with these disorders include the following:

1. Objective information on exposure history (a factory visit is ideal) is important. Direct exposure to chemicals can occur because of spills or routine work levels; indirect exposure can come from contaminated tools, rags, and gloves; and airborne exposures can result from mists, droplets, and sprays.
2. The skin is an important portal of entry for a number of toxic chemicals that may or may not have a direct effect on skin. These chemicals include aniline, carbon disulfide, ethylene glycol ethers, certain pesticides, tetrachloroethylene, and toluene.
3. Patch testing with industrial chemicals should be performed very carefully. Irritants should not be tested, and many require dilution to nonirritating concentrations. Testing with individual chemical components of mixtures is preferable in many cases.
4. Establishing occupational causation for ACD is often a challenge, and recommendations have been published.

Prevention and treatment of occupational contact dermatitis is the same as for ACD.[16]

Subtypes of Contact Dermatitis

PHOTOSENSITIVITY

Photosensitivity refers to a condition in which ultraviolet light in combination with endogenous or exogenous substances, usually drugs or chemicals, evokes an eruption on sun-exposed skin. Most cases are evoked by ultraviolet A, but on occasion, eruptions are caused by ultraviolet B (sunburn irradiation) or by visible light. The most common causes are systemic exposure to photosensitizing drugs [*see Table 6*] or cutaneous exposure, usually accidental, to psoralen in plants.

Photosensitivity reactions are of two types: phototoxicity and photoallergy. Many substances that are photoallergic at low concentrations may be phototoxic at high concentrations.[43]

Phototoxicity

Phototoxicity is analogous to irritation and occurs in any individual after one exposure to sufficient amounts of chemical and light. Phototoxicity has been likened to an exaggerated sunburn response, consisting of delayed erythema and edema followed by pigmentation and desquamation. Asphalt workers and roofers working with pitch develop the so-called smarts when exposed to sufficient sunlight. Phytophotodermatitis, or meadow dermatitis, is a particularly striking phototoxicity characterized by streaky bullae after contact, sometimes while sunbathing, with psoralen containing umbelliferones. Berloque der-

Phenothiazines	PT	Tranquilizers
Dimethylchlorotetracycline	PT	Antibiotic
Griseofulvin	PT	Antifungal
Nalidixic acid	PT	Antibiotic
Sulfonamides	PT	Antibiotic
Psoralens	PT	Photosensitizing drug
Piroxicam	PT?	Nonsteroidal anti-inflammatory drugs, especially in thimerosal-sensitive patients

PA—photoallergenic reaction PT—phototoxic reaction

matitis is a phototoxic dermatitis characterized by the appearance of hyperpigmented, droplike patches on the neck, face, and breast. This reaction is caused by exposure to 5-methoxypsoralen present in perfumes or colognes containing oil of bergamot, and the hyperpigmentation may persist for many months. Photo-onycholysis has been reported with tetracyclines, psoralen, and other phototoxic drugs. Not all cases exhibit obvious skin phototoxicity.[43] Most cases of phototoxicity are caused by administration of phototoxic systemic drugs [*see Table 6*].

Photoallergy

Photoallergy is analogous to ACD and is an immunologic reaction in which exposure of the photosensitizing compound to UV light plays a role in formation of a complete antigen. A delayed eruption, usually eczematous, appears in sun-exposed body areas, usually the face and dorsal hands, typically sparing the submental and retroauricular areas [*see Figure 11*]; shaded areas and covered areas remain relatively clear but occasionally are involved. Most cases are caused by topical photoallergens [*see Table 6*], and the most common photocontact allergens are sunscreen chemicals, which act by absorbing ultraviolet light. Oxybenzone is a common allergen; however, other sunscreen chemicals, such as padimate O and the dibenzoylmethanes, have also been reported to cause photoallergic contact dermatitis.[43]

Photoallergic contact dermatitis is reproduced and diagnosed by photopatch testing, a procedure in which ultraviolet light (usually ultraviolet A) is combined with patch testing. This form of testing is particularly helpful in differentiating eruptions caused by polymorphous light from photoallergic contact dermatitis. Photopatch testing is not indicated in phototoxic drug eruptions. In some persons, photoallergic reactions can persist as chronic actinic dermatitis (CAD), which can be difficult to treat (see below). Patients with photoallergic contact dermatitis often have contact allergy and should also be patch tested.

Treatment of Phototoxicity and Photoallergy

Elimination of exposure to the photoallergen or phototoxic agent is effective for most patients, except for a few with CAD. Broad-spectrum sunscreens or sunblocks, especially those containing micronized titanium, along with sun-protective clothing, may be helpful. Topical corticosteroids are helpful for mildly affected patients, but severely affected patients with CAD may require azathioprine, with or without systemic corticosteroids; psoralen ultraviolet A therapy and cyclosporine have also been used in some severe cases.[17]

LATEX ALLERGY

Latex allergy is an IgE-mediated hypersensitivity to one or more of a number of proteins present in raw or uncured natural rubber latex (NRL). The paradigm for immunologic contact urticaria is latex allergy, which, over the past decade, has become a significant medical and occupational health problem.

Populations at Risk

Individuals at highest risk are patients with spina bifida (30% to 65% prevalence), health care workers, and other workers with significant NRL exposure.[44] Most reported series of occupational cases of latex allergy involve health care workers; 5% to 11% of those studied are affected.[45] Studies of populations of non–health care workers are infrequent; however, evidence indicates that sensitization to NRL is more common in food handlers, construction workers, painters, hairdressers, cleaners, and miscellaneous other occupations in which NRL is utilized.[46] Children with chronic renal failure appear to be at increased risk for latex sensitization.[47]

Risk Factors and Etiology

Predisposing risk factors are hand eczema, allergic rhinitis, allergic conjunctivitis, or asthma in individuals who frequently wear NRL gloves; mucosal exposure to NRL; and multiple surgical procedures.[44,45] The majority of cases of latex allergy involve reactions from wearing NRL gloves or being examined by individuals wearing NRL gloves. Reactions from other medical and

Figure 11 **Photocontact dermatitis characteristically involves areas exposed to the sun.**

Figure 12 **Contact urticaria of the hands in a nurse allergic to her powdered natural rubber latex gloves (latex allergy). She also experienced allergic rhinitis and asthma while at work. Urticaria is often short-lived after gloves are used and may be absent at the time of examination.**

nonmedical NRL devices have occurred; these include balloons, rubber bands, condoms, vibrators, dental dams, anesthesia equipment, and toys for animals or children.

The route of exposure to NRL proteins includes direct contact with intact or inflamed skin and mucosal exposure, such as inhalation of powder from NRL gloves, especially in medical facilities and in operating rooms.[47] Most immediate-type NRL reactions result from exposure to dipped NRL products (e.g., gloves, condoms, balloons, and tourniquets). Dry-molded rubber products (e.g., syringes, plungers, vial stoppers, and baby-bottle nipples) contain lower residual protein levels or have less easily extracted proteins than do dipped NRL products.

NRL allergy is sometimes associated with allergic reactions to fruit (especially bananas, kiwi, and avocados) and to chestnuts. This allergic reaction results from cross-reactivity between proteins in NRL and those found in some fruits and nuts. Symptoms range from oral itching and angioedema to asthma, gastrointestinal upset, and anaphylaxis. Cross-reactivity to NRL may be a factor in other skin eruptions. One report suggests that the use of commercially available black henna tattoos may cause hypersensitivity to NRL.[48]

Diagnosis

Clinical signs of NRL allergy include contact urticaria [*see Figure 12*], generalized urticaria, allergic rhinitis, allergic conjunctivitis, angioedema, asthma, and anaphylaxis.[45] More than 600 serious reactions to NRL, including 16 fatal anaphylactic reactions, were reported to the Food and Drug Administration by the early 1990s.

Diagnosis of NRL allergy is strongly suggested by a history of angioedema of the lips when inflating balloons and by a history of itching, burning, urticaria, or anaphylaxis when donning gloves; when undergoing surgical, medical, and dental procedures; or after exposure to condoms or other NRL devices. Diagnosis is confirmed by a positive wear or use test with NRL gloves, a valid positive intracutaneous prick test with NRL, or a positive serum radioallergosorbent test with NRL.[44] Severe allergic reactions have occurred from prick and wear tests; epinephrine latex-safe resuscitation equipment free of NRL should be available during these procedures.[45]

Treatment and Risk Reduction

Hyposensitization to NRL is not yet feasible, and NRL avoidance and substitution are imperative. Because many patients with NRL allergy have hand eczema, have immediate allergic symptoms, or both, the most important issues for physicians are accurate diagnosis, appropriate treatment, and counseling.

Preventive measures have significantly reduced the prevalence of reported reactions to NRL.[45] Risk reduction and control of NRL allergy include latex avoidance in health care settings for affected workers and patients. Synthetic non-NRL gloves should be available to replace latex gloves. Also, in many cases, low-allergen NRL gloves should be worn by coworkers so as to minimize symptoms and decrease induction of NRL allergy in those allergic to NRL. Allergen content of gloves should be requested from manufacturers and suppliers; lists of glove allergen levels have also been published. Patients with NRL allergy should wear Medic-Alert bracelets identifying them as NRL sensitive, and they should inform health care providers of their sensitivity. These patients should be given lists of substitute gloves, other non-NRL devices, potentially allergenic fruits, latex-safe anesthesia protocols, occult sources of NRL exposure such as toys (for animals and children), and dental prophylaxis cups. Some of this information is available in published sources, government agencies, and latex-allergy support groups that publish newsletters and other relevant information. Some sources have Web sites [*see Sidebar* Internet Resources on Contact Dermatitis].

VI CUTANEOUS ADVERSE DRUG REACTIONS

Neil H. Shear, m.d.
Sandra Knowles, b.sc. pharm.
Lori Shapiro, m.d.

An adverse drug reaction (ADR) is defined as any noxious, unintended, and undesired effect of a drug that occurs at doses used in humans for prophylaxis, diagnosis, or therapy.[1] An ADR may range from a cutaneous eruption to severe syndromes (e.g., drug hypersensitivity syndrome, Stevens-Johnson syndrome [SJS], toxic epidermal necrolysis [TEN], and serum sickness–like reaction). Over the past 20 years, a dramatic shift has occurred in our understanding of drug-induced cutaneous eruptions. It is now believed that many severe cutaneous adverse drug reactions are caused by the formation of reactive oxidative metabolites and perhaps the formation of antibodies to drug-protein complexes and skin proteins, cytochrome P-450 enzymes, or both. The predisposition to drug-induced eruptions may be genetic, and family counseling and in vitro testing are being used in certain centers to manage patients and their families. This chapter reviews the pathophysiology and clinical manifestations that are important for correct diagnosis and treatment of cutaneous ADRs.

Epidemiology

Epidemiologic studies have shown that ADRs occur in 6.7% of all hospitalized patients,[2] and 3% to 6% of all hospital admissions are the result of ADRs.[3] In the Boston Collaborative Drug Surveillance Program,[4] the prevalence of cutaneous ADRs in hospitalized patients was 2.2%. Antibiotics were responsible for 75% of detected reactions. In the Harvard Medical Practice Study, approximately 14% of ADRs in hospital patients were cutaneous or allergic in nature.[5] The cost of drug-related morbidity and mortality has been estimated at $30 billion a year,[6] and ADRs are thought to be between the fourth and sixth leading cause of death in the United States.[2,6]

Etiology

Cutaneous reactions to drugs often occur in complicated clinical scenarios that may include exposure to multiple agents. New drugs started within the preceding 6 weeks are potential causative agents, as are drugs that have been used intermittently, including over-the-counter preparations and herbal and naturopathic remedies.

Diagnosis

CLINICAL MANIFESTATIONS

The morphology of cutaneous eruptions may be exanthematous, urticarial, blistering, or pustular. The extent of the reaction is variable. For example, once the morphology of the reaction has been documented, a specific diagnosis (e.g., fixed drug eruption or acute generalized exanthematous pustulosis) can be made. The reaction may also present as a syndrome (e.g., serum sickness–like reaction or hypersensitivity syndrome reaction). Fever is associated with the more serious cutaneous ADRs.

DIFFERENTIAL DIAGNOSIS

Differential diagnoses can include viral exanthems (e.g., infectious mononucleosis and parvovirus B19 infection), bacterial infections, Kawasaki syndrome, collagen vascular disease, and neoplasia.[7]

LABORATORY TESTS

Penicillin skin testing with major and minor determinants is useful for confirmation of an IgE-mediated immediate hypersensitivity reaction to penicillin.[8] Skin tests are performed 6 weeks to 6 months after complete healing of the cutaneous drug reaction.[9] Oral rechallenges may be useful in the diagnosis of ADRs; however, they should not be used if a serious reaction, such as SJS or TEN, previously occurred. Patch testing may be helpful in the diagnosis of fixed drug eruptions or contact dermatitis.[10]

Exanthematous Eruptions

SIMPLE ERUPTIONS

Exanthematous eruptions, also known as morbilliform, maculopapular, or scarlatiniform eruptions, are the most common cutaneous ADRs.[4] Simple exanthems are erythematous changes in the skin without blistering or pustulation.

Many drugs can cause exanthematous eruptions, including the penicillins, sulfonamides, barbiturates, antiepileptic medications, nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine), and antimalarials.[4,11] Exanthematous eruptions occur in 3% to 7% of patients receiving such aminopenicillins as ampicillin and amoxicillin. However, these eruptions may occur in 60% to 100% of patients taking ampicillin or amoxicillin who are receiving concurrent allopurinol therapy or who have concomitant lymphocytic leukemia, infectious mononucleosis, cytomegalovirus infection, or hyperuricemia.

Studies suggest that some exanthematous eruptions represent cell-mediated hypersensitivity.[12,13] The etiology of the ampicillin rash concurrent with a viral infection is unknown, but the rash does not appear to be IgE mediated, and patients can tolerate all β-lactam antibiotics, including ampicillin, once the infectious process has resolved. A similar reaction was seen in 50% of HIV-infected patients exposed to sulfonamide antibiotics.[14] Recent studies have shown that drug-specific T cells play a major role in exanthematous, bullous, and pustular drug reactions.[15]

Simple exanthems are symmetrical and often become generalized. Pruritus is the most frequently associated symptom. Fever is not associated with simple exanthematous eruptions. These eruptions usually occur within 1 week after the beginning of therapy and generally resolve within 7 to 14 days.[16] The exanthem's turning from bright red to brownish red marks resolution. Resolution may be followed by scaling or desquamation.[17] Some patients with ampicillin- or amoxicillin-induced exanthematous eruptions may have a positive result on a patch test or on a delayed intradermal test.[13,14] In general, however,

skin testing is not considered helpful in the diagnosis of an exanthematous eruption.

The differential diagnosis of drug-induced exanthematous eruption includes viral exanthem (patients should be tested for mononucleosis), collagen vascular disease, bacterial infection, and rickettsial infection. Hypersensitivity syndrome should be considered in the differential diagnosis.

The treatment of simple exanthematous eruptions is generally supportive. For example, oral antihistamines used in conjunction with soothing baths may help relieve pruritus. Topical corticosteroids are indicated when antihistamines do not provide relief. Systemic corticosteroids are used only in severe cases. Discontinuance of the offending agent is recommended in most cases.

COMPLEX ERUPTIONS

Hypersensitivity Syndrome Reaction

Hypersensitivity syndrome reaction is a complex drug reaction that affects various organ systems. A triad of fever, skin eruption, and internal organ involvement signals this potentially life-threatening syndrome. It occurs in approximately one in 3,000 exposures to such agents as aromatic anticonvulsants (e.g., phenytoin, phenobarbital, and carbamazepine), lamotrigine, sulfonamide antibiotics, dapsone, minocycline, and allopurinol.[18]

It has been suggested that the metabolism of aromatic anticonvulsants by cytochrome P-450 plays a pivotal role in the development of the hypersensitivity syndrome reaction with these drugs.[19] In most people, the chemically reactive metabolites that are produced are detoxified by epoxide hydroxylases. If detoxification is defective, however, one of the metabolites may act as a hapten and initiate an immune response, stimulate apoptosis, or cause cell necrosis directly.

In one study, 75% of patients with hypersensitivity syndrome reactions to one aromatic anticonvulsant showed in vitro cross-reactivity to the other two aromatic anticonvulsants.[19] In addition, in vitro testing has shown that there is a familial occurrence of hypersensitivity to anticonvulsants.[19] Although lamotrigine is not an aromatic anticonvulsant, it too can cause a hypersensitivity syndrome reaction.[20,21] There is no evidence that lamotrigine cross-reacts with the aromatic anticonvulsants. Lamotrigine and other anticonvulsants are also associated with more severe reactions (e.g., SJS and TEN) [*see* Complex Eruptions, *below*].

Sulfonamide antibiotics can cause hypersensitivity syndrome reactions in susceptible persons. The primary metabolic pathway for sulfonamides involves acetylation of the drug to a nontoxic metabolite and renal excretion. An alternative metabolic pathway, quantitatively more important in patients who are slow acetylators, engages the cytochrome P-450 mixed-function oxidase system. These enzymes transform the parent compound to reactive metabolites—namely, hydroxylamines and nitroso compounds, which produce cytotoxicity independently of preformed drug-specific antibody. In most people, detoxification of the metabolite occurs. However, hypersensitivity syndrome reactions may occur in patients who are unable to detoxify this metabolite (e.g., those who are glutathione deficient).[22] Although the detoxification defect is present in 2% of the population, only one in 10,000 people will manifest a hypersensitivity syndrome reaction in response to sulfonamide antibiotics. Siblings and other first-degree relatives of patients with the detoxification defect are at increased risk (perhaps one in four) for having a similar defect.

Other aromatic amines, such as procainamide, dapsone, and acebutolol, are also metabolized to chemically reactive compounds. We recommend that patients who develop symptoms compatible with a sulfonamide hypersensitivity syndrome reaction avoid these aromatic amines, because the potential exists for cross-reactivity. However, cross-reactivity should not occur between sulfonamides and drugs that are not aromatic amines (e.g., sulfonylureas, thiazide diuretics, furosemide, and acetazolamide).

Hypersensitivity syndrome reaction occurs most frequently on first exposure to the drug, with initial symptoms starting 1 to 6 weeks after exposure [*see Table 1*]. Fever and malaise, which can be accompanied by pharyngitis and cervical lymphadenopathy, are the presenting symptoms in most patients. This is often followed by edema and swelling of the face, especially upon rising in the morning. Atypical lymphocytosis, with subsequent eosinophilia, may occur during the initial phases of the reaction in some patients. A cutaneous eruption, which occurs in approximately 85% of patients, can range from an exanthematous eruption [*see Figure 1*] to the more serious SJS or TEN. The liver is often involved, resulting in hepatitis, although other internal organs may be affected, such as the kidney (e.g., interstitial nephritis and vasculitis), the central nervous system (e.g., encephalitis and aseptic meningitis), and the lungs (e.g., interstitial pneumonitis, respiratory distress syndrome, and vasculitis). A subgroup of patients may become hypothyroid as part of an autoimmune thyroiditis within 2 months after the initiation of symptoms.[23]

After hypersensitivity syndrome reaction has been recognized from the symptom complex of fever, rash, and lymphadenopathy, some laboratory tests can be used to evaluate internal organ involvement, which may be asymptomatic. A complete blood count, urinalysis, and measurements of liver transaminase and serum creatinine levels should be per-

Table 1 Clinical Features of Hypersensitivity Syndrome Reaction and Serum Sickness–like Reaction

	Rash	*Fever*	*Internal Organ Involvement*	*Arthralgia*	*Lymphadenopathy*
Hypersensitivity syndrome reaction	Exanthem Exfoliative dermatitis Pustular eruptions Erythema multiforme Stevens-Johnson syndrome Toxic epidermal necrolysis	Present	Present	Absent	Present
Serum sickness–like reaction	Urticaria Exanthem	Present	Absent	Present	Present

Figure 1 **This 35-year-old woman developed hypersensitivity syndrome reaction, characterized by fever, rash, and hepatitis, 14 days after starting trimethoprim-sulfamethoxazole therapy. The rash is an extensive, symmetrical, red edematous eruption.**

formed. In addition, the clinician should be guided by symptoms that may suggest specific internal organ involvement (e.g., respiratory symptoms). Thyroid function should be evaluated on presentation of hypersensitivity syndrome reaction and then 2 to 3 months after presentation. A skin biopsy may help confirm the diagnosis when the patient has a blistering or a pustular eruption. Unfortunately, diagnostic or confirmatory tests are not readily available. An in vitro test employing a mouse hepatic microsomal system is used for research purposes to characterize patients who develop hypersensitivity syndrome reaction.[19,24] Because of the severity of the reaction, oral rechallenges are not recommended.

Although the role of corticosteroids is controversial, most clinicians choose to start prednisone at a dosage of 1 to 2 mg/kg/day when symptoms are severe. Antihistamines, topical corticosteroids, or both can be used to alleviate symptoms. Because the risk of hypersensitivity syndrome reaction in first-degree relatives of patients who have had reactions is substantially higher than in the general population, counseling of family members regarding their risk of hypersensitivity syndrome reaction is advised.

Urticarial Eruptions

SIMPLE ERUPTIONS

Urticaria and Angioedema

Urticaria is characterized by pruritic red wheals of varying sizes that can occur with any medication. When deep dermal and subcutaneous tissues are also swollen, the reaction is known as angioedema.

Urticaria and angioedema usually result from a type I immediate hypersensitivity reaction. This mechanism is typified by immediate reactions to penicillin and other antibiotics. Binding of the drug or its metabolite to IgE bound to the surfaces of cutaneous mast cells leads to activation, degranulation, and release of vasoactive mediators such as histamine, leukotrienes, and prostaglandins.[25]

Urticarial reactions may also result from nonimmunologic activation of inflammatory mediators. Drugs such as acetylsalicylic acid and nonsteroidal anti-inflammatory drugs (NSAIDs),[26] radiocontrast media, and narcotic analgesics[27] may directly cause release of histamine from mast cells, independently of IgE. Angiotensin-converting enzyme (ACE) inhibitors are frequent causes of angioedema.[28] The mechanism of this reaction is unclear but may relate to accumulation of bradykinin or activation of the complement system.

Although medications tend to cause urticaria, angioedema, or both, other causal agents are food [*see 6:XVI Food Allergies*], physical factors (e.g., dermatographism and cholinergic urticaria) [*see 6:XIII Urticaria, Angioedema, and Anaphylaxis*], and idiopathic factors. Certain foods containing proteins that can cross-react with latex proteins, such as bananas, kiwifruit, avocados, and chestnuts, can cause oral itching and swelling, hives, or wheezing after ingestion. People at greatest risk for latex allergy include children with spina bifida and health care workers.[29,30] Latex allergy can present as contact urticaria at sites of latex exposure, such as lip swelling in a person who has blown up a balloon or sucked on a pacifier. Contact with aerosolized powder from latex gloves to which the latex protein has adhered may cause mucosal symptoms, such as itchy, swollen eyes; runny nose; sneezing; or wheezing. Anaphylaxis may also occur.[31]

Signs and symptoms of IgE-mediated allergic reactions are typically pruritus, urticaria, cutaneous flushing, angioedema, nausea, vomiting, diarrhea, abdominal pain, nasal congestion, rhinorrhea, laryngeal edema, and bronchospasm or hypotension or both. Fever is not associated with urticaria or angioedema reactions. In general, individual lesions of urticaria last for less than 24 hours, although new lesions can continually develop. With ACE-inhibitor therapy, the onset of the adverse reaction is usually within hours but can occur as late as 1 week to several months into therapy.[32] With treatment, the resulting angioedema usually resolves within 48 hours.

Skin testing may be helpful in cases of IgE-mediated urticaria. For example, penicillin skin testing with the major and minor determinants identifies approximately 99% of patients who have had an IgE-mediated reaction to penicillin.[10] A latex skin test is a sensitive indicator of IgE sensitization.[31] For large-molecular-weight agents, such as insulin,[33] protamine,[34] and egg-containing vaccines, positive immediate skin-test reactions identify patients at risk for IgE-mediated reactions.

Withdrawal of the causative agent is recommended. When angioedema or anaphylaxis occurs, immediate therapy with epinephrine and systemic steroids may be needed. Symptomatic relief can generally be achieved with antihistamines (H_1 receptor blockers).

Differential Diagnosis

Allergic urticaria must be differentiated from urticaria caused by physical factors. Cold urticaria, for example, is precipitated by exposure to cold, occurring within minutes after immersion of hands or body in cold water or after exposure to cold air. In severe cases, systemic symptoms, including wheezing and syncope, can occur. A rare familial form of cold urticaria that is autosomal dominant has been linked to chromosome 1q44.[35]

Cold urticaria can be differentiated from other forms of urticaria by eliciting an urticarial reaction with an ice cube applied to the skin for 5 to 10 minutes. Other physical urticarias also have distinguishing causes or features. Solar urticaria occurs within minutes of exposure to sunlight and can be produced by exposing limited areas of skin to sunlight or to appro-

priate wavelengths of ultraviolet light in a phototherapy response to physical pressure. Cholinergic urticaria, which is characterized by small urticarial papules, can be induced by exposure to heat or by exercise.

Histologically, all the urticarias are characterized by an increase in mast cells in the dermis. Edema, vascular changes, and mononuclear infiltrates are more striking in the dermis of patients with cold urticaria. Mononuclear infiltrates are also more prominent in the deep dermis of patients with delayed pressure urticaria.[36]

As with drug-induced urticaria, first-line therapy of most urticarias consists of oral antihistamines and avoidance of precipitating factors. Psoralen plus ultraviolet A (PUVA) has been used successfully to treat patients with solar urticaria. Montelukast has been used successfully to treat delayed pressure urticaria,[37] and cyclosporine is promising for cases of severe refractory chronic urticaria.[38]

COMPLEX ERUPTIONS

Serum Sickness–like Reactions

Serum sickness–like reactions are defined by fever, rash (usually urticarial), and arthralgias occurring 1 to 3 weeks after drug initiation. Other symptoms, such as lymphadenopathy and eosinophilia, may also be present. In contrast to true serum sickness, serum sickness–like reactions are without immune complexes, hypocomplementemia, vasculitis, and renal lesions [*see Table 1*].

Epidemiologic studies in children suggest that the risk of serum sickness–like reactions is greater with cefaclor than with other antibiotics, including other cephalosporins.[39,40] The overall incidence of cefaclor serum sickness–like reactions has been estimated to be 0.024% to 0.2% per course of cefaclor prescribed.

Although the pathogenesis is unknown, it has been postulated that in genetically susceptible hosts, metabolism of cefaclor produces a reactive metabolite that may bind to tissue proteins and elicit an inflammatory response that manifests as a serum sickness–like reaction.[41]

Other drugs that have been implicated in serum sickness–like reactions are cefprozil,[42] bupropion,[43] and minocycline.[18,44] The incidence of serum sickness–like reactions caused by these drugs is unknown.

Discontinuance of the culprit drug and symptomatic treatment with antihistamines and topical corticosteroids are recommended for patients with serum sickness–like reactions. A short course of oral corticosteroids may be required for patients with more severe symptoms. The drug that caused the serum sickness–like reaction should be avoided. For cefaclor and cefprozil, the risk of cross-reaction with β-lactam antibiotics is small, and the administration of another cephalosporin is usually well tolerated.[45] However, some clinicians recommend that patients who experience serum sickness–like reactions from cefaclor avoid all β-lactam drugs.[46]

Blistering Eruptions

SIMPLE ERUPTIONS

Fixed Drug Eruptions

Fixed drug eruptions usually appear as solitary pruritic, erythematous, bright-red or dusky-red macules that may evolve into an edematous plaque [*see Figure 2*]. In some patients, multiple lesions may be present. Blistering and erosion may occur on mucosal surfaces.

Figure 2 **This 28-year-old man taking tetracycline for acne vulgaris developed a fixed drug eruption.**

Fixed drug eruptions recur in the same skin area after readministration of the causative medication. Many drugs have been implicated in fixed drug eruptions, including phenolphthalein, ibuprofen, sulfonamides, tetracyclines, and barbiturates.[47] The pathogenesis of fixed drug eruptions has not been fully elucidated. A haplotype linkage in the setting of trimethoprim-sulfamethoxazole–induced fixed drug eruptions was recently documented.[48]

Fixed drug eruptions are most common on the genitalia and in the perianal area, although they can occur anywhere on the skin surface. The onset of a fixed drug eruption can be sudden, developing within 30 minutes to 8 to 16 hours after ingestion of the medication. In patients who continue to take the offending drug, the number of eruption sites may gradually increase.[48]

After the initial acute phase, which lasts days to weeks, residual hyperpigmentation develops. Some patients may complain of burning or stinging on the affected skin sites. Systemic manifestations, which are present in approximately 25% of cases, can include fever, malaise, and abdominal symptoms.[48]

No conclusive diagnostic tests are available, but a challenge or provocation test with the suspected drug may be useful in confirming the diagnosis. Patch testing at the site of a previous lesion yields a positive response in up to 43% of patients. Prick and intradermal skin tests are reported to yield positive reactions in 24% and 67% of patients, respectively, but results vary with different drugs and reaction patterns. Patients with maculopapular rashes are more likely to have positive patch tests than patients with urticarial rashes.[49]

Treatment includes discontinuance of the causative agent and symptomatic therapy (e.g., topical corticosteroids).

Pseudoporphyria

Pseudoporphyria is a cutaneous phototoxic disorder that can resemble either porphyria cutanea tarda (PCT) or erythropoietic protoporphyria (EPP). Tetracycline, furosemide, and naproxen have been implicated in PCT- and EPP-pseudoporphyria.[50] The eruption may begin within 1 day after initiation of therapy or may be delayed for as long as 1 year. PCT-pseudoporphyria is characterized by skin fragility, blister formation, and scarring in areas exposed to sunlight; it occurs with normal

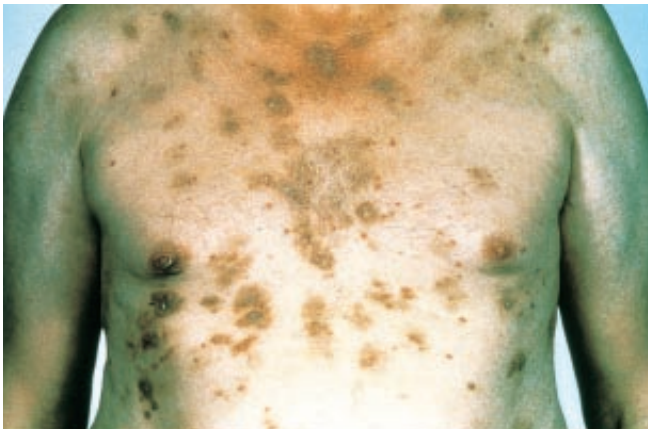

Figure 3 **Pemphigus foliaceus developed in this 64-year-old man taking enalapril.**

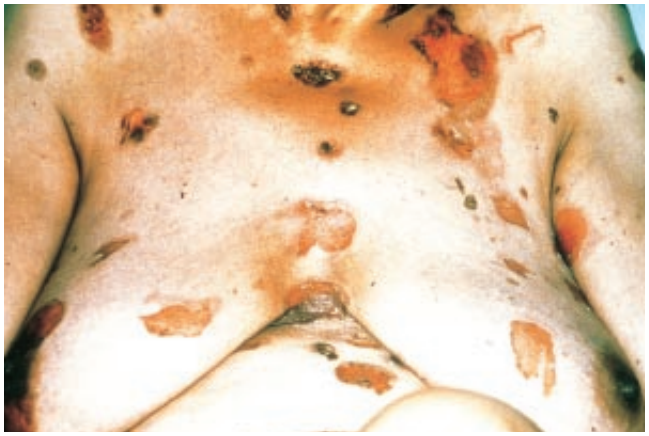

Figure 4 **Pemphigus vulgaris developed in this 59-year-old woman who took penicillamine as treatment for rheumatoid arthritis.**

porphyrin metabolism. The second clinical pattern mimics EPP and presents as cutaneous burning, erythema, vesiculation, angular scars, and waxy thickening of the skin.

Because of the risk of permanent facial scarring, the implicated drug should be discontinued when skin fragility, blistering, or scarring occurs. In addition, broad-spectrum sunscreen and protective clothing should be recommended to the patient.

COMPLEX ERUPTIONS

Drug-Induced Linear IgA Disease

Linear IgA disease is an autoimmune bullous dermatosis that is identified on the basis of the linear deposition of IgA at the basement membrane zone.[51] This disease can be induced by such drugs as vancomycin, lithium, diclofenac, and amiodarone. The drug-induced disease probably represents an immunologic response to the offending drug.

Drug-induced linear IgA disease is heterogeneous in clinical presentation. Cases have shown morphologies resembling erythema multiforme, bullous pemphigoid, and dermatitis herpetiformis. Drug-induced disease cannot be distinguished from the idiopathic variety either clinically, histologically, or immunologically; however, the clinical courses of these presentations differ. In drug-induced disease, spontaneous remission occurs once the offending agent is withdrawn; in idiopathic linear IgA disease, immune deposits disappear from the skin once the lesions resolve. Steroids and dapsone do not influence the healing process in drug-induced disease, whereas these agents have proved effective in treatment of idiopathic linear IgA disease.[52]

Drug-Induced Pemphigus

Pemphigus may be drug induced or drug triggered (i.e., the latent disease is unmasked by the drug exposure).

Drugs that cause pemphigus are penicillin, rifampin, phenylbutazone, propranolol, progesterone, piroxicam, interferon beta, interleukin-2, and levodopa.[53] An active amide group found in masked thiol drugs such as penicillin and cephalosporins and in nonthiol drugs such as enalapril may contribute to the pathogenesis of pemphigus.[53,54] Pemphigus foliaceus [*see Figure 3*] caused by penicillamine and other thiol drugs tends to resolve spontaneously in 35% to 50% of cases.[53] The average interval to onset is 1 year. Antinuclear antibodies are detected in 25% of affected patients.

Nonthiol drug–induced pemphigus manifests clinical, histologic, immunologic, and evolutionary aspects similar to those of idiopathic pemphigus vulgaris [*see Figure 4*]. Drug-induced pemphigus is associated with mucosal involvement. Spontaneous recovery after drug withdrawal occurs in 15% of affected patients.

Treatment of drug-induced pemphigus begins with drug withdrawal. Systemic corticosteroids are often required until all symptoms of active disease disappear. Vigilant follow-up is required after remission for an early relapse to be detected. The patient's serum should be monitored regularly for autoantibodies.[53]

Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis

The eruptions of erythema multiforme (EM), SJS, and TEN may represent variants of the same disease process. Reactions encompass a spectrum ranging from the less serious eruptions seen in EM to more serious reactions seen in SJS and TEN [*see Figure 5*].

A large percentage of EM and SJS cases are not drug related and may develop after a variety of predisposing factors, including infections, neoplasia, and autoimmune diseases. The drugs most frequently cited as causes of EM, SJS, and TEN are anticonvulsants, antibiotics (e.g., sulfonamides), allopurinol, and NSAIDs (e.g., piroxicam).[55] With anticonvulsants, risk appears to be greatest during the first 8 weeks of therapy.[56]

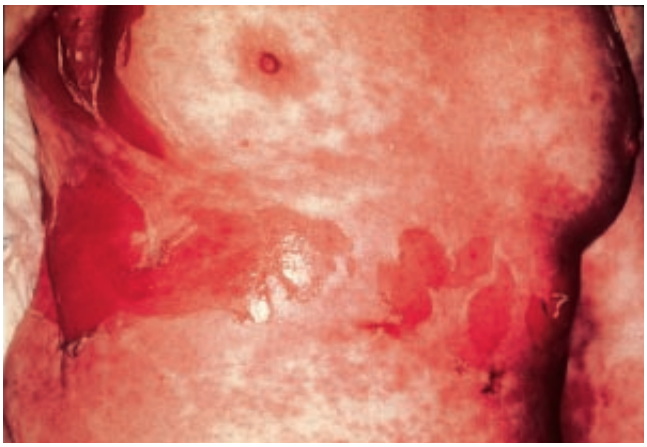

Figure 5 **This 50-year-old woman developed toxic epidermal necrolysis 17 days after starting phenytoin therapy.**

Figure 6 **Acute generalized exanthematous pustulosis (small nonfollicular pustules on a red base) in a 70-year-old man who took cloxacillin as treatment for cellulitis.**

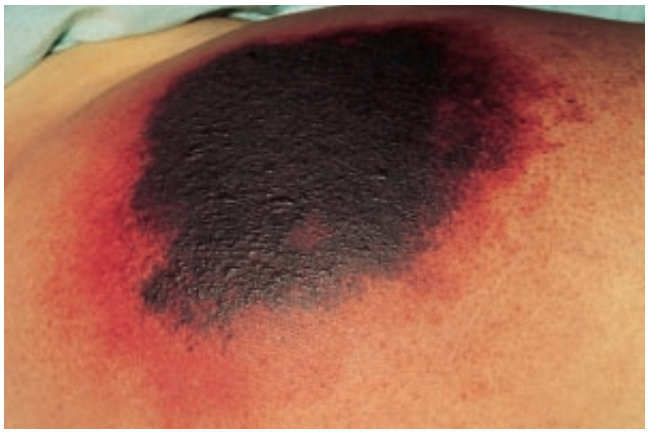

Figure 7 **Coumarin-induced skin necrosis in a 57-year-old woman who was given coumarin as treatment for atrial fibrillation.**

The pathogenesis of severe cutaneous ADRs is unknown, although a metabolic basis has been hypothesized. Sulfonamides and anticonvulsants, the two groups of drugs most frequently associated with SJS and TEN, are metabolized to toxic metabolites that are subsequently detoxified in most persons. However, in predisposed patients with a genetic defect, the metabolite may bind covalently to proteins. In some of these patients, the metabolite-protein adducts may trigger an immune response that leads to a cutaneous ADR.[57]

Clinically, the reaction patterns of EM, SJS, and TEN are characterized by the triad of mucous membrane erosions, target lesions, and epidermal necrosis with skin detachment. SJS is characterized by mucous membrane erosions and blisters on less than 10% of the total body surface area, whereas TEN involves more than 30% of the total body surface area.[58] The more severe the reaction, the more likely it is that it was drug-induced. Cases of severe cutaneous ADRs to lamotrigine (e.g., SJS and TEN) have been reported.[59] The prevalence of severe cutaneous ADRs associated with lamotrigine has been reported to be as high as one in 1,000 in adults and is higher in children. The risk is increased in the presence of valproic acid.

Complete blood counts, liver enzyme measurements, and chest x-rays should be performed to rule out concurrent internal organ involvement.

Treatment of EM, SJS, and TEN includes discontinuance of a suspected drug and such supportive measures as careful wound care, hydration, and nutritional support.[60] The use of corticosteroids in SJS and TEN is controversial.[61] Intravenous immunoglobulin (IVIg, 0.4 to 1.0 g/kg/day for 2 to 4 days), which contains naturally occurring Fas ligand (FasL)–blocking antibodies, has been shown in most reports to halt progression of TEN, especially when IVIg is started early.[62-64] Patients who have developed a severe cutaneous ADR (EM, SJS, or TEN) should not be rechallenged with the drug or undergo desensitization with the medication.

Pustular Eruptions

SIMPLE ERUPTIONS

Acneiform Eruptions

Eruptions morphologically mimicking acne vulgaris may be associated with drug ingestion. Iodides, bromides, adrenocorticotropic hormone, corticosteroids, isoniazid, androgens, lithium, dactinomycin, and phenytoin are reported to induce acne-like lesions.[65] Acne fulminans was induced by testosterone in 1% to 2% of adolescent boys who were treated for excessively tall stature.[66]

Drug-induced acne often appears on the face and back, but it may appear in atypical areas, such as arms and legs, and is usually monomorphous. Comedones are usually absent. Fever is absent. Acneiform eruptions do not affect prepubertal children, indicating that previous hormonal priming is a prerequisite. Topical tretinoin may be useful when the drug cannot be stopped.

COMPLEX ERUPTIONS

Acute Generalized Exanthematous Pustulosis

Acute generalized exanthematous pustulosis is characterized by acute onset, fever, and a cutaneous eruption with nonfollicular sterile pustules on an edematous erythema, generally starting within days of drug ingestion[67] [*see Figure 6*]; leukocy-

Table 2 Clinical Pearls to Identify Anticoagulant-Induced Skin Necrosis

	Interval to Onset	*Location*	*Other*
Coumarin-induced skin necrosis	3–5 days	Adipose-rich sites	—
Heparin-induced thrombocytopenia and thrombosis	4–14 days	Extremities	Thrombocytopenia occurs concurrently
Purple-toe syndrome	3–8 wk	Acral location	Often occurs after angiography

Figure 8 **Leukocytoclastic vasculitis developed in this 47-year-old woman taking hydrochlorothiazide.**

tosis is another common finding. Generalized desquamation occurs 2 weeks later. Differential diagnosis includes pustular psoriasis, subcorneal pustular dermatosis (Sneddon-Wilkinson disease), hypersensitivity syndrome reaction with pustulation, and pustular eruptions of infancy.

Acute generalized exanthematous pustulosis is most commonly associated with β-lactam and macrolide antibiotic usage. Many other drugs have been implicated, however, including calcium channel blockers and analgesics. The estimated incidence rate is approximately one to five cases per million per year.[68] Discontinuance of therapy is usually the extent of treatment necessary in most patients, although some patients may require the use of corticosteroids. Patch testing to the putative drug is often positive, resulting in a localized pustular reaction.

Other Eruptions

ANTICOAGULANT-INDUCED SKIN NECROSIS

Anticoagulant drugs may induce hypercoagulable states with subsequent vascular infarction and cutaneous necrosis [*see Figure 7*]. Both coumarin and heparin can induce skin necrosis. Clinical pearls that can help differentiate these reactions are the location, timing, platelet count, and primary diagnosis [*see Table 2*].

The pathogenesis of coumarin-induced skin necrosis is the paradoxical development of occlusive thrombi in cutaneous and subcutaneous venules caused by a transient hypercoagulable state. This condition results from the suppression of the natural anticoagulant protein C at a greater rate than natural procoagulant factors. Coumarin-induced skin necrosis is associated with protein C and protein S deficiency, but pretreatment screening is not warranted. An association with a heterozygote for the factor V Leiden mutation has been recently reported.[69]

It is estimated that one in 10,000 persons who take coumarin are at risk for this adverse event.[70] The prevalence is four times higher in women than in men. In both sexes, the peak incidence occurs in the sixth and seventh decades of life. Afflicted patients tend to be obese.

Coumarin-induced skin necrosis begins 3 to 5 days after initiation of treatment. Painful red plaques develop in adipose-rich sites such as breasts, buttocks, and hips. These plaques may blister, ulcerate, or develop into necrotic areas. An accompanying infection, such as pneumonia, viral infection, or erysipelas, may occur in as many as 25% of patients. Purple-toe syndrome occurs 3 to 8 weeks after initiation of coumarin therapy.

Treatment entails the discontinuance of coumarin, administration of vitamin K, and infusion of heparin at therapeutic doses. Fresh frozen plasma and purified protein C concentrates have been used.[71] Supportive measures for the skin are recommended. Plastic surgery for remediation is necessary in 60% of affected patients.

DRUG-INDUCED LICHENOID ERUPTIONS

Drug-induced lichen planus produces lesions that are clinically and histologically indistinguishable from those of idiopathic lichen planus. Many drugs, including beta blockers, penicillamine, NSAIDs, gold, and ACE inhibitors, especially captopril, have been reported to produce this reaction.

The latent period between the start of administration of the drug and appearance of the eruption is variable. The mean latent period is between 2 months and 3 years for penicillamine, approximately 1 year for beta-adrenergic blocking agents, and 3 to 6 months for ACE inhibitors. The latent period may be shorter if the patient was previously exposed to the drug.[72] In general, resolution usually occurs within 2 to 4 months.

Rechallenge with the culprit drug has been attempted in a few patients, with reactivation of symptoms within 4 to 15 days.[73] Patch testing has not proved helpful in most cases of drug-induced lichen planus. However, results of patch tests performed with contact inducers of lichen drug eruptions (e.g., color-film developers and dental restorative materials) are usually positive.[72]

DRUG-INDUCED VASCULITIS

Drug-induced vasculitis represents approximately 10% of the acute cutaneous vasculitides and usually affects small vessels [*see Figure 8*].[74] Drug-induced vasculitis should be considered in any patient with small vessel vasculitis that is usually confined to the skin.[75] Drugs that are most frequently associated with vasculitis include propylthiouracil, hydralazine, granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage CSF (GM-CSF), allopurinol, cefaclor, minocycline, penicillamine, phenytoin, and isotretinoin.[73] The average interval to onset of drug-induced vasculitis is 7 to 21 days.[76]

The clinical hallmark of cutaneous vasculitis is palpable purpura, classically found on the lower extremities, although any cutaneous site may be affected. Urticaria can be a manifestation of small vessel vasculitis. Unlike nonvasculitic allergic urticaria, vasculitic urticaria lasts longer than 1 day, may evolve into purpuric lesions, and may be accompanied by hypocomplementemia.[77] Other features are hemorrhagic bullae, urticaria, ulcers, nodules, Raynaud disease, and digital necrosis. The same vasculitic process may also affect internal organs, such as the liver, kidney, gut, and CNS, and is potentially life threatening.

Histologically, the small blood vessels of the dermis display fibrinoid necrosis, polymorphonuclear infiltration into the blood vessel wall, extravasation of red blood cells, and nuclear dust. Direct immunofluorescence may show deposits of IgM and C3 in the blood vessel walls. Therefore, these reactions are immune complex–dependent drug reactions. The immune complexes may be composed of antibodies directed against drug-related haptens, but this has not been proved.

Drug-induced vasculitis can be difficult to diagnose, and diagnosis is often one of exclusion.[78] Alternative causes of cuta-

neous vasculitis, such as infection or autoimmune disease, must be eliminated.

Treatment consists of drug withdrawal.Therapy for patients with severe manifestations includes hemodialysis, pulse corticosteroids, cyclophosphamide, and plasmapheresis.[73]

VII FUNGAL, BACTERIAL, AND VIRAL INFECTIONS OF THE SKIN

Jan V. Hirschmann, m.d.

Despite its large surface area and constant exposure to the environment, the skin resists infection well. The most important protective factor is an intact stratum corneum, the tough barrier of protein and lipid formed on the cutaneous surface by the underlying epidermis.[1] This barricade impedes invasion by environmental pathogens, and its dryness discourages colonization and growth of the many organisms that require moisture to survive, such as gram-negative bacilli. Furthermore, the constant shedding of cells of the epidermis impedes most microbes from establishing permanent residence.

Some organisms, however, can attach to skin cells and reproduce there; the normal cutaneous flora comprises primarily aerobic, gram-positive cocci and bacilli in densities ranging from about 10^2 organisms/cm^2 on dry skin to 10^7 organisms/cm^2 in moist areas, such as the axilla.[2] This resident population inhibits harmful organisms from colonizing the skin by occupying binding sites on the epidermal cells, competing for nutrients, producing antimicrobial substances, and maintaining the skin surface at a low pH (about 5.5). Anaerobes are sparse except in areas with abundant sebaceous glands, such as the face and chest; in the deeper portions of these sites, as well as in hair follicles, anaerobes reach concentrations of 10^4 to 10^6 organisms/cm^2.

Cutaneous infections occur when the skin's protective mechanisms fail, especially when trauma, inflammation, maceration from excessive moisture, or other factors disrupt the stratum corneum. The organisms causing infection may originate from the victim's own resident flora, either on the skin or on adjacent mucous membranes, but many come from other people, animals, or the environment.

Dermatophyte Infections

Dermatophytes are fungi (molds) that can infect the skin, hair, and nails. These organisms, which include *Trichophyton*, *Microsporum*, and *Epidermophyton* species, are classified as anthropophilic, zoophilic, or geophilic, depending on whether their primary source is humans, animals, or the soil, respectively.[3] Geophilic dermatophyte infections occur sporadically, primarily among gardeners and farm workers. Zoophilic dermatophytes (*Trichophyton* and *Microsporum* species) may have a restricted range of hosts (e.g., *M. persicolor* infects only voles) or may afflict many different animals (e.g., *T. mentagrophytes* can infect mice and other rodents, dogs, cats, and horses). Human infections with zoophilic species have occurred after exposure to dogs, cats, horses, cattle, pigs, rodents, poultry, hedgehogs, and voles.

Anthropophilic dermatophytes are the most common cause of fungal skin infections in humans. Transmission of these infections occurs from direct contact between people or from exposure to desquamated skin cells present in the environment—arthrospores can survive for months. Direct inoculation of the spores through breaks in the skin can lead to germination and subsequent invasion of the superficial cutaneous layers.

Dermatophyte infections occur more frequently in certain ethnic groups and in people with impaired cell-mediated immunity. Many of the anthropophilic dermatophyte infections occur more often in one gender or age group.[4]

Infection of the scalp, for example, is primarily a disease of children. Involvement of the feet and groin is most common in adolescents and young adults, especially males, but is unusual in children. Nail infection is more frequent in both men and women of advancing age. The reasons for these differences are unknown.

The anthropophilic dermatophytes also have unique geographic distribution patterns. The most common cause of scalp infection in the United States, for example, is *T. tonsurans*, but in Southeast Asia and the Middle East, it is *T. violaceum*. These differences may relate to climatic or racial factors.

The various forms of dermatophytosis, also called ringworm, are named according to the site involved. These infections include tinea capitis (scalp), tinea corporis (body), tinea barbae (beard area of men), tinea faciei (face), tinea cruris (groin), tinea pedis (feet), tinea unguium (nails), and tinea manuum (hands). The characteristic skin lesion is an annular scaly patch [*see Figure 1*], though the clinical appearance varies not only with the site involved but also with the host's immune status and the type of infecting organism. In general, anthropophilic species elicit little inflammation and cause chronic infections. Zoophilic and geophilic species, however, often provoke intense inflammation, which sometimes leads to eradication of the organisms and healing without treatment.

Clinical Presentations

Tinea Capitis

Tinea capitis occurs primarily in children but may develop in adults—especially the elderly, those who are unkempt, and the impoverished. Transmission can occur between humans by the sharing of combs, brushes, or headgear. Only *Microsporum* and *Trichophyton* species cause tinea capitis. Infection begins with invasion of the stratum corneum of the scalp skin. The hairs then become infected, in one of three microscopic patterns: ectothrix, endothrix, or favus. In ectothrix, the spores are

Figure 1 **Classic annular lesion of tinea corporis shows a raised or vesicular margin with central clearing.**

Figure 2 **A typical kerion presenting as a zoophilic *Microsporum canis* infection of the scalp (tinea capitis).**

outside the hair shaft and destroy the cuticle; in endothrix, they lie within the hair and do not affect the cuticle; and in favus, broad hyphae and air spaces form within the hair, but spores are absent. In all three types, scaling, hair loss, and inflammation of varying degrees are present.[5]

T. tonsurans, the major cause of tinea capitis in adults, characteristically produces a noninflammatory infection with either well-demarcated or irregular and diffuse areas of scaling and alopecia. Because the swollen hairs may fracture a few millimeters from the epidermis in this endothrix infection, the scalp sometimes appears to be marked by small black dots. Like all infections with *Trichophyton* species, these scalp lesions do not fluoresce under a Wood light.

T. schoenleinii causes favus, characterized by an inflammatory crust (scutulum) in which hair appears to be matted in the dried, yellow exudate. Hair shedding late in the infection is common because the hair shaft is not damaged until the infection is well advanced.

M. audouinii, which causes an ectothrix infection, produces well-delineated, noninflammatory patches of alopecia in which the hair breaks at the epidermal surface and is often dull gray because of the presence of numerous spores on the surface of the hair shaft. As in all *Microsporum* infections, these lesions fluoresce under a Wood light. The most severe inflammation, usually from a zoophilic species, results in a kerion, a painful, boggy mass in which follicles may discharge pus and in which sinus tracts form [*see Figure 2*]. Crusting and matting of adjacent hairs are common, and cervical lymph nodes may enlarge.

Tinea Corporis

Tinea corporis typically appears as a single lesion or multiple circular lesions with scaling, well-delineated margins, and a raised, erythematous edge. Often, they have an area of central clearing. The amount of inflammation varies; when the inflammation is intense, pustules, vesicles, and even bullae may occur. Sometimes, involvement of the hair follicles in the middle of a patch of scaling erythema leads to perifollicular nodules, a condition called Majocchi granuloma. This condition usually occurs on the legs of patients infected with *T. rubrum*.

a

b

Figure 3 **(*a*) The scaling of tinea pedis appears between and under the toes and on the plantar surface. (*b*) Tinea pedis may also present as vesicles.**

In immunocompromised hosts, subcutaneous abscesses may develop.

Tinea Barbae

Tinea barbae occurs in adult men and involves the skin and coarse hairs of the beard and mustache area. The usual cause is a zoophilic species, primarily *T. verrucosum* and *T. mentagrophytes*, which are organisms that commonly infect cattle and horses. The victims are generally farm workers, and the infection usually causes erythema, scaling, and follicular pustules. Many hairs become loose and are easily removed with a forceps.

Tinea Faciei

Tinea faciei occurs as an infection of the face in women and children and infection of the area outside the mustache and beard in men. The usual causes are *T. rubrum* and *T. mentagrophytes*; these organisms reach the face through direct inoculation or by spreading from another site of infection on the body. Patients often complain of itching and burning, and symptoms may worsen after exposure to sunlight. The lesions may be scaly, annular erythematous patches, but often they are indistinct red areas with little or no scaling.

Tinea Cruris

Tinea cruris, infection of the groin, is much more common in men than women and is often associated with infection of the feet. *T. rubrum* and *E. floccosum* are the most common causes. The lesions are usually red, scaling, sharply demarcated areas with raised, erythematous borders. The infection, which affects the medial portion of the upper thighs but consistently spares the scrotum, may extend to the buttocks, abdomen, and lower back. Vesicles, nodules, pustules, and maceration may be present.

Tinea Pedis

Tinea pedis is most frequently caused by *T. rubrum*, *E. floccosum*, and *T. mentagrophytes*. The most common form consists of fissuring, scaling, and maceration in the interdigital spaces, especially between the fourth and fifth toes. A second type involves scaling, hyperkeratosis, and erythema of the soles, heels, and sides of the feet. In this kind of tinea pedis, the lesions occur in a so-called moccasin distribution pattern [*see Figure 3a*]. The plantar skin may become very thick and scaly. A third form demonstrates an inflammatory pattern characterized by vesicles, pustules, or even bullae, usually on the soles [*see Figure 3b*].

An important complication of tinea pedis is streptococcal cellulitis of the lower leg. Streptococci do not ordinarily survive on normal skin, but the presence of fungal disease apparently permits streptococci of various groups, including A, B, C, and G, to colonize the toe webs.[6] From this location, these bacteria may invade the skin damaged by the tinea pedis or migrate to locations higher up the leg and enter the skin through any defects.

Tinea Unguium

Nail involvement usually occurs from adjacent fungal infection of the hands or feet. The organisms typically invade the nail from the distal or lateral borders, and infection spreads proximally. The nails are thickened, opaque, and yellowish to brownish. They may crack or crumble, and often, subungual hyperkeratosis lifts the nail plate from the underlying bed (a condition known as onycholysis) [*see Figure 4*]. Splinter hemorrhages are common.

Figure 4 **Nails are usually thickened, cracked, and crumbly in tinea unguium; subungual debris may be present, as shown.**

Tinea Manuum

Tinea manuum is an infection of the hands. Most cases have accompanying involvement of the feet; inexplicably, usually only one hand is affected (so-called two-feet, one-hand disease). The most common finding is scaling or hyperkeratosis of the palms and fingers. Occasionally, vesicles, papules, or follicular nodules form on the dorsal surface of the hands.

DIAGNOSIS

Clinicians should suspect dermatophyte infection in patients with any scaling, erythematous eruption and in patients whose nails exhibit the characteristics of tinea unguium (see above). The diagnosis can be confirmed by microscopy or culture of properly obtained specimens. The optimal method of obtaining specimens from the skin is by scraping the scaly lesions; specimens from the nails are best obtained by taking fragments of subungual debris.

The specimen is prepared for microscopic examination by first placing it on a glass slide and treating it with potassium hydroxide (KOH), which digests the keratin of the skin, nails, and hair, and then heating it to hasten the process. The basic culture medium for isolating dermatophytes is an agar containing Sabouraud medium, often combined with antibiotics to eliminate bacteria and with cycloheximide to inhibit saprophytic fungi. Growth is usually apparent in 3 to 14 days. Dermatophyte test medium culture can be used in the office and is both accurate and inexpensive.[7] When both KOH preparations and cultures are negative, a biopsy may be useful in identifying the infecting organism, usually by special tissue stains such as periodic acid–Schiff or Gomori methenamine-silver stains.

TREATMENT

Tinea corporis, tinea cruris, tinea pedis, and tinea faciei respond to topical agents applied once or twice daily to the affected area, usually for 2 to 4 weeks. Good choices include azoles (e.g., miconazole, econazole, or clotrimazole) or terbinafine. The cost of the preparation can dictate which agent to prescribe. Tinea pedis often recurs after effective therapy, especially in cases of the moccasin form of the disease. When infection reappears, the previous therapy can be resumed without loss of effectiveness.

Oral therapy is necessary for extensive lesions, for infection involving the hair or hair follicles (e.g., tinea capitis and tinea barbae), for tinea unguium, and, often, for tinea manuum and various forms of dermatophytoses in immunocompromised hosts. Five oral agents are currently available: griseofulvin, ketoconazole, itraconazole, fluconazole, and terbinafine. Griseofulvin, a fungistatic agent, is the oldest oral treatment available and is still useful, primarily in infections not involving the nails. Griseofulvin reduces the serum levels of barbiturates and warfarin. Some patients receiving griseofulvin note a diminished tolerance to alcohol.

The azoles include ketoconazole, itraconazole, and fluconazole; like griseofulvin, they are fungistatic. Ketoconazole is usually well tolerated, but hepatotoxicity occurs in about 1 in 10,000 patients, typically after several weeks of use. Fluconazole and itraconazole are very expensive, but they provide protracted levels of antibiotic in the nails, allowing short or intermittent courses of therapy for tinea unguium. Both fluconazole and itraconazole can cause gastrointestinal disorders, rashes, and, occasionally, hepatotoxicity and can have serious interactions with several medications, including cyclosporine, digoxin, and quinidine. Ketoconazole, itraconazole, and fluconazole can interact with other medications; pharmacologic sources should be consulted for potential interactions.

Terbinafine, also an expensive medication, is an allylamine. Unlike both griseofulvin and the azoles, which are fungistatic, terbinafine is fungicidal. It achieves high levels of drug in the nails, and the drug persists for many weeks after discontinuance. Its few side effects include gastrointestinal reactions and, occasionally, skin rashes. Hepatotoxicity and hematologic abnormalities are rare, and drug interactions are uncommon.

These oral antifungals are quite effective for tinea capitis. The adult dosage for griseofulvin is 500 mg twice daily for 8 weeks. The other agents are effective when given for 1 to 3 weeks. Daily doses are as follows: itraconazole, 200 mg; fluconazole, 200 mg; and terbinafine, 250 mg. Of these, griseofulvin is the least expensive, but some *T. tonsurans* isolates are resistant to it. All these medications are effective in cases of tinea barbae, Majocchi granuloma, extensive tinea corporis, and tinea manuum that are unresponsive to topical agents. Griseofulvin and terbinafine appear to be superior to fluconazole and itraconazole for the treatment of tinea capitis.[8]

Tinea unguium is difficult to eradicate, particularly in the toenails. The most effective agent is terbinafine, administered at a dosage of 250 mg daily for 6 weeks for fingernail infections and for 12 weeks for toenail involvement.[9] Because terbinafine persists in the nails for many weeks, it continues to exert antifungal effects long after it is discontinued. The terbinafine regimens produce short-term eradication of infection in about 70% to 90% of patients with fingernail infection and in about 50% to 80% of patients with toenail infection. Relapse is common, and patients often require a second course of treatment. About 75% of patients who receive one or more courses of terbinafine will have a clinical cure 5 years later. This therapy is very expensive, and clinicians must decide in each case whether treatment is warranted.

Yeast Infections

Yeasts are unicellular fungi that reproduce by budding. They may form filamentous projections, which, unlike the hyphae of molds, do not contain separate cells. Accordingly, they are called pseudohyphae. *Candida* species are not part of the normal skin flora, but they commonly reside in the oropharynx, vagina, and colon. From these locations, they may cause infections in adjacent traumatized skin. Alternatively, with reduction in the other flora or with impaired host defense mechanisms, these yeasts may proliferate in large numbers to produce lesions on the mucosal surfaces of the mouth and vagina.

Malassezia furfur (also called *Pityrosporum orbiculare* or *P. ovale*) is a yeast that requires lipids for growth. It normally colonizes the skin of adults, especially of the scalp and upper trunk, where the presence of sebum is highest. For unknown reasons, these organisms, which are ordinarily commensals, can become pathogenic and cause tinea versicolor (also known as pityriasis versicolor) or folliculitis. Cogent evidence suggests that these organisms cause seborrheic dermatitis and dandruff.

CANDIDIASIS

Clinical Presentations

Oral candidiasis One form of oral candidiasis, thrush, appears as white to gray patches (pseudomembranes) on the tongue, soft palate, gingiva, oropharynx, and buccal mucosa. Removing the material from the mucosal surface reveals an underlying erythematous base. Predisposing factors in adults include diabetes mellitus, use of systemic or local corticosteroids, use of broad-spectrum antibiotics, use of radiotherapy or chemotherapy, and impaired cell-mediated immunity, especially from HIV infection. Acute atrophic candidiasis especially follows antibiotic therapy and causes painful, red, denuded lesions of the mucous membranes; the tongue may have erythematous areas with atrophic filiform papillae. In chronic atrophic candidiasis, contamination of dentures with *Candida* causes painful, red, and sometimes edematous lesions with a shiny, atrophic epithelium and well-demarcated borders where the dentures contact the mucous membranes. Poor dental hygiene and prolonged use of dentures are common predisposing factors. Some patients with these predisposing factors have angular cheilitis (perleche), characterized by erythema and fissuring of the corners of the mouth. Other contributing conditions are maceration from excessive salivation or licking, poorly fitting dentures, and a larger fold from diminished alveolar ridge height. *Candida* is present in most, but not all, patients with this disorder.

Chronic hyperplastic candidiasis (candidal leukoplakia) consists of irregular, white, persistent plaques on the tongue or mucous membranes that are difficult to remove; this form of candidiasis occurs especially in male smokers. Soreness, burning, and roughness of the affected areas are the usual symptoms. Candidiasis of the tongue can also take the form of median rhomboid glossitis, a diamond-shaped area of atrophic papillae in the central portion of the lingual surface.

Candidal intertrigo *Candida* infection may occur in any skin fold, causing soreness and itching. Obese patients are especially vulnerable. Commonly affected areas include the groin, inframammary regions, and folds of the abdominal pannus. The lesions are patches of bright erythema accompanied by maceration and an irregular, scalloped border, beyond which papules and pustules (satellite lesions) commonly form [*see Figure 5*].

Candidal vulvovaginitis and balanitis Most women with candidal vulvovaginitis have no underlying disease, but candidal vulvovaginitis may accompany diabetes mellitus and HIV infection. Candidal vulvovaginitis causes white plaques on a swollen, red vaginal mucosa; a creamy vaginal discharge; and erythema, sometimes with pustules, on the vulvar skin. Soreness and burning are common symptoms. Male sexual partners of women with candidal vulvovaginitis—especially male sexual partners who are uncircumcised—may develop balanitis, characterized by erythema, pustules, and erosions on the glans of the penis. Balanitis may occur spontaneously as well.

Candidal paronychia and nail infection Maceration of the tissue surrounding the nail, typically caused by excessive moisture, may cause paronychia, which is characterized by erythema, swelling, and pain of the nail fold with loss of the cuticle [*see Figure 6*]. *Candida* organisms often colonize the area but are probably pathogenic only when pus forms. With chronic colonization, nail involvement may occur, producing yellowish discoloration and separation of the nail plate from the nail bed (onycholysis). For chronic paronychia without purulence, topical corticosteroids, such as triamcinolone cream applied twice daily for 3 weeks, are the best therapy.[10]

Figure 5 **Prominent satellite lesions of discrete vesicles are seen in a patient with candidiasis.**

Figure 6 **In a *Candida* paronychia, seen on this patient's thumb, the nail fold becomes red, swollen, and painful. Nail dystrophy is also seen.**

Diagnosis

Scrapings from cutaneous or mucous membrane lesions may be mixed with KOH solution and examined under the microscope for budding yeasts with pseudohyphae. Gram stains of the same specimen are easier to evaluate because they disclose very large, oval, gram-positive cocci that may demonstrate budding or pseudohyphal formation. These organisms are much larger than bacteria and are much easier to see on Gram stain than on KOH preparation. Culture of specimens may be useful if the microscopy is normal or ambiguous. These organisms grow rapidly on both fungal and conventional bacterial media.

Treatment

Oral candidiasis For oral candidiasis, topical nystatin suspension, 200,000 to 400,000 units three to five times a day, is usually effective; an alternative treatment is clotrimazole troches. For patients in whom topical treatment is ineffective or poorly tolerated, systemic therapies include ketoconazole, 200 mg/day; fluconazole, 100 mg/day; and itraconazole, 100 mg twice a day. Angular cheilitis usually responds to an azole cream, such as miconazole or clotrimazole. Dentures should be cleaned carefully with an effective disinfectant, such as chlorhexidine.

Candidal intertrigo and balanitis Candidal intertrigo and balanitis respond to a topical azole cream, such as miconazole or clotrimazole.

Candidal vulvovaginitis Treatment of vulvovaginitis includes a topical azole in the form of a cream, suppository, or ointment, administered intravaginally, typically once daily for 7 days. A cream may be used for vulvar involvement. An alternative to suppositories is treatment with a single oral dose (150 mg) of fluconazole, which is at least as effective as topical therapy and is often preferred by patients.

Candidal paronychia Patients with candidal paronychia should keep their fingers dry; when wet work is unavoidable, patients should use cotton liners under rubber gloves. Prolonged topical therapy with creams or solutions of various azole preparations, such as clotrimazole, is often necessary to eradicate the infection.

Clinical Presentations

Tinea versicolor (pityriasis versicolor) Because the term tinea traditionally refers to dermatophyte infection, some clinicians prefer the term pityriasis, which means scaling, for this yeast infection. Usually asymptomatic, tinea versicolor may cause itching or skin irritation. The lesions are small, discrete macules that tend to be darker than the surrounding skin in light-skinned patients and hypopigmented in patients with dark skin. They often coalesce to form large patches of various colors (versicolor) ranging from white to tan [*see Figure 7*]. Scratching the lesions produces a fine scale. This infection most commonly involves the upper trunk, but the arms, axillae, abdomen, and groin may also be affected. Most lesions fluoresce a yellowish color under a Wood light.

***Malassezia* folliculitis (*Pityrosporum* folliculitis)** In folliculitis, inflammation of the hair follicle causes red papules and pustules that surround individual hairs. One cause of folliculitis is *M. furfur*. Lesions appear predominantly on the trunk but occasionally occur on the arms as well. The lack of comedones distinguishes the lesion from acne. Pruritus and stinging may be present.

Diagnosis

In patients with tinea versicolor, KOH preparations of scrapings from the lesions demonstrate pseudohyphae and yeasts, which resemble spaghetti and meatballs. This technique is sufficient to establish the diagnosis. The yeast form prevails in folliculitis and is easily seen on Gram stain of purulent material from a pustule, appearing as a large, oval, gram-positive coccus that is much larger than bacteria. Biopsies of these lesions show organisms around and within the hair follicle, with accompanying neutrophilic inflammation. The yeasts are best seen with periodic acid–Schiff or Gomori methenamine-silver stain. Because these yeasts form part of the normal cutaneous flora, growth of the organism on cultures from scrapings of the skin surface is not very helpful diagnostically. Culture of the yeast from the pus of folliculitis, however, is definitive, but it requires special media, such as Sabouraud agar with olive oil, to provide the necessary lipids for growth. Growth typically occurs in 3 to 5 days.

Figure 7 **Tinea versicolor appears on the chest of this patient as oval, hypopigmented, finely scaling macules.**

Figure 8 **Vesicopustules or bullae of impetigo rupture quickly and leave an erythematous base covered with a thin, seropurulent exudate. The exudate dries, forming layers of honey-colored crusts.**

Treatment

Simple treatment of tinea versicolor and *Malassezia* folliculitis involves applying selenium sulfide shampoo from the chin to the waist and from the shoulders to the wrist, allowing the shampoo to dry, and then washing it off after 10 to 15 minutes. Repeating this regimen after 1 week is usually effective; reapplication once every few weeks as necessary should prevent relapses, which are otherwise common. With tinea versicolor, scaling resolves promptly, but the pigmentary changes may take weeks to months to disappear. Topical azoles, such as ketoconazole, miconazole, and clotrimazole, are also effective, but the expense of these drugs makes their use impractical except for small or isolated lesions. For patients who have difficulty applying a topical agent because of physical disabilities or other factors, oral ketoconazole or fluconazole in a single 400 mg dose is an effective alternative. This oral program can be repeated for recurrences.

Bacterial Infections

SKIN INFECTIONS CAUSED BY STREPTOCOCCI, STAPHYLOCOCCI, OR BOTH

Impetigo

Initially a vesicular infection of the skin, impetigo rapidly evolves into pustules that rupture, with the dried discharge forming honey-colored crusts on an erythematous base [*see Figure 8*]. The lesions are often itchy. Impetigo characteristically occurs on skin damaged by previous trauma, such as abrasions or cuts. Exposed areas are most commonly involved, typically the extremities or the areas around the mouth and nose. Impetigo is usually a disease of young children and is more frequent in hot, humid climates than in temperate ones.

The usual cause is *Staphylococcus aureus*, but sometimes, *Streptococcus pyogenes* (group A streptococci) is also present; occasionally, *S. pyogenes* is the sole organism cultured.[11] Some strains of *S. aureus* elaborate a toxin that causes a split in the epidermis and the development of thin-roofed bullae. In this disorder, known as bullous impetigo, superficial, fragile, and flaccid vesiculopustules form and then rupture, with the exu-

date drying into a thin, brown, varnishlike crust. Sometimes, the vesiculopustules are not apparent, and erythematous erosions are the only evident disturbance.

Growth of *S. aureus*, *S. pyogenes*, or both from the skin lesions confirms the diagnosis, but cultures are unnecessary in characteristic cases. For treatment of sparse, nonbullous lesions, topical mupirocin ointment applied three times daily for 7 days is as effective as oral antimicrobials. Systemic antibiotics active against both *S. aureus* and *S. pyogenes*, such as cephalexin or dicloxacillin, represent an alternative to topical treatment. For extensive lesions, these antibiotics are preferred to topical therapy, and they are the treatment of choice for bullous impetigo. Because of the superficial nature of these infections, the lesions heal without scarring.

Ecthyma

Ecthyma (from the Greek word *ekthyma*, meaning pustule) is a deeper infection than impetigo. As with impetigo, *S. aureus*, *S. pyogenes*, or both may be the cause. Ecthyma commonly occurs in patients with poor hygiene or malnutrition or patients who have had skin trauma. The lesions, which are often multiple and are most common on the lower extremities, begin as vesicles that rupture, creating circular, erythematous lesions with adherent crusts. Beneath the scabs, which may spontaneously slough, are ulcers that leave a scar when healing occurs. Culture of the ulcer base yields the causative organisms. Treatment should be with an oral antistaphylococcal agent, such as dicloxacillin or cephalexin.

SKIN INFECTIONS CAUSED BY STREPTOCOCCI

Cellulitis and Erysipelas

Cellulitis and erysipelas are acute, spreading infections of the skin caused by streptococci of groups A, B, C, and G. Erysipelas involves the superficial dermis, especially the dermal lymphatics, and cellulitis affects the deeper dermis and subcutaneous fat. Erysipelas has an elevated, sharply demarcated border, but differences in the clinical appearances of erysipelas and cellulitis are unimportant and often unclear. The most common sites of infection are the face and lower extremities. The causative organisms may enter the skin at obvious areas, such as traumatic wounds and leg ulcers, or through cutaneous inflammation (e.g., eczema); often, however, no point of entry is apparent. Edema from any cause, including venous insufficiency, hypoalbuminemia, and lymphatic damage, is a predisposing factor. Infection commonly occurs on skin that has been permanently damaged by burns, trauma, radiotherapy, or surgery. For example, cellulitis may occur at the site of a saphenous vein removal for cardiac or vascular surgery months to years after the procedure.[12] An important predisposing factor in patients with cellulitis or erysipelas is tinea pedis, especially interdigital involvement; streptococci can invade the skin at sites of tinea pedis through adjacent skin surface disrupted by the fungal infection or can migrate to more proximal locations on the leg and enter through abnormal skin there. Obesity is also a predisposing condition.[13]

Diagnosis Cutaneous findings include rapidly expanding erythema and swelling of the skin [*see Figure 9*], sometimes accompanied by proximal streaks of redness, representing lymphangitis, and tender, enlarged regional lymph nodes. Vesicles, bullae, petechiae, and ecchymoses may occur. The cutaneous surface may resemble the skin of an orange (peau d'orange) because the hair follicles remain tethered to the deeper structures, keeping their openings below the surrounding superficial edema and creating the characteristic dimpling of the skin. On the face, the typical location is on one or both cheeks, with a butterfly pattern of erythema and swelling. Extension to the eyelids, ears, or neck is common. Systemic symptoms, such as fever, headache, and confusion, can accompany these infections; sometimes, such symptoms precede by hours any cutaneous findings on examination. Other patients have no systemic features despite severe skin abnormalities.

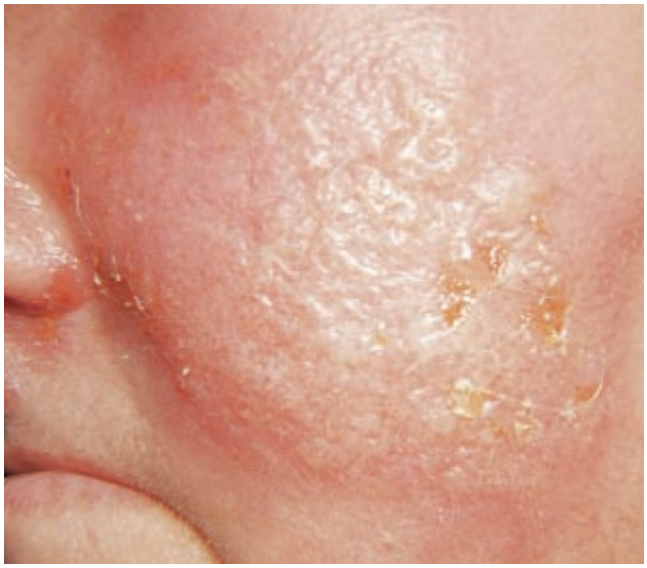

Figure 9 **Erythema, edema, and sharp demarcation of the lesion from the normal surrounding skin characterize facial erysipelas.**

The diagnosis is largely clinical; in a typical case, cultures are unnecessary and usually unrewarding. Needle aspiration of the lesion yields an isolate in about 5% of specimens, as do blood cultures in febrile patients. Because of their low yield, blood cultures are unrewarding in typical cases of cellulitis.[14] Punch biopsies of the skin are culture-positive in about 20% of cases.[15] These results, together with serum antibody tests for streptococci[16] and immunofluorescent studies of skin biopsies,[17] indicate that streptococci cause the vast majority of cases of cellulitis and erysipelas. *S. aureus* is often suspected but rarely implicated in cellulitis in the absence of an abscess or penetrating injury. Additional circumstances in which organisms other than streptococci are likely to be responsible for cases of cellulitis include immunodeficiency, penetrating trauma, immersion injuries in freshwater or saltwater, granulocytopenia, and animal bites or scratches. Cultures are appropriate in these situations.

Treatment Treatment consists of elevation of the affected area to help reduce edema and administration of systemic antibiotic therapy. For patients who do not have serious systemic illness, oral treatment is satisfactory. Penicillin is the drug of choice for streptococcal infections; for outpatients who may not take an oral medication as prescribed, I.M. benzathine penicillin G in an adult dose of 1.2 million units provides a complete course. Instead of penicillin, many clinicians prescribe an antistaphylococcal agent—either a first-generation cephalosporin or a penicillinase-resistant penicillin—because of concerns about *S.*

aureus. Patients often get worse shortly after therapy, with further extension of the cellulitis, higher fever, greater toxicity, and increased white blood cell counts, presumably because rapid killing of the organisms releases potent enzymes, such as streptokinase and hyaluronidase, that cause many of the clinical features. Oral prednisolone, taken for 8 days in doses of 30 mg, 15 mg, 10 mg, and 5 mg, with each dose taken for 2 days, decreases the duration of cellulitis and shortens hospital stay; it is a reasonable regimen in those with no contraindications to systemic corticosteroids.[18]

In patients with leg cellulitis, treatment of tinea pedis is useful in preventing further episodes, which are likely to cause permanent lymphatic damage and can lead to lymphedema and further risk of infection. Other measures to diminish the frequency of future attacks include control of edema by diuretics or mechanical means, such as elastic stockings, and, for those with frequent episodes, prophylactic antibiotics. The easiest approach is the administration of oral penicillin or erythromycin, 250 mg twice daily.[19,20]

INFECTIONS DUE TO *STAPHYLOCOCCUS AUREUS*

Furunculosis

A furuncle is a deep-seated inflammatory nodule with a pustular center that develops around a hair follicle [*see Figure 10*]. With involvement of several adjacent follicles, a mass called a carbuncle may form, with pus discharging from multiple follicular orifices. This infection typically develops on the back of the neck and appears more commonly in patients with diabetes than in the general population. Moist heat is usually adequate for small furuncles, which ordinarily drain spontaneously. Incision and drainage are appropriate for large or multiple furuncles and for all carbuncles. Systemic antibiotics are unnecessary unless there is fever or substantial surrounding cellulitis.

Some patients have recurrent episodes of furunculosis. Although a few patients have definable abnormalities in host defenses, such as neutrophil disorders, most are otherwise healthy people who, like 20% to 40% of the population, carry *S. aureus* in the anterior nares. From this site or occasionally from the perineum or axilla, organisms can spread and enter the skin, presumably through minor, usually inapparent, trauma. Successful prevention of recurrent infection requires eradication of these bacteria from their site of residence, but most systemic antibiotics do not achieve adequate levels of drug in the anterior nares. An exception is clindamycin, which, when given as a single daily dose of 150 mg for 3 months, is very effective in preventing subsequent episodes.[21] A less effective alternative is mupirocin ointment, applied in the anterior nares twice daily for 5 days each month.[22]

Figure 10 **A furuncle, or boil, occurs as an acute, painful, localized staphylococcal abscess surrounding a hair follicle.**

SKIN INFECTIONS CAUSED BY THE RESIDENT CUTANEOUS FLORA

The normal cutaneous flora helps prevent infection by other organisms through the mechanisms mentioned above: occupying available sites of residence, competition for nutrients, establishment of a low pH, and the elaboration of antibacterial substances. Occasionally, however, the resident skin flora causes cutaneous infections, especially with trauma or alterations in the stratum corneum. Examples are erythrasma, pitted keratolysis, trichomycosis axillaris, and most cases of cutaneous abscesses.

Cutaneous Abscesses

Cutaneous abscesses are collections of pus within the dermis and deeper skin tissues. They probably occur as a result of trauma. Sites of trauma associated with cutaneous abscesses may be apparent, as with sites of injections in illicit-drug users,[23] or they may be minor and unnoticed. *S. aureus*, usually in pure culture, causes about 25% of cutaneous abscesses, especially in the axillae, on the hand, and on the breasts of women after childbirth.[24] In other sites, however, the predominant organisms are anaerobes. Anaerobes occur either alone or in the mixture of anaerobes and aerobes that constitutes the normal regional flora; they are sometimes accompanied by microbes from adjacent mucous membranes. In anogenital infections, such as scrotal, inguinal, vaginal, buttock, and perirectal abscesses, the organisms are commonly fecal bacteria, including streptococci, anaerobic gram-positive cocci, and anaerobic gram-negative bacilli, such as *Bacteroides fragilis*. On the extremities, trunk, neck, and head, the usual microbes include coagulase-negative staphylococci, anaerobic gram-positive cocci, and *Propionibacterium acnes*, an anaerobic gram-positive bacillus. These organisms ordinarily possess little virulence, but when introduced into the dermis or subcutaneous tissue by trauma or through a disrupted cutaneous surface, they may become pathogenic.

Cutaneous abscesses usually cause a painful, fluctuant, red, tender swelling, on which may rest a pustule. Treatment is incision and drainage of the area. Gram stain and culture of the pus are ordinarily unnecessary, as are topical antimicrobials. Systemic antibiotics are reserved for patients with extensive surrounding cellulitis, neutropenia, cutaneous gangrene, or systemic manifestations of infection, such as high fever.

Erythrasma

Porphyrin-producing coryneform bacteria, which are gram-positive bacilli that constitute part of the normal cutaneous flora, cause a superficial, usually asymptomatic, skin disorder called erythrasma. One particular species, *Corynebacterium minutissimum*, has often been cited as the sole cause of this infection, but its precise role, if any, remains unclear. The most common site of erythrasma is between the toes, especially in the fourth interdigital space, where it causes fissuring, maceration, and scaling, resembling tinea pedis. Other locations are intertriginous areas, such as the axillae, groin, submammary area, and intergluteal cleft. In these regions, the lesions are usually scaly, brownish-red, sharply circumscribed patches. In hot,

humid climates, more extensive disease may occur. The definitive diagnostic technique is examination of the skin with a Wood light, which, because the organisms produce porphyrins, reveals a coral-red fluorescence. Culture of the lesions, which requires special media, is unnecessary. Because they possess some activity against gram-positive bacteria, topical azoles, such as miconazole and clotrimazole, are effective in the treatment of this infection. Topical erythromycin or clindamycin is also effective. Oral erythromycin (250 mg q.i.d. for 2 weeks) is an alternative.[25]

Pitted Keratolysis

C. minutissimum and a gram-positive coccus, *Micrococcus sedentarius*, either alone or together, cause a disorder that may affect the soles—typically in pressure-bearing areas—or, occasionally, the palms.[26] Pitted keratolysis consists of small pitted erosions about 1 to 7 mm in diameter that may be present on reddened plaques and are often more apparent after soaking in water for a few minutes. This infection occurs with increased moisture, such as caused by excessive sweating, occlusive footwear, or frequent contact with water. It appears more commonly in hot, humid climates than in more temperate ones. An impressive malodor of the feet is often apparent, and although the disorder may cause no symptoms, some patients complain of itching, tenderness, or sliminess of the feet. As in erythrasma, topical azoles, such as clotrimazole and miconazole, are effective, as are topical erythromycin and clindamycin.

Trichomycosis axillaris

Trichomycosis axillaris is characterized by colored concretions of axillary hair that result from infection of the hair shafts by large colonies of various species of *Corynebacterium*. The nodules may be yellow, black, or red; and because the organisms may invade the cuticle, the hair can become brittle. The same process occasionally affects the facial or pubic hair.[27] Excessive sweating, poor hygiene, and failure to use an axillary deodorant are predisposing factors. Shaving the hair is effective treatment; other options include topical erythromycin or clindamycin.

INFECTIONS DUE TO OTHER BACTERIA

Necrotizing Fasciitis

Necrotizing fasciitis, a necrotizing infection of the subcutaneous tissue, can be caused by streptococci; more often, however, the responsible organisms are a combination of aerobic bacteria—such as gram-negative enteric organisms (e.g., *Escherichia coli)* and gram-positive cocci—and anaerobes, including *B. fragilis*.[28] Necrotizing fasciitis usually occurs after a penetrating wound to the extremities. The injury is typically deep, but sometimes, infection occurs after apparently trivial trauma, such as abrasions or lacerations. The necrotizing process may develop from extension of an adjacent infection, especially in the second most common location, the anogenital area. There, infection typically arises from a perianal abscess; as an extension of a periurethral gland infection, especially in men with urethral strictures; through retroperitoneal suppuration from perforated abdominal viscera; or as a complication of a preceding surgery. Necrotizing infection involving the genitalia is called Fournier gangrene.

These infections typically begin with fever, systemic toxicity, severe pain in the affected site, and the development of a painful, red swelling that rapidly progresses to necrosis of the subcutaneous tissue and overlying skin. Early on, the pain may appear disproportionate to the clinical findings. In some cases involving *S. pyogenes* infection, the characteristics of the streptococcal toxic-shock syndrome may appear[29] [*see 7:I Infections Due to Gram-Positive Cocci*]. When anaerobes or certain aerobic gram-negative bacilli cause the infection, gas may form in tissues, evident as crepitus on physical examination or visible on radiographic studies. Although the disease may resemble uncomplicated cellulitis, the following signs and symptoms should suggest the presence of a necrotizing subcutaneous infection: edema beyond the apparent limits of the infection; rapid development of bullae and ecchymoses; cutaneous gangrene; fluctuance; crepitus; and radiographically visible gas. Computed tomography or magnetic resonance imaging may be helpful in some cases in detecting the infection and defining its extent. Aspiration of the affected tissue may yield purulent fluid, which on Gram stain demonstrates only gram-positive cocci in chains when *S. pyogenes* is responsible or reveals a variety of many different organisms when a mixed infection is present. The findings on Gram stain and culture of pus should dictate antibiotic choice, but a good initial program is gentamicin in combination with clindamycin. Most important is incision and drainage of the affected area, which should include removal of any necrotic tissue. Often, the amount of disease revealed at surgery is much greater than was apparent on the preoperative clinical examination, because the infection typically extends far beyond the borders of cutaneous inflammation. Repeat operation after 24 hours is typically prudent to detect new areas of infection and necrotic tissue.

Folliculitis

Folliculitis is an inflammation at the opening of the hair follicle that causes erythematous papules and pustules surrounding individual hairs [*see Figure 11*]. The most common location is the trunk. The initiating factor seems to be occlusion of the opening of the follicle, which may occur from contact with chemicals, such as oils or cosmetics; overhydration of the skin from excessive moisture; or repetitive trauma, such as friction from tight-fitting clothing, which elicits hyperkeratosis and follicular plugging. Subsequently, inflammation develops, which may be provoked by bacteria, yeast, or other nonmicrobial substances trapped beneath the occluded ostium.

Among bacteria, *S. aureus* is often suspected but rarely found. When bacteria are present in the pustules, the culture usually yields normal skin flora. In these patients, oral erythromycin or doxycycline may be effective in eradicating the lesions. Another cause is *M. furfur*, a yeast that is a normal resident on the skin. In other patients, the avoidance of oily substances on the skin or tight clothing leads to resolution of the problem.

Occasionally, *Pseudomonas aeruginosa* is responsible, as a consequence of inadequate disinfection of hot tubs, swimming pools, or whirlpools.[30] This gram-negative bacillus grows well in hot water. Outbreaks occur an average of 48 hours after exposure, with a range of several hours to several days. Erythematous, pruritic papules, often with a pinpoint central pustule, appear in areas exposed to the contaminated water; lesions are particularly numerous in regions occluded by tight-fitting swimming suits. The lesions disappear spontaneously over several days, leaving no scars; ordinarily, no topical or systemic therapy is necessary. Some patients have sore throat,

a

b

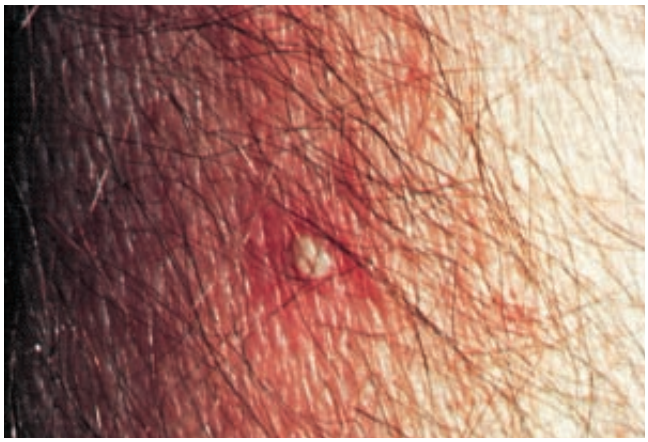

Figure 11 **Folliculitis is a superficial or deep inflammation of the hair follicles, appearing at follicular openings as small pustules surrounded by erythema (*a*). Folliculitis may also occur as an isolated lesion (*b*).**

rhinitis, earache, and headache, but fever or bacteremia is very rare. Cultures of the skin lesions and the contaminated water usually yield the organism.

Cutaneous Anthrax

Spores of *Bacillus anthracis* sent through the mail in the fall of 2001 as an act of bioterrorism caused cases of inhalational and cutaneous anthrax in several states. Otherwise, anthrax has been very rare in the United States over the past few decades. Ordinarily, this bacterium resides in the soil, where it forms spores that can persist for years. When ingested—primarily by herbivores (cattle, horses, sheep, and goats) grazing on contaminated land—these spores may cause infection. This veterinary disease is most frequent in tropical and subtropical areas, but extensive vaccination can markedly diminish its frequency.

Except for cases associated with bioterrorism [*see 8:V Bioterrorism*], humans usually develop anthrax from exposure to affected animals or their products, such as hides. Occasional laboratory-acquired cases also occur. The cutaneous form develops when spores enter the skin through abrasions and then transform into bacilli, which produce toxins that cause local tissue edema and necrosis. Macrophages can transport spores to regional lymph nodes, but bacteremia is uncommon. After an incubation period of about 1 to 7 days, a painless, pruritic papule forms at the entry site, most commonly the head, neck, and extremities. Over the next few hours the lesion enlarges, and a ring of erythema may form around it. In 1 to 2 days, vesicles appear, surrounding the papule and containing numerous bacteria but few neutrophils. Painless, gelatinous, nonpitting edema then encircles the lesion, often spreading extensively to adjacent skin and soft tissue [*see Figure 12*]. This pronounced edema is especially characteristic of anthrax. After enlarging, the vesicles become hemorrhagic and rupture. In the depressed center of the lesion, a black eschar forms and sloughs within 1 to 2 weeks, leaving a shallow ulcer that heals with minimal, if any, scarring. In the early days of illness, patients commonly have headache, malaise, and fever. Regional lymph nodes often enlarge, causing pain and tenderness.

Diagnosis *B. anthracis*, a broad, encapsulated gram-positive rod, is visible on Gram stains of material from a skin lesion as single organisms or chains of two or three bacilli. It grows readily at 37° C on blood agar media. Skin biopsies reveal necrosis, hemorrhage, and massive edema. Organisms are demonstrable with tissue Gram stain or immunohistochemical staining for the bacteria's cell wall antigen. Because it requires acute and convalescent blood specimens, serologic testing for antibodies to *B. anthracis* is unhelpful for immediate diagnosis but may establish a retrospective diagnosis of suspected but unconfirmed cases.

Treatment Treatment for cutaneous anthrax unassociated with bioterrorism is penicillin V (500 mg q.i.d. orally) or amoxicillin (500 mg t.i.d. orally) for mild cases and, for more severe disease, penicillin G (6 to 8 million units I.V. daily). For penicillin-allergic patients or cases arising from bioterrorism, the recommended therapy is oral ciprofloxacin (500 mg b.i.d.) or doxycycline (100 mg b.i.d). Antibiotic therapy does not alter the course of eschar formation and healing, but it does decrease the risk of systemic disease. Ordinarily, the duration of therapy is 7 to 10 days, but the recommended regimen for cases associated with bioterrorism is 60 days because of the possibility of simultaneous aerosol exposure.[31]

Figure 12 **Cutaneous anthrax lesion, seen on the seventh day after infection.**

WARTS

Warts, or verrucae, are caused by human papillomaviruses (HPVs), a subgroup of DNA-containing papovaviruses, of which there are more than 70 types. Humans are the only known reservoir; transmission probably occurs from close contact with infected people or possibly from exposure to sloughed, infected epidermal cells. The virus presumably enters through small breaks in the skin. The incubation period is difficult to discern but is probably several months. Autoinoculation from one portion of the body to another also occurs. Cell-mediated immunity appears important in controlling these infections, which can be very extensive and refractory to treatment in immunocompromised patients.

Verrucae vary according to location. They include the common, elevated wart (verruca vulgaris), typically appearing on the hands; the flat wart (verruca plana), on the face and legs; the moist wart (condyloma acuminatum), in the anogenital area; and the callus-covered plantar wart (verruca plantaris), on the sole of the foot. A histologic feature that distinguishes a wart from other papillomas is the presence in the upper epidermis of large, vacuolated cells that contain numerous viral particles.

Verruca Vulgaris

The common wart consists of single or multiple skin-colored papules, which often have a hyperkeratotic, papillary surface. They are commonly present on the fingers. The estimated nationwide prevalence of hand warts is 3.5% for people 18 to 64 years of age; the greatest frequency (5.5%) occurs in men 18 to 24 years of age. The warts may be filiform, with a small base and a thin projection of several millimeters, especially on the face.

Liquid nitrogen is a common initial treatment of choice for many warts. Administered with a cotton-tipped applicator or cryospray device, liquid nitrogen freezes the lesion, causing it to blister and subsequently dissolve. More than one application at 2- to 3-week intervals may be necessary for large or periungual warts. Electrodesiccation and curettage or laser surgery are effective for persistent or recurrent lesions.

Verruca Plana

The flat wart is a skin-colored or light-brown, slightly elevated, smooth papule commonly seen on the face and the dorsum of the hand. These may be difficult to treat, but freezing with liquid nitrogen, application of trichloroacetic acid, or painting the lesions with 10% salicylic acid and 10% lactic acid in flexible collodion may be effective.

Verruca Plantaris

The plantar wart is often painful and disabling. A mosaic wart, a variant of verruca plantaris, consists of multiple discrete or confluent superficial lesions and is often difficult to treat. A plantar wart that is covered by a callus can be distinguished from an ordinary callus by paring off the surface keratin; multiple, pinpoint dots, representing thrombosed vessels, or bleeding points from surface capillaries will become apparent if it is a wart. Paring of the wart can be followed by immediate treatment with liquid nitrogen, the application of strong acid (50% trichloroacetic acid), or the nightly administration of salicylic acid in plasters, an acrylic vehicle, or collodion.

Figure 13 **Condyloma acuminatum may appear as a large cauliflower-like mass that resembles a malignant tumor.**

Condyloma Acuminatum

Anogenital warts consist of skin-colored or gray, discrete or confluent cauliflower-like excrescences that may cause no symptoms or produce itching, burning, pain, or tenderness [*see Figure 13*]. The incidence is highest in young adults; most often, it is a sexually transmitted disease, though some anogenital warts may develop from autoinoculation or may be acquired in other ways.[32]

Infection with some types of HPV predisposes to malignancy. Most cases of squamous carcinoma of the cervix are caused by HPV, especially HPV-16 and HPV-18, but fortunately, these types represent only a small percentage of the isolates from anogenital warts. Genital verrucous carcinoma, also called giant condyloma acuminatum of Buschke-Löwenstein, is a low-grade genital malignancy caused by HPV-6 and HPV-11. Squamous carcinoma of the anus is associated primarily with HPV-16.

Anogenital warts may be difficult to eradicate, and several treatments are often necessary.[33] Therapies administered by clinicians include liquid nitrogen, podophyllin resin, trichloroacetic or bichloroacetic acid, surgical removal, laser therapy, or intralesional interferon. Patient-applied treatments are podophyllotoxin, which the patient applies twice daily for 3 days, or imiquimod cream, used at bedtime three times a week for up to 16 weeks. Another approach involves fluorouracil (5-FU) cream administered twice daily for 1 to 3 weeks. This medication is particularly suitable for large wart plaques and warts of the urethral meatus, but side effects, including discomfort and painful erosions, are common.

Figure 14 **Benign lesions of bowenoid papulosis, as seen on the shaft of the penis, may histologically resemble carcinoma in situ.**

Bowenoid Papulosis

Bowenoid papulosis consists of benign-appearing erythematous or pigmented papules in the anogenital area that histologically resemble Bowen disease (squamous cell carcinoma in situ) [*see Figure 14*]. Its course, however, is not aggressive, and the papules should be treated as anogenital warts (see above). HPV-16 is a common cause, however, and malignancy does occasionally develop, especially in women.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

VIII PARASITIC INFESTATIONS

Elizabeth A. Abel, m.d.

Ectoparasites may cause severely pruritic infectious diseases of the skin. With early detection and treatment, parasitic infestations can be cured and their spread to other persons prevented. The most common parasitic diseases of the skin that occur in nontropical environments are scabies, which is caused by itch mites, and pediculosis capitis, pediculosis corporis, and pediculosis pubis, which are caused by bloodsucking lice.

An increase in international travel, including vacation travel to tropical destinations and immigration from such areas, has led to the occurrence of parasitic disorders endemic to tropical regions in persons living in temperate climates. The differential diagnosis of skin disorders in patients treated at a tropical disease clinic in Paris over a 2-year period included cutaneous larva migrans, pyodermas, arthropod-reactive dermatitis, myiasis, tungiasis, urticaria, and cutaneous leishmaniasis.[1] The prevalence of ectoparasitoses in the general population is usually low, but it can be high in vulnerable groups. Management of some infestations (e.g., scabies and head lice) can be complicated because resistance to insecticides is spreading and unpredictable.[2]

Scabies

Scabies is caused by infestation with *Sarcoptes scabiei*, an ectoparasite that bores into the corneal layer of human skin, forming burrows in which it deposits its eggs. The incubation period is 2 to 6 weeks in a person who has not been previously exposed. During this time, the host develops delayed hypersensitivity to mite antigens. Upon reinfestation, symptoms occur in sensitized persons within 24 to 48 hours after exposure.[3]

The scabies mite does not survive for more than 48 hours away from the host. Therefore, most infestations are transmitted through direct personal skin-to-skin and sexual contact.[3] However, transfer of organisms can occur by exposure to fomites such as contaminated bedding, clothing, or furniture and is a common cause of epidemics of scabies in nursing homes and other institutions.[3,4]

Diagnosis

Clinical Features

Scabies causes severe itching, which is usually worse at night. Characteristic sites of infestation are the webs of the fingers, the flexor aspects of the wrists, the axillae, the buttocks, the umbilicus, the penis and scrotum of males, and the breasts and nipples of females. The disease is more generalized in infants and children than in adults.

The burrow of the female *Sarcoptes* may be seen as an irregular zigzag line in the stratum corneum, with a black dot at one end that indicates the presence of the mite [*see Figure 1*]. Secondary lesions represent immunologic reactions to the mites and usually appear as small erythematous papules and vesicles with surrounding edema and scratch marks [*see Figure 2*]. The type and number of lesions depend predominantly on the immune status of the host. Occasionally, nodular lesions, which may resemble lesions of histiocytosis X (Langerhans cell granulomatosis) or lymphoma, occur as a hypersensitivity reaction to retained mite parts. Fewer lesions occur in people who practice good hygiene, and the condition may be masked in those who are using topical steroids. Secondary bacterial infection with impetiginization is common, especially in children and in elderly patients who actively excoriate their lesions.

Atypical presentations of scabies have been described in immunosuppressed persons, including organ transplant recipients, patients with lymphoma or leukemia, and patients with AIDS. Itching and scratching, with elimination of mites and burrows, may be minimal in patients who lack an immunologic host response, allowing for thousands of mites to reproduce and thrive.[3] Crusted scabies, which was originally described in Norway, is associated with widespread hyperkeratotic lesions and deep fissures in the skin. Crusted scabies can develop in patients with malnutrition or severe mental deficiency and in institutionalized patients. The condition is highly contagious because of the large number of mites present in the exfoliating skin.

A severe form of scabies with unusual clinical features consisting of crusted lesions and a widespread pruritic papular dermatitis has been described in HIV-infected patients.[3,5] In these patients, multiple treatment applications may be needed because of the large mite population and the patients' impaired immunologic response.

Skin Scrapings

A skin scraping that demonstrates the presence of mite eggs or mite products can confirm a diagnosis of scabies. A No. 15 surgical blade is used to scrape across one or more burrows. Saline solution or mineral oil is used to remove scrapings from the blade. The scrapings are then placed on a glass slide with a coverslip and examined under a microscope at low-power magnification. The scraping is positive if the gravid female, eggs, or scybala (fecal pellets) are seen [*see Figure 3*]. The yield is greatest in burrows that are not yet excoriated, which may be difficult to find. For this reason, if the scraping is negative but the clinical suspicion of scabies is high, the patient should be treated empirically. Histopathologic examination of a skin biopsy sample is also diagnostic if it reveals the mite or the superficial skin bur-

Figure 1 **Typical scabies lesions are small erythematous papules and vesicles with surrounding edema.**

row and its contents.[6] In atypical or subtle cases of scabies, epiluminescence microscopy (ELM) or polymerase chain reaction may be useful in confirming the diagnosis.[7,8] ELM, which allows visualization of the skin down to the superficial papillary dermis, is able to detect the presence of scabies within minutes, with no discomfort to the patient. PCR can amplify *S. scabiei* DNA when the number of mites is so few that diagnosis by standard means is inconclusive.

Figure 2 **The burrow of the female *Sarcoptes* frequently appears as an irregular line several millimeters to a few centimeters long in the stratum corneum.**

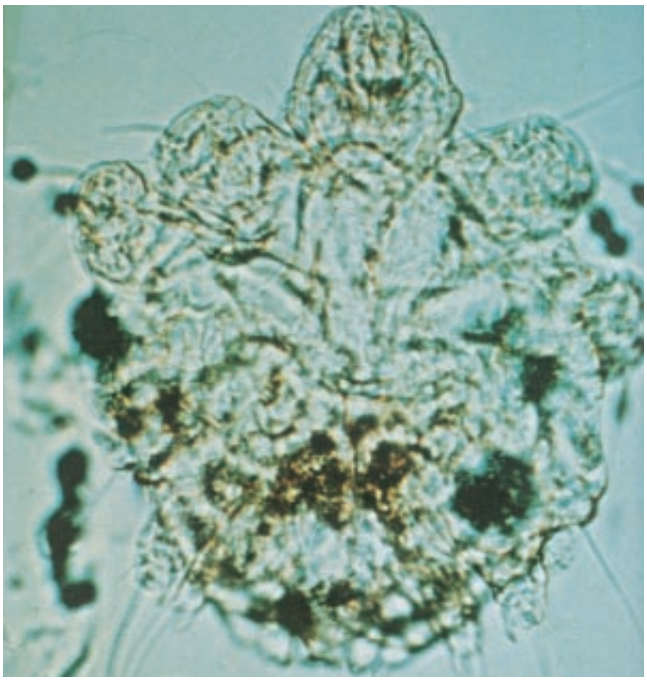

Figure 3 **Observation of the *Sarcoptes scabiei* or its eggs and feces confirms the diagnosis of scabies. Magnification is 400 times.**

DIFFERENTIAL DIAGNOSIS

Clinical differential diagnosis includes drug eruption, papular urticaria, folliculitis, atopic dermatitis, dermatitis herpetiformis, and contact dermatitis, particularly from fiberglass. Crusted scabies may be mistaken for eczema. Papular urticaria is an intensely itchy eruption caused by a hypersensitivity reaction to bites from such insects as fleas, bedbugs, and animal scabies. Lesions occur as small papules that may have a central punctum, often occurring in groups on exposed skin.

TREATMENT

Initial Treatment

After a cleansing bath or shower, the patient should allow the skin to dry and cool and then apply a scabicide over the entire body, excluding the face and scalp. Care must be taken to include skin folds such as toe webs and the skin under the nails. The medication is left in place for 8 to 12 hours, usually overnight. In the morning, the patient showers and changes clothes. All clothing worn within 2 days before treatment, in addition to towels and bed linens, is laundered in hot water or drycleaned. Chairs and mattresses should be vacuumed.

First-line treatment for uncomplicated scabies is permethrin 5% cream (Elimite, Acticin); other available scabicides include 1% lindane, or gamma benzene hexachloride, lotion or cream (Kwell, Gamene); 10% to 20% benzyl benzoate lotion; crotamiton cream (Eurax); and 6% precipitated sulfur ointment [*see Table 1*]. Ivermectin, although not approved by the Food and Drug Administration as a scabicide, has shown promising results in several trials.

Permethrin, a synthetic pyrethroid with low toxicity, has proved to be safe and effective for use in infants, children, and pregnant women.[9] Natural pyrethrins, which are derived from chrysanthemum flowers, have greater toxicity and less insecticidal activity than the synthetic pyrethroids. The low toxicity of the drug is a result of its rapid breakdown into inactive metabolites. Permethrin cream can be safely used in children and infants older than 2 months and in the elderly. Acticin is a form of permethrin in a base that has a lower viscosity to promote ease of application. Alternative scabicides that can be used for young children and pregnant or lactating women include crotamiton cream and sulfur ointment. Six-percent precipitated sulfur ointment is applied three times: at diagnosis, after 24 hours, and at 1 week. Crotamiton cream is applied for 2 or more consecutive days but is less effective than permethrin. Permethrin appears to be more effective than crotamiton in clinical and parasitic cure rates.[9]

Lindane is lipophilic and can accumulate in fat and bind to brain tissue. Toxic reactions may occur in patients who have increased absorption; infants and young children, who have a higher ratio of skin surface to body volume than do adults, are especially susceptible. Excessive treatment with lindane has been reported to cause central nervous system toxicity resulting in convulsions and seizures.[10] In 2003, the FDA issued a label change for lindane emphasizing its use as second-line therapy; treatment with lindane should be considered only if other medications have failed or cannot be tolerated (information on lindane can be found on the Internet, at http://www.fda.gov/cder/drug/infopage/lindane/default.htm). Lindane lotion should be used with caution in persons weighing less than 110 lb; its use in infants is not recommended.[11] Nevertheless, low cost, ease of application, and experience with the drug have made lindane one of

Table 1 Drug Therapy for Scabies Infestations

Route	Drug	Dosage	Relative Efficacy	Comments
Topical	Permethrin 5% cream	Single total-body application left on for 8–12 hr	First-line therapy	Effective and safe for use in infants older than 2 mo, pregnant women, and elderly patients; for a treatment failure, a second application is given 1 wk later
	Crotamiton cream	Total-body applications on 2 or more consecutive days	Alternative first-line therapy	Safe for infants and pregnant women but less effective than permethrin
	Precipitated 6% sulfur ointment	3 total-body applications: at diagnosis, 24 hr, and 1 wk	Alternative first-line therapy	Safe for infants and young children; must be compounded
	Lindane 1% lotion†	Apply for 8 hr once weekly for 2 wk	Second-line therapy; consider after failure of first-line therapy	Associated with neurotoxicity; indicated if other medications have failed or cannot be tolerated; should be used with caution in persons weighing < 110 lb; use in infants is not recommended
Oral	Ivermectin*	Single dose, 200 mg/kg	Alternative first-line therapy for uncomplicated scabies	Safe and effective in children 6 mo of age or older; advantage of oral medication is ease of use and increased compliance
		200 μg/kg initially and 2 wk later	First-line therapy for resistant scabies	Effective for treatment of crusted and resistant scabies in HIV patients; successfully used to treat outbreaks in institutional settings

*Not approved by the Food and Drug Administration for use as a scabicide.
†Gamma benzene hexachloride.

the most commonly prescribed scabicides; the FDA considers the benefits of lindane to outweigh the risks when the medication is used as directed.

Oral ivermectin is another treatment option that has been found to be safe and effective in children as young as 6 months[12] and in HIV-positive patients. A single oral dose of 200 μg/kg of ivermectin was used to treat uncomplicated scabies in 11 otherwise healthy patients and in 11 patients with HIV infection.[13] Clearing was documented by negative skin scrapings at 2 weeks and 4 weeks after treatment, and cure was achieved in all of the otherwise healthy patients and in eight of the HIV-infected patients. Advantages of an oral medication are its ease of use, lack of treatment-associated dermatitis, and increased compliance. In a comparative study of oral ivermectin and topical permethrin, a single application of permethrin was found to be superior to a single dose of ivermectin. Two doses of ivermectin were required for eradication of scabies. The lack of ovicidal activity of ivermectin may explain the difference in effectiveness between the two drugs.[14] Ivermectin is toxic to invertebrate nerve and muscle cells but may not be effective against younger stages of the parasite that do not have a developed nervous system. Permethrin acts at early stages of the life cycle of the parasite, and topical application ensures adequate drug concentration in the skin.[14]

Oral ivermectin has been used successfully to control outbreaks of scabies infestations in institutional settings[4,15]; it may prove to be the treatment of choice in nursing homes and other institutions in which topical therapy is impractical.

Topical ivermectin has also been investigated for treatment of scabies. A total of 75 patients were found to be cured, on the basis of clinical and parasitologic examinations, within 48 hours after a single application of ivermectin. Postscabies itching, which persisted in 50% of the patients, was effectively treated by a second application of ivermectin within 5 days.[16]

Postscabies Itch

Postscabies itch is thought to represent a hypersensitivity reaction to the mite or mite products and is not caused by active infestation. The pruritus may persist for weeks to months and can be treated with an antipruritic or anti-inflammatory agent, such as a low-potency to midpotency corticosteroid cream, in addition to oral antihistamines. Overtreatment with the scabicide may result in a primary irritant dermatitis that may be confused with persistent infestation. The use of bland emollients and a corticosteroid cream and avoidance of skin irritants may reduce the dermatitis. Patients should be evaluated at 4 weeks, which is the time required for viable eggs to mature to the adult stage, to determine the efficacy of treatment. If lesions are healed and no new outbreaks have occurred, the patient is considered cured.[3]

Resistant Scabies

Overuse and misuse of certain scabicides, notably lindane, have decreased their efficacy. Differing resistance patterns have been identified within a single city; more commonly, resistance corresponds to local or regional patterns.[2] If treatment failure occurs with one scabicide, the use of a different scabicide may be indicated. For example, treatment failure with topical permethrin may prompt the consideration of lindane as a second-line therapy. Pyrethroids are effective in cases of lindane-resistant scabies.[17] Treatment failures can also occur in cases involving impetiginized or crusted scabies. In these cases, treatment with the appropriate oral antibiotic is initiated along with application of the scabicide and is followed within a week by a second application of the scabicide. Keratolytics are useful as an aid in removal of the crusts.

Oral ivermectin has been used to treat resistant scabies.[18] Although it has not been approved by the FDA for this purpose, oral ivermectin is rapidly gaining acceptance as an effective therapy for resistant scabies. Combination treatment with one or two doses of ivermectin 8 days apart, in addition to permethrin and mechanical removal of subungual debris, has been advocated for outbreaks of crusted scabies in the geriatric population.[19]

In Europe, combination therapy with oral ivermectin, 200 mg/kg, and benzylbenzoate, 15% solution applied twice daily for 3 days, was found to be more effective than either agent alone for the treatment of crusted scabies in patients with HIV.[20]

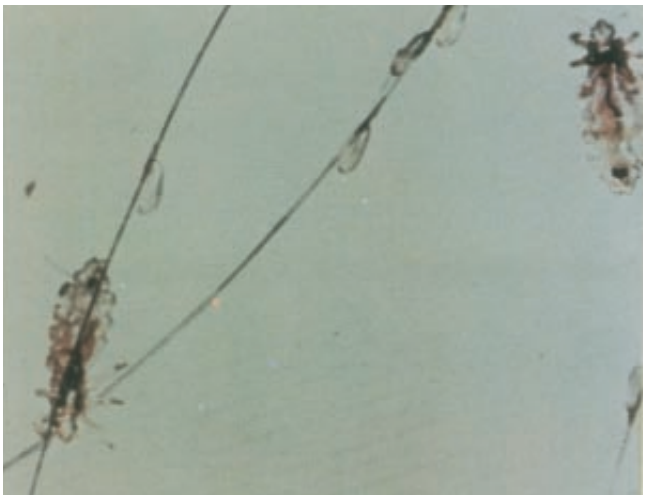

Figure 4 **Pediculosis capitis is caused by infestation of the scalp with *Pediculus humanus* var. *capitis*. Magnification is 10 times.**

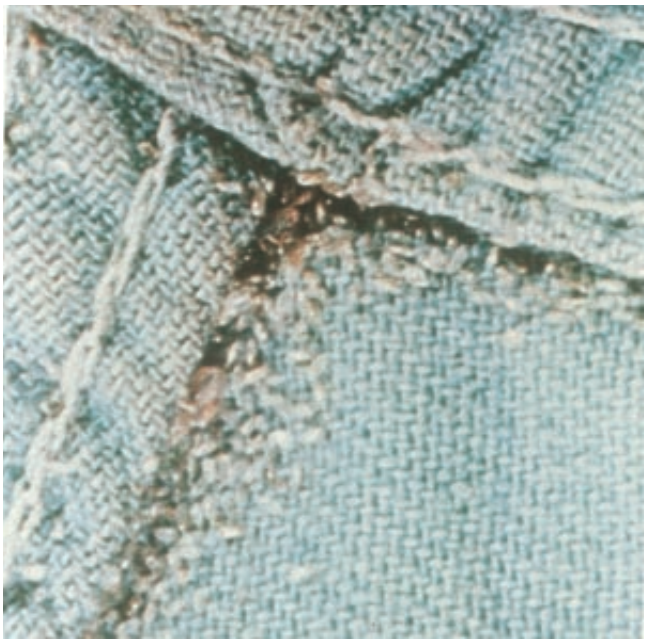

Figure 5 **Pediculosis corporis is caused by infestation with *Pediculus humanus* var. *corporis* organisms, which live in the seams of clothing.**

In the United States, a combination of oral ivermectin, total body therapy with permethrin cream, and keratolytic agents to hasten removal of crusts was used successfully to treat crusted scabies in patients with HIV.[21]

Cases of apparent resistant scabies may be the result of reinfestation. Therefore, family members and sexual partners of persons with scabies should be treated because they may be asymptomatic carriers. Scabies occurring in patients and personnel in long-term health care facilities may be difficult to diagnose and manage. In this setting, it is extremely important to treat all nursing contacts, as well as family members and other visitors of affected patients. In addition to the patients with scabies, other patients in the facility need to be assessed, and care must be coordinated to treat all affected persons simultaneously. In cases of crusted scabies, the head and neck must be treated, as well as subungual areas, which may also harbor the mites.[4]

ANIMAL SCABIES

Animal scabies is a common disorder in farm animals and domestic animals—especially dogs, in which the external ear is frequently infested with a species-specific mite. In persons who handle affected animals, an extremely pruritic papular eruption can develop that differs from ordinary scabies in several ways: distribution of lesions is proximal, with involvement of the thighs, abdomen, and forearms. Burrows are usually absent. The course is self-limited, provided there is no reexposure. Other persons in the household do not have to be treated, because human-to-human transmission of animal scabies does not occur.

The *Cheyletiella* mite is an ectoparasite that resides in the fur of dogs, cats, and rabbits. Persons who hold infested house pets, especially cats, are susceptible to a dermatitis from the mite bites. However, the mites do not live on humans, so diagnosis requires a high index of suspicion. Lesions may appear as urticarial papules, vesicles, or bullae on the arms, trunk, and legs. Cases most commonly occur in the fall or winter. An important part of the overall treatment of *Cheyletiella* infestation is treatment of the household pets by a veterinarian.[22]

Pediculosis

The three types of bloodsucking lice that cause pediculosis are *Pediculus humanus* var. *capitis* (head louse), *Pediculus humanus* var. *corporis* (body louse), and *Phthirus pubis* (pubic, or crab, louse). The first two types are closely related. The third is a separate genus and is distinctive not only in appearance and location on the body but also in its characteristic attachment to the skin for long periods. Any form of pediculosis causes intense pruritus, which is aggravated by scratching and is often complicated by secondary bacterial infection.[23]

The most common infestation is pediculosis capitis. Infestations of *P. captitis* have been reported worldwide, and an estimated 12 million cases occur annually in the United States alone.[23] Pediculosis corporis, which is usually less prevalent than pediculosis captitis, becomes widespread under conditions of overcrowding and poor sanitation or in wartime. In pediculosis capitis and pediculosis corporis, the lice may be transmitted directly from person to person or indirectly through contact with contaminated personal objects such as combs and brushes, clothing, and bedding. Pediculosis pubis (also called crabs) is usually transmitted sexually; only occasionally are the lice transmitted through contact with fomites such as contaminated bedding or toilet seats. Epidemiologic data indicate that *P. capitis* infestations are more frequent in the warmer months, whereas *P. pubis* infestations occur more frequently in the cooler months.[24]

The natural history of lice is important because it suggests specific preventive measures. The life expectancy of the organism is about 1 month. Eggs live up to 10 days but need the body heat of the host to hatch. Eggs ordinarily hatch in 7 to 8 days, and organisms reach adulthood and attain sexual reproductive capacity in 3 to 4 weeks. Lice can survive 48 hours without a blood meal.

DIAGNOSIS

Pediculosis capitis is confined to the scalp and is most prevalent in women and children. Louse infestation may present as scalp pruritus, excoriations, cervical lymphadenopathy, or conjunctivitis.[23] Examination of the itchy scalp may reveal the lice, which look like tiny black dots that are barely visible to the

Figure 6 **Pediculosis pubis, also called crabs, is caused by infestation with *Phthirus pubis*. Magnification is 100 times.**

naked eye, and lice eggs (nits), which are white and are attached to the hair shafts [*see Figure 4*]. Except in conditions of increased warmth and high humidity, viable nits are attached close to the scalp. Those that occur several millimeters away from the surface on hairs that have grown out are empty egg cases. The hair may become matted because of exudation and secondary infection of lesions. Visual examination may not detect infestation; the use of a louse comb is recommended because it is four times more efficient than visual examination alone in the diagnosis of active pediculosis capitis.[25]

Pediculosis corporis, also called vagabond disease, affects areas of the body covered by clothing. Body lice live in the seams of clothing, and they attach to the body only to feed [*see Figure 5*]. They may serve as vectors of infectious disease under conditions of overcrowding or poor hygiene, as in wartime or during natural disasters. Characteristic lesions include erythematous macules and wheals. Lesions are most common on the shoulders, buttocks, and abdomen; furunculosis is an occasional complication. Excoriations and secondary infection may result from intense scratching. After the eggs hatch, the organisms reach adulthood in 10 days and complete their life cycle in approximately 1 month. Adult lice lay about 10 eggs a day.

Pediculosis pubis, which is caused by infestation with *Phthirus pubis* [*see Figure 6*], tends to be limited to the pubic area but occasionally affects the axillae, eyelashes, or other hairy parts of the body. Examination will reveal lice attached to the skin and lice eggs attached to the hair shafts [*see Figure 7*]. Blue macules, which are caused by the lice's sucking blood from the dermis, may be seen on the thighs or pubic area.

TREATMENT

Pediculosis Capitis

Over-the-counter preparations available for the treatment of pediculosis capitis include synergized pyrethrin products, such as RID, R&C Spray, A-200, and a 1% permethrin cream rinse (Nix) [*see Table 2*]. These products are cosmetically acceptable and require only 10 minutes to apply but may not always be effective. Repeat treatment in 7 to 10 days is advisable because the initial treatment does not kill all the eggs. If pyrethrin or permethrin fails to eradicate the infestation, the treatment of choice is malathion.[26] Malathion, which was recently reintroduced in the United States as a prescription medication for head lice, is an effective, fast-acting pediculicide and ovicide; it has not been associated with treatment resistance or notable adverse effects.[27,28] In children, proper use of malathion is safe; however, serious side effects can occur with ingestion.[29]

One of the most widely used remedies for pediculosis capitis in the United States is 1% lindane (Kwell, Gamene). However, potentially serious adverse effects associated with lindane shampoo prompted the FDA to issue a label change for this medication; treatment with lindane is now indicated only if other medications have failed or cannot be tolerated.[11,27] For the treatment of pediculosis capitis, 2 tbsp (30 ml) of the shampoo is applied to affected and adjacent areas of the scalp for at least 4 minutes, followed by thorough rinsing and drying. Adherent nits may be removed with a fine-tooth comb. Distilled white vinegar can be used to soften the nit cementing material to aid in removal of the nits.

Resistance to lindane has emerged over the past 2 decades,[30] and treatment of lice infestation has been complicated by the development of resistance to permethrin.[28] Mechanical methods of removing head lice and nits[31] and application of occlusive oils or ointments[32] have been advocated for treatment of resistant head lice. Oral ivermectin has been administered as a single dose of 12 mg (2 to 6 mg tablets), followed by a second dose 7 to 10 days lat-

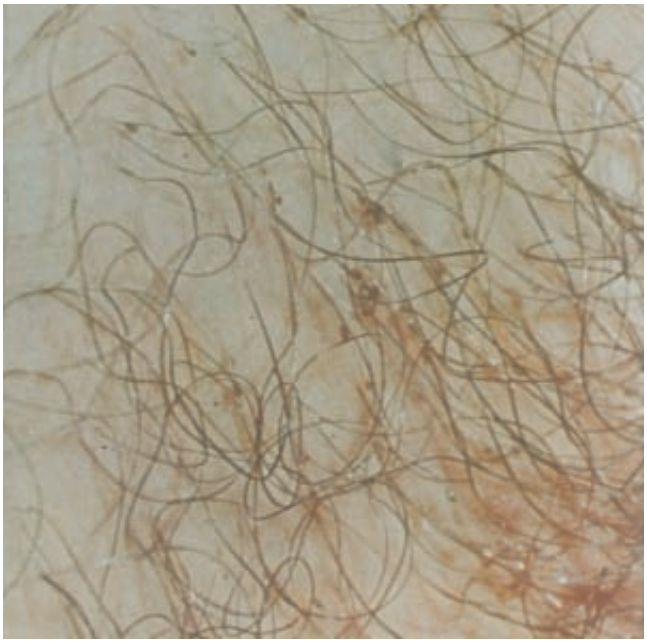

Figure 7 **Lice attached to the skin and lice eggs attached to the hair shafts can be seen on a patient with pediculosis pubis.**

Table 2 Drug Therapy for Pediculosis Infestations

Disease	*Drug*	*Dosage*	*Relative Efficacy*	*Comments*
Pediculosis capitis	Pyrethrin 0.3% shampoo and permethrin 1% cream rinse	Apply shampoo for 10 min and rinse; repeat in 7–10 days	First-line therapy	Effective and safe for use in children
	Malathion 0.5% lotion	Apply for 8–12 hr daily for 1 wk	First-line therapy; most effective therapy for resistant head lice	Safe and effective in children; potential serious adverse effects if ingested
	Lindane shampoo†	2 tbsp of shampoo applied to affected and adjacent areas of scalp and allowed to stand for at least 4 min	Second-line therapy	Associated with neurotoxicity; indicated if other medications have failed or cannot be tolerated; should be used with caution in persons weighing < 110 lb; use in infants is not recommended
	Ivermectin (oral)*	Single dose of 12 mg (2–6 tablets), followed by second dose 7–10 days later	Alternative first-line therapy	Safe and effective in children 6 mo of age or older; advantage of oral medication is ease of use and increased compliance
Pediculosis pubis, pediculosis corporis	Pyrethrin 0.3% shampoo or lotion	Apply shampoo or lotion for 10 min and rinse	First-line therapy	Resistance may occur
	Lindane lotion†	1 oz applied to affected areas	Second-line therapy	Associated with neurotoxicity; caution is advised in prescribing lindane for patients with conditions that increase risk of seizure

*Not approved by the Food and Drug Administration for use as a pediculicide.
†Gamma benzene hexachloride.

er.[23] Current evidence suggests that permethrin, pyrethrin, and malathion are equally effective in the treatment of head lice; the best choice of therapy depends on local resistance.[33]

Pediculosis Pubis and Pediculosis Corpis

To treat hairy areas of the body infested with *P. pubis*, a cleansing bath or shower should first be taken and the skin dried with a towel. One ounce of lindane cream or lotion is applied to the affected and surrounding areas and left on for 12 to 24 hours. To discourage percutaneous absorption, the lotion should be applied only after the skin has become cool and dry. Lotions containing pyrethrins and piperonyl butoxide are acceptable alternatives, and their use is preferred in select patients and children (see below).[11] After another bath or shower, freshly laundered clothing should be donned; bedsheets and towels should also be changed. Lindane may be applied a second time after 1 week if infestation continues. Lindane should not be applied to the face and eyelids, because it causes irritation; eyelash infestation may be treated by local application of 0.25% physostigmine ophthalmic ointment. An alternative treatment for eyelash infestation that is effective and nonirritating is the application of a thick layer of petrolatum twice a day, followed by mechanical removal of the nits.

Neurologic complications can ensue from absorption of lindane after extensive or prolonged topical application [*see* Scabies, *above*]; severe adverse reactions have also occurred after a single use (information on lindane can be found on the Internet, at http://www.fda.gov/cder/drug/infopage/lindane/default.htm). Careful consideration should be given before prescribing lindane to patients with conditions that increase the risk of seizure (e.g., HIV infection, history of past seizure, or severe hepatic cirrhosis) or whose concomitant medications include drugs that lower risk of seizure. Alternative treatments are indicated in infants (who are especially susceptible), young children, pregnant women, and the elderly.

A combination of pyrethrins with piperonyl butoxide (RID or A-200) has been shown to be considerably less toxic than lindane in animal experiments and in clinical experience. However, this combination irritates the eyes and mucous membranes and may also cause allergic contact dermatitis in susceptible people.

General Treatment Measures

All family members should be carefully examined for pediculosis and treated, if necessary, to avoid spread or reinfection of previously treated persons. In the case of pediculosis pubis, sexual contacts should be examined and treated. Because sexually transmitted diseases are frequently present in persons infested with *P. pubis*, a serologic test for syphilis and screening for HIV are usually done. To prevent spread of pediculosis, contaminated clothing and other articles, such as towels and bedding, should be boiled, machine washed in hot water, and placed in a dryer using a 20-minute hot cycle or should be dry-cleaned. Items such as combs and brushes may be cleaned with medicated shampoo or soaked in 5% Lysol. To eradicate *P. corporis*, the patient's clothing must be put through the same decontamination process as that used for *P. pubis*. A hot iron with pressure applied, especially to the seams of clothing, may also be used to kill *P. corporis*. Systemic antibiotics should be prescribed for concomitant secondary bacterial infections such as furunculosis and impetigo, both of which are commonly associated with pediculosis capitis.

Miscellaneous Infestations

FLEA INFESTATIONS

Fleas are small (approximately 3 mm), bloodsucking, wingless ectoparasites of the insect order Siphonaptera. Fleas are medically significant because they are vectors of infectious disease [*see 7:XI Infections Due to Brucella, Francisella, Yersinia Pestis, and Bartonella and 7:XVII Infections Due to Rickettsia, Ehrlichia, and Coxiella*]. They can also cause considerable cutaneous symptoms, particularly if the symptoms are associated with an allergic hypersensitivity reaction, as seen in papular urticaria. There are ap-

proximately 250 species of flea, 20 of which can infest humans. Two common species that infest cats and dogs are *Ctenocephalides felis* and *C. canis*. They are not host specific and can therefore infest humans as well. *Pulex irritans*, the house flea, infests humans and in most places is not a problem for pets. Flea bites appear as erythematous edematous papules with hemorrhagic puncta in clusters or groups on the lower extremities, especially on the ankles. Occasionally, vesicles and bullae appear, as well as larger urticarial lesions. Secondary impetiginization may occur because of scratching.[34]

Fleas are difficult to eradicate because of their unpredictable life cycle, which consists of egg, larva, pupa, and adult stages. The eggs are laid on the host but can drop to the ground; onto carpets, pet bedding , and furniture; and into floor cracks. Eggs hatch in 2 to 21 days into larvae. A larva molts twice and, in the third larval stage, spins a cocoon, in which it becomes a pupa. Within 7 days to 1 year or more, the adult emerges, depending on various trigger factors (e.g., a vibration caused by a nearby pet or human). The life cycle from egg to adult generally ranges from 14 to 21 days but, under ideal conditions, can be as long as 20 months.[34]

Eradication of the fleas may require consultation with a veterinarian. Pets must be treated more than once with topical agents to kill the eggs, larvae, and pupae, as well as the residual fleas. Systemic agents are available to protect pets from reinfestation. A household flea spray should be combined with a fogger to fumigate the house. A proper extermination procedure includes vacuuming the furniture and vacuuming or steam cleaning carpets or rugs. The yard should be sprayed and cleared of organic debris. Treatment of flea bites consists of cool-water compresses, application of a corticosteroid cream and an antipruritic lotion, and oral antihistamines in the case of allergic hypersensitivity reaction. Systemic antibiotics are prescribed for secondary bacterial infection.

Tungiasis

Cutaneous infestation by the sandflea *Tunga penetrans* is endemic in Central and South America, parts of Mexico, tropical Africa, Pakistan, and the west coast of India. Isolated cases have been reported in the United States, Australia, and New Zealand. Tungiasis is more prevalent in poverty-stricken areas and is associated with domestic animals such as pigs, dogs, and cattle, which serve as intermediaries in the biologic life cycle.[35] The female adult sandflea exists in sandy soils and requires a warm-blooded host to complete its life cycle. The organism penetrates the stratum corneum, resulting in erythematous nodules with a central dark spot. Common sites of skin involvement are the soles of the feet, the web spaces between fingers and toes, the ankles, the perineal area, and the buttocks.

Infestation can be prevented by wearing shoes and proper clothing and by the use of insecticides.

MYIASIS

Myiasis is caused by the larvae (maggots) of feeding flies of the order Diptera. The larvae may invade the skin primarily[36] or become secondarily implanted in a preexisting skin wound.[37] Many species of the genus *Cuterebra* can cause myiasis, but in North America, *C. cuterebra* and *C. dermatobia* cause furuncular cutaneous infestations. Mosquitoes act as vectors by transporting fly eggs from infected animals to human hosts.[38] The skin lesions appear as nonhealing single or multiple nodules on the upper trunk, usually at the site of a painful bite wound. Skin lesions may be misdiagnosed as cellulitis, boils, or sebaceous cysts. Myiasis is commonly reported in travelers to endemic areas such as Central and South America and tropical and subtropical Africa. Preventive measures include the use of insect repellents, the wearing of protective clothing to prevent mosquito bites, and the avoidance of direct skin contact with sand that may be infested with eggs. Furuncular myiasis is effectively treated by removal of the larvae by incision and drainage with debridement. Antibiotics are prescribed for secondary bacterial infection. Occlusion with such agents as liquid paraffin, lubricating jelly, and even the fatty portion of raw bacon has been suggested to cause suffocation of the larvae or migration of the larvae from the wound.[39]

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans is caused by penetration and migration of larval hookworms (usually *Ancylostoma braziliense*) within the skin. Patients are usually travelers returning from seawater beaches in tropical areas and commonly present to the dermatologist with pruritic skin lesions. The abdomen or feet are most often involved, with a characteristic eruption consisting of one or several erythematous linear to serpiginous thin lines in the skin.

Optimal management is controversial, and most treatment trials have been of low quality; however, it is generally agreed that the most effective agents in treating cutaneous larva migrans are topical or oral anthelmintics, including albendazole, thiabendazole, and ivermectin. Regimens include topical thiabendazole (10% to 15% cream) three times daily for 5 to 10 days; oral albendazole, 400 mg daily for 3 to 5 days; oral ivermectin, single dose of 12 mg; and oral thiabendazole, 50 mg/kg weekly for 2 to 3 weeks. Topical thiabendazole (10% cream) is effective and safe in children,[40,41] but it is difficult to obtain. Systemic therapy, either with albendazole or ivermectin, may be preferable to topical therapies. Oral albendazole has a high cure rate and appears to be effective in cases of multiple lesions.[42,43] Oral ivermectin is effective and reportedly safe.[43] Oral thiabendazole has been reported to cure long-standing cutaneous larva migrans, but it may cause side effects such as headaches, nausea, and vomiting.[44]

SEABATHER'S ERUPTION

Seabather's eruption, also known as sea lice by laypersons, is an acute pruritic dermatitis that occurs within 24 hours of seawater exposure and resolves spontaneously after 3 to 5 days.[45] Lesions affect areas of the skin covered by swimwear, particularly those that are subjected to pressure or friction, such as the waistline, axillae, neck, and inner thighs [*see Figure 8*]. The larvae of the thimble jellyfish *Linuche unguiculata*, which are washed ashore by ocean currents, have been identified as the cause of seabather eruption in southern Florida and the Caribbean.[46] Similar outbreaks on Long Island, New York, are thought to be caused by larvae of the sea anemone *Edwardsiella lineata*.[47] Treatment is symptomatic and includes antihistamines, topical antipruritic agents, and steroids.

SWIMMER'S ITCH

Cercarial dermatitis, known as swimmer's itch, is caused by an avian schistosome, *Microbilharzia variglandis*. The skin eruption appears approximately 12 hours after contact with seawater as a pruritic papulovesicular dermatitis on exposed skin sites.[48] The inflammatory response is attributed to dermatologic penetration by cercariae, which are the free-swimming larvae of *M. variglandis* and other bird schistosomes.

Figure 8 **Seabather's eruption is characterized by the development of pruritic papules on areas covered by the patient's bathing suit.**

Treatment is symptomatic and includes antihistamines, topical antipruritic agents, topical corticosteroids, and antibiotic treatment of superimposed bacterial infection.

CUTANEOUS AND MUCOCUTANEOUS LEISHMANIASIS

There are distinctive skin lesions associated with the cutaneous and mucocutaneous forms of leishmaniasis [*see Figure 9*]. Leishmaniasis is caused by an obligate intracellular parasite introduced by the *Phlebotomus* sandfly, which feeds on infected animals. *Leishmania braziliensis* and *L. mexicana* are the most common causes of American, or New World, leishmaniasis. *L. donovani* causes Old World leishmaniasis, which is endemic in Asia and West Africa [*see Section 7:XXXIV Protozoan Infections*]. Infection by *L. major* is the cause of cutaneous leishmaniasis in United States military personnel returning from Afghanistan and Iraq.[49]

Cutaneous leishmaniasis—the initial, or primary, form of the disease—appears as a localized, usually single, lesion involving the mouth and nose. A red-brown papule develops at the site of inoculation into a nodule that becomes verrucous or ulcerates, and satellite nodules may form. Spontaneous healing with an atrophic scar occurs in most cases. Old World leishmaniasis is usually limited to the skin, whereas New World leishmaniasis can cause mutilating mucocutaneous involvement.[50] After a period of months to years, the mucocutaneous, or secondary, form of the disease may develop, depending on host immunologic factors. Lesions in this stage range from edema of the lips and nose to perforation of the nasal cartilage. A rare form, disseminated cutaneous leishmaniasis, which has widespread nodules resembling lepromatous leprosy, may occur in immunosuppressed patients.

Figure 9 **Leishmaniasis can present as chronic cutaneous ulcerations.**

The differential diagnosis includes various inflammatory and neoplastic disorders, including squamous cell carcinoma. Diagnosis is made by skin biopsy with histopathologic examination. Cultures from skin biopsy may be inconclusive; PCR shows promise as a sensitive single diagnostic test.[51] Appropriate therapy depends on species identification. A pentavalent antimony compound, such as sodium stibogluconate, is the drug of choice for New World leishmaniasis, which tends to be more aggressive. Lesions acquired in the Middle East and North Africa may spontaneously involute or may respond to local therapy, including cryosurgery, heat therapy, or intralesional injection of antimonials.

Delusions of Parasitosis

Patients with delusions of parasitosis express the conviction that there are scabies, insects, lice, fleas, worms, or other vermin infesting their skin and producing a crawling, itching, or prickling sensation.[52] They may have excoriations or skin inflammation and erosions consistent with factitial dermatitis. Frequently, patients will bring small containers filled with lint, hairs, pieces of skin, fibers, or other debris for examination. Despite the lack of objective evidence for infestation—including negative results from clinical examination, microscopic examination of skin scrapings, and skin biopsy—the delusions persist. Associated underlying psychiatric disturbances may range from a phobic-obsessive state or anxiety reaction to a frank psychosis with either depression or paranoia. Not infrequently, the delusion is shared by the spouse or other family members, as in the classic folie à deux or folie à famille. The patient usually functions in a highly organized manner in other aspects of his or her life. Such patients typically resist seeking psychiatric evaluation.

Treatment with pimozide, a high-potency antipsychotic neuroleptic of the diphenylbutylpiperidine group, has been used successfully.[52] The effectiveness of the drug may be mediated by its ability to specifically block central dopamine receptors. As is characteristic of high-potency antipsychotic drugs, pimozide has fewer cardiovascular and anticholinergic effects but greater neurologic toxicity, especially with long-term use, than does low-potency antipsychotic drugs. Tardive dyskinesia, an extrapyramidal syndrome characterized by involuntary movements of facial muscles and extremities, may occur in 10% to 20% of patients on antipsychotic drugs. Other side effects may include skin discoloration, dermatitis, and blurred vision. Thorough medical and psychiatric evaluation should be obtained before antipsychotic medication is instituted.

The author has served as advisor or consultant to Amgen, Inc., Biogen Idec, Inc., Genentech, Inc., Abbott Laboratories, Ligand Pharmaceuticals, Inc., and 3M Co.

The drug ivermectin has not been approved by the FDA for uses described in this chapter.

IX VESICULOBULLOUS DISEASES

Elizabeth A. Abel, m.d.
Jean-Claude Bystryn, m.d.

Vesiculobullous diseases, which number more than 50, are characterized by fluid-filled blisters in the skin. Blisters smaller than 0.5 cm are called vesicles, and larger ones are called bullae. Vesicles and bullae are reaction patterns of skin to injury and thus can be caused by a wide variety of conditions.

Most primary vesiculobullous diseases are either immunologic or genetic. They are caused by autoimmune reactions to components of skin, by allergic reactions to external agents in which the skin is the major organ system affected, and by genetic conditions in which some components of the skin are missing or abnormal. The final common pathway is disadhesion: one or more of the structures that hold the skin together separate, and a fluid-filled cavity appears. The different diseases are classified by the structure or structures affected and the mechanism or mechanisms by which disadhesion occurs [*see Table 1*]. In this subsection, several paradigmatic vesiculobullous diseases are discussed in the context of a general diagnostic approach to the patient with blistering lesions.

General Clinical Assessment

Diagnosis is based on clinical features, histologic findings, and immunologic findings. Clinical features of diagnostic importance include the following:

1. The history. Is the condition acute or chronic? Is it aggravated by sun or physical trauma?
2. The appearance of individual lesions [*see Table 2*]. Is the lesion a vesicle or bulla? Is it tense, flaccid, or umbilicated? Does the skin at the base of the blister appear normal, urticarial, or scarred? Is the border of each urticarial lesion annular or oval or is it irregular? Is the blister in the middle of urticarial plaques or on the periphery? Do more than one bulla arise from the same plaque?
3. The grouping of individual lesions. Are the lesions in closely spaced groups (as occurs in herpes simplex), or are they randomly distributed?
4. Sites of involvement. Are lesions on mucosal surfaces as well as on the skin? Are they predominantly on flexural or extensor surfaces; on the palms and soles or on the dorsa of the hands and feet; on the scalp, face, and upper torso; or on areas exposed to trauma?

The most important histologic finding is the layer of skin where the blister forms. If the blister forms in the epidermis, does it form immediately above the basal cell layer or higher up (beneath the stratum corneum)? If it forms in the basement membrane zone, is it within the lamina lucida or below the lamina densa? The precise location may be determined by immunofluorescence or by electron microscopic procedures.

The most important immunologic finding is the presence or absence of abnormal circulating or tissue-fixed antibodies to skin. These are usually detected by immunofluorescence techniques: (1) indirect immunofluorescence to detect circulating antibodies and (2) direct immunofluorescence on skin biopsy specimens to detect tissue-fixed antibodies. Recently, enzyme-linked immunosorbent assays (ELISAs) using purified antigens have become available to detect the antibodies that occur in some of the bullous diseases, such as pemphigus.

Pemphigus

definition and pathogenesis

Pemphigus is characterized by blisters that arise within the epidermis and by a loss of cohesion of the epidermal cells (acantholysis) that results in the formation of clefts above the basal cell layer. Autoantibodies directed against adhesion molecules cause epidermal keratinocytes to separate, resulting in intraepidermal bullae. There are two types of pemphigus: deep (e.g., pemphigus vulgaris) and superficial (e.g., pemphigus foliaceus). They differ in the epidermal layers that are injured, in the clinical manifestations of the diseases, and in the associated immunologic abnormalities.[1] In the deep forms, the blisters form immediately above the basal cell layer and are associated with autoantibodies to desmoglein 3; about half the cases are associated with antibodies to desmoglein 1 glycoprotein keratinocyte adhesion molecules.[2] In the superficial forms, the bullae form immediately below the stratum corneum. The superficial forms of pemphigus are associated with antibodies to desmoglein 1.

clinical features

Pemphigus Vulgaris

Pemphigus vulgaris is the most common form of pemphigus. It can develop at any age but usually occurs in persons between 30 and 60 years old. The disorder tends to affect persons of Mediterranean ancestry but can occur in persons of any ethnicity. Pemphigus is more common in persons with certain HLA allotypes. The occurrence of the disease in first-degree relatives, although rare, suggests an inherited susceptibility transferred as a dominant trait. However, other unknown factors are required for expression of the disorder in predisposed persons.[3] Studies of HLA class II alleles in Japanese patients as well as in other ethnic groups show an association with HLA-DRB1*04 and HLA-DRB1*14 in patients with pemphigus vulgaris across racial lines.[4]

Pemphigus vulgaris usually, but not invariably, begins with chronic, painful, nonhealing ulcerations in the oral cavity [*see Figure 1*]. Bullae are rarely seen because they rupture easily, leaving ulcerated bases. The ulcerations are usually multiple, superficial, and irregular in shape. Any oral mucosal surface can be involved, but the most common sites are the buccal and labial mucosae, the palate, and the gingiva. The occurrence of multiple ulcerations differentiates these lesions from ulcerated malignant tumors of the oral cavity, which are usually single. A diagnosis of pemphigus is usually considered only after lesions have been present for weeks to months.

Skin lesions can also be the initial manifestation, beginning as small fluid-filled bullae on otherwise normal-looking skin. The blisters are usually flaccid because the thin overlying epidermis cannot sustain much pressure. Bullae therefore rupture rapidly, usually in several days, and may be absent when a patient is examined. Sharply outlined, coin-sized, superficial erosions with a collarette of loose epidermis around the periphery of the erosions may appear instead. The upper chest, back,

scalp, and face are common sites of involvement, but lesions can occur on any part of the body. The condition progresses over weeks to months [*see Figure 2*]. Sites often overlooked include the periungual areas (manifested as painful, erythematous, paronychial swelling), the pharynx and larynx (pain on swallowing and hoarseness), and the nasal cavity (nasal con-

Table 1 Differentiating Features and Standard Therapy for Selected Blistering Diseases

	Disease	*Features*	*Therapy*
Epidermal	Pemphigus vulgaris Pemphigus vegetans	Chronic, painful ulcerations in the oral cavity; small, flaccid bullae *or* coin-sized superficial erosions arising from normal skin; positive Nikolsky sign; IgG and C3 at intercellular spaces; serum antidesmoglein 1 or 3 antibodies Hypertrophic proliferation of epidermis in intertriginous areas; IgG and C3 at intercellular spaces; serum antidesmoglein 3 antibodies	*Localized:* Intralesional or topical corticosteroids, low-dose systemic corticosteroids *Extensive or rapidly progressive disease:* corticosteroids, adjuvant therapy with cytotoxic and immunosuppressive agents *Refractory disease:* plasmapheresis, IVIg, pulse therapy with megadoses of I.V. methylprednisolone
	Pemphigus foliaceus Pemphigus erythematosus Fogo selvagem	Small, pruritic, crusted lesions on upper torso, face, or scalp; chronic superficial erosions; rare oral involvement; immunopathology higher in epidermis Erythematous scaly to crusted eruption on face and upper chest; lupuslike immunologic abnormalities (granular deposits of IgG and C3 at epidermal-dermal junction) Features similar to pemphigus foliaceus (primarily affects persons < 30 yr in rural areas of Brazil, Colombia, Tunisia)	*Localized:* Intralesional or topical corticosteroids, low-dose systemic corticosteroids *Extensive or rapidly progressive disease:* corticosteroids, adjuvant therapy with cytotoxic and immunosuppressive agents
	Paraneoplastic mixed bullous disease (paraneoplastic pemphigus)	Large, tense bullae; target lesions on skin; oral erosions; keratinocyte necrosis; clinical features overlap between pemphigus and erythema multiforme; subepidermal separation; IC and BMZ antibodies on direct IF	Difficult (standard treatments for autoimmune blistering diseases fail in most patients)
	Hailey-Hailey disease	Multiple vesicles on inflammatory bases in intertriginous areas and other areas subject to friction or pressure; loss of bridges between epidermal cells; no circulating or tissue-fixed autoantibodies	Involved areas kept dry and free of friction; administration of topical and systemic antibiotics; topical, intralesional corticosteroids; ablation of involved areas
Subepidermal	Bullous pemphigoid	Crops of large, tense blisters recurring from urticarial plaques on torso and flexures; negative Nikolsky sign; oral lesions (10%–25% of patients); circulating BMZ antibodies; IgG and C3 at BMZ in a linear pattern on direct IF	Administration of systemic corticosteroids at doses lower than those used for pemphigus (≤ 80 mg/day prednisone) [*see also* Bullous Pemphigoid, Treatment, *in text*]
	Cicatricial pemphigoid	Blisters on mucosal surfaces (oral cavity, esophagus, eyes) that heal with scarring, often occurring repeatedly at same site; diffuse, painful erythema and atrophy of the gingival mucosa; IgG and C3 at BMZ in a linear pattern on direct IF	Combination therapy with systemic corticosteroids and dapsone or azathioprine; long-term therapy with systemic corticosteroids, sometimes combined with immunosuppressive agents; intralesional corticosteroids
	Herpes gestationis	Pruritic urticarial plaques occurring in pregnancy (beginning around the umbilicus, spreading to abdomen and thighs); laminal blisters with linear deposits of C3 or IgG at the epidermal-dermal junction; circulating complement-fixing BMZ antibodies on indirect IF	Normally clears after delivery
	Dermatitis herpetiformis	Clusters of intensely pruritic, small, polymorphic vesicles on elbows, knees, buttocks, scapular area, and scalp; accumulations of neutrophils and eosinophils in dermal papillae; granular deposits of IgA in BMZ; no circulating antibodies to normal skin components	Administration of sulfones (dapsone, 100–200 mg/day; sulfapyridine, 1–3 g/day in divided doses; or sulfamethoxypyridazine); reduction of gluten intake
	Linear IgA dermatosis	Blisters resembling those of dermatitis herpetiformis or erythema multiforme; linear deposition of IgA in BMZ on direct IF	Administration of sulfones
	Erythema multiforme	Sudden eruption of crops of lesions on elbows, knees, hands, and feet; target papule or vesicle with halo of erythema; subepidermal edema, deep perivascular inflammatory infiltrate	Elimination of underlying causes (e.g., infectious agents, drugs); *in mild cases,* topical glucocorticoids, anti-inflammatories, antipruritics, antibiotics; *in severe cases,* prednisone 40–120 mg/day in divided doses
	Toxic epidermal necrolysis	Rapidly progressive painful denudation of epithelium (usually a drug reaction); full-thickness epidermal necrosis; absence of immune reactants within skin blood vessels; little dermal inflammation	Meticulous wound care with debridement of necrotic tissue, fluid and electrolyte replacement, and prevention of sepsis; IVIg [56]
	Staphylococcal scalded skin syndrome	Scarlatiniform eruption accompanied by skin tenderness, fever, and irritability; lack of mucous membrane involvement or target lesions	Intravenous penicillinase-resistant penicillins
	Epidermolysis bullosa	[*See* Epidermolysis Bullosa, *in text*]	Supportive therapy; counseling; promotion of wound healing; prevention of complications

BMZ—basal membrane zone IC—intercellular IF—immunofluorescence IVIg—intravenous immunoglobulin

Table 2 Pathologic Typology of Blisters[57]

Blister Type	*Mode of Formation*	*Site of Formation*	*Disease*
Subcorneal blister	Detachment of horny layer	Epidermis (subcorneal layer)	Miliaria crystallina Impetigo
Blister due to intracellular degeneration	Separation of cells from one another	Upper epidermis	Friction blisters
Spongiotic blister	Intercellular edema	Epidermis	Dermatitis (eczema) Miliaria rubra
Acantholytic blister	Dissolution of intercellular bridges	Epidermis (suprabasal layer)	Keratosis follicularis (Darier disease) Pemphigus vulgaris
		Epidermis (subcorneal layer)	Pemphigus foliaceus
Viral blister	Ballooning degeneration leading to acantholysis	Epidermis	Herpes simplex Herpes zoster Varicella
Blister due to degeneration of basal cells	Cytolysis of basal cells	Basal cell layer	Epidermolysis bullosa simplex Erythema multiforme (epidermal type)
	Loss of dermal contact by damaged basal cells	Basal cell layer	Lichen planus Lupus erythematosus
Blister due to degeneration of basement membrane zone	Damage in the structures that cause coherence of basal cells	Basement membrane zone	Bullous pemphigoid Dermatitis herpetiformis Erythema multiforme (dermal type)
Dermolytic blister	Anchoring fibrils are decreased and rudimentary	Dermis	Dystrophic epidermolysis bullosa Acquired epidermolysis bullosa

gestion and a bloody mucous discharge, particularly noticeable upon blowing the nose in the morning).

A characteristic feature of all severe active forms of pemphigus is the Nikolsky sign, in which sliding firm pressure on normal-appearing skin causes the epidermis to separate from the dermis. The Nikolsky sign is elicited most easily on clinically uninvolved skin adjacent to an active lesion.

If left untreated, the erosions and bullae of pemphigus vulgaris gradually spread, involving an increasing surface area, and can become complicated by severe infections and metabolic disturbances. Before the advent of corticosteroids, pemphigus was almost invariably fatal—approximately 75% of patients died within a year.[5] However, as better techniques have permitted the diagnosis of earlier, milder forms of the disease, the prognosis has improved significantly.[6] Mild forms may regress spontaneously, and the progression of even the most severe forms can be reversed in most cases. With treatment (see below), lesions normally heal without scarring. Most patients treated for pemphigus will enter a partial remission within 2 to 5 years. They can then be maintained lesion-free with minimal doses of corticosteroids (approximately 15 mg of prednisone daily). In a longitudinal study of outcome in 40 patients with pemphigus vulgaris, 45% entered a complete and long-term remission after 5 years and 71% after 10 years. Patients in remission remained lesion-free without any therapy.[7] The hyperpigmentation that is commonly associated with pemphigus usually resolves after several months.

In pregnancy, pemphigus appears to be associated with an increased incidence of premature delivery and fetal death.[8] The lesions of pemphigus can appear on the skin of the neonate; however, they normally resolve spontaneously in several weeks.

Pemphigus Foliaceus

Pemphigus foliaceus is the second most common form of pemphigus. It usually begins with small (approximately 1 cm), pruritic, crusted lesions resembling corn flakes on the upper torso and face. The crusts are easily removed, leaving chronic, superficial erosions.

Over weeks to months, the condition progresses, with an increasing number of lesions appearing on the upper torso, face, and scalp. In extensive cases, lesions develop over the entire body, become confluent, and can progress to an exfoliative erythroderma. In contrast to the deep forms of pemphigus, oral involvement in pemphigus foliaceus is very rare.

The prognosis of untreated pemphigus foliaceus is more favorable than that of pemphigus vulgaris. The lesions of pemphi-

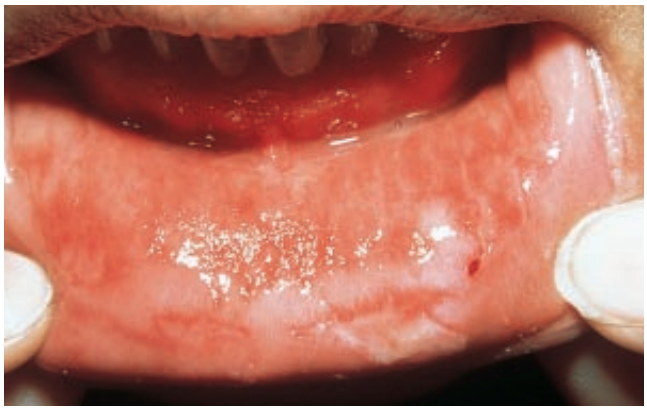

Figure 1 **Painful ulcerations or erosions in the mouth may be present many months before the onset of generalized pemphigus vulgaris.**

Figure 2 **Flaccid bullae of pemphigus vulgaris have broken down to form erosions and crusts, particularly under the breasts.**

gus foliaceus are not as deep, and there is less chance for infection, fluid loss, and metabolic disturbance. Although pemphigus foliaceus is less severe, the doses of medications required for control are similar to those used for pemphigus vulgaris. There are two clinical variants: pemphigus erythematosus and fogo selvagem. Pemphigus erythematosus (also known as Senear-Usher syndrome) has features of lupus erythematosus. Fogo selvagem (Portuguese for "wild fire"; also known as endemic pemphigus and Brazilian pemphigus) [*see Table 1*] may be triggered by exposure to one or more environmental antigens.[9]

Drug-Related Pemphigus

Both pemphigus vulgaris and pemphigus foliaceus can be either induced or triggered (i.e., latent disease unmasked) by certain drugs. Pemphigus that continues after a patient stops using a drug is referred to as triggered, whereas lesions that clear soon after withdrawal are referred to as induced. Although drug-related pemphigus is uncommon, its possibility must be excluded in all patients with newly diagnosed disease. The clinical, histologic,[10] and immunofluorescence abnormalities[11] of drug-induced pemphigus are similar to those of the idiopathic variety. However, pemphigus caused by drugs containing a sulfhydryl radical (thiol drugs) is clinically distinct from pemphigus caused by nonthiol drugs. The presence or absence of a sulfhydryl radical appears to influence both the type of pemphigus that is expressed and the prognosis of the drug-induced condition. Thiol drugs are more likely to induce pemphigus foliaceus, which is more likely to regress spontaneously when the drug is discontinued [*see 2:VI Cutaneous Adverse Drug Reactions*]. Nonthiol drugs are more likely to trigger pemphigus vulgaris, which can persist even after the drug is stopped. The most commonly implicated agents are thiol drugs such as penicillamine and captopril. Other responsible drugs include sulfur-containing drugs such as penicillins and cephalosporins. These undergo metabolic changes to form thiol groups and are termed masked thiol drugs. Nonthiol drugs that contain an amide group (e.g., dipyrone and enalapril) can provoke a disease that is indistinguishable from spontaneously occurring pemphigus vulgaris.[11]

Endemic Pemphigus

Epidemiologic features of fogo selvagem in rural areas of Brazil suggest that the production of pathologic antibodies to desmoglein 1 is linked to exposure to one or more environmental antigens.[9]

Paraneoplastic Mixed Bullous Disease

Paraneoplastic pemphigus is an autoimmune disease of the skin and oral mucosa that develops in patients with an underlying neoplasm. It is characterized by large, tense bullae. Unfortunately, standard treatments for autoimmune blistering diseases fail in most cases. Paraneoplastic pemphigus shares clinical features of both pemphigus and severe erythema multiforme.[12]

Hailey-Hailey Disease

Familial benign chronic pemphigus, or Hailey-Hailey disease, is an autosomal dominant disorder marked by multiple vesicles on inflammatory bases in skin subject to friction or pressure, such as intertriginous areas. In addition to pharmacologic treatment (see below), therapy includes keeping involved areas dry and free of friction.

HISTOLOGIC AND IMMUNOLOGIC FINDINGS

The diagnosis should always be confirmed by histopathologic examination and immunofluorescence studies.[13] Biopsies for pemphigus and all other bullous diseases should be performed at the edge of a lesion, so as to include clinically uninvolved adjacent skin. Acantholysis (the separation of keratinocytes from each other) is the fundamental abnormality in all forms of pemphigus.

All forms of pemphigus are associated with circulating and tissue-fixed intercellular (IC) autoantibodies that react against cell-surface keratinocyte antigens. The detection of these antibodies is very helpful in establishing the diagnosis, because they rarely appear in other conditions. Circulating IC autoantibodies are detected by indirect immunofluorescence assays on serum, and tissue-fixed IC autoantibodies are detected by direct immunofluorescence on skin biopsies. In both cases, they cause a lacelike pattern of fluorescence within the epidermis. Low titers of IC autoantibodies may also be present in burns, fungal infections, and allergic drug reactions. Antibodies against ABO blood group antigens, which are present in approximately 5% of the normal population, are the most common cause of false positive tests for IC autoantibodies. Tissue-fixed IC autoantibodies are present in lesions and adjacent normal skin in approximately 90% of patients with pemphigus and are more sensitive and specific for the diagnosis of pemphigus than are circulating IC autoantibodies. The most common autoantibodies are IgG, but IgM and IgA (with or without C3) may also be deposited.

TREATMENT

Initial Therapy

Initial therapy is determined by the extent and rate of progression of lesions. Localized, slowly progressive disease can be treated with intralesional injections of corticosteroids (triamcinolone acetonide, 10 to 20 mg/ml) or topical application of high-potency corticosteroids. New lesions that continue to appear in increasing numbers can be controlled in some cases with low-dose systemic corticosteroids (prednisone, 20 mg/day). Patients with extensive or rapidly progressive disease are treated with moderately high doses of corticosteroids (prednisone, 70 to 90 mg/day). This dose is rapidly escalated every 4 to 14 days in 50% increments until disease activity is controlled, as evidenced by an absence of new lesions and the disappearance of skin pain or itching. If the disease remains active despite high doses of corticosteroids (e.g., 120 to 160 mg/day of prednisone), one of the following approaches should be considered for rapid control:

1. Plasmapheresis, normally performed three times a week for removal of 1 to 2 L of plasma per procedure.[14]
2. Intravenous immunoglobulin (IVIg), usually given at a dosage of 400 mg/kg/day for 5 days or in higher doses for 3 days.[15] The procedure may need to be repeated every 2 to 3 weeks for several cycles. It is very expensive. The use of IVIg for the treatment of skin diseases has recently been reviewed.[16] With both IVIg and plasmapheresis it is important to concurrently administer an immunosuppressive agent such as cyclophosphamide or azathioprine to minimize rebound in the level of pemphigus antibodies,[14] and it is also important to monitor the level of these antibodies to ensure that the patient is responding to treatment.
3. Pulse therapy with megadoses of intravenous methylprednisolone, given at a dosage of 1 g/day for 5 days.[17]

No comparative studies have yet evaluated the relative effectiveness of these procedures. On the basis of such limited experience, IVIg may be preferred because it has fewer side effects than the other procedures and is associated with a significantly higher response rate. Once disease activity is controlled, the patient is maintained on the type and dose of medications required to establish control until approximately 80% of lesions are healed. Therapy should not be tapered while new lesions are appearing.

Rituximab, an anti-CD20 chimeric monoclonal antibody, is approved for use in non-Hodgkin lymphoma. However, there is a case report of partial remission from recalcitrant, life-threatening pemphigus vulgaris after treatment with rituximab.[18]

Adjuvant Therapy

The role of adjuvants in the treatment of pemphigus remains controversial. Because of a lack of controlled studies, it is not known whether the potential benefits of adjuvants outweigh the additional toxicities.[5] Indications for adjuvant therapy include the presence of relative contraindications to systemic corticosteroids, development of serious corticosteroid side effects, and repeated flares of disease activity that make it undesirable to reduce corticosteroid doses.[7] Because they require 4 to 6 weeks to become effective, adjuvants are not used to control active, rapidly progressive disease.

Adjuvant treatments for pemphigus include a variety of cytotoxic and immunosuppressive agents (e.g., cyclophosphamide, azathioprine, cyclosporine, methotrexate, and mycophenolate mofetil[19]); dapsone; anti-inflammatory agents (e.g., gold); antimalarials; and certain antibiotics (e.g., tetracycline and minocycline).

Bullous Pemphigoid

PATHOGENESIS

The immediate cause of bullous pemphigoid (BP) appears to be an autoantibody response to the 180 kd (BP180) and 230 kd (BP230) basement membrane zone antigens.[20] Passive transfer of these antibodies into animals can cause lesions of the disease[21]; anti-BP180 autoantibodies have been found to be a poor prognostic factor in a study of 94 elderly patients.[22]

CLINICAL FEATURES

BP is a nonscarring, subepidermal blistering disease that is characterized by recurrent crops of large, tense blisters arising from urticarial bases. Lesions normally appear on the torso and flexures, particularly on the inner thighs. Blisters can range in size from a few millimeters to several centimeters [*see Figure 3*]. They

Figure 3 **Tense bullae characteristically occur in bullous pemphigoid.**

are usually filled with a clear fluid, but they can be hemorrhagic. Erosions are much less common than in pemphigus, and the Nikolsky sign is negative. A characteristic feature is that multiple bullae usually arise from large (palm-sized or larger), irregular, urticarial plaques. This is in contrast to the bullae of erythema multiforme (see below); in erythema multiforme, a single bulla arises from the center of a smaller (coin-sized) urticarial base.

In acute flares of BP, bullae may arise from normal-appearing skin. Oral lesions occur in 10% to 25% of patients; ocular involvement, however, is rare. Without treatment, the disease may become very extensive.

BP is a sporadic disease that occurs mainly in the elderly but can occur at any age and in any race. It has been reported in a 2-month-old infant.[23] Precipitating factors include trauma, burns, ionizing radiation, ultraviolet light, and certain drugs. In a case-control study of 116 incident cases, neuroleptics and diuretics—particularly aldosterone antagonists—were more commonly used by patients who developed BP than by control subjects.[24] There is still controversy as to whether BP is associated with an increased incidence of cancer[25]; however, correlations between flare in disease activity and recurrence of underlying cancer suggest such an association in individual patients.

BP is characterized by spontaneous remissions followed by flares in disease activity that can persist for years. Even without therapy, BP is often self-limited, resolving after a period of many months to years. The disease is nonetheless serious, particularly in older patients who have been treated with high doses of oral corticosteroids.[26] Mortality is low in younger persons but is significant in the elderly. In one study of patients older than 68 years, nearly a third died of the disease or complications (mainly sepsis and cardiovascular disease) within 1 year.[22]

HISTOLOGIC AND IMMUNOLOGIC FINDINGS

The earliest lesion of BP is a blister arising in the lamina lucida, between the basal membrane of keratinocytes and the lamina densa. This is associated with loss of anchoring filaments and hemidesmosomes. Histologically, there is a superficial inflammatory cell infiltrate and a subepidermal blister without necrotic keratinocytes. The infiltrate consists of lymphocytes and histiocytes and is particularly rich in eosinophils. There is no scarring.

Approximately 70% to 80% of patients with active BP have circulating antibodies to one or more basement membrane zone antigens. On direct immunofluorescence, the antibodies are de-

posited in a thin linear pattern; and on immune electron microscopy, they are present in the lamina lucida. By contrast, the antibodies to basement membrane zone antigens that are present in the skin of patients with systemic lupus erythematosus are deposited in a granular pattern.

Two less common subepidermal blistering diseases that are closely related to BP are cicatricial mucous membrane pemphigoid and herpes gestationis [*see Table 1*]. The differential diagnosis also includes dermatitis herpetiformis and acquired epidermolysis bullosa (see below). Scar formation in mucous membrane pemphigoid and acquired epidemolysis bullosa can lead to major disability.[27]

TREATMENT

Treatment of BP is generally similar to that of pemphigus.[28] The differences are as follows: (1) BP normally, but not invariably, responds to lower doses of systemic corticosteroids (alone or combined with other oral or topical agents), with most patients improving on prednisone at a dosage of 80 mg/day or less; (2) in an open prospective study of 18 cases, low-dose methotrexate was shown to be effective for maintenance of clinical remission induced by initial short-term use of potent topical steroids[29]; and (3) BP is more likely to respond to dapsone[30] or to the combination of tetracycline and niacinamide.[31,32] Considering that the prognosis of untreated BP is better than that of pemphigus, side effects of treatment are of greater concern. Two small studies of severe ocular mucous membrane pemphigoid suggest that this condition responds more favorably to treatment with cyclophosphamide combined with prednisone, whereas dapsone suppresses some cases of mild to moderate disease.[27]

Dermatitis Herpetiformis

Dermatitis herpetiformis (DH) is a rare vesiculobullous disease characterized by intensely pruritic, small vesicles that are grouped in small clusters and typically appear on the extensor aspects of the extremities and on the buttocks, scalp, and back. The condition is believed to be an immune-mediated disorder and is associated with abnormal granular deposits of IgA at the basement membrane zone and with asymptomatic, gluten-sensitive, spruelike enteropathy. The disease is chronic, with periods of exacerbation and remission. Lesions may clear if patients follow a strict gluten-free diet. Linear IgA dermatosis [*see Table 1*] is an uncommon subepidermal blistering disease that may clinically resemble DH or erythema multiforme (see below).

Figure 4 **Dermatitis herpetiformis, an extremely pruritic eruption, commonly presents as excoriated, grouped papulovesicles, often in a symmetrical distribution.**

PATHOGENESIS

The cause of DH is unknown. It may be related to gluten-sensitive celiac disease; there is a strong association between the two conditions, and they share a similar genetic basis (both are associated with HLA-B8 and HLA-DR3). DH is thought to result from an abnormal IgA immune response to an unidentified antigen (possibly found in gluten) that contacts the gut. Skin lesions may result from deposition of immune complexes against this antigen in skin.

CLINICAL FEATURES

Skin lesions of DH are polymorphic. They usually begin as small, very pruritic urticarial papules or vesicles that are grouped in a herpetiform pattern [*see Figure 4*]. Actual vesicles or other primary lesions are rarely seen because they are excoriated by patients' scratching. The distribution of lesions is characteristic: they occur most commonly on the elbows, knees, buttocks, scapular area, and scalp. Sometimes, lesions are scattered over the entire body. The lesions tend to appear suddenly and symmetrically, sometimes after ingestion of large amounts of gluten. Lesions heal, leaving hyperpigmentation; scarring may result from scratching or secondary infection. Involvement of mucous membranes is rare.

The disease is twice as common in men as in women. It predominantly affects persons between the ages of 20 and 50 years. There may be an associated patchy duodenal and jejunal atrophy that resembles the gluten-sensitive enteropathy of adult celiac disease.[33,34] The enteropathy is usually asymptomatic and, like celiac disease, responds to gluten restriction. Because celiac disease is associated with gastrointestinal lymphoma, there is concern that the same may be true for DH. However, although lymphomas of the small intestine have been reported in DH,[35] the association appears to be rare.

HISTOLOGIC AND IMMUNOLOGIC FINDINGS

Two characteristic laboratory features of DH are used for diagnosis. First, the disease is characterized histologically by accumulations of neutrophils and eosinophils in microabscesses at the tips of dermal papillae. In more severe cases, edema appears and can progress to subepidermal blisters appearing just below the lamina densa. Secondly, granular deposits of IgA are found at the basement membrane zone in almost all patients. These are often associated with granular deposits of C3 and, occasionally, of IgG and IgM. When found alone, IgA is one of the most sensitive and specific diagnostic markers for DH. When IgA is found with deposits of IgG, IgM, or C3, immune complex vasculitis and systemic lupus erythematosus are added to the differential diagnosis. Although basement membrane zone deposits of IgA alone also occur in linear IgA disease,[36] the deposits in that condition are linear rather than granular. There are no circulating antibodies to normal skin components in DH.

TREATMENT

DH responds rapidly and dramatically to sulfones. Dapsone at a dosage of 100 to 200 mg/day is most commonly used for treatment. Glucose-6-phosphate dehydrogenase (G6PD) deficiency must be excluded before starting therapy, because lack of this enzyme can result in severe drug-induced anemia. Sulfapyridine at a dosage of 1 to 3 g/day in divided doses (or sulfamethoxypyridazine) can be used in patients who cannot tolerate dapsone. Doses of these drugs are gradually reduced to the lowest amount that will suppress pruritus and development of new lesions. As indicated, patients also respond to a gluten-free diet; however, such diets are difficult to follow. Nevertheless, even a partial decrease in gluten intake will result in a decreased requirement for sulfones and should therefore be encouraged.

Erythema Multiforme

Erythema multiforme is an acute, recurrent, self-limiting disease that affects all age groups and races. It is characterized by the sudden eruption of crops of lesions, which represent a cell-mediated hypersensitivity reaction of the skin and mucous membranes to a variety of precipitating factors, including infectious agents and drugs [*see Table 3*].[37] Recent or recurrent infection with herpes simplex virus is a principal risk factor for erythema multiforme.[38]

CLINICAL FEATURES

Lesions may be localized or widespread and may affect both the skin and the mucous membranes. The eruption often occurs bilaterally and symmetrically on the extensor surfaces of the extremities and on both the dorsal and the volar areas of the hands and feet. Lesions vary from well-defined, red or purple, edematous macules and papules to vesicular or bullous lesions that may ulcerate, encrust, erode, and become infected. A target lesion consisting of a papule or vesicle surrounded by a region of normal skin and a halo of erythema at the periphery [*see Figure 5*] is characteristic.

Stevens-Johnson syndrome is a severe form of erythema multiforme that is usually disseminated, fulminant, and multisystemic [*see Figure 6*]. The syndrome may be accompanied by high fever, malaise, chills, headache, tachycardia, tachypnea, and prostration. Drugs are more commonly the underlying etiologic agent than infection. Some of these include long-acting sulfonamides (particularly trimethoprim-sulfamethoxazole), anticonvulsants, barbiturates, and nonsteroidal anti-inflammatory drugs. The mucous membranes in the mouth, the anus, and the vagina contain round or oval erythematous macules that form vesicles, bullae, and ulcers. Ocular lesions are bilateral yellowish-gray papules that often ulcerate and become secondarily infected, resulting in conjunctivitis. Ocular involvement has produced blindness.

Toxic epidermal necrolysis (TEN) has a potentially fatal outcome because of detachment of large areas of epidermis. TEN is considered by some to be a form of erythema multiforme, usually a reaction to medication. However, the absence of immune reactants within the blood vessels in the skin and the paucity of dermal inflammation have led other researchers to consider TEN a separate disease.

Staphylococcal scalded skin syndrome also causes large areas of epidermal necrosis. This syndrome, which results from toxins produced by *Staphylococcus aureus*,[39] is sometimes confused with TEN [*see Table 1*].

Table 3 Precipitating Factors in Erythema Multiforme

Viral diseases	Herpes simplex Hepatitis Influenza A Vaccinia Mumps
Fungal diseases	Dermatophytoses Histoplasmosis Coccidioidomycosis
Bacterial diseases	Hemolytic streptococcal infections Tuberculosis Leprosy Typhoid
Collagen vascular disorders	Rheumatoid arthritis Systemic lupus erythematosus Dermatomyositis Allergic vasculitis Polyarteritis nodosa
Malignant tumors	Carcinoma Lymphoma after radiation therapy
Hormonal changes	Pregnancy Menstruation
Drugs	Penicillins Sulfonamides Barbiturates Salicylates Halogens Phenolphthalein
Miscellaneous	*Rhus* dermatitis Dental extractions *Mycoplasma pneumoniae* infection

HISTOLOGIC AND IMMUNOLOGIC FINDINGS

Characteristic cutaneous histologic findings of erythema multiforme include subepidermal edema, bulla formation, epidermal cell necrosis, and a deep perivascular inflammatory infiltrate composed of mononuclear cells involving vessels in the upper dermis. The chemokine profile, with dominance of lymphocytic attractant chemokines at the dermoepidermal junction, is a feature of the interface dermatitis.[40] There are no specific immunofluorescence findings and no circulating antibodies, although direct immunofluorescence may show granular deposits of C3 and fibrin at the dermoepidermal junction and deposits of IgM, C3, and fibrin in the dermal blood vessels.

In vitro studies suggest that different immunopathogenic processes may be involved in herpes-mediated erythema multiforme and the drug-mediated forms of the disease.[41]

TREATMENT

Erythema multiforme eruptions may recur without warning, despite preventive measures. It is therefore important to identify and eliminate underlying causes. Mild cases are treated symptomatically with topical glucocorticoids and topical anti-inflammatory, antipruritic, or antibiotic preparations. Oral acyclovir may be effective in the prophylaxis of recurrent postherpetic erythema multiforme. In more severe cases, treatment with prednisone, 40 to 120 mg/day in divided doses, is indicated. If the eyes

Figure 5 **Target lesions are characteristic of erythema multiforme.**

are involved, prompt ophthalmologic consultation should be obtained. Patients with large areas of epidermal necrosis (e.g., those with Stevens-Johnson syndrome) may require specialized intensive care, such as in a burn unit.

Early treatment with high-dose IVIg has been reported to be safe and effective in improving survival of patients with TEN.[42] However, there is no standard treatment of TEN that can be used as a basis for comparative studies.[43]

Epidermolysis Bullosa

Epidermolysis bullosa (EB) comprises a group of genetically based disorders with a prevalence of approximately one in 500,000 persons. There are more than 20 different phenotypes of EB, which may be inherited as an autosomal recessive trait. These disorders are characterized by blistering and erosions that arise after minor skin trauma or friction and heal with or without scarring. Extent of involvement ranges from localized blisters (e.g., on the palms and soles) to severe widespread sloughing of the skin, with a risk of severe morbidity and mortality from secondary infection, fluid and electrolyte imbalance, anemia, or other complications.

Figure 6 **Stevens-Johnson syndrome is a fulminating form of erythema multiforme associated with marked mucocutaneous involvement, eye involvement, and severe constitutional symptoms.**

EB is classified primarily on the basis of an ultrastructural level of skin cleavage in the basement membrane zone [*see Figure 7*]. Three major subtypes include EB simplex or epidermolytic (intraepidermal), junctional EB (intra–lamina lucida), and dystrophic or dermolytic EB (sub–lamina densa). Electron microscopy examination localizes the lesions to a specific layer.[44] Because this technology may not be widely available, immunofluorescence mapping with monoclonal antibodies can be used to target components of the basement membrane layers such as BP antigen (basal cell layer), laminin (lamina lucida), and type IV collagen (lamina densa).[45] The prenatal diagnosis may be made by immunocytochemical probes for antigenic components of the basement membrane in fetal skin biopsy, such as in the junctional EB pyloric atresia syndrome.[46]

EPIDERMOLYSIS BULLOSA SIMPLEX

There are three major forms of EB simplex.[47] The most common type is a mild autosomal dominant form that appears at birth or shortly thereafter as either localized or generalized blisters that do not usually result in scarring. A second type is Weber-Cockayne disease, which can be either localized or generalized. In the localized form, blisters appear acrally on the palms and soles during childhood or adolescence. In the generalized form, disease activity is usually greater in a warm climate.

The Dowling-Meara variant (EB herpetiformis) is a less common form of EB simplex that presents as severe generalized blistering in infancy; it resembles recessive junctional and dystrophic EB. EB herpetiformis becomes less severe with age.

JUNCTIONAL EPIDERMOLYSIS BULLOSA

Junctional EB is a recessively inherited group of disorders that exhibit a decreased number of hemidesmosomes and hypoplasia of hemidesmosomes, as revealed by electron microscopy, and separation at the level of the lamina lucida. Mucosal involvement and dystrophic nails are common. The most severe form, EB letalis, occurs within the first few days or months of life and has a high mortality. Patients with EB letalis have a high incidence of respiratory arrest at an early age because of laryngeal and tracheal involvement. Less severe forms of junctional EB exhibit severe generalized blistering at birth that gradually improves. Esophageal strictures may develop.

DYSTROPHIC EPIDERMOLYSIS BULLOSA

There are two forms of dystrophic EB that are inherited in an autosomal dominant fashion. Hyperplastic EB dystrophica (Cockayne-Touraine syndrome) appears in early infancy or childhood as serosanguineous blisters, predominantly on extensor aspects of the lower extremities, in association with nail dystrophy. The albopapuloid type of EB dystrophica is characterized by white papules that develop during adolescence on the trunk or extremities; however, blistering is present in the perinatal period. In both forms, ultrastructural examination reveals sublaminal dermal separation, with abnormalities in anchoring fibrils or a decrease in their number.

Recessive forms of EB dystrophica appear during the neonatal period as severe serosanguineous blistering that is either localized to sites of skin trauma or generalized. Milium formation is uncommon, but lesional scarring may result. Other complications include dental abnormalities, nail dystrophy or loss, digital fusion, flexion contractures, and esophageal strictures [*see Figure 8*]. Growth retardation, malnutrition, and chronic anemia also occur. Patients with recessive EB dystrophica are at increased

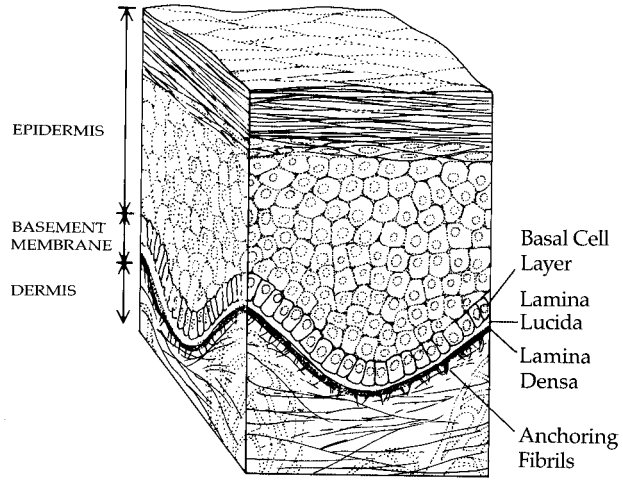

Figure 7 **Three major forms of epidermolysis bullosa (EB) have been recognized: EB simplex, in which a split occurs within the basal cell layer; junctional EB, which is characterized by separation within the lamina lucida; and dystrophic EB, in which separation occurs below the basement membrane zone.**

risk for squamous cell carcinoma, with a high incidence of fatal metastases.

Prenatal diagnosis of recessive dystrophic EB may be made by fetoscopy and skin biopsy; ultrastructural analysis of the tissue reveals dermolytic blister formation. An alternative method for prenatal diagnosis of recessive dystrophic EB involves testing of chorionic villus samples for mutation and haplotype analysis in the type VII collagen gene.[48]

Supportive treatment of EB is directed toward promotion of wound healing and prevention of complications. Daily skin care may include wet dressings or whirlpool baths, antibiotic ointment, and nonadhesive dressings, such as fine-mesh gauze (N-terface). A multidisciplinary approach that includes genetic counseling, psychological or psychiatric counseling, and support systems for the patient and family is essential, particularly for managing the severe forms of the disease.

A national registry has been established by the Dystrophic Epidermolysis Bullosa Research Association of America (http://www.debra.org) to collect epidemiologic data, to assess economic and social aspects of EB, and to register patients willing to participate in various research protocols.

Figure 8 **Recessive dystrophic epidermolysis bullosa may cause severe scarring and syndactyly.**

ACQUIRED EPIDERMOLYSIS BULLOSA

Acquired epidermolysis bullosa, or epidermolysis bullosa acquisita (EBA), is a trauma-induced blistering disorder in adults who have no genetic basis for disease. Both circulating and tissue-bound IgG anti–basement membrane zone antibodies may be demonstrated by immunohistology. The blisters develop below the epidermis and heal with atrophic scars and malformation. They are usually confined to the extremities at sites of mechanical trauma. Oral lesions and nail dystrophy may be associated with EBA. Underlying malignant, autoimmune, and inflammatory diseases may be associated with this condition. The presence of ulcerative colitis or Crohn disease in approximately 30% of cases suggests that EBA should be included among the extraintestinal manifestations of inflammatory bowel disease.[49]

The diagnosis is made by excluding other bullous disorders, particularly BP (see above) and porphyria cutanea tarda. Immunoelectron microscopy may be used as an additional diagnostic aid, although this technique may not be widely available. Direct immunofluorescence with the use of salt-split skin to separate the lamina lucida aids in the differential diagnosis. With this method, the IgG antibodies appear on the dermal side of the split specimens in EBA and on the epidermal side in pemphigoid.[50] The antigen of EBA has been identified as the globular carboxyl terminus of type VII procollagen,[51] a major constituent of anchoring fibrils.[12] EBA may also be triggered by certain drugs, such as penicillin, cephalosporins, diclofenac, and captopril.[52]

Differential Diagnosis of Vesiculobullous Disorders

The major forms of bullous diseases occurring on an autoimmune or inherited basis have been discussed. The differential diagnosis includes a number of additional conditions in which vesicles or bullae are less common or appear secondary to other disease processes.

Acantholytic blisters occur in keratosis follicularis (Darier disease) as well as in pemphigus. Such blisters are a histologic rather than a clinical finding. Darier disease is an autosomal dominant disorder that manifests as greasy papules and plaques on seborrheic areas and in the flexures; almost all patients have nail abnormalities. Unlike pemphigus vulgaris, Darier disease is most effectively treated with oral retinoids.[53]

A fixed drug eruption may produce localized bullae that appear after ingestion of a particular drug [*see 2:VI Cutaneous Adverse Drug Reactions*]. Eczematous dermatitis results in spongiotic vesicles caused by intercellular edema [*see 2:IV Eczematous Disorders, Atopic Dermatitis, and Ichthyoses*]. This is manifested clinically by large bullae in acute allergic contact dermatitis triggered by poison ivy or poison oak. Systemic lupus erythematosus [*see 15:IV Systemic Lupus Erythematosus*] occasionally produces bullae by causing degeneration of basal cells.

A bullous eruption on the dorsa of the hands and other sun-exposed sites in patients receiving long-term hemodialysis may resemble porphyria cutanea tarda [*see 9:V The Porphyrias*].[54] Porphyrin levels are usually within normal limits. Intraepidermal or subepidermal bullae, primarily on the extremities, may be a cutaneous sign of diabetes mellitus.[55] Bacterial infections of the skin, such as impetigo, may be associated with subcorneal bulla formation. Bullae may occur on the feet in patients with severe dermatophytosis.

Various viral infections, including varicella (chickenpox), herpes simplex, and herpes zoster, also must be considered in the differential diagnosis [*see 2:VII Fungal, Bacterial, and Viral Infections of the Skin, 7:XXVI Herpesvirus Infections, and 7:XXXIII HIV and AIDS*]. Lastly, blisters from physical trauma, burns, or cold must also be considered.

X MALIGNANT CUTANEOUS TUMORS

Allan C. Halpern, m.d.
Patricia L. Myskowski, m.d.

Malignant tumors can arise from cells of any layer of the skin—keratinocytes, melanocytes, fibroblasts, endothelial cells, or adipocytes—as well as from cells such as lymphocytes, which normally transit through the skin. Cutaneous metastases may also arise from other primary sites. In this chapter, we review the most common malignant cutaneous tumors in their order of frequency.

Malignant Tumors of the Epidermis

Epidermal skin cancers are the most common cancers in humans. They arise in the keratinocytes and the melanocytes of the epidermis. Epidermal skin cancers present a unique opportunity for effective intervention with both early detection and primary prevention. They are amenable to clinical diagnosis by simple visual inspection and to pathologic diagnosis by minimally invasive biopsy.

Basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) originate from the keratinocytes of the epidermis. Because these two cancers share many features, they are often lumped together under the term nonmelanoma skin cancer (NMSC).

Malignant melanoma is a malignancy arising from a melanocyte. Although malignant melanomas can arise in any melanocyte of the body, including the eye, the vast majority occur in the skin. Cutaneous malignant melanoma has been categorized into four major histogenetic types: lentigo maligna melanoma, superficial spreading melanoma, nodular melanoma, and acral lentiginous melanoma.

SUN EXPOSURE AND SKIN CANCER

Several lines of evidence implicate ultraviolet (UV) radiation in the pathogenesis of all three of the major epidermal skin cancers.[1] Epidemiologic data implicate long-term cumulative sun exposure in the development of SCC and intense intermittent sun exposure in the development of BCC and melanoma. Laboratory studies indicate that both UVA (320 nm to 400 nm) and UVB (290 nm to 320 nm) radiation from sunlight can damage DNA both directly and through oxidative damage. In addition, UV radiation can suppress the cutaneous immune system.[2] The association of some SCCs with chemical carcinogens and the occurrence of acral lentiginous and mucosal melanomas in unexposed areas of the body underscore the need for studies to identify additional etiologic agents.

Recognition of the important role of sunlight in the etiology of skin cancer affords an opportunity for primary prevention through the use of sun protection. Unfortunately, the exact timing and doses of UV exposure involved in the development of skin cancer in humans are not known and likely vary among the types of skin cancer. Accordingly, patients should be educated about the deleterious effects of sun exposure and tanning. Sun-protection efforts should be geared to an overall reduction of sun exposure through the avoidance of sun-seeking behavior and the use of sun-protective clothing. Broad-spectrum sunscreens with a sun protection factor (SPF) of 15 or greater are a useful adjunct to sun protection, but they should not be used to increase the amount of time spent in direct sunlight.[3] The use of tanning beds should be avoided. The use of sunless tanning agents is safe, but the darkening of the skin that results from the use of these agents does not offer significant UV protection. For individuals who are assiduous in their sun protection efforts, attention should be given to adequate vitamin D intake through diet or supplements.[4]

NONMELANOMA SKIN CANCER

NMSC typically occurs as pink lesions on the sun-exposed skin surface. Any pink skin lesion that persists or recurs in the same location, especially if easily irritated by minor trauma, should raise the suspicion of NMSC. Some forms of NMSC will fade with changes in season (i.e., with reduced sun exposure) or with the application of topical steroids, and the clinician should advise patients that any lesion that recurs warrants further attention.

Basal Cell Carcinoma

BCC is a malignant cutaneous tumor arising from the basal keratinocytes of the epidermis.

Epidemiology BCC is the most common skin cancer. The reported incidence ranges from 3.4 per 100,000 per year in African Americans to over 1,100 per 100,000 per year in Townsville, Queensland, Australia.[5,6] Although rare, metastases and death from BCC do occur.

Etiology and risk factors UV radiation—specifically, intense intermittent sun exposure—appears to play an important role in the development of BCC. Studies of basal cell nevus syndrome (Gorlin syndrome) have yielded dramatic insights into the genetics of BCC. The patched gene, which was first recognized as a developmental gene in the fruit fly *Drosophila,* has been identified as playing a critical role in the development of BCC. Almost all patients with basal cell nevus syndrome appear to inherit a mutated copy of the patched gene, and studies of sporadic BCC suggest that mutations in the patched gene pathway (i.e., the sonic hedgehog pathway) are a necessary and often sufficient step in the development of most BCCs.[7]

Diagnosis The majority of BCCs occur on the head and neck. They occur in nodular and superficial forms, as well as in a variety of less common forms.

Nodular BCC appears as a raised, pearly, translucent, pink bump on the skin surface. It is often easily irritated, fragile, and associated with episodes of superficial ulceration or hemorrhage. When ulceration is prominent, it can lead to the appearance of a so-called rodent ulcer, in which the pearly translucent border is barely appreciable. Some nodular BCC lesions appear more white than pink and, on close observation, often demonstrate small telangiectasias. They tend to have a smoother, shinier surface and a firmer texture than common dermal nevi [*see Figure 1*].

Superficial BCC appears as a pink patch of skin. On close inspection, most superficial BCCs demonstrate a thready, translucent border, with areas of seemingly normal or slightly fibrotic skin within the lesion. Superficial BCC is usually found on the upper trunk, arms, and legs.

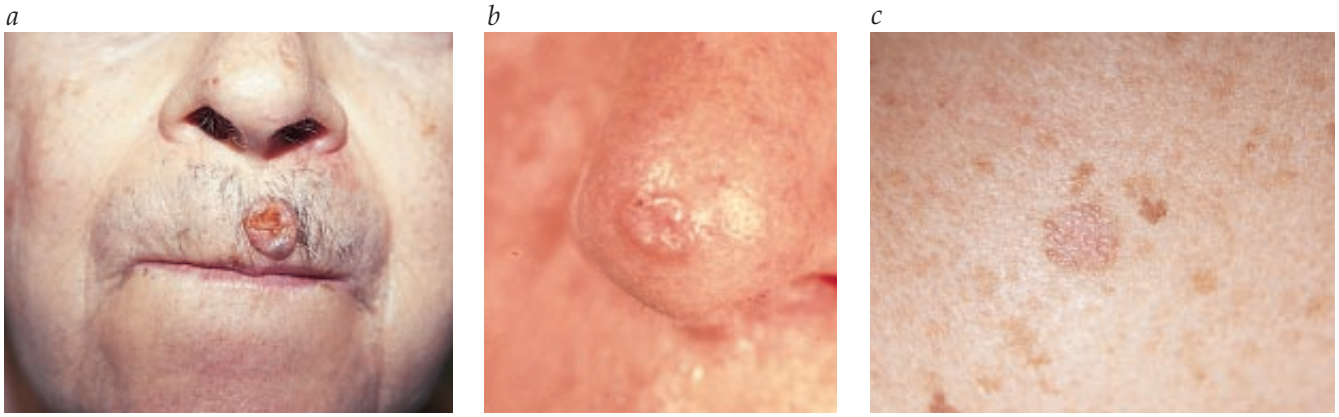

Figure 1 **Nodular basal cell carcinoma—shown here above a patient's lip, with a so-called rodent's ulcer (*a*)—commonly presents as a raised, pearly, translucent pink bump on the skin surface (*b*). A superficial form appears as a pink patch of skin (*c*).**

Less common clinical variants of BCC include morpheaform, pigmented, and cystic lesions. Morpheaform BCCs have an infiltrative pattern that histologically and clinically resembles a scar. Pigmented BCCs typically contain specks of blue-black pigment, but they may be deeply pigmented throughout. Pigmented lesions are most commonly a variant of nodular BCC. Cystic BCCs tend to be softer than typical nodular BCCs and may have a clear to blue-gray appearance.

Patient history plays a critical role in the diagnosis of BCC. When questioned about lesions that become easily irritated or bleed from minor trauma, patients can often alert the clinician to early lesions that would otherwise elude detection. With the patient under local anesthesia, a biopsy should be obtained of any suspicious lesion.

Differential diagnosis Nodular BCC can be confused with angiofibromas, dermal nevi, amelanotic melanoma, cutaneous metastases, dermatofibroma, and a host of benign adnexal tumors (e.g., trichoepithelioma). Superficial BCCs mimic several inflammatory dermatoses (e.g., eczema and tinea) and share several clinical features with actinic keratoses. Pigmented BCC can easily be confused with a primary melanocytic neoplasm. Cystic BCCs can be confused with cystic adnexal tumors and inflammatory lesions.

Treatment The goal of therapy is to adequately eradicate the lesion and ensure the best cosmetic and functional outcome. Multiple factors—such as the size, location, and histologic subtype of the lesions and attributes of the patient, including age, general health, skin color, and skin laxity—should be taken into consideration in choosing an optimal therapy.

The vast majority of BCCs are amenable to surgical treatment. The primary options include curettage and electrodesiccation, excision, and Mohs micrographic surgery. A small but significant subset of BCCs can be treated effectively with Mohs micrographic surgery, which entails microscopic examination of frozen sections of the entire undersurface of the excised specimen at the time of surgery. The technique may be indicated for recurrent lesions and lesions that have a high likelihood of recurrence. Such lesions include ill-defined lesions, large lesions (> 2 cm), lesions with a high-risk histology (i.e., aggressive growth pattern, sclerosing pattern, or perineural involvement), and lesions overlying embryonal fusion planes (e.g., ocular canthi or nasofacial sulcus). The cure rate of Mohs micrographic technique is significantly higher than the cure rates of other treatments of these high-risk lesions.[8]

Radiation therapy can be an effective, painless, and well-tolerated alternative that is typically reserved for older patients who are poor surgical candidates. Radiation therapy should be avoided, however, in patients with basal cell nevus syndrome. Cryotherapy is another therapeutic option for BCC in patients who are poor surgical candidates.

Topical therapy combined with pharmacotherapy using the immune response modifier imiquimod five times weekly for 6 weeks has been approved by the Food and Drug Administration for the treatment of superficial BCC of the trunk and extremities. One packet (250 mg) of imiquimod 5% cream is applied to 25 cm^2 of affected skin.

Experimental therapies under investigation include intralesional chemotherapy, next-generation topical immune modulators, and photodynamic therapy.

All patients treated for BCC are at risk for local recurrence, and they are at significant risk for the development of additional skin cancers. Patients should be instructed in the self-examination of their skin, as well as in methods of sun protection. In addition, they should receive routine professional follow-up.

Prognosis The risk of local recurrence relates to the lesion's size, location, and histology. Metastases are very rare: a prevalence of 0.0028% was reported in a series of 50,000 Australians.[9] Metastases occur through both the lymphatic and the hematogenous routes; risk factors include basal cell nevus syndrome, immunosuppression, and previous exposure to ionizing radiation. Metastases that are not amenable to surgical management are associated with a poor outcome.

Squamous Cell Carcinoma

Like BCC, cutaneous SCC arises from the keratinocytes of the epidermis. Histologically, the cells of well-differentiated SCC resemble the cells of the superior portion of the epidermis.

Epidemiology An estimated 150,000 to 250,000 new cases of cutaneous SCC were diagnosed in the United States in 1994.[10] The estimated mortality from SCC in the United States in 1988 was approximately 0.5 per 100,000. Several lines of data suggest significant increases in SCC incidence. In Australia, for example,

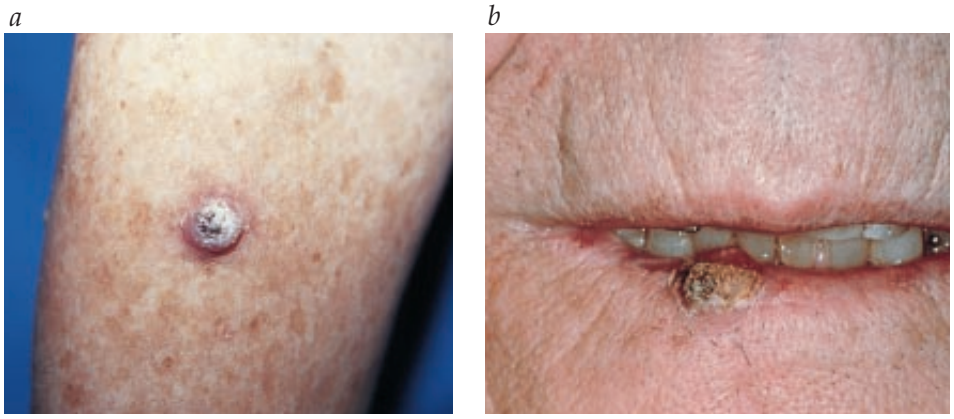

Figure 2 **A squamous cell carcinoma is shown on an arm (*a*) and lower lip (*b*).**

the incidence of SCC increased by 51% between the years 1985 and 1990.[11] In the United States, some of the highest rates of NMSC have been detected in the southwest. A population-based survey in New Mexico found the incidence of SCC doubled in both males and females between 1978 and 1999.[12]

Etiology and risk factors In addition to sunlight, other known etiologic agents that contribute to the development of cutaneous SCC are ionizing radiation, chemical carcinogens, thermal burns, and chronic nonhealing wounds. Sun-related SCCs demonstrate a lower risk of metastases and death than SCCs related to other exposures. Factors involved in predisposition to SCC from sun exposure include light skin color, a tendency to burn, and an inability to tan.

Pathophysiology and pathogenesis Sun-related SCC is often associated with a precursor lesion called an actinic keratosis. Such lesions occur on the scalp, the face, the extensor surfaces of the forearms, and the backs of the hands. They tend to be rough-surfaced, irregularly shaped, and pink. They are often more readily felt than seen. The majority of patients with actinic keratoses have multiple lesions. The risk of SCC in these individuals has been estimated to be as high as 20%.[13] SCC may also appear on normal-looking skin.

SCC of the oral or genital mucosa may arise in precursor lesions termed leukoplakia or erythroplakia. Mucosal SCCs are associated with a significant risk of metastases. Immune surveillance affects the progression of SCC. Immunosuppression, as occurs in transplant recipients and patients with lymphoma, is associated with a high incidence of SCC.[14] In these patients, infection with human papillomavirus appears to play an etiologic role in conjunction with sun exposure. SCCs tend to be more aggressive in immunosuppressed persons.

Diagnosis Most lesions occur in areas of the body that are usually exposed to the sun. The lesions are pinkish, firm plaques that often have a rough, scaly surface [*see Figure 2*]. Biopsy is required for definitive diagnosis.

Differential diagnosis The differential diagnosis of SCC includes keratoacanthoma, Bowen disease, verrucous carcinoma, BCC, hypertrophic actinic keratosis, and common warts.

Keratoacanthomas share many features with SCC, both clinically and histologically. They arise de novo on normal-looking skin and grow very rapidly. They are typically pink, dome-shaped, shiny bumps with a central crateriform keratotic plug that occur on the surface of the skin. They may become very large. Although keratoacanthomas are not associated with a risk of metastasis, they can be locally destructive. Spontaneous regression of keratoacanthoma over the course of months has been well documented.

Bowen disease is SCC that is confined to the epidermis. It appears as red, scaly, minimally elevated plaques with well-defined, irregular borders. The reported association of Bowen disease with internal malignancy has not held up to closer scrutiny.[15]

SCCs that lack a scaly keratotic surface can be confused with a host of other adnexal and dermal skin tumors.

Treatment Small SCCs evolving from an actinic keratosis can be adequately treated with simple curettage and electrodesiccation. Larger actinic lesions, as well as lesions arising in non–sun-exposed areas of skin, are best treated with definitive surgical excision with confirmation of negative margins. High-risk, ill-defined lesions, especially those occurring in the surgically sensitive areas of the face, genitalia, hands, and feet, are often best treated by Mohs micrographic surgery.

Fractionated radiation therapy is an alternative treatment of primary SCC in older patients who are poor surgical candidates. The benefits of adjuvant radiation therapy are less clear, as are the benefits of sentinel lymph node biopsy and elective lymph node dissection (ELND) for patients with high-risk SCC of the head and neck.

Cytotoxic chemotherapy and biologic response modifiers have been used in patients who have advanced SCC; this therapeutic approach has been reported to have complete response rates of up to 68%, but there are few long-term survivors.[16] Actinic keratoses are treated with cryotherapy, curettage, topical therapies (e.g., fluorouracil, imiquimod, or diclofenac), photodynamic therapy, and laser resurfacing to prevent progression to SCC.[17] Regularly updated guidelines for the treatment of SCC and BCC are available through the National Comprehensive Cancer Network (NCCN).[18]

Prognosis Regardless of the therapy employed, high-risk lesions have a significant rate of local recurrence at 5 years. High-risk SCCs include those in specific anatomic sites (e.g., ears, lips, genitalia, and other non–sun-exposed areas), those greater than 2 cm in diameter, those with aggressive histologic features (depth > 4 mm, Clark level IV and above, and poorly differentiated histology), and those in immunosuppressed patients.[19] The primary route of SCC metastasis is via lymphatic spread to regional lymph nodes. Reported rates of metastasis vary from as low as 0.3% in small, sun-derived lesions to 33% in larger, poorly differentiated lesions.[19] Reported overall 5-

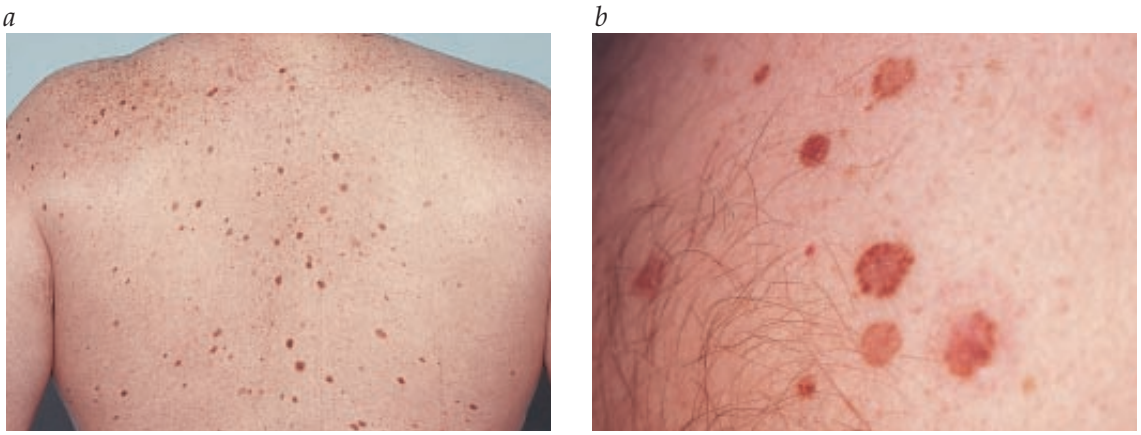

Figure 3 **Dysplastic nevi typically are larger than common moles (*a*) and have variegate pigmentation and ill-defined borders (*b*).**

year survival rates for patients with regionally metastatic SCC have ranged from 25% to 47%.[19]

MALIGNANT MELANOMA

Epidemiology

In the United States, a person's lifetime risk for developing melanoma is about 1 in 75 (1.3%).[20] Between 1973 and 1994, the incidence of melanoma rose by 121%, and the mortality rose by 39%.[21] Encouraging trends include a shift toward the detection of earlier disease, as well as a stabilization of incidence rates in some segments of the population. In terms of both morbidity and mortality, however, the burden of melanoma-related disease continues to increase. Although melanoma can occur in anyone, it is primarily a disease of whites. Melanomas occurring in blacks are more commonly of the acral lentiginous variety.

Table 1 Adjusted Estimated Relative Risks of Melanoma by Nevus Type and Number[25]

Type	*Number*	*Adjusted Relative Risk**
Nevi > 2 mm and < 5 mm	0–24	1.0
	25–49	1.8 (1.3–2.5)
	50–99	3.0 (2.1–4.4)
	≥ 100	3.4 (2.0–5.7)
Nondysplastic nevi > 5 mm	0	1.0
	1	0.9 (0.7–1.3)
	2–4	1.3 (1.0–1.8)
	5–9	1.7 (1.0–2.7)
	≥ 10	2.3 (1.2–4.3)
Dysplastic nevi	None	1.0
	Indeterminate	1.0 (0.7–1.6)
	1	2.3 (1.4–3.6)
	2–4	7.3 (4.6–12.0)
	5–9	4.9 (2.5–9.8)
	≥ 10	12.0 (4.4–31.0)

*Mutually adjusted and adjusted for age, sex, center, referral pattern, morphologic dysplastic nevi < 5 mm, sunburns, freckles, solar damage, scars, nevus excisions, and family history of melanoma (confidence interval = 95%).

Etiology and Risk Factors

Sun exposure Although strong epidemiologic and basic-science evidence supports an association between melanoma and sun exposure, the relationship appears to be complex.[22] Lentigo maligna melanoma is associated with long-term cumulative sun exposure. Superficial spreading melanoma and nodular melanoma appear to be associated with intense intermittent sun exposure, especially in youth. Acral lentiginous melanoma has no apparent association with sun exposure. Basic-science studies and animal models have implicated different wavelengths of UV in melanoma carcinogenesis; UV wavelength may vary among types of melanoma.

Skin color Melanoma can occur in all racial/ethnic groups but is much more common in lighter-skinned individuals. Among whites, several additional risk factors have been identified, such as fair complexion, a tendency to burn, an inability to tan, freckling, and a family history of melanoma.[22] Screening of the family members of patients with melanoma (particularly multiple melanomas) may be a useful preventive and diagnostic measure.[23]

Moles and dysplastic nevi The strongest phenotypic markers of melanoma risk are moles (nevi)—more specifically, increased numbers of moles and the presence of atypical moles (dysplastic nevi). Melanoma can arise in a preexisting mole or may arise de novo on normal-appearing skin.

Several epidemiologic studies have correlated dysplastic nevi with melanoma risk. Clinically, dysplastic nevi are large (> 5 mm) moles with variegate pigmentation and ill-defined borders [*see Figure 3*]. Histologically, dysplastic nevi are characterized by the presence of architectural atypia and random cytologic atypia. The degree of melanoma risk associated with dysplastic nevi depends on the genetic context. In families with familial melanoma–dysplastic nevus syndrome, the abnormal mole phenotype appears to be inherited in an autosomal dominant fashion. Members of these families with dysplastic nevi have a lifetime melanoma risk that approaches 100%.[24] Outside the context of familial melanoma, dysplastic nevi occur in approximately 5% to 15% of whites. In this general population, dysplastic nevi are markers of increased melanoma risk [*see Table 1*].[25]

Genetic Factors

Approximately 5% of patients with melanomas have a family history of melanoma. Mutations in the cell-cycle regulatory gene *p16* (cyclin-dependent kinase inhibitor–2a) are associated with melanoma in approximately 40% of familial-melanoma families, with linkage of the gene to chromosome 9p.[26] A highly specific activating somatic mutation in the *BRAF* proto-oncogene (a member of the RAF family of kinases) is found in the majority of melanomas and benign nevi, suggesting a pivotal role for this genetic pathway in melanocytic tumor progression.[27] Genomic analyses are beginning to distinguish biologically distinct subsets of melanoma.[28]

Diagnosis

As a pigmented lesion occurring on the surface of the skin, melanoma is amenable to early detection by simple visual inspection at an easily curable stage. Left untreated, melanoma is among the deadliest and most therapeutically unresponsive forms of cancer.

Physical examination Early recognition of melanoma requires attention to pigmented lesions on all body surfaces. Despite the strong association of melanoma with sun exposure, melanomas can occur anywhere on the skin or mucosa. Patients' self-examination, as well as physician examination, must therefore include all skin surfaces, including the scalp, genitalia, and soles of the feet. Any pigmented skin lesion with recent change or with features described by the ABCD mnemonic (asymmetry, border irregularity, color variation, diameter > 6 mm) warrants consideration of the possibility of melanoma. Although any mole may change gradually over time, any that change color, shape, or size relative to a patient's other moles deserve special attention [*see Figure 4*].[29] Dysplastic nevi present both opportunity and challenge in melanoma detection. On one hand, their recognition allows efficient targeting of a high-risk group. On the other, they can complicate attempts at melanoma detection by clinically mimicking early melanomas. Although some dysplastic nevi may progress to melanoma, the overwhelming majority remain benign. Furthermore, not all melanomas arising in patients with dysplastic nevi develop in a preexisting mole. Wholesale removal of dysplastic nevi is an impractical approach to melanoma prevention. In patients with dysplastic nevi, melanoma detection is predicated on specialized visual examination aided by self-examination and professional follow-up to identify changing lesions.[30]

Diagnostic aids Several specialized aids to the diagnosis of melanoma in patients with dysplastic nevi are under development. Dermoscopy entails the use of a handheld otoscope-like device to magnify a pigmented lesion while applying pressure and oil to the surface. The technique allows the visualization of pigment patterns and features not apparent with simple visual inspection. With experience and training, dermoscopy can be a useful aid in distinguishing melanoma from benign pigmented lesions; however, when used inexpertly, dermoscopy may actually decrease diagnostic accuracy.[30,31] Another aid to melanoma detection in high-risk individuals is photographically assisted follow-up.[32] A baseline set of whole-

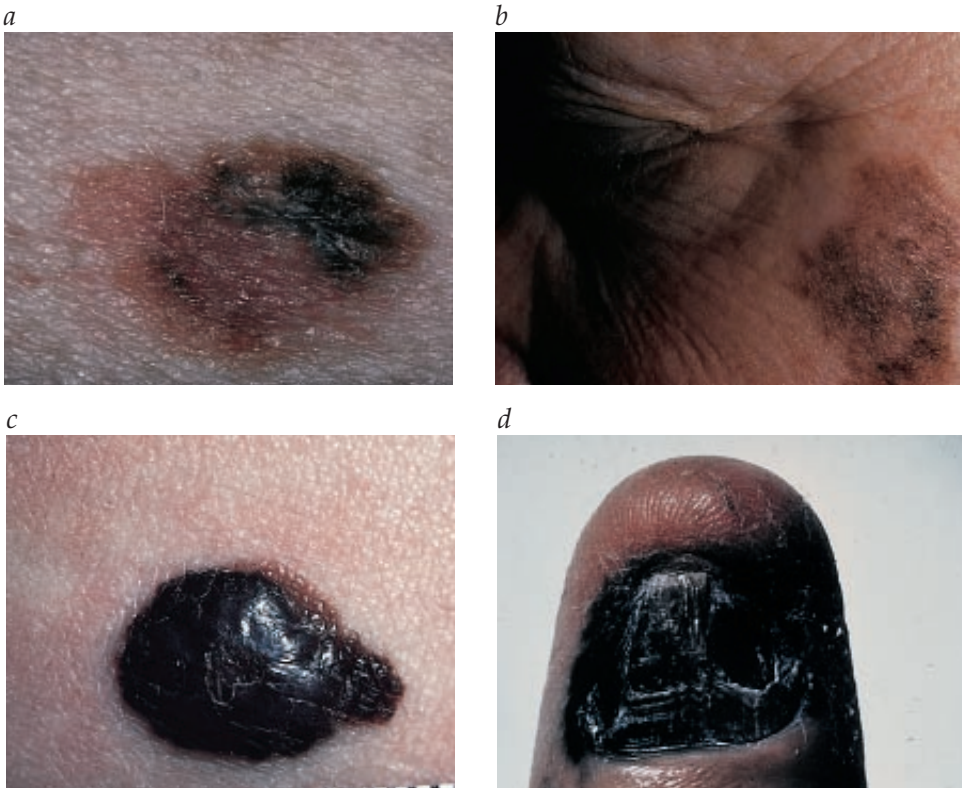

Figure 4 **Superficial spreading malignant melanoma begins as a small, irregular brown lesion (a). Variation in color and contour is characteristic of lentigo maligna melanoma (*b*). Nodular melanoma often grows more in thickness than in diameter (*c*). Acral lentiginous melanoma can resemble a hematoma under the nail (*d*).**

body photographs of the skin are used during self-examination and professional follow-up examination to assess change in the lesions. This procedure helps to prevent unnecessary excision of stable lesions and improves the sensitivity of examinations in detecting change. New imaging technologies such as in vivo confocal scanning laser microscopy hold promise for future improvements in the noninvasive diagnosis of melanoma.[33]

Full-thickness excision and biopsy Any lesion that raises a clinical suspicion of melanoma requires definitive diagnosis. Full-thickness excision is the preferred technique for biopsy of a suspicious pigmented lesion. Partial biopsy can lead to misdiagnosis through sampling error or by depriving the pathologist of a view of the overall architecture and cytology of the lesion. Incisional biopsies with good clinicopathologic correlation may be appropriate, however, in the assessment of large lesions and of lesions occurring in surgically sensitive areas. There is no evidence to suggest that incisional biopsy increases the risk of metastasis.

Differential Diagnosis

Dysplastic nevi share many features with early superficial spreading melanoma. Other common lesions that may mimic melanoma include lentigines, sunburn freckles, traumatized nevi, thrombosed angiomas, pigmented BCCs, pigmented Bowen disease, dermatofibromas, and atypical seborrheic keratoses. Two other challenges in the differential diagnosis of melanoma deserve special mention. Amelanotic melanomas (melanomas without pigment) present as pink lesions that may be misdiagnosed as BCCs or Spitz nevi. Spitz nevi can be difficult to differentiate from melanoma both clinically and histologically. Spitz nevi occur most commonly in children, but they also occur in adults. Like nodular melanomas, Spitz nevi tend to appear suddenly and range in color from red to reddish brown.

Treatment

Primary site Primary cutaneous melanoma is managed surgically with definitive reexcision. The wide excisions of the past have given way to resections with more modest margins. Multiple prospective, randomized trials have investigated the surgical resection of primary cutaneous melanoma utilizing different margins of resection; these studies have focused on varied and overlapping patient populations. On the basis of these data, the NCCN recommends resection margins of 1 cm for melanomas less than 1 mm in thickness, margins of 1 to 2 cm for melanomas between 1 and 2 mm in thickness, and margins of 2 cm for melanomas greater than 2 mm in thickness.[34,35] Primary closure and reconstructive flaps are preferable, cosmetically and functionally, to skin grafts and should be used instead of grafts whenever possible.

Lymph nodes Patients with clinically evident regional lymph node disease are treated with therapeutic lymph node dissection.[34] Elective lymph node dissection in patients with primary melanoma and who have no clinical evidence of lymph node involvement has been abandoned on the basis of the failure of multiple randomized trials to demonstrate an overall survival benefit with this procedure.

Sentinel lymph node biopsy is being increasingly used in patients with primary cutaneous melanoma. This technique utilizes lymphoscintigraphy to identify the draining regional lymph node basins for the skin at the site of the primary melanoma. At the time of definitive reexcision of the melanoma, a blue dye and radioisotope are injected into the dermis around the melanoma site. A small incision is made over the spot that has been identified on lymphoscintigraphy as the proximal area of drainage of the regional lymph node basin. The first lymph node identified as taking up the blue dye and radioisotope (i.e., the sentinel node) is then excised.

The sentinel node is then histologically evaluated, often with the use of immunohistochemical techniques and occasionally with the use of polymerase chain reaction, which is more sensitive. The absence of melanoma in the sentinel node is highly sensitive for ruling out the presence of metastases in the remainder of the lymph node basin when the procedure is performed by an experienced team. When the sentinel node is found to be positive for melanoma, a "completion" lymph node dissection of the affected basin is typically performed. Prospective studies have demonstrated sentinel node status to be strongly correlated with 5-year survival.[36] Patients with positive sentinel nodes are appropriate candidates for consideration of adjuvant therapy [*see* Adjuvant Therapy, *below*]. Several multicenter trials are currently under way to assess the clinical utility of this procedure.[37] Initial reports from the first of these trials have failed to indicate an overall survival advantage associated with the procedure.[38]

In-transit metastases In-transit metastases are metastases that establish tumors within regional dermal and subcutaneous lymphatics before reaching the regional lymph nodes. In-transit metastases can remain confined to a single limb for prolonged periods. Amputation does not appear to provide a long-term survival benefit in this setting.[34] Slow-growing individual in-transit metastases can be managed surgically. More extensive disease can be treated with sensitization therapy with dinitrochlorobenzene (DNCB), intralesional interferon, or topical agents for modifying the immune response. For extensive in-transit metastases confined to an extremity, limb perfusion therapy can result in dramatic palliation and limb salvage. The procedure entails isolation of the vasculature of the involved extremity from the systemic vasculature and perfusion of the isolated limb with chemotherapeutic agents, biologic agents, or both at doses that could not be tolerated if given systemically.[39]

Distant metastases Despite the development of several novel approaches to the treatment of patients with metastatic melanoma, including multiagent chemotherapy, biologic therapy, immunotherapy, and combinations of these treatments, no regimens have demonstrated a clear survival advantage over single-agent chemotherapy. Monotherapy with dacarbazine (2 to 4.5 mg/kg daily for 10 days, repeated every 4 weeks) or recombinant interleukin-2 (IL-2) (600,000 IU/kg every 8 hours for up to 14 doses) are the only treatment regimens approved by the FDA for the treatment of metastatic melanoma. Objective responses to dacarbazine are seen in approximately 5% to 20% of patients; durable complete responses are rare.[40] Objective responses to IL-2, a significantly more toxic agent, are seen in approximately 15% of patients; durable responses are seen in about 5%. Radiation therapy can play an important palliative role. In the absence of more effective clinically proven therapy, patients with distant metastases should be offered the opportunity to participate in clinical trials of experimental therapy. Many current experimental therapies are

Table 2 AJCC TNM Classification[45]

TNM Classification	*Tumor Thickness, Node Number, Metastases Site*	*Subclassification*
T classification T1	≤ 1.0 mm	a: Without ulceration and Clark level II or III b: With ulceration or Clark level IV or V
T2	1.01–2.0 mm	a: Without ulceration b: With ulceration
T3	2.01–4.0 mm	a: Without ulceration b: With ulceration
T4	> 4.0 mm	a: Without ulceration b: With ulceration
N classification N1	One lymph node	a: Micrometastasis* b. Macrometastasis†
N2	2–3 lymph nodes	a: Micrometastasis* b. Macrometastasis† c: In-transit met(s)/satellites(s) without metastatic lymph nodes
N3	4 or more metastatic lymph nodes, matted lymph nodes, or combination of in-transit met(s)/satellite(s) with metastatic lymph nodes	—
M classification M1a	Distant skin, subcutaneous, or lymph node mets	Normal LDH
M1b	Lung mets	Normal LDH
M1c	All other visceral mets Any distant mets	Normal LDH Elevated LDH with any M

*Micrometastases are diagnosed after sentinel or elective lymphadenectomy.
†Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy; the term also applies to nodal metastases that exhibit gross extracapsular extension.

predicated on decades of experience with immunotherapy of melanoma, as well as the recent availability of pharmacologic inhibitors of elements of the Ras signaling pathway that are implicated in melanoma pathogenesis.[40]

Adjuvant therapy Patients with cutaneous or regional disease who have been surgically rendered disease free but who are at high risk for recurrence or metastasis are potential candidates for adjuvant therapy.[41] Various adjuvant therapies have been used in melanoma, including immunostimulants such as bacillus Calmette-Guérin, *Corynebacterium parvum,* and levamisole. Several chemotherapeutic agents have been tried as well. More recently, immunotherapies with cytokines, such as interferons, and active immunization with vaccines have been studied**.** A high-dose regimen of interferon alfa (20 million units/m^2 I.V. daily for 1 month followed by 10 million units/m^2 S.C. three times a week for 48 weeks) has been approved by the FDA for use as adjuvant therapy for melanoma. Two studies have demonstrated a small but statistically significant improvement in overall survival with this regimen. Multiple studies have failed to demonstrate improved long-term overall survival with the use of adjuvant interferon in intermediate-dose or low-dose regimens.[42,43]

A host of novel strategies, including active immunization, passive immunization, and myriad biologic therapies, are currently being studied and may provide opportunities for patients who are appropriate candidates for trials.[44]

Prognosis

Stage The single strongest prognostic factor for melanoma is stage of disease. Various staging classifications have been used over the years. All staging systems for melanoma take into account the classic TNM classification of tumor size (T), lymph node involvement (N), and distant metastases (M). The differences across staging systems relate largely to the staging of the primary site. New staging systems attempt to use the attributes of the primary tumor that strongly correlate with outcome. These attributes include thickness, ulceration, and, in the case of thin melanomas measuring less than 1 mm thick, the Clark level of invasion. The advent of sentinel node biopsy has led to the inclusion of microstaging of lymph nodes in the staging system [*see Tables 2 and 3*].[45,46]

Attributes of the primary tumor Several attributes of the primary tumor have been identified as predictors of outcome from primary cutaneous melanoma. A strong predictor of outcome is the Breslow tumor thickness, which is measured in millimeters from the granular layer of the epidermis to the deepest tumor cell. Other important histologic parameters are the Clark level of tumor invasion, the presence or absence of ulceration, the rate of mitosis, the presence of tumor-infiltrating lymphocytes, and vascular invasion. For thin primary melanomas, one of the strongest predictors of outcome is growth phase.[47] Radial-growth-phase melanoma does not appear to metastasize, whereas vertical-growth-phase melanoma (characterized by the for-

Table 3 AJCC Staging System and Survival Rate[45]

Pathologic Stage	*TNM*	*5-Year Survival*	*10-Year Survival*

AJCC—American Joint Committee on Cancer

mation of a tumor nodule in the dermis) is associated with significant risk of metastasis even in lesions less than 1 mm thick.[48] Patient characteristics associated with improved survival from melanoma include young age (< 60 years), female sex, and location of the melanoma on an extremity other than the palms or soles. Multivariable models for predicting outcome from melanoma have been developed [*see Table 4*].[49]

Malignant Tumors of the Dermis

METASTATIC TUMORS

Cutaneous metastases occur in approximately 5% of patients with solid tumors and are usually associated with widespread disease. The relative frequency of skin metastases is gender specific, reflecting the rates of the primary cancers.[50] In women, two thirds of metastases are from breast cancer, but lung cancer, colorectal cancer, melanoma, and ovarian cancer are also frequent. In men, lung cancer is most common, followed by cancer of the large intestine, melanoma, SCC of the head and neck, and cancer of the kidneys.[50] The anatomic distribution of skin metastases is not random. Cutaneous metastases from breast cancer often involve the chest wall and may appear as nodules, lymphedema, or cellulitis. The scalp is a common site for metastasis, especially of cancer from the lung and kidney (in men) and breast (in women). Head and neck cancers may invade the skin by local extension, giving rise to a firm, dusky-red edema of the skin that resembles cellulitis. Abdominal wall metastases, often called Sister Joseph's nodules, may occur with gastrointestinal or ovarian malignancies.[50] Clinically, cutaneous metastases are often minimally symptomatic dermal papules or nodules and are flesh-colored or pink; dissemination occurs via lymphatic or vascular pathways. Cutaneous metastases may clinically reflect the histology of the primary tumor (e.g., black, brown, or gray nodules with metastatic melanoma, and vascular nodules with renal cell or thyroid carcinoma).

PRIMARY TUMORS

Primary malignancies of the dermis may develop from any of the myriad structures of the skin, including sebaceous glands (sebaceous carcinoma), connective tissue (dermatofibrosarcoma protuberans), smooth muscle (leiomyosarcoma), and other adnexal tissue (eccrine carcinoma). Most of these primary dermal neoplasms are rare; they may exhibit aggressive biologic behavior. Although these neoplasms are quite varied histologically, many share a common clinical presentation of a rapidly growing flesh-colored to pink or red subcutaneous nodule that occasionally resembles a sebaceous cyst.

Merkel cell carcinoma This neoplasm is a dermal malignancy of neuroendocrine origin. It usually appears as a red to violaceous dermal papule or nodule on the head and neck of elderly patients, although all age groups are affected. The treatment of choice is wide local excision with or without lymphadenectomy. Sentinel node biopsy has been proposed by some for evaluation of the regional lymph nodes. Adjuvant radiation therapy can be considered. Local recurrences are frequent, and distant metastases occur in more than one third of patients. Chemotherapy of metastases is generally disappointing.[51,52]

Paget disease A rare malignancy of the skin associated with an underlying adenocarcinoma,[50,51] Paget disease usually presents as an erythematous, often weeping unilateral dermatitis of the breast that involves the nipple and areola. The differential diagnosis includes eczema, psoriasis, contact dermatitis, and impetigo. For this reason, biopsy of an inflammatory, nonresolving dermatitis of the nipple or areola is imperative. In Paget disease, the biopsy will reveal typical pale-staining Paget cells in the epidermis. Appropriate surgical resection of the cutaneous and underlying neoplasm is the treatment of choice; lymph node metastases often occur.[51]

Extramammary Paget disease Extramammary Paget disease is even more uncommon than Paget disease. It typically presents as red, often ulcerated, plaques in the perineal areas of elderly persons.[50,51] Lesions may be pruritic or asymptomatic, are often long-standing, and may have been misdiagnosed as psoriasis, contact dermatitis, or chronic fungal infection. Underlying associated tumors include rectal and genitourinary carcinomas. Even without an associated internal malignancy, extramammary Paget disease is difficult to treat, and it is associated with a high local recurrence rate.[51]

Angiosarcoma A rare, often highly aggressive vascular malignancy,[51] angiosarcoma may appear as multicentric reddish-purple patches or nodules in a lymphedematous limb, such as on a lymphedematous arm after a mastectomy (Stewart-Treves syndrome). Another presentation is violaceous patches or plaques on the head or neck (especially scalp) of elderly persons. Patients with angiosarcoma have a poor prognosis, with pulmonary metastases frequently developing despite surgery or radiation.[51]

Dermatofibrosarcoma protuberans Dermatofibrosarcoma protuberans is a slow-growing, locally aggressive malignancy that rarely metastasizes but often recurs. Lesions typically present as firm reddish-brown or purple nodules, usually on the trunk or non–sun-exposed extremities. The differential diagnosis includes keloids and benign dermatofibroma. Young adults are most often affected, although the tumor may occur at any age. Wide local excision with or without Mohs micrographic surgery offers the best chance of cure.[51]

KAPOSI SARCOMA

Kaposi sarcoma (KS) is a multicentric cutaneous neoplasm that has four distinct clinical variants.[53-56] In spite of its name, KS is not a true sarcoma. Although the cell of origin has not been clearly established,[53,54] KS cells share phenotypic markers with lymphatic endothelium, as well as vascular smooth muscle cells, suggesting a vascular or pluripotent mesenchymal cell origin.[56] In its classic form, KS is an indolent disease of elderly men of Mediterranean or eastern European origin, in which violaceous nodules and plaques develop on the lower extremities.[53-55] A second variant, lymphadenopathic KS, is endemic to some areas of Africa. African KS, which typically affects young adults and children, pursues a more aggressive course than classic KS, with frequent bone, lymph node, and visceral involvement.[53-55] A third variant of KS occurs in iatrogenically immunosuppressed patients, especially organ transplant recipients.[57] In this variant, men are affected slightly more often than women.[53-55] The fourth variant is an aggressive epidemic KS that occurs in AIDS patients.

Epidemiology

Before the advent of AIDS, KS was rare in the United States, with an age-adjusted annual incidence of 0.29 per 100,000 population in men and 0.07 per 100,000 population in women.[54] KS was an AIDS-defining illness for 30% to 40% of patients in the earliest years of the HIV epidemic.[53] During that period, the incidence of KS in HIV-infected homosexual men was 73,000-fold higher than in the general United States population; in HIV-infected women and HIV-infected nonhomosexual men, the incidence was 10,000-fold higher.[52,53] The incidence has significantly declined since the introduction of highly active antiretroviral therapy (HAART). For example, in a large European-based study of HIV-infected patients, there was an estimated 39% annual reduction in the incidence of KS between 1994 and 2003, such that the incidence of KS in 2003 was 10% less than that reported in 1994.[58]

Etiology and Risk Factors

Human herpesvirus type 8 The epidemiology of KS has long suggested a transmissible infectious agent or cofactor.[53-55] Kaposi sarcoma–associated herpesvirus (KSHV), also known as human herpesvirus type 8 (HHV-8), has been detected in all variants of KS.[59] HHV-8 has also been found in patients with body cavity–based lymphoma, Castleman disease, and angioblastic lymphadenopathy, as well as in certain skin lesions of organ transplant recipients.[53] The mechanism by which HHV-8 infection leads to KS tumorigenesis is unclear but probably involves a complex combination of inflammation, angiogenesis, and neoplastic proliferation.[53,54] The prevalence of KS largely parallels the rate of HHV-8 infection in various populations.[54] Although the incidence of HHV-8 infection may be as high as 2% to 10% in the general population, the incidence of KS is very low, suggesting that the majority of infections are subclinical.[53,54]

Host factors Host factors, particularly immunosuppression, are crucial in some populations with KS.[47,48,50] HIV may play an indirect role in the development of KS through $CD4^+$ T cell depletion and stimulated production of growth factors and cytokines such as IL-1 and IL-6.[53,54,56] Immunosuppressive drugs, especially cyclosporine, azathioprine, and prednisone, increase the risk of developing KS, primarily in kidney and liver transplant recipients.[49]

Despite the prevalence of KS in some ethnic groups, the role of any possible genetic factors is unclear. An increased incidence of HLA-DR5 in patients with classic KS has been debated.[54] Fa-

Figure 5 **HIV-associated Kaposi sarcoma lesions vary from pink patches (shown) to deep-purple plaques.**

milial KS is extremely rare, suggesting that genetic factors alone are not responsible.

Finally, gender appears to be a significant risk factor, especially in classic KS, in which the male-to-female ratio may range from 3:1 to 10:1.[53,54] The reasons for this male predominance remain unclear.[48,49]

Diagnosis

Clinical manifestations The clinical manifestations of KS differ among the variants of the disorder.[53-55] In classic KS, faint reddish-purple macules or patches or purple nodules first appear on the feet, especially the soles. Lymphadenopathy (especially inguinal) is present on rare occasions. Lesions may also occasionally develop on the arms and genital areas. As the disease progresses, the lesions coalesce into violaceous plaques.

HIV-associated KS usually presents as cutaneous lesions, but the first lesions may appear in the oral mucosa or lymph nodes. In contrast to classic KS lesions, HIV-associated KS lesions often begin on the upper body (face, trunk, or arms). Most typically, HIV-associated KS lesions are purple-red, often oval, papules that follow a pityriasis rosea–like distribution [*see 2:II Papulosquamous Disorders*].[53-55] Lesions vary from pink macules to deep-purple plaques [*see Figure 5*] or may resemble ecchymoses, especially in patients with low $CD4^+$ T cell counts. Oral lesions are typically red-purple plaques or nodules on the palate, gingiva, or buccal mucosa. Patients with darker skin may have dark-purple to black lesions or hyperpigmented plaques.[54]

As HIV-associated KS progresses, lymphedema may develop in the feet, scrotum, genitalia, and periorbital regions, and lymphadenopathy (especially inguinal) may occur. Gastrointestinal lesions are usually submucosal and asymptomatic but may result in gastrointestinal hemorrhage. Pulmonary KS carries a poor prognosis.[54]

Laboratory studies Laboratory workup of patients with KS should include HIV antibody testing, complete blood count, fecal occult blood testing, and chest radiograph. $CD4^+$ T cell counts are indicated in HIV-positive patients. A complete medical history and physical examination should be performed, with special attention paid to the presence of opportunistic infections in HIV-infected or otherwise immunosuppressed patients. Skin biopsy should be obtained in patients with suspected KS. The histopathology of KS is characterized by the presence of spindle-shaped cells in the dermis, with extravasated red blood cells present in slits between irregular vascular spaces.[55]

Differential Diagnosis

The clinical differential diagnosis of KS includes dermatofibroma, purpura, pyogenic granuloma, bacillary angiomatosis, metastatic melanoma, and BCC. Other histopathologic entities that may resemble KS include angiosarcoma and stasis dermatitis.[55]

Treatment

Classic Kaposi sarcoma The therapy for KS is palliative. In classic KS, where the disease is indolent and the patients are elderly, aggressive systemic therapy is rarely warranted.[53,54] Instead, radiation therapy is the treatment of choice.[54,60] KS is very radiosensitive: single doses of 800 cGy have been used for rapid palliation in patients with poor prognoses. Total doses of 800 to 3,500 cGy have yielded 50% complete responses and 46% partial responses, with more than half of patients needing no follow-up treatment for as long as 13 years.[60] A treatment regimen equivalent to 3,000 cGy in 10 fractions over 2 weeks has been advocated.[60]

For patients with classic KS who have only one or two papules, excisional biopsy may be sufficient for both diagnosis and treatment. Cryotherapy with liquid nitrogen may be useful for isolated papules. Systemic therapy for classic KS may be indicated in cases of extensive cutaneous disease or visceral involvement. Single-agent chemotherapy with vinca alkaloids (i.e., vincristine or vinblastine) is commonly used. Low-dose recombinant interferon alfa may also be effective in classic KS; however, side effects (e.g., fever, chills, myalgias, and fatigue) may not be well tolerated by elderly patients.[53,54]

Transplant-associated Kaposi sarcoma Spontaneous KS regression has been observed in transplant recipients after withdrawal of cyclosporine and corticosteroids.[54] Sirolimus (rapamycin), an immunosuppressive drug with antineoplastic and antiangiogenic properties, was successfully used in 15 renal transplant recipients who developed KS. After KS was diagnosed, cyclosporine and mycophenolate mofetil were discontinued and sirolimus was started. Cutaneous KS resolved in all patients, without episodes of acute rejection or changes in renal graft function.[58]

HIV-associated Kaposi sarcoma Although KS is more aggressive in HIV-infected patients, the extent of immune suppression and the presence of opportunistic infections or other systemic illnesses may be of equal importance in staging, determining prognosis, and choosing appropriate therapy.[53,54] Clinical features that were traditionally associated with a more favorable outcome included a $CD4^+$ T cell count higher than 200 cells/mm^3, a lack of systemic illness, KS limited to the skin or lymph nodes, and minimal (i.e., not nodular) oral KS; poor risk factors included a $CD4^+$ T cell count below 200 cells/mm^3, KS-associated lymphedema, visceral KS, ulcerated KS, nodular oral KS, and opportunistic infection.[61] With the advent of HAART, however, physicians treating patients with HIV-associated KS now have the opportunity to influence and even reverse immune suppression by affecting both HIV viral load and the $CD4^+$ T cell count. Regression of KS has been observed after initiation of HAART, often during the first few months of therapy[56,62]; consequently, this

is often first-line therapy for patients with limited cutaneous HIV-associated KS.[54]

Local therapy is a reasonable approach in KS patients with limited disease, those with infectious complications, and those who cannot tolerate systemic therapy.[62] Radiation therapy is effective in HIV-associated KS in doses similar to those used for classic KS (see above). Responses in HIV-associated KS are generally short-lived, however.[54] Topical alitretinoin (9-*cis*-retinoic acid) gel may be effective in HIV-associated KS and has been approved by the FDA for this use.[62] Intralesional injections of vinblastine or interferon have also been useful in selected lesions.[53,54] Cryotherapy with liquid nitrogen is effective for small lesions[62]; however, cryotherapy is contraindicated in dark-skinned patients in whom posttreatment hypopigmentation may appear much worse cosmetically than the original KS lesion.

Systemic therapy has included conventional chemotherapy and biologic response modifiers. For patients with slowly progressive, limited cutaneous KS (< 25 lesions), systemic antitumor therapy may not be necessary; HAART with or without local therapy may be sufficient.[51] However, HAART alone has not been demonstrated to be the treatment of choice for advanced HIV-associated KS.[63] Liposomal anthracyclines (e.g., doxorubicin, daunomycin) are approved by the FDA as first-line therapy of HIV-associated KS.[64-66] A reasonable approach to the treatment of advanced HIV-associated KS is the use of a combination of HAART and liposomal anthracyclines, followed by a combination of HAART plus paclitaxel if response to the first regimen is inadequate.[56,63,65] Promising investigational approaches for HIV-associated KS include antiangiogenic compounds, thalidomide, matrix metalloproteinase inhibitors, and retinoids. Prevention of HIV-associated KS may also be achieved through antiviral therapy of HHV-8.[62]

Complications

Bacterial infections and sepsis are common in patients with KS and may be associated with ulcerated tumors of the legs and feet. Opportunistic infections may intervene, especially in patients with very low $CD4^+$ T cell counts.

Prognosis

The total $CD4^+$ T cell count is the most important predictor of survival in HIV-associated KS.[61] Large tumor burdens, lymphedema, and pulmonary KS are also predictive of poorer outcomes.[61,65]

Cutaneous Lymphoma

Lymphomas may be of B cell or T cell lineage and may involve the skin primarily or secondarily [*see 12:IV Principles of Cancer Treatment*]. B cell lymphomas, particularly non-Hodgkin lymphomas, may involve the skin secondarily in advanced disease. They typically appear as reddish-purple subcutaneous plaques or nodules. Primary B cell lymphomas of the skin are even rarer. They appear as reddish nodules that often remain localized to the skin but may progress to systemic disease. The vast majority of primary cutaneous lymphomas fall into the spectrum of cutaneous T cell lymphoma (CTCL).

CTCL includes mycosis fungoides (MF) and Sézary syndrome, which is a leukemic variant of MF.[66,67] MF is the largest subset of CTCL; the two terms, however, sometimes are used interchangeably. Another variant of CTCL is associated with human T cell lymphotropic virus type I (HTLV-I) and is part of the spectra of adult T cell lymphoma/leukemia and peripheral T cell lymphoma.[66]

EPIDEMIOLOGY

CTCL is a rare disorder. In the United States, approximately 1,000 new cases of CTCL are diagnosed annually.[66] From 1973 to 1984, the incidence of CTCL rose from 0.19 per 100,000 population to 0.42 per 100,000 population. CTCL primarily affects middle-aged adults; the median age at presentation is 50 years.[68] The male-to-female ratio is approximately 2:1; blacks are twice as likely as whites to develop CTCL.[68]

ETIOLOGY

Host susceptibility and an environmental antigen, perhaps viral, are hypothesized as playing important roles in the pathogenesis of CTCL.[66] Genetic factors may be related to major histocompatibility antigens, such as an increase in HLA-DRB1*11 (formerly HLA-DR5) and HLA-DQB1*03.[69] Chronic antigenic stimulation (e.g., infection) may play an etiologic role.[66] For example, HTLV-I infection may be an etiologic factor in the development of the peripheral T cell lymphoma variant.[66]

DIAGNOSIS

Clinical Manifestations

The clinical manifestations of MF typically evolve over many months to years. In one classic study, the mean duration of symptoms before diagnosis was 7.5 years.[70] Flat, erythematous patches, often scaling and occasionally atrophic, begin most commonly on the trunk and thighs, especially in a so-called bathing-trunk distribution [*see Figure 6*]. Lesions are asymptomatic or mildly pruritic and may spontaneously remit or respond to topical corticosteroid therapy. Patients may also report improvement after sun exposure. As MF progresses, patches tend to enlarge and thicken into plaques. The color may become dark red; in dark-skinned persons, the lesions may initially be hyperpigmented or hypopigmented and may acquire an erythematous or violaceous hue. In advanced MF, tumors may develop or transform to a large-cell lymphoma.[66,67,71]

In approximately 10% of cases, tumors are the initial presentation of CTCL (tumor d'emblé). Generalized erythroderma with circulating atypical T cells (in Sézary syndrome) is the presentation in 5% of CTCL patients.[66,67]

Physical examination of patients with suspected CTCL includes complete skin examination, including classification of lesions (patch, plaque, or tumor) and extent of body surface area involved. Lymph nodes, the liver, and the spleen should be palpated.

Skin Biopsy

Skin biopsy is necessary for the definitive diagnosis of CTCL. The presence of atypical lymphoid cells with hyperconvoluted cerebriform nuclei in clusters in the epidermis (Pautrier microabscesses) and a bandlike lymphocytic infiltrate in the upper dermis are diagnostic of CTCL.[66,67] The malignant cell is a T cell, with most of the cells expressing the pan–T cell markers CD2, CD3, and CD5, as well as frequent deletion of CD7, CD26, or both.[66,67,72] The use of T cell receptor gene rearrangement studies to confirm clonality in early disease may be an aid to diagnosis.[66] Neither immunophenotypic studies nor electron microscopy may be considered to be definitively diagnostic of CTCL; clinicopathologic correlation is necessary.

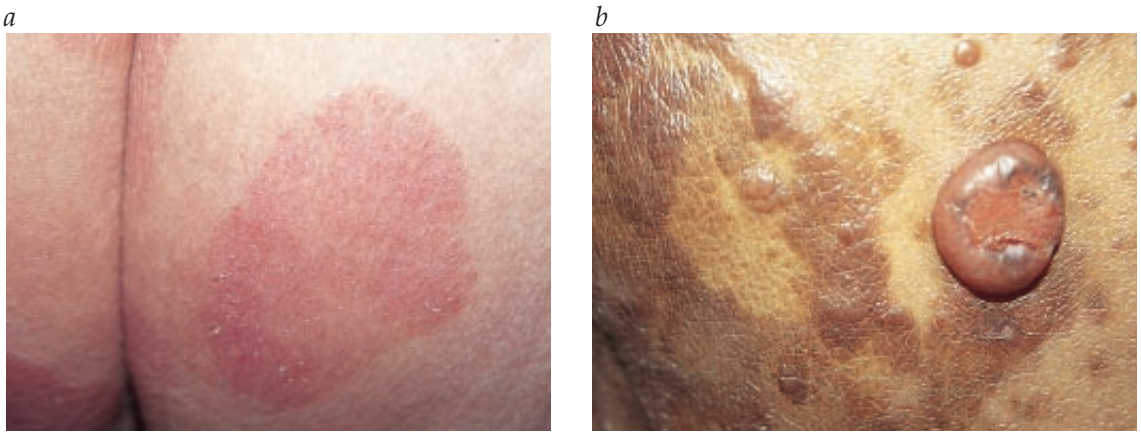

Figure 6 **Cutaneous T cell lymphoma is shown in the large-patch stage (*a*) and as tumor-stage mycosis fungoides (*b*).**

Laboratory Studies

The laboratory evaluation for CTCL includes complete blood count, eosinophil count, Sézary cell count, lactic dehydrogenase level, and liver function tests. Bone marrow biopsy is unnecessary in the absence of circulating leukemic cells. HTLV-I testing should be considered for patients with risk factors or atypical presentations. Lymph node biopsy should be considered for palpable nodes, especially those larger than 2 cm. Abdominal computed tomography or chest radiography may be important in patients with tumors or suspected visceral involvement.

DIFFERENTIAL DIAGNOSIS

In its early stages, CTCL may resemble any of a number of benign inflammatory disorders (e.g., drug reaction, eczema, psoriasis, or contact dermatitis). These disorders should be ruled out before contemplating therapy.

STAGING

The staging of CTCL is based on an evaluation of the type and extent of skin lesions and the extent of lymph node, peripheral blood, and visceral involvement.[70,71] Early disease is characterized by limited patch or plaque disease (stage IA) or generalized patch or plaque disease without evidence of extracutaneous involvement (stages IB and IIA); more advanced disease is characterized by cutaneous tumors (stage IIB), extracutaneous disease (stage III), and extracutaneous disease involving either lymph nodes (stage IVA) or viscera (stage IVB).

TREATMENT

Topical Therapy

Topical therapy is the mainstay of the treatment of early disease (stage IA, IB, and IIA). Early aggressive therapy with radiation and chemotherapy has not proved to be superior to local approaches in controlling disease or improving survival in patients with limited disease.[66,67] A rational approach for treating early limited (or histologically equivocal) disease is topical corticosteroids.[73] Topical nitrogen mustard (mechlorethamine), in either aqueous or ointment form, is the most frequently used topical chemotherapy. In one series, the overall response rate to nitrogen mustard was 83%, with a complete response rate of 50%, after a median treatment time of 12 months.[74] Median time to relapse was also 12 months.[74]

Carmustine (BCNU) solution, applied daily to lesions, is another useful regimen. Treatment generally lasts 8 to 16 weeks but has been continued for up to 6 months. Because systemic absorption can result in bone marrow suppression, complete blood counts must be monitored.[62] Bexarotene, a topical retinoid, has been shown to be effective in CTCL; it is approved by the FDA for use in CTCL.[75]

Ultraviolet Radiation

Radiation therapy for CTCL takes several forms, from ultraviolet light to ionizing radiation. UVB is useful in stage I disease. In a retrospective study of 21 patients with stage I disease, narrowband UVB led to complete remission in 81% of patients and to partial remission in 19%; the mean relapse-free interval was 24.5 months.[76]

Another effective approach to treatment of CTCL is the combination of psoralen and UVA (PUVA). In one study, 65% of patients with stage I CTCL had complete clinical clearing, with a mean relapse-free interval of 43 months; the disease-free survival rates at 5 and 10 years for stage IA were 56% and 30%, respectively.[77] In another study, complete remission was observed in 71% of early-stage patients; in this study, the mean relapse-free interval was 22.8 months.[76]

Radiation Therapy

Total skin electron beam (TSEB) radiation delivers radiotherapy to the skin surface without a significant internal dose. It is especially useful with plaque disease. Typical doses are 2,400 to 3,600 cGy, fractionated over several weeks with 4 to 9 MeV electron beam radiation.[78] Treatment responses are related to CTCL stage[79]; early-stage (stage IA) patients have a 95% response rate, but 50% will experience relapse within 10 years. TSEB may also be useful in stage IB disease (90% remission rate), but two thirds of patients treated with this modality will experience relapse within 5 years.[73] Patients with tumor-stage (stage IIB) CTCL may receive effective palliation from TSEB, especially in combination with other therapies.[79]

Systemic Therapy

Systemic therapy has been undertaken as primary therapy in advanced CTCL (stages III through IVB); in early-stage disease, systemic therapy is used as part of sequential therapy to promote more durable responses.[66,67]

Oral bexarotene has yielded response rates of up to 45% in advanced CTCL, and it is approved by the FDA for use in this disease.[80] Another systemic therapy used in the treatment of advanced CTCL is denileukin diftitox [DAB(389) IL-2].[81] This receptor-targeted cytotoxic fusion protein binds to the IL-2 receptor on T cells; it achieved a 30% response rate in heavily-pretreated patients.[81]

Extracorporeal photopheresis, which is an accepted therapy for advanced CTCL, appears most useful in erythrodermic CTCL and Sézary syndrome.[66,67] In this treatment, the patient is given a photoactivating drug (8-methoxypsoralen), the patient's white blood cells are collected via leukapheresis and irradiated with UVA, and the irradiated cells are returned to the patient intravenously. Advanced CTCL characterized by cutaneous tumors (stage III) or visceral involvement (stage IV) has also been treated with single-agent and combination chemotherapy using methotrexate, adenosine analogues, interferon alfa, and retinoids.[66,67,82]

Combination Therapy

Early aggressive treatment using TSEB followed by combination chemotherapy provides no survival advantage over sequential topical therapy.[83,84] In a randomized controlled trial, 103 patients with MF received TSEB followed by either parenteral chemotherapy with cylophosphamide, doxorubicin, etoposide, and vincristine or sequential topical treatment. Patients receiving combined therapy had a significantly higher rate of complete response than those receiving sequential topical therapy; however, there was no difference in the rates of disease-free and overall survival between the two groups after a mean follow-up of 75 months.[83] In an uncontrolled study, multimodality therapy was examined in patients with early and advanced disease. In this study, 95 CTCL patients received in consecutive phases of therapy interferon alfa and oral isotretinoin, TSEB, and maintenance therapy consisting of topical nitrogen mustard and interferon alfa. Patients with advanced disease also received six cycles of combination chemotherapy before TSEB. Although multimodality therapy resulted in high response rates (85% response, 60% complete response), the study provided no evidence that this form of combination therapy could improve the overall survival rates currently achieved with sequential topical therapy.[80] In general, the heterogeneity of reported combination therapy regimens in CTCL makes it virtually impossible to compare results.

Future Directions

A number of experimental approaches are being investigated in CTCL, including allogeneic bone marrow transplantation, histone deacetylase inhibitors, monoclonal antibodies, and fusion toxins.[67] Other investigative modalities include cytokines such as recombinant IL-12 and IL-2.[66]

COMPLICATIONS

The most serious complications of CTCL are infections. Sepsis from ulcerated cutaneous tumors is a common cause of death. Visceral CTCL may occur, as may transformation to large cell lymphoma in some CTCL patients (39% probability after 12 years).[71] In long-term survivors with early disease, local therapies (e.g., TSEB or PUVA) may contribute to the development of other skin cancers (e.g., BCC or SCC) and cataracts.[85]

PROGNOSIS

Many different attempts have been made to classify CTCL into useful prognostic groups. An early and still valid study that used the TNM system identified three major groups: good-risk patients (stages IA, IB, and IIA, with plaque-only skin disease and no lymph node, blood, or visceral involvement [median survival, > 12 years]); intermediate-risk patients (stages IIB, III, and IVA, with cutaneous tumors, erythroderma, or plaque disease and node or blood involvement but no visceral disease or node effacement [median survival, 5 years]); and poor-risk patients (stage IVB, with visceral involvement or node effacement [median survival, 2.5 years]).[70]

Eosinophilia is also associated with shortened survival.[70] Other long-term studies have revealed that stage IA patients do not have a reduced life expectancy and that fewer than 10% of these patients experience disease progression to more advanced stages.[86] Survival of patients with generalized patch/plaque MF (stage IB or IIA), at a median of 11.7 years, is significantly worse than that of a race-, age-, and sex-matched control population.[87] Gender and race appear to have no effect on survival, but older patients (> 58 years) have shorter disease-specific survivals.[68]

Allan C. Halpern, M.D., has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

Patricia L. Myskowski, M.D., has received grant or research support from Merck & Co., Inc., and is a consultant for Ligand Pharmaceuticals Inc.

Topical corticosteroids, topical nitrogen mustard, and carmustine have not been approved by the FDA for treatment of cutaneous T cell lymphoma; interferon alfa, sirolimus, and HAART have not been approved by the FDA for treatment of Kaposi sarcoma.

XI BENIGN CUTANEOUS TUMORS

Elizabeth A. Abel, m.d.

General Considerations

classification

Tumors of the cutaneous surface may arise from the epidermis, dermis, or subcutaneous tissue or from any of the specialized cell types in the skin or its appendages. Broad categories include tumors derived from epithelial, melanocytic, or connective tissue structures. Within each location or cell type, lesions are classified as benign, malignant, or, in certain cases, premalignant.[1,2]

Benign epithelial tumors include tumors of the surface epidermis that form keratin; tumors of the epidermal appendages; and cysts of the skin.

Melanocytic, or pigment-forming, lesions are very common. One of the most frequently encountered forms is the nevus cell nevus. The term nevus has two meanings: a malformation commonly involving the entire skin layer (tissue nevus) and a benign growth of melanocytic cells (nevus cells).

Nevus cells are closely related to melanocytes and may be defined as modified neuroectodermal melanin-producing elements. The word mole, often used as a synonym for nevus, is an imprecise term because it refers to birthmarks that may or may not contain nevus cells. Neural tumors, such as neurofibromas, are related to melanocytic tumors because both are of neuroectodermal origin.

Tumors that are derived from connective tissue include fibromas, histiocytomas, lipomas, leiomyomas, and hemangiomas.

histologic evaluation

For cases in which it is not possible to distinguish clinically between benign and malignant cutaneous tumors, histopathologic examination is extremely important. The type of biopsy performed depends on the location, size, and nature of the lesion and on cosmetic considerations. In all cases, the clinical features must be correlated with the distinctive microscopic appearance of the tumor to confirm or exclude the diagnosis on the basis of physical examination.

Epithelial Tumors

seborrheic keratosis

Diagnosis and Classification

Seborrheic keratosis (seborrheic wart) consists of a sharply circumscribed, rough or smooth papule or plaque that is 1 mm to several centimeters in size and dirty yellow or light to dark brown in color. The lesions often have the appearance of being stuck on and are characterized by prominent follicular plugging. They are most common in light-skinned races, first appearing in adults on the face and upper trunk and occurring more frequently with increasing age [*see Figure 1*].

Transient eruptive seborrheic keratoses have been associated with inflammatory skin conditions, including erythroderma associated with psoriasis and drug eruptions. These keratoses tend to resolve when the skin inflammation clears.[3] These transient keratoses should be distinguished from eruptive seborrheic keratoses—the sign of Leser-Trelat—which are associated with internal malignancy, particularly adenocarcinoma. The true value of the sign of Leser-Trelat as a marker of underlying malignancy is a subject of debate.

Dermatosis papulosa nigra is similar to seborrheic keratosis, but it is seen in dark-skinned races; it usually appears on the face and presents at an earlier age than seborrheic keratosis [*see Figure 2*].

Differential Diagnosis

The differential diagnosis of seborrheic keratosis and dermatosis papulosa nigra includes lentigo, wart, and nevus cell nevus. A biopsy may be required to rule out a pigmented basal cell carcinoma or, in the case of an inflamed seborrheic keratosis, malignant melanoma or squamous cell carcinoma. A shave biopsy that includes the base of the lesion may be performed before treatment with curettage.

Treatment

Curettage is a satisfactory treatment. When multiple lesions are present, anesthesia may be achieved by freezing the affected area with an ethyl chloride spray before performing curettage. For larger lesions, electrodesiccation is unnecessary and may cause scarring. Smaller lesions may be successfully treated with electrodesiccation, cryotherapy, or topical application of 50% trichloroacetic acid.

epidermal nevus

Diagnosis

Epidermal nevus consists of closely set, skin-colored or hyperpigmented papules that either may be localized to one side of the body and arranged in linear fashion or may be widespread. When localized, the condition is termed nevus unius lateris [*see Figure 3*]. When widespread, it is called systematized nevus. Lesions affect about one in 1,000 people; they are present at birth or appear in early childhood. The lesions have no malignant potential but may constitute a serious cosmetic problem.

Histologically, epidermal nevi exhibit hyperplasia of the epidermis; the structure or maturation of these lesions is not significantly different from that of normal epidermis. One variant, the inflammatory linear verrucous epidermal nevus, shows psori-

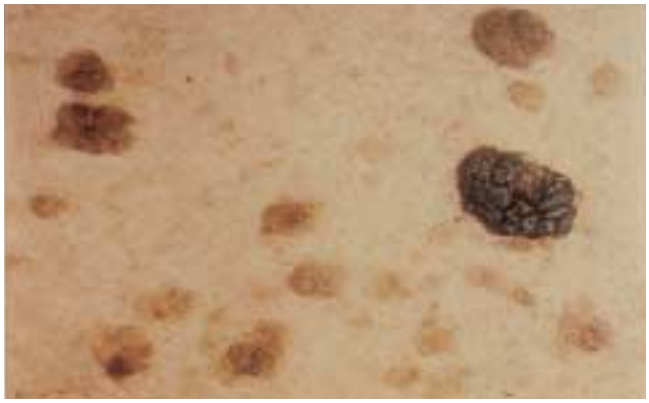

Figure 1 **Verrucous, hyperpigmented lesions of seborrheic keratosis with a stuck-on appearance are present on the trunk of this patient.**

Figure 2 **Dermatosis papulosa nigra, as seen on the face, appears in dark-skinned races at a younger age than seborrheic keratosis.**

Figure 3 **Epidermal nevus with discrete and confluent brown papillomas is present in a somewhat linear arrangement.**

Figure 4 **Skin-colored or yellowish, often umbilicated papules of sebaceous hyperplasia, as seen on the forehead, may clinically resemble basal cell carcinomas.**

asiform hyperplasia. Another variant, which is common in systematized nevi, shows granular degeneration of epidermolytic hyperkeratosis histologically. This type of epidermal nevus is a mosaic genetic disorder of suprabasal keratin. Mutations in the *K10* gene are associated with lesions of the skin, whereas the normal gene is found in unaffected skin.[4]

Variants

The epidermal nevus syndrome involves a spectrum of different types of epidermal nevi associated with disturbances in the skeletal, urogenital, cardiovascular, and nervous systems.[5] This rare syndrome is apparent at birth; the presence of widespread epidermal nevi should trigger a search for associated anomalies.

Nevus comedonicus is a variant of an epidermal nevus affecting the pilosebaceous structures; it occurs as clusters of comedonelike papules, usually in a linear pattern on the face, neck, upper arms, and trunk.[5]

Nevus sebaceous is a benign tumor that shows sebaceous differentiation. The lesion has a yellow hue and a granular surface and occurs in a linear pattern on the face or scalp. At puberty, nevus sebaceous may become more elevated; in adulthood, there is an associated risk of basal cell carcinoma.

Treatment

Treatment of epidermal nevi with electrodesiccation and curettage is often unsuccessful and may cause scarring. Surgical or laser removal may be indicated for localized lesions. Disturbances involving other organ systems must be evaluated and managed appropriately through a multidisciplinary approach.

Tumors of the Epidermal Appendages

There are a large number of benign tumors of the hair follicles, the sebaceous glands, and the apocrine and eccrine glands. Solitary skin tumors of these epidermal appendages are typically nonhereditary, whereas multiple neoplasms may show an autosomal dominant inheritance pattern.[6]

sebaceous hyperplasia

Sebaceous hyperplasia is a common clinical condition that appears as multiple skin-colored or yellowish, often umbilicated papules or plaques, usually on the forehead, nose, or cheeks of persons after the fifth decade of life. These lesions consist of enlarged sebaceous gland lobules with a central dilated duct. Sebaceous hyperplasia may respond to cryotherapy with liquid nitrogen or the application of a dilute solution of trichloroacetic or bichloroacetic acid. Lesions may sometimes be confused clinically with basal cell carcinoma [*see Figure 4*]. In the familial form of this disorder, onset occurs in puberty; with the passage of time, the lesions increase in extent over the face, neck, and upper thorax. This condition must be distinguished from acne vulgaris, rosacea, and the angiofibromas of tuberous sclerosis. Three patients with this condition responded favorably to oral isotretinoin at a dosage of 1 mg/kg/day. To maintain the response, this dosage was tapered after 6 weeks.[7] Isotretinoin is a known teratogen that cannot be given to women of childbearing age unless strict precautions are observed [*see 2:XII Acne Vulgaris and Related Disorders*].

trichoepitheliomas

Trichoepitheliomas usually present as multiple yellowish-pink, translucent papules distributed symmetrically on the cheeks, eyelids, and nasolabial areas [*see Figure 5*]. Often inherited as an autosomal dominant trait, the papules first appear at puberty and grow slowly for years. The gene for multiple familial trichoepitheliomas has been mapped to chromosome 9p21.[8] Lesions may be confused both clinically and histologically with basal cell carcinoma, though trichoepithelioma usually shows differentiation toward the formation of hair. A single or localized trichoepithelioma may be removed by electrodesiccation and curettage. Multiple lesions are difficult to treat and may be a cosmetic problem.

Figure 5 **Symmetrical papules of trichoepithelioma appear on the eyelids and nasolabial areas and may be inherited as an autosomal dominant trait.**

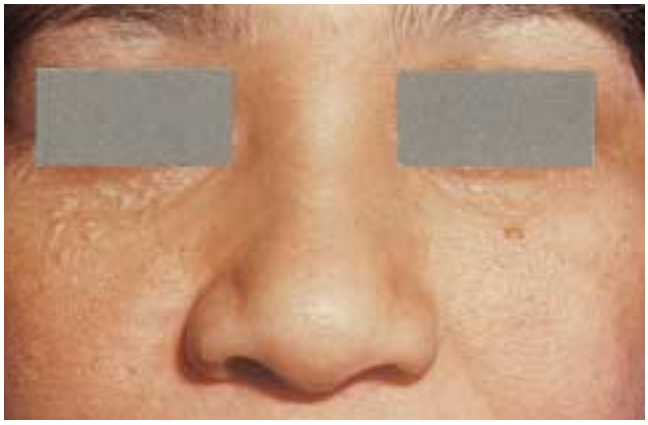

Figure 6 **Syringomas—benign tumors of eccrine ducts—are commonly seen on the face, especially on the lower eyelids.**

syringomas

Syringomas usually present in groups of multiple small papules that are distributed symmetrically over the face, especially on the lower eyelids [*see Figure 6*]. Eruptive syringoma, a rare condition, is characterized by widespread lesions.

Histologically, there is a benign proliferation of the eccrine ducts.

epidermoid cyst

Diagnosis

Commonly called wens, epidermoid cysts have a lining that resembles the epidermis. Several types of cyst exist, but they are usually clinically indistinguishable from one another. On histologic examination, most of these cysts appear to be derived from hair follicles.

The epidermoid cyst is commonly located on the back and consists of one or more slow-growing, elevated, firm nodules, often with a central pore [*see Figure 7*]. The diameters of the lesions vary from 0.2 to 5.0 cm.

Treatment

The epidermoid cyst may be incised with a pointed scalpel to express its wall and contents, which consist of a thick keratinous material. If the cyst wall is not completely removed, there may be a recurrence of the lesion. Occasionally, the entire cyst has to be excised. Preliminary treatment with a systemic antibiotic, such as erythromycin, and warm-water compresses applied three or four times daily may be instituted if the cyst is inflamed and infected. When the inflammation and infection resolve, the lesion can be removed. Repeated episodes of infection may cause fibrosis, after which the cyst may have to be surgically excised.

Other Cysts

The pilar cyst, which is less common, has a wall that contains keratin similar to that found in hair. The contents of these cysts are semifluid and often have a rancid odor.

A milium is similar to an epidermoid cyst but differs mainly in size. Milia are white, hard subepidermal keratin cysts, 1 to 2 mm in diameter, that commonly arise spontaneously on the face [*see Figure 8*]. They may also arise secondarily in scars or in association with certain bullous diseases. Incision and expression of contents with a comedo extractor may be performed.

Familial Tumor Syndromes

Multiple cutaneous neoplasms may be a feature of familial tumor syndromes that are thought to be mediated by inactiva-

Figure 7 **This large epidermoid cyst has a central pore, contains thick keratinous material, and has a lining that resembles the epidermis.**

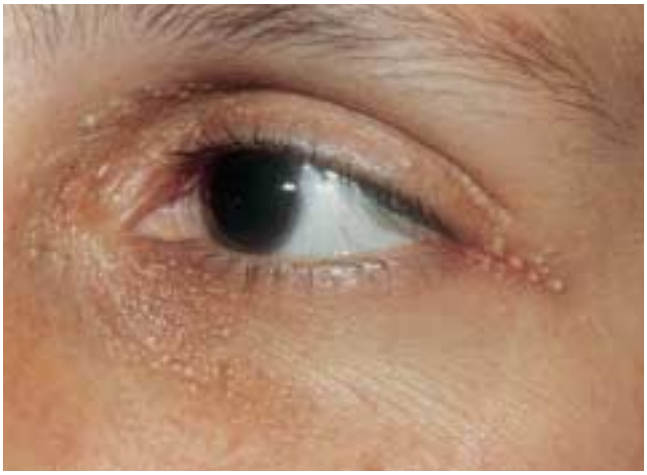

Figure 8 **Milia, which are multiple small subepidermal inclusion cysts, can be observed in the periorbital area of this patient.**

tion of tumor suppressor genes. It is important to recognize these syndromes because they may be associated with underlying malignancies.

muir-torre syndrome

Muir-Torre syndrome (MTS), previously known as Torre syndrome, consists of sebaceous gland neoplasms that are associated with visceral carcinoma and that arise from colonic epithelium. Sebaceous gland tumors may include, in decreasing order of frequency, adenomas, epitheliomas, and carcinomas.[9] Keratoacanthomas and sebaceous hyperplasia are also seen in patients with MTS. Colorectal cancer develops in 51% of patients with MTS a decade earlier than it develops in the general population. Genitourinary cancer develops in 24% of MTS patients. A germline mutation in the DNA mismatch repair gene *hMSH2* has been identified in patients with MTS. Predictive diagnosis in family members should be preceded by careful genetic counseling.[9]

gardner syndrome

Gardner syndrome consists of the triad of intestinal polyposis, bony tumors, and soft tissue lesions; it has an autosomal dominant inheritance. The colonic polyps eventually become malignant if left untreated. Soft tissue lesions include epidermoid cysts, sebaceous cysts, desmoid tumors, and scattered lentigines on the head and extremities.[10]

cowden syndrome

Cowden syndrome is characterized by facial trichilemmomas and acral fibromas, and it is associated with an increased risk of cancer of the breast, thyroid, and gastrointestinal tract. This rare genodermatosis, which is also known as multiple hamartoma syndrome, is inherited as an autosomal dominant trait. It is important to make a prompt diagnosis of this syndrome because of the high risk of malignancy, particularly cancer of the breast in women.

birt-hogg-dubé syndrome

Birt-Hogg-Dubé syndrome (BHDS) is an autosomal dominant multisystem disorder characterized by the cutaneous triad of fibrofolliculomas, trichodiscomas, and acrochordons. Fibrofolliculomas are benign tumors of the hair follicle. Fibrofolliculomas are firm, pink or skin-colored papules measuring 1 to 3 mm that appear on the face, particularly the nose, earlobes, and forehead. In the original kindred described by Birt (a dermatologist), Hogg (a pathologist), and Dubé (a pathologist), family members were afflicted with medullary carcinoma of the thyroid. Subsequently, there appeared reports of patients with BHDS who had intestinal polyps, adenocarcinoma of the colon, parathyroid adenomas, and renal cell carcinoma. The skin tumors begin in early adulthood; systemic tumors appear years later. In families with recognized renal cell carcinoma, BHDS may account for 6% of the cases.[11,12]

Melanocytic (Pigment-Forming) Tumors

Benign tumors of pigment-forming cells, including those containing nevus cells (melanocytic nevi) and those of epidermal or dermal melanocytes, are of neuroectodermal origin.

melanocytic nevus

Melanocytic nevus, also called nevus cell nevus, has a characteristic life history of evolution and involution. Melanocytic nevi are the most common of all skin tumors; each young adult has an average of 20 to 40 of them. Their incidence increases with age up to the second or third decade of life, after which they occur less commonly.

Risk Factors for Melanoma

An increase in the total number of melanocytic nevi is a risk factor for melanoma.[13] In a study of 716 patients with newly diagnosed melanoma, an increased number of small nevi (25 to 49) was associated with a twofold increase in risk of melanoma; greater numbers of nevi were associated with further increased risk.[14] The presence of one clinically dysplastic nevus was associated with a twofold increase in risk of melanoma; and 10 or more, with a 12-fold increase in risk. Criteria for dysplastic nevi included large size (over 5 mm), flatness (entirely macular or having a macular component), and at least two of the following: irregular pigmentation, asymmetry, and indistinct borders [*see 2:X Malignant Cutaneous Tumors*]. The presence of freckling conferred additional risk of melanoma for all types of nevi.

The relation between sun exposure and melanocytic nevi has been investigated to determine what environmental factors influence melanoma and to facilitate preventive measures. Studies suggest that melanocytic nevi are more common on sun-exposed skin sites and reach a peak incidence earlier in age on these sites than on covered areas of the body.[15] A study of Australian schoolchildren showed an increasing prevalence of nevi with decreasing latitude, particularly in children 6 and 9 years of age.[16] Sun exposure during childhood was considered to be a factor in the development of melanocytic nevi and an associated risk factor for melanoma.[16] In Australia, however, sun exposure may be sufficient to maximally induce nevi regardless of latitude. Further studies need to be performed on persons living at higher latitudes to see whether the relation between sun exposure and nevi continues into adulthood.

Diagnosis

A melanocytic nevus that is present at birth or appears during the first year of life is considered to be congenital. Certain syndromes are associated with congenital nevi, including epidermal (linear sebaceous) nevus syndrome, neurocutaneous melanosis, premature-aging syndrome, and occult spinal dysraphism or tethered cord syndrome.[17] Various neuroectodermal defects and multisystem abnormalities may also be present. Giant congenital melanocytic nevi are associated with an increased risk of melanoma (see below).

Acquired melanocytic nevi vary considerably in form, ranging from flat to pedunculate. They may be hairy or hairless and may be skin colored, dark brown, or even black. Nevi that are flat and darkly pigmented are called junctional nevi. Slightly raised nevi are often compound; that is, they contain both epidermal and dermal components. Nevi that are predominantly intradermal are usually more elevated and contain less pigment than compound or junctional nevi. Nevi that are papillomatous, dome shaped, or pedunculate are usually intradermal [*see Figures 9 through 11*].

Differential Diagnosis

The differential diagnosis of melanocytic nevi includes ephelis (freckle), lentigo, café au lait spot (see below), wart, seborrheic keratosis, and skin tag (a small pedunculate protrusion of skin that does not contain nevus cells). Ephelis is a tan macule, commonly seen in children after sun exposure; it often dis-

Figure 9 **A flat junctional nevus with dark pigmentation is seen in this patient.**

Figure 10 **This slightly raised compound nevus typically has less pigmentation than a junctional nevus.**

Figure 11 **A skin-colored intradermal nevus with a dome-shaped configuration is seen on the face.**

appears in the winter. Lentigo, also called senile lentigo or liver spot, is a tan or brown macule commonly seen on exposed skin areas, such as the face, the backs of the hands, and the neck. The labial melanotic macule is a distinct entity that appears in adults as a well-defined brown or black pigmented macule on the lip. In a study of 79 patients, the majority of melanocytic lesions (94%) were on the central third of the lower lip, suggesting that exposure to ultraviolet light has a causative role.[18] Patients followed for up to 13 years had no adverse developments, a finding indicative of the benign nature of this lesion.

Treatment

No treatment is required for melanocytic nevi. However, shave biopsy or excisional biopsy may be performed for cosmetic reasons or when a nevus is subject to irritation because of pressure from clothing or because it is located in an intertriginous area. Patients should be followed with serial photographs. Biopsy should be performed for nevi that appear prone to malignant transformation; nevi that show severe dysplasia should be removed. Removal of mildly or moderately dysplastic nevi is advocated by some but not all experts [*see 2:XI Malignant Cutaneous Tumors*].

café au lait spots

Café au lait spots are common benign congenital or acquired birthmarks. They are tan, round to oval macules ranging in size from several millimeters to 10 to 20 cm. They can occur on any area of the body but are more common on the trunk, buttocks, and lower extremities. The presence in a prepubertal child of five or more café au lait spots larger than 0.5 cm may be a marker for neurofibromatosis-1 (NF-1) (see below).[19] Histologically, café au lait spots show an increased number of dihydroxyphenylalanine (DOPA)-positive melanocytes that produce an increased concentration of melanosomes. The café au lait spots seen in Albright hereditary osteodystrophy are usually unilateral and show jagged rather than smooth margins. An association of juvenile xanthogranulomas with café au lait macules carries an increased risk of underlying systemic disorders, including leukemia.[20]

halo nevus

A halo nevus consists of an acquired zone of hypopigmentation surrounding a pigmented tumor, most commonly a compound nevus [*see Figure 12*]; other tumors, even malignant melanoma, may also be surrounded by a depigmented halo. The halo lesion typically involutes during a period of months in the absence of clinical signs of inflammation. Histologically, a chronic lymphocytic infiltrate surrounds the nevus cells, which may represent an autoimmune phenomenon.

spindle cell nevus

Formerly called benign juvenile melanoma, spindle cell nevus usually arises in childhood as a pink or reddish-brown, smooth or slightly scaly, firm papule with a predilection for the face, especially the cheeks [*see Figure 13*].[21] Although benign, spindle cell nevus may closely resemble a malignant melanoma. Excisional biopsy is therefore advisable in many cases.

mongolian spot

The mongolian spot is a bluish macule that is seen in newborns of dark-skinned races. The discoloration is caused by persistence of dermal melanocytes, often in the lumbosacral region [*see Figure 14*]. The lesion usually disappears by 3 or 4 years of age.

blue nevus

The common blue nevus occurs as a solitary, sharply circumscribed, blue-black papule [*see Figure 15*]. This malformation consists of a group of melanocytes with long, thin surface projections in the middle and lower thirds of the dermis and

Figure 12 **The halo nevus may represent an autoimmune phenomenon; a zone of hypopigmentation may appear around a nevus, with subsequent involution of the pigmented tumor.**

Figure 13 **The spindle cell nevus is an active compound nevus that may be difficult to distinguish histologically from a melanoma.**

Figure 14 **The bluish pigmentation of a mongolian spot is seen in the lumbosacral area and is caused by the persistence of dermal melanocytes.**

in subcutaneous fat. The common blue nevus does not show a tendency toward malignant transformation. The cellular blue nevus, which appears as a blue-black nodule or an indurated plaque, contains two types of cells: spindle shaped and rounded. The cellular blue nevus may in rare instances become malignant.

nevus of ota

The nevus of Ota occurs in infancy or appears in adolescence as a blue-gray macule in the distribution of the trigeminal nerve. The lesion is unilateral in 90% of cases. Asian females are most commonly affected. Histologically, a benign dendritic melanocytosis is present in the papillary and upper reticular dermis. High-energy fluences of the Q-switched ruby laser results in lightening of the lesion, without scarring, after a few treatments.[22]

becker nevus

A malformation of epidermal melanocytes, Becker nevus occurs as a large area of hyperpigmentation and increased hair growth and is usually located on one shoulder. It appears most commonly in males during adolescence [*see Figure 16*]. Underlying bony and soft tissue abnormalities may be associated with this disorder.[23]

Light microscopy reveals hyperpigmentation of the basal layer of the epidermis, with melanin-containing phagocytes in the dermis but no nevus cells.

congenital giant pigmented nevus

Giant pigmented nevus is an uncommon birthmark appearing sporadically in one in 20,000 live births. Its features are different from those of an ordinary acquired nevus. Lesions are often darkly pigmented, hairy, and slightly infiltrated, eventually becoming verrucous or nodular. They tend to occur in the distribution of a dermatome and may be quite extensive, as in bathing trunk nevus [*see Figure 17*]. Satellite lesions may be present. The condition not only is of cosmetic concern but also has a high association with malignant melanoma, with a reported 10% to 15% of nevus patients developing melanoma. Histologic features of an ordinary compound nevus, an intradermal nevus, a neural nevus, or a blue nevus may be present.[1] Treatment consists of multiple operations to excise as much of the lesion as possible.

neurocutaneous melanosis

Lesions on the scalp and neck may be associated with neurocutaneous melanosis of the leptomeninges that can be complicated by epilepsy, mental retardation, or central nervous system melanoma. Large congenital melanocytic nevi (LCMN) carry a poor prognosis in the presence of CNS signs or symptoms such as abnormal reflexes, hydrocephalus, and papilledema. Posterior axial LCMN, especially in association with satellite nevi, is a risk factor for CNS melanosis. Magnetic resonance imaging should be considered in the evaluation of newborns with these findings. In one study, CNS involvement occurred in 33 of 289 patients with LCMN. All the patients with CNS involvement had nevi in the posterior axial location. Satellite nevi were present in 31 of the 33 patients.[24] These findings suggest that melanocytic malformation occurs during the migration of neural crest cells that give rise to cutaneous leptomeningeal melanocytes. Malformation resulting in LCMN on the extremities occurs after migration from the neural crest and is not associated with CNS melanosis.

Neural Tumors

Neural tumors, such as neurofibromas, are of neuroectodermal origin, as are melanocytic tumors. Neurilemmomas (also called schwannomas) are benign nerve sheath tumors that extend subcutaneously adjacent to a peripheral nerve. They usually occur in solitary form but may occur as multiple lesions in the

Figure 15 **The presence of melanocytes in the middle and lower dermis is responsible for the color of the blue nevus.**

Figure 16 **Becker nevus, an acquired localized malformation of epidermal melanocytes that may be associated with hypertrichosis, is seen on the shoulder.**

syndrome of neurilemmomatosis.[25] These tumors are usually painful and may be associated with nerve compression. Other benign tumors that must be considered in the differential diagnosis of painful skin nodules are neuromas, angiolipomas and angiomyolipomas, leiomyomas, eccrine spiradenomas, glomus tumors, and the blue rubber bleb nevus.

neurofibromatosis

Neurofibromatosis represents a spectrum of disorders involving the skin, central and peripheral nervous systems, bones, and blood vessels. This neurocutaneous syndrome is transmitted via an autosomal dominant gene at an estimated frequency of one in 3,000 persons with almost complete penetrance.[26]

Diagnosis and Classification

Two distinct forms of neurofibromatosis are recognized, but variant forms also exist.

Neurofibromatosis-1 The most common form (occurring in 85% to 90% of all cases) is NF-1, or von Recklinghausen disease [*see Figure 18*]. This is a common autosomal disorder, with an incidence of one in 3,500 persons. It is characterized by the presence of café au lait spots, intertriginous freckling, multiple spinal and peripheral neurofibromas, plexiform neuromas, bilateral iris hamartomas (also known as Lisch nodules), neurologic impair-

Figure 17 **This form of congenital giant pigmented hairy nevus is associated with an increased risk of malignant melanoma, which develops within the lesion.**

Figure 18 **Multiple neurofibromas, as seen in von Recklinghausen disease, usually appear in late childhood and increase in size and number with age.**

ment, and bone abnormalities. The disease is progressive and is associated with a predisposition to a malignant state.

Sarcomatous degeneration of skin lesions is rare but may occur in extracutaneous tumors. Café au lait spots of NF-1 may be present at birth and may be best visualized under a Wood light. Neurofibromas begin to appear at puberty as soft, globoid, and pedunculated tumors that are skin colored or violaceous. Lesions may be large and numerous, causing complications resulting from impingement on surrounding structures.

Neurofibromatosis-2 A second form of the disease, neurofibromatosis-2 (NF-2), is characterized by bilateral acoustic neuromas, which are Schwann cell tumors that arise from vestibular nerves.[27] Associated features may include meningiomas, gliomas, paraspinal neurofibromas, and subcapsular cataracts. Skin tumors and café au lait spots are less commonly seen in NF-2 than in NF-1.

Variants Other forms of neurofibromatosis include segmental cases in which café au lait spots or neurofibromas are localized to a single dermatome. The gene for NF-2 is located on chromosome 22. In this autosomal dominant disorder, the *merlin* tumor suppressor gene encoded in chromosome band 22q12 is inactivated. This results in an alteration in DNA with substitution of tyrosine for asparagine at position 220 of the merlin cytoskeletal associated protein.[28]

Genetic Counseling

Patients with either NF-1 or NF-2 should seek genetic counseling because there is a 50% risk that their offspring will also be affected with neurofibromatosis. In NF-1, optic glioma can appear in early childhood; patients with NF-1 may also have scoliosis. In NF-2, bilateral acoustic neuromas can cause deafness. The genes for the two distinct forms of neurofibromatosis have been located on two separate chromosomes. This finding may lead to improved diagnosis, which would facilitate genetic counseling and enable prenatal testing.[27]

Treatment

For treatment of selected neurofibromas, surgical excision is more successful than scalpel removal or electrodesiccation and curettage. In a preliminary study, the use of ketotifen, a benzocycloheptathiophene compound that acts as a mast cell stabilizer, was evaluated in the treatment of patients with neurofibromatosis.[29] All treated patients showed a decrease in symptoms of pruritus, pain, or skin tenderness and experienced a decreased rate of neurofibroma growth. Long-term double-blind studies are required, however, to confirm and extend these preliminary findings.

The bilateral acoustic neuromas of NF-2 may be visualized by computed tomography or MRI. Hearing loss is an early symptom that may begin in the second or third decade of life; it can be detected by an audiologic study with brain stem auditory-evoked response. Unilateral acoustic neuromas that are not associated with neurofibromatosis and that are not inherited are more common in older persons and pose fewer management problems.[27] Surgical removal of small acoustic neuromas may improve neurologic or audiologic status.

Connective Tissue Tumors

Fibroma of the skin comprises multiple conditions that may represent reactions to hemorrhage, infection, or chronic irritation.

skin tag

Skin tag, also called acrochordon, commonly occurs as multiple skin-colored or tan, filiform or smooth-surfaced papules that are 2 to 3 mm in diameter. Lesions are often located on the neck or axillae but may also appear in the groin or on the extremities, often as isolated larger polypoid growths [*see Figure 19*]. The fibrous stalk consists of loose connective tissue with dilated capillaries. Lesions may become inflamed if they are irritated or are traumatized from twisting of the stalk. Biopsy is performed if the clinical diagnosis is uncertain. Skin tags may be removed for cosmetic reasons by using scissors to clip the pedunculate lesions at the base.

dermatofibroma

Dermatofibroma, also called histiocytoma, is a firm, skin-colored or reddish-brown sessile papule or nodule that arises spontaneously or after minor trauma, usually in adults [*see Figure 20*]. A dermatofibromatous lesion may occur, for example, after an insect bite on an extremity. A solitary lesion is most common, though multiple or eruptive histiocytomas have been reported. It may be necessary to perform a biopsy when the diagnosis is uncertain. Treatment is necessary only for cosmetic reasons.

keloid and hypertrophic scar

Normal wound healing in response to tissue injury involves several integrated processes: inflammation, production of granulation tissue, formation of the extracellular matrix, wound con-

Figure 19 **Skin tags, also called acrochordons or soft fibromas, are skin-colored or tan papules. They are commonly seen in such intertriginous areas as the groin or axillae.**

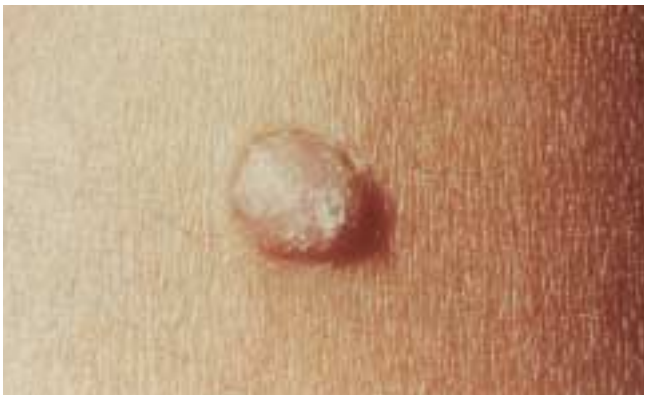

Figure 20 **Dermatofibroma appears as a firm skin-colored or reddish-brown papule and may arise spontaneously or follow minor trauma to the skin.**

traction, and, finally, scar formation. In the final phases of wound healing, fibroblasts degrade and produce bundles of collagen fibers. These bundles become thicker and are aligned along the lines of tension to which the tissues are exposed. As a result of these changes, wound tensile strength gradually increases. The resulting scar is relatively acellular and has fewer macrophages, blood vessels, and fibroblasts than the unwounded tissue.

Diagnosis and Classification

Scars may be normotrophic, atrophic, hypertrophic, or keloidal. Both hypertrophic and keloidal scars are abnormal responses to tissue injury. Hypertrophic scars mature and flatten over time, usually after 6 months. The keloid appears as a shiny, smooth, raised proliferation of scar tissue with typical crablike extensions beyond the site of the original injury [*see Figure 21*]. Keloids differ from hypertrophic scars in that their development is delayed, sometimes occurring months after tissue injury. Keloids do not regress, and they frequently cause pain, itching, and burning. Keloids are more common in African Americans, Hispanics, and persons with a personal or family history of keloids. Other factors associated with the development of keloids include wound tension, especially in skin sites such as the chest, shoulders, and back; ear piercing; healing by second intention; pregnancy; young age; and deep laceration.[30]

In atrophic scars, there is thinning of the skin and loss of normal architecture. Striae distensae, a so-called stretch mark, is a common dermal atrophic scar that tends to appear during periods of rapid weight gain and in the presence of excess glucocorticoid, as well as late in gestation.

Treatment

Treatment with intralesional steroids, 10 to 40 mg / ml once a month for up to 6 months, can effectively flatten keloid and hypertrophic scars. Cryotherapy (a 30-second application once a month for 3 months) has been found to be safe and effective.[31] Topical silicone gel sheeting, which was first used for burn scars, has been used in the treatment of keloids and hypertrophic scars.[32] There is no release of silicone into the skin, and there are no adverse side effects from this treatment. The mechanism of action is unknown. Potential side effects of intralesional corticosteroid treatment include atrophy, depigmentation, telangiectasia, and ulceration and dose-related systemic effects.

Vascular Birthmarks

Vascular proliferations are broadly classified as hyperplasias that show a tendency to regress or as benign vascular tumors that persist.[33,34] Vascular hyperplasias include pyogenic granuloma and pseudo-Kaposi sarcoma. Vascular hemangiomas can be further subdivided according to their histologic cell of origin (endothelial cell, pericyte, glomus cell), depth of tissue involvement (superficial or deep), and size of involved vessels (capillaries, venules, arterioles, veins, or arteries). Vascular birthmarks such as nevus flammeus and salmon patch may resemble angiomas but are nonproliferative malformations that usually do not involute.

epidemiology

Hemangiomas (see below) occur in a female-to-male ratio of 5:1, whereas vascular malformations occur with equal frequency in males and females. A rare familial occurrence of hemangiomas, vascular malformations, or both has been reported in six kindreds, suggesting autosomal dominant inheritance in these cases.[35]

Figure 21 **The proliferation of scar tissue in a keloid may extend beyond the original site of injury.**

Vascular malformations are congenital developmental defects that are generally of unknown etiology. Port-wine stains may result from progressive ectasia of the superficial vascular plexus in the skin as a result of abnormal neural regulation of blood flow.[36] In the Klippel-Trénaunay-Weber syndrome, a mesodermal abnormality affecting differentiation of the limb bud may occur during the third to sixth week of gestation.[37]

pathogenesis

The etiopathogenesis of hemangiomas and vascular malformations is not well understood. Hemangiomas arise in response to an angiogenic stimulus that may begin in utero. Through use of immunohistochemical techniques, infantile hemangiomas and placental microvessels were found to coexpress the vascular antigens GLUT-1 and Lewis Y antigen (LeY).[38] These antigens are not present in other vascular tumors, such as pyogenic granulomas, or in vascular malformations. A pathogenic link involving aberrant differentiation of vascular precursor cells or embolization of placental cells to fetal tissue has been hypothesized.[38] These antigens are also absent in congenital nonprogressive hemangioma, a distinctive hemangioma consisting of lesions that are fully formed at birth and that either remain static or rapidly involute.[39]

overview of management

Evaluation and management of hemangiomas and malformations require a multidisciplinary approach. Specific diagnosis may be aided by imaging techniques such as CT and MRI to assess depth of involvement and extension to adjacent structures and to evaluate associated abnormalities. Laboratory evaluation for associated systemic disease may be required in addition to ophthalmologic, neurologic, and cardiologic assessment for complications of vascular tumors and dysmorphic syndromes.

hemangiomas

Hemangiomas are proliferating vascular tumors that are not necessarily present at birth. The vascular lesion may appear in neonates as a faint pink patch that subsequently undergoes rapid proliferation over a period of months to years before the lesion stabilizes and regresses.

Figure 22 **The strawberry, or capillary, hemangioma appears between the second and fifth weeks of life and undergoes spontaneous involution over a period of several years.**

Figure 23 **A nevus flammeus is present at birth as a reddish or violaceous macular discoloration, often in a unilateral and segmental distribution; it shows little tendency to involute later in life.**

The biologic classification of hemangiomas is very different from that of vascular malformations. Vascular tumors can be classified according to their cell or origin, the size of the involved vessels, and the depth of involvement. Such classifications have led to refinement in terminology.[40] The terms strawberry hemangioma and cavernous hemangioma are descriptive clinical terms that do not specify the type of vessels that are involved.

Diagnosis and Classification

Capillary hemangioma, also known as strawberry hemangioma, appears as a single vascular lesion or multiple lesions during the second to the fifth week of life. Infantile hemangiomas are bright-red, soft, lobulated tumors that increase in size for a period of months [*see Figure 22*]. Lesions spontaneously involute, sometimes with fibrosis, over a period of several years.[33] Histologically, the capillary hemangioma shows a proliferation of endothelial cells that form many new small vessels.

Treatment

It is important to realize that most hemangiomas are uncomplicated and regress without treatment early in life with minimal residual scarring. Follow-up studies have shown that in 90% of patients, hemangiomas regress by 9 years of age.[41] Parents may require considerable reassurance that the best course is to refrain from treatment. Care must be taken to prevent trauma and infection, which may lead to scarring.

There is considerable controversy as to when to intervene in the treatment of complicated hemangiomas because of potential side effects, such as scarring. The ideal time to treat would be at the beginning of the period of rapid growth, but this is difficult to predict. Indications for treatment include involvement of a vital orifice, infection, ulceration, ocular involvement, and severe cosmetic deformity. Medical options include intralesional or systemic steroids, the latter at a dose of 1 to 3 mg/kg/day. Antimetabolites have been used for their antiproliferative effect. Interferon alfa has been used for severe hemangiomatosis, but its use is associated with systemic side effects and the potential risk of spastic diplegia. Laser surgery with 585 nm pulsed dye laser may be used to treat the superficial proliferative component.[41] Radiation therapy may lead to scarring and is discouraged in children because of long-term radiation effects, including risk of malignancy. Interventional techniques involving embolization of vessels may be required in cases involving airway obstruction or other life-threatening complications. A multidisciplinary team approach involving the dermatologist, pediatrician, radiologist, surgeon, and other specialists is needed for optimal management of complicated cases.[42]

vascular malformations

Vascular malformations are usually present at birth. They are permanent or progress in the form of ectasias but do not proliferate. Vascular malformations may be subdivided into the following groups: venous, lymphatic, combined arteriovenous, and capillary (such as port-wine stain).[43] Dysmorphic syndromes such as Sturge-Weber and Klippel-Trénaunay-Weber syndromes are more commonly associated with vascular malformations than with hemangiomas.

Diagnosis and Classification

Salmon patch The salmon patch, one of the most common vascular birthmarks, is a dull-pink macule that appears on the nape of the neck, central forehead, or eyelids. Although the salmon patch is sometimes classified as a nevus flammeus, it is distinguished from the latter by its tendency to fade in early life. The salmon patch is caused by the persistence of fetal capillary ectasia in the dermis.[33]

Port-wine stain Port-wine stain, also called nevus flammeus, appears at birth as a reddish or violaceous macular discoloration, usually in a unilateral, segmental distribution [*see Figure 23*]. Mature dilated capillaries are present in the dermis. After puberty, nevus flammeus lesions may become thickened and nodular or papular. There is little tendency toward involution. Nevus flammeus lesions may be associated with abnormalities of the larger vessels and with neurologic manifestations.

Sturge-Weber syndrome A facial port-wine stain that involves the skin innervated by the first branch of the trigeminal nerve is a feature of the Sturge-Weber syndrome (also known as encephalotrigeminal angiomatosis). Other features of the Sturge-

Figure 24 **A spider angioma, which has a central arteriole from which fine vessels radiate, blanches with pressure.**

Weber syndrome include ipsilateral congenital glaucoma and contralateral seizures caused by leptomeningeal angiomatosis. Ophthalmologic and neurologic evaluation may be warranted in patients with the Sturge-Weber syndrome.

Klippel-Trénaunay-Weber syndrome The triad of findings seen in Klippel-Trénaunay-Weber syndrome includes a port-wine stain, usually in a patchy distribution on the involved extremity; varicose veins; and soft tissue or bony hypertrophy. The most common site of involvement is the lower leg; the next most common sites of involvement are the arms and trunk.[37]

Venous malformation Formerly referred to as cavernous hemangiomas, vascular malformation consists of a collection of abnormal veins and venous pouches that commonly occur around the head and neck but can occur anywhere on the body. They are frequently multiple or have satellite lesions. Superficially, they appear as a subcutaneous swelling with a bluish hue on the skin surface or mucous membrane. Deeper components may be invisible on clinical examination. Lesions enlarge for several months, become stationary for an indefinite period, and spontaneously resolve.

Treatment

Because vascular malformations do not proliferate, treatment may be cosmetic and can be postponed to later in life. However, a multidisciplinary approach is needed to treat potential complications of vascular malformations associated with dysmorphic syndromes. Salmon patch tends to fade in early life and usually requires no treatment.

Treatment of port-wine stains by excision, tattooing, ionizing radiation, cryosurgery, or dermabrasion is largely unsatisfactory. Use of the argon laser has resulted in lightening of vascular lesions; however, there is wide variability in response. The effectiveness of this treatment results from the selective absorption of the monochromatic 585 nm laser light by red hemoglobin pigment, which produces thermal energy with resultant photocoagulation of tissue.[44] Thinner lesions are more responsive than thicker lesions that have undergone progressive vascular ectasia. In a study of 100 patients of different age groups who had port-wine stains of the head and neck and who were treated with a flashlamp pulsed dye laser, treatment was no more effective when given in early childhood than when given at a later date.[45]

Acquired Vascular Disorders

diagnosis and classification

Spider Angioma

Spider angioma, also called spider nevus or arterial spider, appears as a central red punctum from which fine vessels radiate; the appearance of the lesion is suggestive of a red spider [*see Figure 24*]. The central arteriole may be pulsatile. These telangiectasias (dilated capillaries) are commonly seen on the face, neck, trunk, and upper extremities and occur most commonly in middle-aged or elderly persons. They may arise spontaneously or in association with pregnancy or hepatic dysfunction. Spider angiomas may be treated with laser therapy for cosmetic reasons.

Unilateral Telangiectasia

Acquired unilateral telangiectatic nevi are uncommon, but those that have been reported resulted from mechanical or physical trauma, including sun damage.[46]

Cherry Angioma

Cherry angioma, also called senile angioma, appears as multiple bright-red, soft, dome-shaped papules on the trunk of middle-aged or older persons. Trauma produces slight bleeding. Electrodesiccation may be performed for cosmetic purposes.

Pyogenic Granuloma and Other Vascular Tumors

The pyogenic granuloma is a soft red lesion that is solitary, raised, and nonpulsatile; it often appears after minor skin trauma, such as a puncture wound. Other predisposing factors include hormonal effects, infection, viral oncogenes, microscopic arteriovenous anastomoses, and growth factors.[47] Epulis gravidarum is a variant of a pyogenic granuloma. The lesion was formerly believed to be caused by a pyogenic infection of a small wound; histologically, however, an early lesion resembles a capillary hemangioma. The thin, sometimes verrucous epidermis is friable and apt to become eroded or ulcerated. Lesions rapidly reach a size of 1 to 2 cm and then remain static. Common sites of involvement are the fingers, feet, and face [*see Figure 25*]. Biopsy is performed to rule out malignant tumors, such as Kaposi sarcoma and amelanotic melanoma.

Other benign tumors with a vascular component include angiofibroma, angioleiomyoma, and angiolipoma. Some of these can be painful. Differential diagnosis of painful skin tumors includes glomus tumor, angiolipoma, angioleiomyoma, neuromas, and eccrine spiradenoma.[34] Lesions are usually easily removed by electrodesiccation and curettage. If they recur or if satellite lesions appear after such treatment, excisional biopsy is recommended.

Kimura Disease

Kimura disease and angiolymphoid hyperplasia with eosinophilia are rare tumors of unknown cause that occur mainly on the head and neck in young adults and may resemble pyogenic granuloma.[48] Kimura disease, which was first reported in Korea, is most common in Asians. It appears as a granulomatous proliferation of lymphoid tissue that may be accompanied by peripheral eosinophilia and contiguous lymphadenopathy. Lesions may occasionally be seen on the trunk, extremities, and genitalia in addition to the head and neck. Angiolymphoid hy-

Figure 25 **The pyogenic granuloma, which may show a smooth, verrucous, eroded, or friable surface, may be confused with a malignant tumor.**

Figure 26 **Leiomyomas are sometimes painful papules that arise from smooth muscle of blood vessels or the arrector pili.**

perplasia with eosinophilia, which may or may not represent a different disease, appears as localized single or multiple nodules. Infectious, allergic, hormonal, and traumatic mechanisms have been postulated. Immunodermatopathologic studies suggest an unusual distribution of adhesion molecules, IgE, and CD23 in these angioproliferating tumors.[49]

Lipoma

The lipoma, which is a soft, rounded to lobulated subcutaneous tumor of mature fat cells, is commonly seen on the trunk, neck, or forearms. Lesions are rubbery in consistency and freely movable under the overlying skin, which appears normal. There may be a single lesion or multiple lesions, and they are usually asymptomatic unless they impinge on a nerve. Lipomas are of variable size and grow slowly. Histologically, the tumors are usually encapsulated and show fat cells that are indistinguishable from normal adipose tissue. Admixture of other tissue components may result in fibrolipomas (fibrous tissue), angiolipomas (blood vessels), and myolipomas (smooth muscle). Excision may be performed for cosmetic reasons. If a lesion grows rapidly, biopsy should be performed, though lipomas rarely become malignant.

Leiomyoma

The leiomyoma is an uncommon tumor of smooth muscle that appears as a single brownish-red papule or as multiple papules or small nodules, which are sometimes painful [*see Figure 26*]. Leiomyomas may arise from the arrector pili (the smooth muscle attached to the hair follicle sheath) or from the smooth muscle surrounding cutaneous blood vessels (angioleiomyoma). Painful lesions can be excised.

Lymphangioma Circumscriptum

Lymphangioma circumscriptum is characterized by groups of persistent localized or diffuse translucent vesicles. Indications for treatment include severe cosmetic problems, persistent leakage of lymphatic fluid or blood, and recurrent infection. The vesicles frequently recur after surgery, radiotherapy, electrocautery, or cryosurgery because of the persistence of deep lymphatic cisterns. Carbon dioxide laser in a vaporization mode has been used to ablate superficial cutaneous lesions in patients with lymphangioma circumscriptum.[50] The major advantage of this technique is that it may reduce the frequency of recurrences because it seals the communicating channels to the deeper cisterns by vaporizing the superficial lymphatics.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XII ACNE VULGARIS AND RELATED DISORDERS

Mark Lebwohl, m.d.

Acne and its clinical variants are among the most common causes of patient visits to the physician for cutaneous disorders. Severe forms of these disorders can be disfiguring and debilitating; and because the face is the primary site of involvement, patients will often seek therapy for even mild forms. Therapeutic approaches will therefore be stressed in this chapter.

Epidemiology and Etiology

Acne vulgaris is the most common dermatologic problem of adolescent years; it usually begins in puberty. Age of onset and severity of disease are affected by sex, genetics, and external factors such as cosmetics and medications. Acne is usually more severe in males than in females and often begins earlier (i.e., in early adolescence) in males. Acne often subsides after the teenage years, but the disease can remain a problem for adults in the third and fourth decades and beyond. A significant portion of women experience premenstrual flares of acne; this phenomenon may be more common in older women.[1]

Genetic factors clearly play a role in severe acne. A family history of severe acne can often be elicited during the workup of affected patients. Various external factors, such as occlusive cosmetics, can contribute to acne, and certain medications (e.g., corticosteroids, adrenocorticotropic hormone [ACTH], phenytoin sodium, isoniazid, lithium, progestins, potassium iodide, bromides, and actinomycin D) can cause acnelike lesions [*see 2:VI Cutaneous Adverse Drug Reactions*].

Pathogenesis

Multiple factors contribute to the development of acne in susceptible persons. Among the most significant are alterations in keratinization, accumulation of sebum, and inflammation. Androgenic influences may contribute to some of these factors.

Modified keratinization of the follicular infundibulum leads to proliferation and increased cohesiveness of keratinocytes, which causes plugs to form. These plugs block follicular outlets, allowing cellular debris in sebum to form comedones (the noninflammatory lesions of acne that are the precursor lesions of inflammatory acne).

The composition of sebum does not appear to be altered in patients with acne; however, sebaceous glands are often larger and sebum production is often greater in persons affected with acne than in unaffected persons.[2] Sebum is comedogenic and inflammatory, which may account for its role in acne.[3] Inflammation in acne has also been attributed to the anaerobic diphtheroid *Propionibacterium acnes.* The presence of *P. acnes* correlates with the occurrence of acne in adolescents.[4] The microbe's role in inflammation has been attributed to lipases, proteases, and hyaluronidases, as well as to chemotactic factors. For example, *P. acnes* may activate Toll-like receptor 2 and thereby trigger inflammatory cytokine responses.[5]

Androgens play a role in the development of acne, as evidenced by increased levels of dehydroepiandrosterone sulfate (DHEAS) in girls with acne[6] and an association of acne with endocrinopathies characterized by increased levels of circulating androgens. For example, the occurrence of acne is increased in patients with congenital adrenal hyperplasia, polycystic ovaries, and some ovarian and adrenal tumors. Androgens act to increase sebum production and enlarge sebaceous glands; they may also contribute to the follicular hyperkeratinization that leads to acne. However, serum androgen levels are usually within the normal range in patients with acne. Some researchers have postulated that local production of androgens in the skin can lead to acne. Skin biopsies from patients with acne show increases in 5α-reductase activity.[7] This increased androgenic activity may result in the conversion of testosterone to dihydrotestosterone in the skin, leading to the development of acne.

Diagnosis

Clinical Features

The characteristic skin lesions of acne include open and closed comedones, erythematous papules, pustules, nodules, cysts, and scars. The most commonly affected site is the face, but in more severely affected individuals, the back and chest can be involved as well.

Comedonal Acne

Comedones consist of keratinized cells and sebum. Comedonal acne consists of a predominance of open and closed comedones. Open comedones (blackheads) are black papules measuring 0.1 to 2 mm that are easily extruded with gentle pressure. The material that is removed is greasy and has a gray-white color. Contrary to popular belief, the dark color of open comedones is caused by melanin, not by dirt or oxidized fatty acids. Closed comedones (whiteheads) consist of white papules measuring 0.1 to 2 mm; unless extracted, they persist somewhat longer than open comedones, often for weeks to months.

Inflammatory Acne

Erythematous papules, pustules, nodules, and cysts are the predominant lesions in inflammatory acne [*see Figure 1*]. Erythematous papules range in size from 3 to 10 mm and can develop into pustules or resolve into an erythematous macule that fades. Postinflammatory hyperpigmentation can occur. Pustules are superficial and usually dry in a few days. Nodules, which are 1 cm or larger, are erythematous and tender. They can be firm at onset but often become fluctuant. In severely affected individuals, these lesions form fluctuant sinuses that open to the surface through multiple tracts. Postinflammatory pigmentary changes and scarring commonly occur.

Clinical Variants of Acne

Acne conglobata Acne conglobata is a severe, scarring form of acne in which large cysts and abscesses become confluent to form draining sinus tracts. Scarring is often severe. Topical acne therapy and oral antibiotics are frequently ineffective; patients may require treatment with oral isotretinoin [*see* Treatment, *below*]. Intralesional injection of corticosteroids and drainage of abscesses are temporarily helpful.

Figure 1 **Inflammatory acne is characterized by erythematous papules and pustules.**

Acne cosmetica A persistent, low-grade form of acne can result from the use of greasy, occlusive cosmetics, moisturizers, and sunscreens. Women are most commonly affected.

Acne excoriée Picking of minor acne lesions can cause large ulcers and erosions that heal with scarring. Young women are most typically affected.

Acne mechanica An acneiform eruption can result from repeated trauma associated with the wearing of sports helmets, shoulder pads, and bras and from the chin rests of violins and violas (so-called fiddler's neck).

Pomade acne A form of acne results from the use of thick oils in the hair. Comedones, papules, and pustules are usually found close to the hairline. Black men and women are most commonly affected.

Acne in neonates and children Neonatal acne has been attributed to maternal androgens, as well as androgens secreted by the neonatal adrenal gland. Erythematous papules and pustules may last for 2 to 3 months after birth but usually resolve spontaneously.

Infantile acne develops between 3 and 6 months after birth. This condition is characterized by inflamed papules and pustules; it signals early secretion of androgens by the gonads, particularly in boys. This condition may last until age 5. It has been suggested that affected infants may be predisposed to severe acne later in life.

LABORATORY TESTS

The clinical features of acne are so commonly recognized that laboratory investigation is usually not necessary. Laboratory tests should be considered, however, for female patients who have other signs of hyperandrogenism, such as hirsutism or irregular menses. Serum for determining DHEAS and free testosterone levels and for determining the ratio of luteinizing hormone to follicle-stimulating hormone (LH:FSH) should be obtained 2 weeks before the onset of menses [*see Table 1*]. Tests should also be undertaken in patients whose conditions do not respond to adequate doses of isotretinoin, the most potent treatment available for acne [*see* Treatment, *below*].

Differential Diagnosis

Clinical features of acne are sufficiently distinctive that diagnosis is usually obvious. Nevertheless, a number of disorders can be mistaken for acne.

Folliculitis The perifollicular pustules of folliculitis can be distinguished from the lesions of acne by their distribution. Folliculitis can affect the trunk and extremities and is not limited to the usual sites of acne (i.e., the face, back, and chest). Malassezia folliculitis is characterized by erythematous acneiform papules that do not respond to typical acne therapies. Gram stain of pus from the lesions reveals gram-positive budding yeast [*see 2:VII Fungal, Bacterial, and Viral Infections of the Skin*].

Gram-negative folliculitis In patients on long-term antibiotics, superficial pustules or nodules can develop at the anterior nares and spread outward on the face. This condition responds promptly to oral ampicillin; however, isotretinoin has become the treatment of choice.[8]

Milia Milia are white pinpoint cysts that resemble closed comedones. They frequently occur around the eyes but can develop anywhere on the face. If untreated, they last for months or years. Milia can be opened with a small surgical blade and their contents easily drained.

Perioral dermatitis Long-term use of topical corticosteroids on the face can result in acneiform, erythematous, inflamed papules on the chin and cheeks. Despite the name, the area immediately around the mouth is typically spared in perioral dermatitis. A similar eruption can occur in patients who have not used corticosteroids.

Chloracne Cysts and closed comedones that resemble acne lesions can be caused by exposure to halogenated hydrocarbons.

Hidradenitis suppurativa Hidradenitis suppurativa is a chronic condition in which inflamed cysts in the axillae and groin form fluctuant sinuses with draining tracts.

Favre-Racouchot disease Numerous open and closed comedones can appear around the eyes of elderly patients, especially men who have worked outdoors for much of their lives. This condition has been attributed to a lifetime of sun exposure.

Table 1 Laboratory Evaluation for Women with Acne and Signs of Hyperandrogenism

Finding	*Suspected Condition*
DHEAS	
4,000–8,000 ng/ml	Congenital adrenal hyperplasia
> 8,000 ng/ml	Adrenal tumor
LH:FSH ratio > 2.0	Polycystic ovary disease
Testosterone (unbound)	
20–40 yr, > 107.5 pmol/L	Polycystic ovary disease; ovarian tumor
41–60 yr, > 86.7 pmol/L	Polycystic ovary disease; ovarian tumor
61–80 yr, > 69.3 pmol/L	Polycystic ovary disease; ovarian tumor

DHEAS—dehydroepiandrosterone sulfate FSH—follicle-stimulating hormone
LH—luteinizing hormone

Rosacea Rosacea is a common condition that usually begins after 30 years of age. It is so similar to acne in some individuals that it has been called acne rosacea. Skin lesions consist of erythematous papules, pustules, and telangiectasia [*see Figure 2*]. Facial flushing is a common feature. In patients with a predominance of inflamed papules and pustules, differentiation from acne can be difficult. Presence of telangiectasia and the occurrence of flushing help distinguish rosacea from acne, as does the absence of comedones.

Common triggers of rosacea include alcohol, exercise, extremes of temperature, and hot or spicy foods. With long-standing disease, hypertrophy of sebaceous glands, swelling, erythema, and scarring of the nose lead to rhinophyma. Ocular involvement is common in rosacea and can include blepharitis and conjunctival hyperemia or, less commonly, iritis, episcleritis, superficial punctuate keratopathy, and corneal neovascularization.[9]

Helicobacter pylori may play a role in the pathogenesis of rosacea.[10] Further work must be done, however, to confirm the contribution of *H. pylori* to this antibiotic-responsive condition. An immunologic reaction to the mite *Demodex folliculorum* has been suggested, but not proved, as a contributing factor.

Treatment

Treatment of acne depends on the type and severity of lesions and on the patient's response to treatment. Comedonal acne is usually best managed with topical retinoids and acne surgery; inflammatory acne is treated with a range of topical therapies and may require oral therapy in moderate to severe cases. Because nodules and cysts are more likely than comedones to cause scarring, they are treated more quickly with oral antibiotics and, if necessary, isotretinoin (see below). Intralesional corticosteroids administered by dermatologists can prevent scarring from cysts. Incision and drainage of infected cysts may be necessary but can contribute to scarring. Unroofing of sinus tracts and other surgical procedures are best performed by physicians with expertise in dermatologic surgery [*see Table 2*]. Scars can be treated with dermabrasion or laser abrasion. The appearance of depressed scars can be improved by chemical peels and other resurfacing procedures, as well as by the injection of filler substances such as injectable collagen.[11]

Numerous over-the-counter cleansing agents are available to help patients remove seborrhea and oily debris from the skin, resulting in subjective improvements. Overmanipulation of lesions by picking, squeezing, or excessive washing can lead to exacerbation of lesions and even scarring.

Figure 2 **Erythematous papules, pustules, telangiectasia, and flushing are features of rosacea.**

Table 2 Surgical Treatments for Acne Lesions and Acne Scars

Lesions	Extraction of comedones Drainage of pustules and cysts Intralesional injection of corticosteroids in cysts Excision and unroofing of sinus tracts and cysts
Scars	Dermabrasion Laser abrasion Acid peels Injection of filling materials (e.g., collagen) Excision Punch autografts

Topical preparations, including sunscreens, soaps, and cosmetics, should be oil-free and noncomedogenic. Many over-the-counter oil-free, noncomedogenic moisturizers are available for persons who have dry skin and acne.

There is no role for dietary change in the management of acne. Previous beliefs that chocolate or oily foods cause acne have been disproved.

TOPICAL THERAPY

Comedonal Acne

Topical retinoids are among the most effective therapies for comedonal acne; these preparations unplug follicles and allow penetration of topical antibiotics and benzoyl peroxide. Retinoids can be used in combination with antibacterial agents and are also effective in the management of inflammatory acne.[12] They are often irritating when first applied; patients can reduce the irritation by reducing the frequency of application. Significant improvement is evident within 6 weeks and can continue for 3 to 4 months, at which time the frequency of application can be reduced, depending on the patient's response.

Newer formulations of retinoids that are purportedly less irritating include a tretinoin microsponge vehicle and adapalene, but few comparative studies examining irritation have been performed.[13,14] Tazarotene, a topical retinoid used for acne and psoriasis, can be used effectively in a short-contact method, in which it is applied for seconds to minutes.[15]

Inflammatory Acne

Topical antibiotics are not as effective as retinoids or benzoyl peroxide for inflammatory acne, but they are less irritating and better tolerated. The resistance of *P. acnes* to antibiotics has been well documented; such resistance threatens the efficacy of this form of acne therapy in the future.[16,17] It is therefore useful to prescribe antibiotics in combination with benzoyl peroxide, which does not induce resistance. A combined formulation of clindamycin 1% and benzoyl peroxide 5% has been found to produce faster and greater reductions in *P. acnes* than formulations containing clindamycin alone.[18] Moreover, the combination of benzoyl peroxide and clindamycin resulted in greater improvement in acne than either of its individual components alone.[19]

A commonly used regimen includes the combined antibiotic–benzoyl peroxide gel in the morning and topical retinoid in the evening. Azelaic acid, an anticomedonal and antibacterial

Table 3 Topical Therapies for Acne

Medication	*Formulation*	*Frequency of Application*	*Primary Mechanism of Action*	*Adverse Effects*
Azelaic acid	20% cream	b.i.d.	Anticomedonal, antibacterial	Stinging, irritation
Benzoyl peroxide	2.5%, 5%, 10% creams, gels, lotions, washes	b.i.d.	Antibacterial	Dryness, irritation, allergic contact dermatitis
Antibiotics				
Clindamycin	1% solutions, lotions, gels	b.i.d.	Antibacterial	Antibiotic resistance
Erythromycin	2% solutions, creams, gels, pledgets, wipes	b.i.d.	Antibacterial	Antibiotic resistance
Erythromycin–benzoyl peroxide	3% erythromycin–5% benzoyl peroxide gel	b.i.d.	Antibacterial	Dryness, irritation, allergic contact dermatitis; deteriorates if not refrigerated
Sodium sulfacetamide–sulfur	10% sodium sulfacetamide, 5% sulfur lotions	b.i.d.	Antibacterial	Dryness, irritation, allergic contact dermatitis
Retinoids				
Adapalene	0.1% gels	q.d.	Comedolytic	Dryness, irritation, photosensitivity
Tazarotene	0.05%, 0.1% gels	q.d.	Comedolytic	Dryness, irritation, photosensitivity
Tretinoin	0.025%, 0.05%, 0.1% creams; 0.01%, 0.025% gels; 0.05% solutions	q.d.	Comedolytic	Dryness, irritation, photosensitivity
Sulfur and resorcinol	2% resorcinol, 8% sulfur lotions, creams	q.d., b.i.d.	Comedolytic	Dryness, peeling, allergic contact dermatitis
Salicylic acid	0.5%–2% gels, pads, soaps	q.d., b.i.d.	Comedolytic	Dryness, irritation

agent, offers yet another choice for the topical treatment of acne. It, too, can be used in combination with topical retinoids, benzoyl peroxide, or topical antibiotics.[20] Salicylic acid, an over-the-counter comedolytic agent, plays a minor role in the treatment of acne. Skin-colored sulfur-resorcinol lotions are available; these very effective drying and peeling agents can be useful for treating individual lesions [*see Table 3*].

SYSTEMIC THERAPY

Systemic agents are warranted for patients with nodulocystic acne or inflammatory acne that is not responsive to topical therapy. Oral antibiotics are usually the first line of systemic treatment. Isotretinoin has generally been reserved for patients whose acne is refractory to antibiotics. Isotretinoin may be used as initial therapy in patients with particularly severe acne to prevent scarring and in patients with a history of antibiotic intolerance.

Antibiotics

Antibiotics have both antibacterial and anti-inflammatory effects that are beneficial in treating acne. The antibiotics most commonly used for acne are doxycycline, erythromycin, minocycline, tetracycline, and trimethoprim-sulfamethoxazole [*see Table 4*]. Because antibiotic resistance is a major problem with many of the older antibiotics, minocycline has been prescribed for many acne patients even though it is considerably more expensive. Strains of *P. acnes* that are resistant to minocycline have begun to emerge, however, and this may limit the usefulness of this drug in the future.[21] The duration of treatment with oral antibiotics depends on patient response. Azithromycin given at a dosage of 500 mg/day for 4 days, repeated at 10-day intervals for four cycles, is as effective as minocycline given at a dosage of 100 mg/day for 6 weeks.[22] Further refinements of regimens with these newer antibiotics will undoubtedly be performed before they achieve more widespread usage.

A lupuslike syndrome has been reported in patients taking oral minocycline. Synovitis, the presence of antinuclear antibodies, and elevations in hepatic transaminase levels were reported, but renal disease and central nervous system disease do not occur.[23] Upon discontinuance of minocycline, symptoms resolve, but upon retreatment, the syndrome recurs.

Controversy about the long-term use of antibiotics for the treatment of acne was raised by a 2004 study that suggested a correlation between antibiotic use and breast cancer risk. The study found that an increase in the cumulative number of days of antibiotic use—including use of tetracyclines and macrolides, which are prescribed for acne—was associated with greater breast cancer risk.[24] Although the results of this study have been questioned because of the way the study was performed and other shortcomings of the study, the possibility of increased risk remains a concern.

Isotretinoin

Oral isotretinoin is the most effective agent available for the treatment of acne. It results in long-lasting remissions or cures in the majority of patients treated. Because of its serious potential adverse effects, however, isotretinoin is not generally used as first-line therapy except for unusual cases.

Most of the side effects of isotretinoin are dose related and affect a majority of patients treated. For example, cheilitis uniformly occurs in patients treated with significant doses. Myalgias, dryness of mucous membranes, dry eczematous skin changes, and hyperlipidemia frequently occur. Total serum cholesterol levels can rise in patients taking isotretinoin, and triglyceride levels can rise sufficiently to cause pancreatitis.

Teratogenicity occurs with the administration of even a single dose of isotretinoin to pregnant women. Birth control counseling is an essential part of the management of women for whom isotretinoin is prescribed. The use of two forms of contraception is advised. Despite major educational efforts, pregnancies in women receiving isotretinoin continue to occur, resulting in severe birth defects.[25] With the introduction of generic isotretinoin, concern over teratogenicity increased. In response, the manufacturers of isotre-

Table 4 Commonly Prescribed Systemic Therapies for Acne

Medication	*Dosage*	*Advantages*	*Adverse Effects*
Antibiotics			
Doxycycline	50–100 mg p.o., b.i.d.	Inexpensive	Photosensitivity, GI symptoms, candidiasis
Erythromycin	250–500 mg p.o., b.i.d.	Alternative to tetracyclines	GI symptoms, candidiasis
Minocycline	50 mg p.o., q.d.–100 mg p.o., b.i.d.	Highly effective; antibiotic resistance rare at 200 mg/day	GI symptoms, candidiasis, vertigo, lupuslike syndrome (rare), autoimmune hepatitis (rare)
Tetracycline	250 mg p.o., q.d.–500 mg p.o., q.i.d. (b.i.d. dosing preferred)	Inexpensive	Photosensitivity, GI symptoms, candidiasis
Trimethoprim-sulfamethoxazole	160 mg trimethoprim–800 mg sulfamethoxazole b.i.d.	Alternative to tetracyclines and erythromycin	Bone marrow suppression, drug eruption
Other Agents			
Isotretinoin	0.5–2.0 mg/kg/day, in two divided doses	Most effective treatment; long-lasting remissions	Teratogenicity, hyperlipidemia, cheilitis, alopecia, pyogenic granulomas, dry eyes, epistaxis, rare pseudotumor cerebri (especially with concomitant antibiotics)
Norgestimate–ethinyl estradiol	0.18 mg norgestimate, 0.035 mg ethinyl estradiol p.o., q.d., for 21 days; repeat every 4 wk	Alternative to antibiotics and isotretinoin; less androgenic activity than progestins in other contraceptives	Thromboembolic disorders; ?antibiotic interaction; ?increased breast carcinoma; gallbladder disease; reduced glucose tolerance; headache; fluid retention; hypertension; breakthrough bleeding; breast swelling and tenderness
Drospirenone–ethinyl estradiol	3 mg drospirenone and 0.3 mg ethinyl estradiol p.o., q.d., for 21 days, followed by 7 days of inert pills; repeat monthly	Alternative to antibiotics and isotretinoin; less androgenic activity than progestins in other contraceptives	Thromboembolic disorders; ?antibiotic interaction; ?increased breast carcinoma; gallbladder disease; reduced glucose tolerance; headaches; fluid retention; hypertension; breakthrough bleeding; breast swelling and tenderness
Estrophasic contraceptive	1 mg norethindrone acetate and increasing doses of ethinyl estradiol: 20 μg, days 1–5; 30 μg, days 6–12; 35 μg, days 13–21; then 1 wk of inert tablet; repeat cycle every 4 wk	Alternative to antibiotics and isotretinoin; less androgenic activity than progestins in other contraceptives	Thromboembolic disorders; ?antibiotic interaction; ?increased breast carcinoma; gallbladder disease; reduced glucose tolerance; headaches; fluid retention; hypertension; breakthrough bleeding; breast swelling and tenderness

tinoin started a program in which physicians and pharmacists who prescribe and administer isotretinoin must register and agree to require that patients receiving isotretinoin undergo pregnancy testing on a regular basis.[26] Unfortunately, this program failed to eliminate pregnancies in women treated with isotretinoin. Attempts to enforce guidelines on the safe use of isotretinoin[27] have been deemed inadequate, and as a result, more stringent barriers to the prescription of isotretinoin are being instituted.[28]

There have been several instances of suicide and depression occurring in patients receiving oral isotretinoin.[29,30] Teenagers with severe acne may be at increased risk for suicide, regardless of the treatment they are using. A study compared the risk of depression, psychotic symptoms, suicide, and attempted suicide in acne patients receiving isotretinoin with the risk in acne patients being treated with oral antibiotics. The relative risk of depression or psychosis for isotretinoin-treated patients was 1.0, and the relative risk of suicide and attempted suicide was 0.9, suggesting that isotretinoin does not cause depression.[31] A study of pharmacy prescriptions yielded similar results. Prescriptions for antidepressants were quantified in 2,821 patients who filled isotretinoin prescriptions for the first time, and they were again quantified for patients filling isotretinoin prescriptions for a second time. The ratio of antidepressant use with the first prescription of isotretinoin to antidepressant use with the second prescription was not significantly different from 1.0—a finding that does not support an association between the use of isotretinoin and the onset of depression.[32]

Pseudotumor cerebri is a rare side effect of isotretinoin. It occurs more commonly in patients who are concomitantly given oral antibiotics.

Extensive counseling and monitoring—including complete blood counts, chemistry screens, and pregnancy tests when appropriate—should be done before treatment with isotretinoin; such counseling and monitoring should continue at 2-week intervals during the first month of treatment and monthly thereafter. Depending on patient response, treatment with 0.5 to 1.0 mg/kg/day in two divided doses should be continued to a cumulative dose of 120 to 150 mg/kg. Some clinicians have continued low-dose isotretinoin therapy for more than 6 months. Rarely, a second course of therapy is indicated when acne recurs.

Hormone Therapy

Estrogens in the form of oral contraceptives can be beneficial for patients with acne; progestins, however, can exacerbate the condition. The newer progestins—desogestrel, norgestimate, and gestodene—have less androgenic activity and therefore are less likely to exacerbate acne. A combination of ethinyl estradiol and norgestimate has been shown to be beneficial in the treatment of acne.[33] An oral contraceptive containing ethinyl estradiol in graduated doses, along with stable doses of norethindrone acetate, has been shown to have minimal androgenic activity and is also used for the treatment of acne.[34] A combined oral contraceptive containing ethinyl estradiol and drospirenone has also been found to effectively treat acne.[35] These agents are ideal for women who are seeking birth control methods and for women who are not candidates for, or who have not responded to, oral antibiotics or isotretinoin. Oral contraceptives can be particularly helpful to women with polycystic ovary syndrome. It is noteworthy that the beneficial effects of combined oral contraceptives are diminished in patients who are obese.[36]

Some concerns have been raised about the concomitant use of antibiotics and oral contraceptives because some antibiotics may interfere with contraceptive activity. Reviews of large numbers

of patients treated concomitantly with oral contraceptives and antibiotics have not revealed significant increases in pregnancies.[37] Nevertheless, caution is advisable when a patient uses an antibiotic and an oral contraceptive together, especially one of the newer contraceptives that contain low doses of estrogen.

PHOTOTHERAPY

A number of light sources have been tested for the treatment of acne. Photodynamic therapy using topical δ-aminolevulinic acid has demonstrated efficacy for acne. Photodynamic therapy did not reduce *P. acnes* numbers or sebum excretion, so the mechanism by which it works is not entirely known.[38] A blue light administered twice weekly for 4 consecutive weeks has demonstrated efficacy for acne but not for nodulocystic lesions.[39] The 1,064 nm Q-switched neodymium:yttrium-aluminum-garnet (Nd:YAG) laser has proved useful for the treatment of acne scarring.[40]

TREATMENT OF ROSACEA

Avoidance of triggers such as alcohol, hot or spicy foods, and heat are an important part of the therapeutic regimen offered to patients with rosacea. Sunscreens are likewise important. Telangiectasia can be treated with laser therapy. Papules and pustules respond to the same topical and oral antibiotics used for acne, although benzoyl peroxide is less commonly used for rosacea. Flushing is difficult to treat. Azelaic acid may offer some benefit for the erythema associated with rosacea.[41]

Additional Information

Additional information about acne and its related disorders is available from the American Academy of Dermatology (http://www.aad.org) and the National Rosacea Society (http://www.rosacea.org).

XIII DISORDERS OF HAIR

David A. Whiting, m.d.

Physiology and Evaluation of Hair Growth

A basic knowledge of the hair growth cycle is needed to evaluate disorders of hair growth.[1,2] Scalp hair follicles cycle independently of one another. On average, of 100,000 scalp hairs, approximately 90% are in the anagen (growing) phase and 10% in the telogen (resting) phase at any given time. Anagen lasts an average of 3 years, with a range of 1 to 7 years. Telogen usually lasts 3 months, after which the resting hairs are shed and new hairs grow in. The average rate of scalp hair growth is approximately 0.35 mm/day, or 1 cm/month (1 in. every 2 to 3 months).

An average loss of 100 hairs a day is normal, with larger numbers of hairs being lost on shampoo days. When obtaining a history, it is important to determine whether shedding is abnormal and whether the shed hairs break off or come out by the roots.[3] Hair normally comes out by the roots; however, trauma or excessive fragility may cause hair to break.

Examination of the patient should include a routine check for broken-off hairs and the performance of hair-pull tests on the top, sides, and back of the scalp. The hair-pull test is performed by grasping groups of 10 to 20 hairs between the index finger and thumb and pulling steadily.[4,5] Extraction of more than 20% of the grasped hairs indicates a potential for abnormal shedding, usually involving telogen hairs. Telogen hairs (club hairs) are easily recognized by their whitish club-shaped bulbs and lack of root sheaths. Anagen hairs are normally difficult to detach and have blackish, indented roots with intact root sheaths.

Androgenetic Alopecia

Androgenetic alopecia is the common type of nonscarring hair loss affecting the crown. It results from a genetically determined end-organ sensitivity to androgens. It is often referred to as common baldness, male-pattern alopecia, and female-pattern alopecia.

epidemiology and pathogenesis

Androgenetic alopecia affects at least 50% of men by 50 years of age and 50% of women by 60 years of age.[6,7] Males have more androgen than females and therefore are usually affected earlier and more severely. Male-pattern alopecia often starts between 15 and 25 years of age. Male-pattern alopecia has two characteristic components, bitemporal recession and vertex balding [*see Figure 1*], which in pronounced cases can progress to complete balding of the crown.[6,7] Female-pattern alopecia is more likely to start between 25 and 30 years of age (or sometimes later, after menopause). It is characterized by an intact frontal hairline and an oval area of diffuse thinning over the crown [*see Figure 2*]. Bitemporal recession in women is much less obvious than it typically is in men, or it can be nonexistent. In general, androgenetic alopecia in women progresses to mild, moderate, or severe thinning but not to complete baldness. The best predictor of outcome is the degree of progression in affected relatives.

Androgenetic alopecia is an autosomal dominant disorder with variable penetrance. Susceptible hairs on the crown are predisposed to miniaturize under the influence of androgens, notably dihydrotestosterone. In both sexes, miniaturization results from a shortening of the anagen cycle, from years to months or weeks. Miniaturized hairs are characterized by reduced length and diameter; this accounts for the appearance of hair loss.[8] Androgenetic alopecia largely spares the back and sides of the scalp.

diagnosis

The diagnosis of androgenetic alopecia is usually obvious from the clinical pattern of hair loss from the top of the head.[9] In some men, a female pattern of alopecia (see above) causes diagnostic confusion but has no other significance. In women, a male pattern of alopecia (i.e., bitemporal recession and vertex balding) occurring with menstrual irregularities, acne, hirsutism, and a deep voice is significant. The virilism indicates significant hyperandrogenism, the cause of which must be identified and treated [*see 3:III Ovary and 3:IV The Adrenal*].

Scalp biopsies are rarely necessary to diagnose androgenetic alopecia. Biopsies cut horizontally are sometimes useful, however, in differentiating female-pattern alopecia from chronic telogen effluvium (see below).

treatment

Depending on the severity of the condition, management of androgenetic alopecia ranges from watchful inactivity to medical and surgical treatment, or a hairpiece or wig may be used in the most refractory cases.

Topical Therapy

The Food and Drug Administration approved topical 2% minoxidil for use in men in 1987 and in women in 1989. Minoxidil is applied twice daily with a dropper, spread over the top of the scalp, and gently rubbed in. The drug should be tried for at least a year. Minoxidil acts by initiating and prolonging anagen. It produces visible hair growth in approximately one third of male and female patients, fine-hair growth in approximately one third, and no growth in approximately one third. It is more effective as a preventive agent, retarding hair loss in approximately 80% of patients.[6]

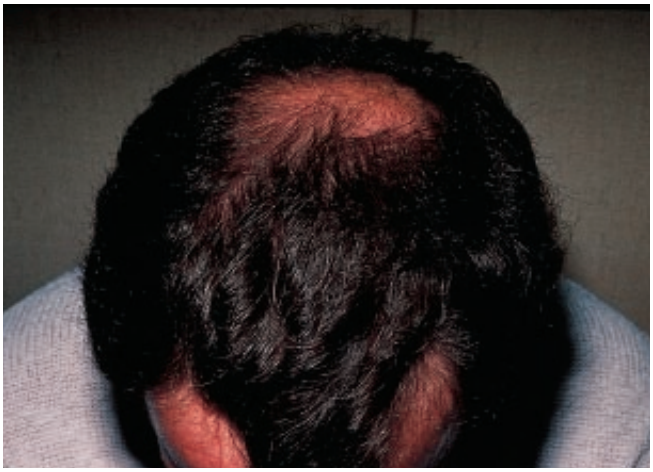

Figure 1 **Bitemporal recession and vertex balding are present in this patient with male pattern androgenetic alopecia.**

Figure 2 **Intact frontal hairline and diffuse thinning over the crown are characteristic of female pattern androgenetic alopecia.**

Topical 5% minoxidil, which was approved for use in men in 1997, produces visible hair growth in 45% of patients in less time than the 2% solution. Both concentrations are available over the counter. Side effects are not significant and include scalp irritation and increased facial hair.[10] The medication has to be continued indefinitely.[11]

Systemic Therapy

Oral finasteride, at a dosage of 1 mg/day, was approved by the FDA for the treatment of male-pattern alopecia in 1997. Finasteride is a powerful type II 5α-reductase inhibitor that prevents formation of dihydrotestosterone in the prostate gland and in the hair follicle. It reduces circulating dihydrotestosterone by 65% to 70%. When administered at a dosage of 1 mg/day for 2 years to male patients with androgenetic alopecia who are between 18 and 41 years of age, finasteride grew visible hair in 66% and prevented further hair loss in 83%.[12] The efficacy of finasteride was maintained in a 5-year study.[13] Hair-weight studies have shown that finasteride increases hair length and diameter, producing better coverage from existing hairs.[14]

Side effects in men are minimal and include lack of libido, lack of potency, and mild reduction in semen in approximately 0.5% of patients. These effects are reversed when the drug is stopped and often disappear as the drug is continued. A 1-year trial of finasteride at a dosage of 1 mg/day in postmenopausal women failed to show any positive effects.

Because of the likelihood of finasteride to cause severe side effects in the male fetus, the drug is contraindicated in premenopausal women.

Therapy for Hair Loss in Women

Topical minoxidil is currently the best available treatment for androgenetic alopecia in women.[10,15] However, various antiandrogenic drugs have been used. Oral contraceptives (e.g., ethinyl estradiol–ethynodiol diacetate [Demulen], desogestrel–ethinyl estradiol [Desogen], and ethinyl estradiol–norgestimate [Ortho Tri-Cyclen]) can reduce hair loss and occasionally lead to slight hair growth.[6] Oral spironolactone (Aldactone) in dosages of 75 mg/day to 200 mg/day can produce androgen blockade. Dexamethasone in dosages of 0.125 mg/day to 0.5 mg/day can suppress adrenal overactivity. Cyproterone acetate, which is not available in the United States, is not as effective as minoxidil in female pattern hair loss unless other signs of hyperandrogenism are present.[16]

Therapy for Refractory Cases

In patients who do not respond to the treatments listed above, the next step may be hair transplantation. Micrografts and minigrafts can produce a good cosmetic appearance in patients who have a sufficient reserve of hair on the back and sides of the scalp.[17] If all therapies fail, a hairpiece may be an option.

Diffuse Alopecia

Diffuse alopecia is generalized hair loss over the entire scalp. Because the loss is so diffuse, it is often unnoticeable until 30% to 50% of scalp hair is shed. Causes of diffuse alopecia include telogen effluvium, anagen arrest, drug reactions, and a number of systemic and nonsystemic conditions [*see Table 1*].[18,19]

TELOGEN EFFLUVIUM

Telogen effluvium is the most common form of diffuse alopecia.[20] It presents as a generalized shedding of telogen hairs from normal resting follicles. The basic cause of telogen effluvium is a premature interruption of anagen, leading to an increase in the number of hairs cycling into telogen. When the 3-month telogen period ends, new anagen hairs grow in and numerous telogen hairs fall out. Patients may need reassurance that this apparent loss of hair is actually a sign of regrowth.

Acute telogen effluvium can be caused by childbirth, febrile illnesses, surgery, chronic systemic diseases, crash diets, traction, severe emotional stress, and drug reactions [*see Table 2*]. It can also be a physiologic reaction in neonates.[21]

During acute telogen effluvium, pull tests are positive all over the scalp, yielding two to 10 club hairs. Telogen effluvium is often accompanied by bitemporal recession; this is a useful diagnostic sign in women [*see Figure 3*]. The acute form usually ends within 3 to 6 months. The diagnosis is usually made on the basis of the history of an initiating event 3 months before the onset of shedding. No treatment is needed for acute telogen effluvium, because the hair invariably regrows within a short time.

Chronic telogen effluvium has a long, fluctuating course of 6 months to 7 years or more. Very often, no identifiable cause can be found.

Diagnosis

The diagnosis of telogen effluvium is usually clinical; biopsies may be necessary to distinguish telogen effluvium from an acute onset of widespread androgenetic alopecia.[22] Other causes of

Table 1 Causes of Diffuse Alopecia[45]

Telogen effluvium (acute and chronic)
Anagen arrest
Reactions to drugs and other chemicals
Thyroid disorder
Iron deficiency and other nutritional deficiencies
Malabsorption
Renal failure
Hepatic failure
Systemic disease
Miscellaneous causes (e.g., diffuse alopecia areata, congenital hypotrichosis) and idiopathic causes

Table 2 Categories of Drugs That Can Cause Alopecia[5]

Category	*Selected Agents*
Alpha blockers	Doxazosin, prazosin, terazosin
Angiotensin converting enzyme inhibitors	Captopril, enalapril
Anticancer drugs	Bleomycin, cyclophosphamide, cytarabine, dactinomycin, daunorubicin, doxorubicin, etoposide, floxuridine, fluorouracil, methotrexate, mitomycin, mitoxantrone, procarbazine, thioguanine, vinblastine, vincristine
Anticoagulant drugs	Dicumarol, heparin, warfarin
Anticonvulsant drugs	Ethotoin, mephenytoin, paramethadione, phenytoin, trimethadione, valproate sodium
Antithyroid drugs	Carbimazole, methylthiouracil, methimazole, propylthiouracil
Beta blockers	Acebutolol, atenolol, labetalol, metoprolol, nadolol, pindolol, propranolol, timolol
Calcium channel blockers	Diltiazem, verapamil
Cholesterol reducers	Clofibrate, lovastatin
H_2 receptor blockers	Cimetidine, famotidine, ranitidine
Nonsteroidal anti-inflammatory drugs	Fenoprofen, ibuprofen, indomethacin, ketoprofen, meclomen, naproxen, piroxicam, sulindac
Retinoids and retinol	Acitretin, etretinate, isotretinoin, vitamin A overdose
Tricyclic antidepressants	Amitriptyline, amoxapine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine

hair loss should be excluded by a careful drug history and tests for iron deficiency, syphilis, and disorders of the thyroid, kidney, and liver.

Treatment

As mentioned above, no treatment is needed for acute telogen effluvium because the hair invariably regrows within a short time. In chronic telogen effluvium, topical minoxidil in a 2% or 5% solution may be indicated. The patient should be reassured that telogen effluvium rarely causes permanent baldness.

ANAGEN ARREST (ANAGEN EFFLUVIUM)

So-called anagen effluvium represents a diffuse loss of anagen hairs from growing follicles.[23] The term anagen effluvium is a misnomer. Normally, hairs pass through a brief transition phase (catagen) between the anagen and telogen phases before falling out by the roots. In anagen arrest, inhibition of cell division in the hair bulb matrix leads to a progressive narrowing of the hair shaft and sometimes failure of hair formation. As the growing hair narrows near the skin surface, it may break off. The resultant shedding can occur within a few weeks, unlike in telogen effluvium, in which shedding takes 3 months to occur.

Causes of anagen arrest include reactions to cytostatic drugs and other toxic agents, radiation therapy, endocrine diseases, alopecia areata, cicatricial alopecia, trauma and pressure, and severe protein calorie malnutrition. Because 90% of scalp hairs are in anagen at any given time, this condition causes obvious and severe baldness [*see Figure 4*].

Diagnosis

The diagnosis of anagen arrest is easily made by the history, evidence of extensive hair loss, and hair-pull tests that yield easily broken hairs with proximal tapering.

Treatment

Treatment of anagen arrest lies in elimination of the underlying cause. Once the antimitotic influence is removed, the anagen

Figure 3 **In women, marked bitemporal recession is often a sign of telogen effluvium.**

Figure 4 **Anagen arrest causes severe, diffuse hair loss.**

Table 3 Miscellaneous Chemicals That Can Cause Alopecia[45]

Chemical	*Common Source*
Abrin	Plant source (*Abrus precatorius* [rosary pea, jequirity bean, or precatory bean])
Arsenic	Pesticides
Bismuth	Old treatment for syphilis
Boric acid	Mouthwashes, occupational exposure
Chloroprene dimers	Occupational exposure (synthetic-rubber manufacturing)
Lead	Paints
Mercury	Cosmetics, teething powders, antiseptics
Mimosine	Plant source (*Leucaena glauca*)
Selenocystothione	Plant source (*Lecythis* species)
Thallium salts	Rodenticides

hair will regrow promptly with a normally tapering shaft. Unbroken hairs that regrow often show the Pohl-Pinkus deformity (i.e., a constriction that results in a dumbbell shape).

ALOPECIA CAUSED BY DRUGS AND CHEMICALS

Substance-induced alopecia is relatively common but is often hard to diagnose because of the large number of drugs and chemicals that can cause hair loss [*see Tables 2 and 3*]. It often takes time to identify the underlying cause by trial and error: many patients are exposed to several alopecia-inducing substances, and removal of the causative agent may not result in immediate regrowth of hair.

OTHER CAUSES OF DIFFUSE ALOPECIA

Hypothyroidism and iron deficiency should be excluded in patients with diffuse hair loss [*see Table 1*]. Appropriate treatment may lead to hair regrowth.

Alopecia Areata

Alopecia areata is typically characterized by patchy hair loss; however, involvement can vary from a single patch on the scalp or elsewhere to total body baldness (alopecia universalis).[24]

EPIDEMIOLOGY AND PATHOGENESIS

In the United States, alopecia areata affects 1.7% of the population younger than 50 years.[25] Some 70% to 75% of cases are not associated with any other disease. In these patients, alopecia areata often starts in the 20s and 30s, although it can occur at any age. In only about 6% of these patients with alopecia areata does the disease progress to total loss of scalp hair. Even total alopecia can reverse itself.

Alopecia areata is currently regarded as an autoimmune disease. A positive family history in 20% of alopecia areata patients indicates a genetic predisposition to this disease. Certain HLA groups have been associated with mild or severe cases of alopecia areata.[26] Although the exact cause is unknown, many researchers presume that an infectious agent such as a virus is the offending agent. Stress, seasonal factors, and infection are among the trigger factors for active episodes of hair loss.

Some 5% of alopecia areata cases—usually those occurring in middle-aged patients—are associated with autoimmune disease, either in the patient or in the patient's family. Some 10% of these patients will experience loss of all scalp hair in the course of the disorder. Approximately 20% to 25% of cases—often those occurring in childhood—may be associated with atopic disease (e.g., hay fever, asthma, or eczema). The incidence of complete scalp hair loss is much higher in these patients.

Despite its long course, often recurring over many years, the prognosis of alopecia areata is often favorable. Most patients will regrow hair at one time or another. In cases of extensive alopecia areata, alopecia totalis, and alopecia universalis, however, hair loss may be permanent.

DIAGNOSIS

Active alopecia areata is characterized by a spreading, annular area of hair loss; a smooth, depressed area of scalp that is slick to the touch is surrounded by hairs that often include so-called exclamation-point hairs (i.e., broken hairs 3 to 4 mm long, usually with an expanded tip and a telogen bulb). These hairs are not always seen but are diagnostic when present. They delineate the active spreading margin of alopecia areata. The bald patches generally affect the scalp but can also involve eyebrows, eyelashes, beard hair, and body hair. Spontaneous regrowth is common.

This condition is extremely unpredictable, often fluctuating without any obvious reason. However, seasonal outbreaks are noted in many patients. The initial patch may enlarge, or additional patches may develop and become confluent [*see Figure 5*]. The condition can progress to large irregular areas of baldness. In severe cases, patients lose all scalp hair or all body hair.

Ophiasis is a chronic and difficult to treat form of alopecia areata in which a band of baldness circles the scalp, very often around the inferior margin. This slowly extending lesion is often present for several years before any regrowth occurs. Permanent hair loss may result in some areas.

TREATMENT

The treatment of alopecia areata depends on the severity of the disease.[27] Small patches of alopecia areata often regrow hair without treatment. If not, they usually respond to medium- or high-potency topical corticosteroids or to intralesional injections of triamcinolone acetonide at a concentration of 5 mg/ml.

In more severe cases, intralesional corticosteroids may be tried; however, these may not be feasible in extensive hair loss. Daily, short-contact topical therapy with 0.25% to 1% anthralin cream for up to an hour at a time may help and is suitable for children and adults. Psoralen and ultraviolet A (PUVA) therapy has also been used with some success.

Topical 5% minoxidil can be tried to speed hair regrowth and lengthen existing hairs. Minoxidil has no effect on the course of the disease but may improve hair coverage. It has few side effects and is often used in older children; however, the FDA has approved minoxidil for use only in persons 18 years of age and older. Systemic steroids are effective; however, they have shown a potential for side effects and do not prevent future recurrences.[28] Prednisone (20 to 40 mg daily in the morning for 1 or 2 months followed by slow tapering) has controlled the disease in adults; a change to alternate-day therapy is advisable whenever possible.

Topical immunotherapy with the sensitizing chemical diphencyprone has been used in some centers; it has a response rate comparable to that of systemic corticosteroids.[29] Success with this treatment usually requires supervision in a specialized clinic.[27]

Figure 5 **Circumscribed patches of hair loss are present in alopecia areata.**

Sulfasalazine has been reported to have a 23% success rate in the treatment of severe alopecia areata.[30] Other immunosuppressive drugs, such as oral cyclosporine, have been used experimentally. Such therapies are risky and expensive, however, and have not been approved in the United States for alopecia areata.

TRAUMATIC ALOPECIA

Traumatic alopecia may be caused by a variety of physical or chemical injuries to the hair and scalp. These injuries may be deliberate or accidental, inflicted by self or others, and acute or repetitive. The cause may be obvious or unclear.[31] Potential causes include trichotillomania, habit tics, pruritic dermatoses, traction, pressure and friction, heat, radiation, and chemicals. In most cases of traumatic alopecia, management is removal of the underlying cause. In areas with permanent damage, hair transplantation may be necessary.

TRICHOTILLOMANIA

Trichotillomania is a compulsion to pull out one's hair. It is characterized by an increasing sense of tension before, and a sense of relief after, the hair is pulled. Trichotillomania is now classified as a specific disorder of impulse control.[31,32] It is more common in children, in whom it is often caused by insecurity resulting from sibling rivalry, lack of attention, divorce of parents, learning disabilities, or unhappiness or teasing at school. In adolescents and adults, trichotillomania may be accompanied by mood disorders, anxiety disorders, or mental retardation and is often harder to treat than in children.

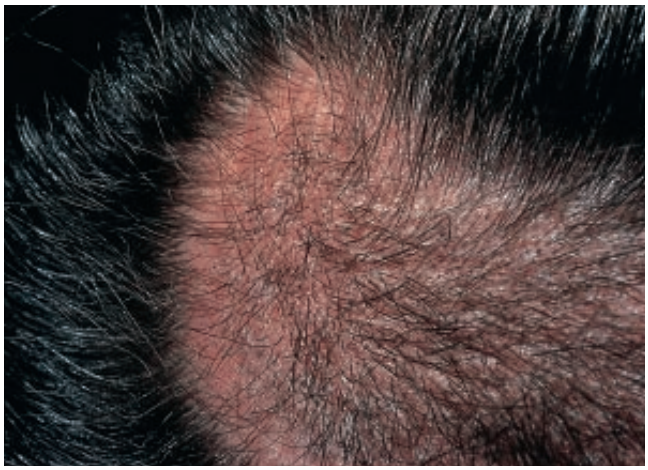

Figure 6 **Irregular, broken-off hairs are seen in trichotillomania.**

The diagnosis is based on the presence of irregular, broken-off hairs in patches on the scalp [*see Figure 6*]. The hairs are irregular in length because they are broken off at different times. The scalp itself is normal. Occasionally, biopsies are necessary to confirm the diagnosis. The best treatment is to explain cause and remedy to the patient in a nonconfrontational manner; usually, reassurance and understanding go a long way in the treatment of this condition. In more difficult cases, psychiatric consultation may be indicated.[33] If habit tics or head rolling and banging are found to be causing traumatic hair loss, those behaviors should be treated.

OTHER CAUSES OF TRAUMATIC ALOPECIA

Pruritic Dermatoses

Pruritic dermatoses such as acne necrotica, folliculitis, lichen simplex chronicus, pediculosis capitis, prurigo nodularis, psoriasis, seborrheic dermatitis, and neurotic excoriations can lead to hair loss from excoriation. They need to be identified and treated.

Traction Alopecia and Loose Anagen Syndrome

Traction alopecia may be acute (caused by accidental or deliberate avulsion of the scalp) or may arise from a familial condition, the loose anagen syndrome. Common causes of traction alopecia are excessive brushing and combing; backcombing and pulling the hair into braids, cornrows, and ponytails; weaving; and application of rollers.[31]

Loose anagen syndrome is usually seen in fair-haired children 2 to 5 years of age.[34] It often presents as patchy hair loss following an incident of hair tugging. Prompt hair regrowth is the rule. The condition becomes asymptomatic with gentle hair care. Diagnosis is made on the basis of positive hair pull tests showing many anagen hairs.

Alopecia Caused by Pressure and Friction

Prolonged pressure on a localized area of the scalp in immobilized neonates or patients under anesthesia, in coma, or with debilitating illness may result in ischemia leading to pressure alopecia. The hair usually regrows with time, but if the damage is severe, permanent hair loss and scarring may result.[31] Alopecia caused by friction from vigorous massage has been described but is easily remedied.

Alopecia Caused by Heat, Radiation, and Chemicals

Excessive heat from hot oils and pomades, hot combs, and hot rollers is a common cause of chronic hair loss. Overheated hair dryers frequently cause the fluid droplets in wet hair shafts to expand, leading to the formation of bubble hairs.[35] These brittle hairs are a frequent cause of follicle damage. The source of the overheating needs to be identified and removed.

Radiation dermatitis can cause hair loss. Permanent scarring alopecia is still seen in patients who were overtreated with x-rays for tinea capitis before oral antifungal agents became available.

Many chemicals, such as hair dyes, moisturizers, oils and pomades, permanent waves, relaxers and straighteners, setting lotions, certain cationic and detergent shampoos, and saltwater, are possible causes of hair loss.[36] A careful history of hair care and grooming is needed to uncover these causes.

Cicatricial Alopecia

Cicatricial alopecia results from permanent scarring of the hair follicles. It may be widespread or localized and is sometimes difficult to identify. The causes of cicatricial alopecia may be primary or secondary.[37] It can result from hereditary or congenital conditions, infections, injuries, neoplasms, and dermatoses [*see Table 4*].

DIAGNOSIS

On clinical examination, scarring is detected by the absence of follicular orifices and a pearly or scarred appearance of the skin. The scar may be depressed or hypertrophic. Associated lesions such as folliculitis, follicular plugs, scales, and telangiectasias may be found, along with broken, twisted, or easily extractable hairs. Other lesions may be present on skin or mucous membranes. If the disease is active, a specific diagnosis may be possible; but in an inactive case, the initial cause is often inapparent.

Clinical Variants

The common variants of primary cicatricial alopecia of the scalp include discoid lupus erythematosus, lichen planopilaris, folliculitis decalvans, and pseudopelade.[38,39] The end phases of these conditions are similar; they are characterized by a lack of pores and by inflammation in white, scarred areas. For an accurate diagnosis, an early biopsy from an area of activity might show the identifying pathology. In the final scarring stage, it is usually not possible to identify the original cause.

Discoid lupus erythematosus Lesions are often itchy at onset and lead to erythema, scaling, telangiectasia, follicular spines, and atrophy [*see Figure 7*]. They often occur centrally in bare patches of scarring with an inactive border [*see 15:IV Systemic Lupus Erythematosus*].

Lichen planopilaris Central scarring characterizes these lesions. The condition generally starts with bare, white patches that bud out from one another like pseudopods. Prominent follicular hyperkeratosis is present around the residual terminal hairs at the edges of the lesion, and varying degrees of erythema, scaling, and telangiectasia may occur. Itching may be present.

Folliculitis decalvans Crops of follicular pustules surrounding multiple, slowly expanding, and round or oval areas of alopecia characterize this condition. It may involve large areas of the skin. Secondary infection may be severe, with crusting and oozing. Eventually this condition gradually loses activity and looks like other forms of chronic cicatricial alopecia.

Pseudopelade (nonspecific cicatricial alopecia) The majority of cases classified as pseudopelade are in fact cases of nonspecific cicatricial alopecia in which the initial cause has not been established. In general, there is an insidious spread of a scarring process, which is apparently noninflammatory. It often involves the crown and occurs mainly in middle-aged women. It may represent the final common pathway of various causes, such as lichen planopilaris in particular or discoid lupus erythematosus. It is characterized by patchy areas of alopecia with irregular extensions. The affected skin is smooth, white, and devoid of erythema, scaling, or pores, causing the so-called footprints in the snow. The course is variable and may last for a few years or several decades.

The original cases were described as a specific entity in the late 19th century and were reported as pseudopelade of Brocq.

Table 4 Causes of Cicatricial Alopecia[46]

Dermatoses	Cicatricial pemphigoid, dermatomyositis, folliculitis decalvans, lichen planopilaris, lupus erythematosus, neurotic excoriations, pseudopelade, scleroderma
Hereditary and congenital disorders	Aplasia cutis, epidermal nevi, epidermolysis bullosa
Infections	
Bacterial	Acne keloidalis, dissecting cellulitis, folliculitis, syphilis
Fungal	Favus (tinea capitis), kerion, mycetoma
Protozoan	Leishmaniasis
Viral	Herpes zoster, varicella
Injuries	Burns, mechanical trauma, radiodermatitis
Neoplasms	Angiosarcoma, basal cell epithelioma, lymphoma, melanoma, metastatic tumors, squamous cell carcinoma

This eponym is rarely used nowadays except perhaps for a small cohort of cases with no inflammatory phase at all, particularly occurring in children. Most cases of so-called pseudopelade of Brocq are explainable as an end stage of lichen planopilaris or other causes.[37]

TREATMENT

Treatment depends on the level of activity of the underlying disease. Discoid lupus erythematosus and lichen planopilaris may respond to topical, intralesional, or systemic steroids or oral chloroquine therapy. Topical minoxidil is sometimes helpful in regrowing any surviving hairs, which may be normal, dystrophic, or in a resting stage. The application of a 2% or 5% solution twice daily should be tried for at least a year on scarred areas that show

Figure 7 **Atrophic scarring with erythema, scaling, telangiectasia, and follicular spines are characteristic of discoid lupus erythematosus.**

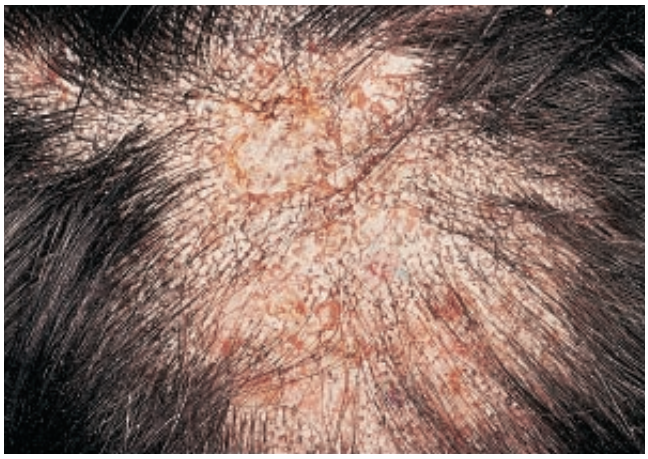

Figure 8 **In endothrix tinea capitis, black dots represent brittle, infected hairs snapped off flush with the scalp.**

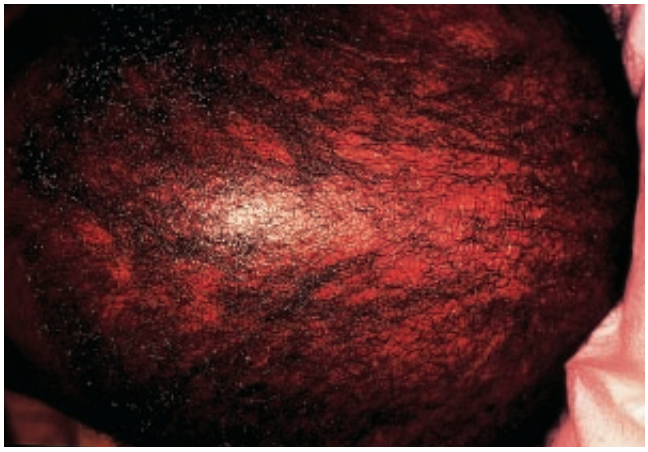

Figure 9 **The characteristic irregular, so-called moth-eaten diffuse alopecia caused by syphilis is seen here.**

some hair. Folliculitis decalvans may respond to treatment with long-term antibiotics such as tetracycline (500 mg), minocycline (100 mg), erythromycin (250 mg), trimethoprim-sulfamethoxazole (regular strength), or rifampin (300 mg, with regular-strength trimethoprim-sulfamethoxazole, given twice daily for at least 3 months). When the conditions have burned themselves out, either scalp reduction or hair transplants may be helpful.

Miscellaneous Causes of Hair Loss

As mentioned earlier, less common causes of hair loss include infections (e.g., tinea capitis),[40] infestations, hair shaft abnormalities, hereditary and congenital conditions, and various dermatoses involving the scalp.

In the United States, tinea capitis is now largely caused by *Trichophyton tonsurans*, an endothrix that infects the inside of the hair shaft. This makes the shaft brittle, which causes it to snap off flush with the skin, leaving a characteristic black dot of hair [*see Figure 8*]. The clinical diagnosis depends on this finding of black dots in patchy areas of hair loss. Removing the black dot with a small scalpel blade and dissolving it in potassium hydroxide (KOH) should reveal many spores that were packed inside the affected hair shaft. Ectothrix ringworm caused by *Microsporum canis* and *M. audouinii* is much less common; it can usually be diagnosed by Wood's light or by a finding of fungal spores around the hair shaft with KOH. Suitable oral antifungal treatments include griseofulvin, itraconazole, terbinafine, and fluconazole.

Secondary syphilis can cause a somewhat nondescript, moth-eaten type of diffuse alopecia [*see Figure 9*]. In such cases, a routine serologic test for syphilis is indicated.

Scalp lice should always be sought in cases of hair loss accompanied by pruritus. Lice are most likely to be found around and behind the ears and on the nape of the neck. Lymphadenopathy may also be present. Suitable treatment with permethrin shampoo or 0.5% malathion can be given.

Hair shaft abnormalities frequently present as broken-off hairs. Structural abnormalities of the hair shaft include fractures, irregularities, coiling and twisting, and extraneous matter.[41,42]

There are many different types of congenital and inherited hair loss.[43] These include congenital hypotrichosis with or without associated defects, congenital triangular alopecia, and many ectodermal dysplasias that affect the hair, teeth, nails, and sweat glands. One major form of congenital hypotrichosis is the Marie-Unna syndrome, which affects large families that have a dominant gene.[44] Minor forms of hypotrichosis can occur in patients with other hereditary syndromes and chromosomal abnormalities. In most of these conditions, a reduction of hair follicles accounts for the hair loss. Some patients have surviving hairs that are often in telogen and may benefit from topical minoxidil.

The author is a consultant and participates in the speakers' bureaus for Pharmacia & Upjohn, Merck & Co., Inc., and GlaxoSmithKline.

Oral contraceptives and antiandrogens discussed in this subsection have not been approved by the FDA for use in androgenetic alopecia; topical minoxidil discussed in this subsection has not been approved by the FDA for use in chronic telogen effluvium and cicatricial alopecia; diphencyprone, sulfasalazine, and cyclosporine discussed in this subsection have not been approved by the FDA for use in alopecia areata; and rifampin discussed in this subsection has not been approved by the FDA for use in folliculitis decalvans.

XIV DISEASES OF THE NAIL

James Q. Del Rosso, d.o.
C. Ralph Daniel iii, m.d.

The human nail is a complex unit composed of five major modified cutaneous structures: the nail matrix, nail bed, nail plate, nail folds, and cuticle (eponychium).[1] These components are structurally supported by specialized mesenchyme, which provides a ligamentlike function, anchoring the soft tissue structures of the nail to the underlying phalangeal bone. The primary function of the human nail is to provide protection for the distal digits. Nails also assist in performance of fine touch and digital dexterity. For many individuals, nails serve as an important aesthetic symbol of optimal appearance, enhanced self-image, or individuality; several cosmetic techniques are available to modify the appearance of the nail plate. The basic anatomic components of the nail unit are diagrammed [*see Figure 1*].

Nail Structure, Function, and Pathophysiology

NAIL MATRIX

The nail matrix is the dynamic, germinative portion of the nail unit that produces the nail plate.[2-4] The lunula is the visible portion of the nail matrix, appearing under the proximal nail plate as a gray-white half moon projecting just distal to the proximal nail-fold cuticle. That lunula decreases with age in approximately 20 % of persons.[5]

Nails are usually devoid of pigmentation because of the relatively sparse number of melanocytes present in matrix epithelium.[1,2] Because nail-matrix or nail-bed melanocytes tend to be more numerous in blacks, Asians, and Hispanics, persons of these racial backgrounds may present more commonly with diffuse or banded nail-plate or nail-bed hyperpigmentation.

Pathophysiology Affecting the Nail Matrix

Because of the diagonal orientation of the ventral nail matrix, the proximal portion of the nail matrix produces the superior portion of the nail plate.[6] As a result, disorders of the proximal matrix produce surface abnormalities of the nail plate. A characteristic example is nail-plate pitting secondary to psoriasis. Diseases of the distal nail matrix result in abnormalities of the undersurface of the nail plate, changes that are visible at the free edge of the nail, or both. Permanent damage to the matrix as the result of trauma, surgical intervention, or disease may result in permanent nail-plate dystrophy.

NAIL BED

The nail bed is a layer of epithelium lying between the lunula and the hyponychium (the distal epithelium at the free edge of the nail). The surface epithelium of the nail bed is longitudinally ridged, with small superficially oriented vessels coursing along the same axis, interdigitating with a complementary array of ridges on the undersurface of the nail plate.[3] This anatomic feature explains the longitudinal linearity of splinter hemorrhages, which are foci of extravasation wedged between the bed and the plate. As outgrowth of the nail plate occurs, splinter hemorrhages progress distally.

Pathophysiology Affecting the Nail Bed

The epidermis of the nail bed is thin and minimally keratinized, without a granular layer. If there is prolonged loss of nail plate as a result of disease or surgical intervention, in-

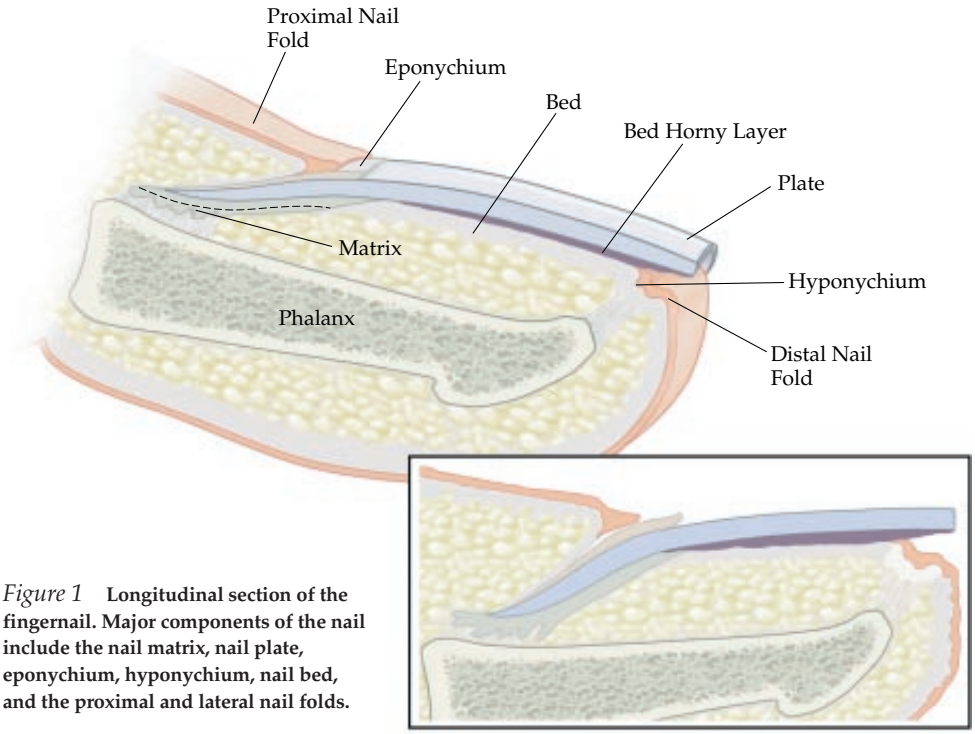

Figure 1 **Longitudinal section of the fingernail. Major components of the nail include the nail matrix, nail plate, eponychium, hyponychium, nail bed, and the proximal and lateral nail folds.**

creased nail-bed keratinization with development of a granular layer prevents the firm attachment of the ingrowing nail plate to the underlying nail bed. Melanocytes are more sparsely distributed in nail-bed epithelium than in the nail matrix [*see* Nail Matrix, *above*]. The dermal layer of the nail bed is very thin and is supported by very sparse subcutaneous tissue; it is firmly attached to the underlying bony phalanx.

NAIL PLATE

The nail plate, which is composed of densely compacted keratinized epithelial cells, is produced by the matrix and progesses distally toward the free edge of the nail as newly formed plate slowly pushes forward in a distal direction. Formation and outgrowth of the nail plate is a continual process. A fully formed nail plate extends from below the proximal nail-fold cuticle to beyond the hyponychium and extends laterally below the cuticle of the lateral nail folds. Nail-plate abnormalities frequently occur secondary to changes or disorders affecting function of the nail matrix; infections such as onychomycosis; or trauma.

Age-Related Nail-Plate Findings

The growth rate of an adult fingernail plate is approximately 3 mm/mo, with marked variability among individuals.[2] Toenail plate growth occurs at one third to one half the rate of fingernail growth. A general rule is that adult fingernails take approximately 6 months to grow out fully; adult toenails, 12 to 18 months. Nail-plate growth is faster in children, peaking between 10 and 14 years of age; there is a slowly progressive decline after the second decade of life.[2] Linear nail-plate growth decreases by 50 % over a lifetime, with periods of slow decline alternating with periods of rapid decline in approximate 7-year increments.[7] Nail-plate growth increases during pregnancy and decreases during lactation, after use of chemotherapeutic agents, and in conditions characterized by limb paralysis, persistently diminished circulation, or malnutrition.[2,3,8] Yellow nail syndrome is characterized by very slow or absent growth of nail plate; it usually affects both fingernails and toenails and is seen in association with several underlying conditions, such as lymphedema, respiratory disorders (e.g., bronchiectasis and pleural effusions), and nephrotic syndrome.[9]

Constitutional age-related findings in the nail plate include changes in nail color and luster, longitudinal ridging, changes in convexity, and brittle nails.[8,10] Nail plates, especially of toenails, often develop a yellow or gray color with a dull, opaque appearance. Longitudinal ridging may affect some or all nails and may present as slightly indented grooves or projection ridges or as beading. Over time, the surface of the nail plate may become flattened (platyonychia) or spooned (koilonychia). Temporary koilonychia, especially of the toenails, is also seen in infants.[6]

Pathophysiology Affecting the Nail Plate

Brittle nails is a common complaint; its incidence is 20% in the overall population (27% in female patients) and increases with advancing age.[10] When nail water content falls below 16%, nail plates become brittle; when the water content rises above 25%, nail plates become soft. The most common cause of brittle nails is dehydration, which can be caused or exacerbated by external factors such as use of nail-polish remover or exposure to dry climate. Onychoschizia, which presents as a layered, superficial splitting of the nail plate, may increase in incidence with age. This condition is seen much more frequently in female patients. It is likely related to recurrent exposures to water or irritants, such as during nail-care procedures.

Fingernails demonstrate a tendency to become thinner and more fragile over time. Toenails usually become thicker and harder. Onychogryphosis is a marked thickening, usually of the large toenail, resulting in a compacted mass of heaped-up dystrophic nail plate.[8] Contributing factors appear to be advanced age, poor nail care, chronic trauma, decreased peripheral circulation, and neuropathy. Poor-fitting shoewear causes long-term exposure to lateral pressure and friction, resulting in gryphotic changes (marked thickening or heaping of nail plate), usually of the first and fifth toenails.

NAIL FOLDS

The nail folds are the cutaneous soft tissue that houses the nail unit, invaginating proximally and laterally to encompass the emerging nail plate. The proximal nail fold, with the exception of the lunula, covers the underlying matrix and is devoid of sebaceous glands and dermatoglyphic skin markings.[11] The term paronychia describes inflammation of the nail folds. Paronychia may be acute or chronic and may occur secondary to a variety of conditions, including contact dermatitis, psoriasis, bacterial infection, and fungal infection.[12,13] The cuticle (eponychium) is a thin, keratinized membrane of modified stratum corneum that extends from the distal portion of the nail fold, reflecting onto the nail-plate surface. Intact cuticle serves as a seal that protects the space between the nail folds and the nail plate from exposure to external irritants, allergens, and pathogens. Loss of cuticle allows for exposure and trapping of these deleterious external agents, providing an environment in which either inflammatory or infectious paronychia can develop.

Nail Findings Associated with Disease States

Several nail findings have been associated with both underlying systemic and dermatologic conditions. The following is a review of selected, recognized associations. Diagnosis is based on proper evaluation of clinical findings; treatment is based on a confirmed etiology or the recognition of an underlying systemic association.

Special care must be taken when performing biopsy of the nail bed or matrix to avoid trauma to the tissue specimen and surrounding structures upon specimen removal. The most appropriate plane of dissection during nail-bed or nail-matrix biopsy is subdermal. The sampled tissue should be manipulated very gently throughout the biopsy procedure to avoid crush artifact, which may interfere significantly with histopathologic evaluation. It is also important to carefully dissect along the undersurface of the specimen, ensuring nontraumatic separation of the biopsy tissue from its underlying firm attachment to bone.

SPLINTER HEMORRHAGES

Splinter hemorrhages may be secondary to trauma, high altitude, primary dermatoses (i.e., psoriasis), or several underlying conditions (e.g., arterial emboli, collagen vascular disease, or thromboangiitis obliterans). The simultaneous appearance of splinter hemorrhages in several nails should raise suspicion of a possible underlying systemic disorder, especially in female patients.[14]

KOILONYCHIA

Koilonychia may be found in association with other conditions, including congenital conditions, iron deficiency anemia, cardiac disease, endocrinopathy, occupational exposures, and trauma.[3,15]

TRANSVERSE NAIL-PLATE DEPRESSIONS (BEAU LINES)

Beau lines present as well-delineated, transverse depressions in the nail plate. They are believed to occur secondary to temporary growth arrest of the nail matrix. The grooves become evident weeks after the occurrence of an abrupt, stressful event, such as an acute febrile illness. The width of the groove reflects the duration of interrupted nail-matrix function. When limited to one or a few digits, Beau lines may be associated with trauma, carpal tunnel syndrome, or Raynaud disease, or they may occur subsequent to tourniquet application during hand surgery.[15] Approximately 1 to 2 months after birth, infants may demonstrate physiologic Beau lines, which mark the transition from intrauterine to extrauterine life.[16] Multiple transverse grooves (stepladder appearance) may be seen in association with repeated cycles of chemotherapy, or they may be related to zinc deficiency. Multiple Beau lines should not be confused with the multiple transverse depressions that are stacked longitudinally along the central nail plate (washboard nails), resulting from the obsessive habit of repeatedly pushing back the cuticle or picking at the proximal nailfold margin (habit-tic deformity) [*see Figure 2*].[15,17] There is no specific treatment for Beau lines. They grow out over time after resolution of the growth-arrest period.

Figure 2 **Stacking of transverse linear grooves traversing the entire length of the central nail plate, resulting from the repeated picking of the proximal nail fold margin (habit-tic deformity). Note the marked hypertrophy of the lunula, which is typical of this disorder.**

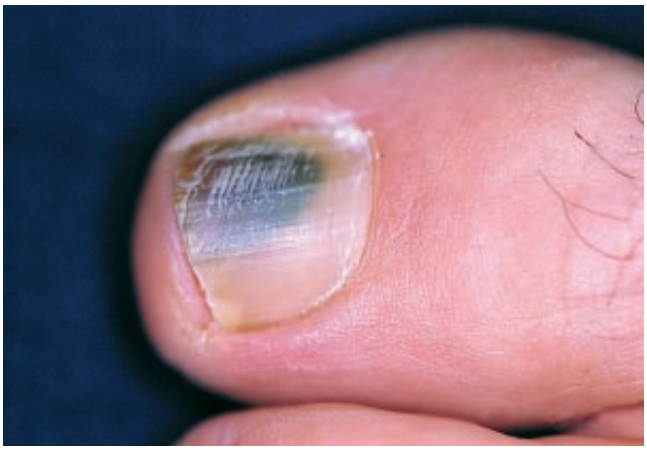

Figure 3 **Colonization of the closed space between the nail bed and nail plate with *Pseudomonas aeruginosa,* causing a green nail. Moisture trapped in the onycholytic space provides an optimal environment for proliferation of this bacterium.**

ONYCHOLYSIS

Onycholyis is defined as the separation of the nail plate from the nail bed. In most cases, onycholysis begins distally; it is often related to acute or chronic trauma that produces a lever effect, lifting the nail plate upward and away from its bed. Other causes of onycholysis are chemical exposure (allergic or irritant dermatitis), onychomycosis, and primary dermatoses (e.g., psoriasis or lichen planus).[13] Associations with underlying systemic disease (e.g., thyroid disease) have been sporadically reported but are less commonly encountered in clinical practice. When moisture accumulates under onycholytic nail plate, bacterial proliferation may occur. This can cause a green discoloration of the nail plate as a result of a pigment produced by certain organisms (e.g., *Pseudomonas aeruginosa*) [*see Figure 3*].

Treatment requires avoidance of precipating factors for onycholysis, debridement of separated nail plate, and the twice-daily topical application of diluted acetic acid solution (consisting of equal parts white vinegar and water), gentamicin, or the combination of polymyxin B and bacitracin.[18]

LEUKONYCHIA

Leukonychia, a white discoloration of the nail plate or subungual tissue, has multiple presentations. Small 1 to 3 mm white spots (punctate leukonychia) or irregular transverse streaks (leukonychia variegata) of the nail plate are the most common varieties.[15] These two presentations are generally secondary to repeated microtrauma to the matrix, growing out distally with outgrowth of the nail plate. Mee lines specifically refer to transverse 1 to 2 mm white bands, which usually are demonstrated at the same site in multiple nails and reported in association with arsenic intoxication, Hodgkin disease, sickle cell anemia, renal failure, and cardiac insufficiency. Leukonychia is also associated with systemic infection and chemotherapy.[19-21]

Half-and-half nails (Lindsay nails) present as a diffuse, dull whitening of the proximal nail bed that obscures the lunula and as a distal region of pink or reddish-brown discoloration that occupies from 20% to 60% of the nail length.[15,22] The most commonly reported association with half-and-half nails is chronic renal failure. When the distal brown band of discoloration constitutes less than 20% of the total nail length, the anomaly is known as Terry nails, which occurs in association with chronic congestive heart failure, hepatic cirrhosis, type 2 (non–insulin-dependent) diabetes mellitus, and advanced age. In both half-and-half nails and Terry nails, the proximal portion of the nail bed may be light pink, exhibiting a more normal appearance, rather than white.

Muehrcke nails present as paired, white, narrow transverse bands of the nail bed, separated by normal-appearing thin pink bands.[15,22] Muehrcke nails have been associated with chronic hypoalbuminemia. Resolution of this nail finding correlates with normalization of serum albumin levels.[15]

CLUBBING

When the normal angle between the proximal nail fold and the nail plate exceeds 180°, digital clubbing is present. The morphologic changes of clubbing typically include hypertrophy of the surrounding soft tissue of the nail folds as a result of hyperplasia of dermal fibrovasculature and edematous infiltration of the pulp tip.[21] Radiologic changes are identified in fewer than 20% of cases.[15]

Clubbing may be hereditary, or it may be seen in association with several underlying disease states, such as hypertrophic pulmonary osteoarthropathy, chronic congestive heart failure, congenital heart disease associated with cyanosis, polycythemias associated with hypoxia, Graves disease, chronic hepatic cirrhosis, lung cancer, Crohn disease, and irritable bowel disease.[15,22,23] When clubbing is unilateral, consideration should be given to underlying causes of obstructed circulation, such as aneurysm, arteriovenous fistula, and a pulmonary sulcus tumor (Pancoast tumor); disorders producing soft tissue edema; and diseases causing localized changes in underlying digital bone (e.g., sarcoidosis). Unilateral clubbing can also be found in cases of hemiplegia,[24] and a case of subungual perineurioma caused by unilateral clubbing has been reported.[25] Paronychia and distal phalangeal resorption may cause changes that simulate true clubbing (pseudoclubbing).

NAIL-PLATE PITTING

Nail-plate pitting (onychia punctata) develops as a result of focal defects in nail-plate formation from the proximal nail matrix. The number, size, and shape of the superficial depressions may vary.[15] The extent and duration of involvement with nail pitting correlates with the duration of nail-matrix abnormality. Psoriasis, the most common association with nail pitting, may produce a random array of shallow or deep pitted indentations, usually affecting one or more fingernails.[26,27]

Psoriasis of the nails often responds poorly to treatment, and it tends to recur. Topical corticosteroids, topical tazarotene, and intralesional corticosteroid injection may help in some cases.[28,29] It is a common misconception that nail pitting is pathognomonic for psoriasis.[27] Nail pitting may also be seen in association with alopecia areata, punctate keratoderma, idiopathic trachyonychia, occasionally in normal nails, and rarely in association with collagen vascular disease or syphilis. Fingernail pitting occurs in one third of children with alopecia areata; mild disease involving only a few nails is observed in approximately 20% of cases.[27] Compared to psoriasis, nail pitting seen in alopecia areata is typically more uniform and patterned, often presenting as orderly rows of shallow pitted depressions. Currently, there is no available treatment for this type of nail pitting.

LONGITUDINAL PIGMENTED BANDS

Longitudinal pigmented bands (melanonychia striata), also referred to as longitudinal melanonychia, is the presence of single or multiple longitudinally oriented brown or black bands [*see Figure 4*]. Homogeneous longitudinal bands occur in approximately 75% of African Americans older than 20 years. It usually affects the thumb and index finger.[30,31] Melanonychia striata is also commonly seen in Hispanics, may be found in up to 20% of Japanese, and is rare in whites.[30]

The deposition of melanin in the nail plate may result from increased melanin synthesis by matrix melanocytes that are usually nonfunctional; it may also occur as a result of a proliferation of matrix melanocytes.[30] Melanonychia striata affecting a single nail may result from a benign melanocytic nevus or a subungual melanoma. Thus, it is important to distinguish between a benign cause and a malignant cause of a longitudinal pigmented band. Factors suggesting the presence of melanoma or an atypical melanocytic proliferation are (1) single digit involvement; (2) periungual spread of pigment onto the nail-fold region (Hutchinson sign); (3) border irregularity or variegated color within the linear streak; and (4) changes in appearance (e.g., color or borders) involving an established longitudinal band.[32] Because of the severity of subungual melanoma and the importance of making a prompt diagnosis, the index of suspicion must be high. A simple biopsy of the nail plate is not satisfactory in establishing the diagnosis, because it will only demonstrate the presence of melanin. An appropriate biopsy inclusive of the nail matrix, as well as the nail bed if clinically indicated, should be performed by a surgeon who is familiar with the intricacies of performing a nail biopsy.[33] Because of limited experience and the difficulties that are commonly con-

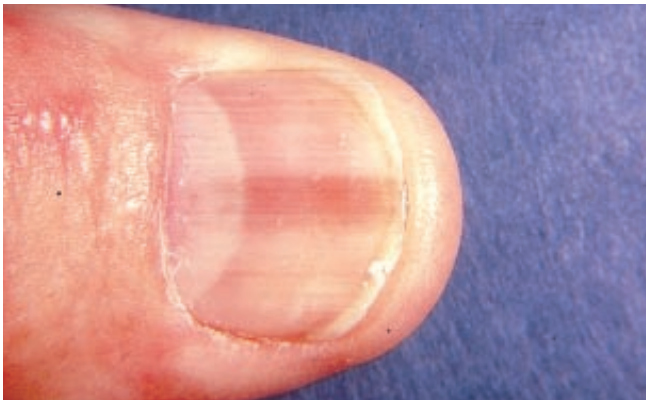

Figure 4 **Melanonychia striata (longitudinal pigmented band) produced by a melanocytic nevus of the nail matrix. A high index of suspicion for subungual melanoma is very important when a longitudinal pigmented band of the nail is identified.**

Figure 5 **Psoriasis of the nail, characterized by subungual hyperkeratosis and loss of distal onycholytic nail plate. This patient was unsuccessfully treated with oral antifungal therapy after an erroneous diagnosis of onychomycosis was made on the basis of clinical diagnosis alone. Careful examination of the proximal intact nail plate reveals pitting, a feature characteristic for psoriasis and not onychomycosis.**

a

b

Figure 6 **(*a*) When obtaining a nail specimen for potassium hydroxide (KOH) preparation, it is important to expose the affected nail bed by first trimming away and discarding the distal, separated (onycholytic) nail plate. (*b*) Small specimen fragments of subungual hyperkeratosis of the nail bed and exposed undersurface of the nail plate are effectively obtained using a small curette. The smaller fragments are more easily dissolved by KOH, allowing for more accurate microscopic visualization, and can be easily plated on fungal culture medium.**

fronted in the histologic interpretation of nail specimens, biopsies of melanonychia striata are best interpreted by a dermatopathologist.[34]

When nail-bed pigmentation is noted, other causes such as systemic drugs (e.g., antimalarials, zidovudine, bleomycin, doxorubicin, minocycline, and hydroxyuria) or systemic disease (e.g., Addison disease and HIV infection) must be considered; however, these causes usually result in a broader, more diffuse pigmentation, often involving multiple nails.[35] Another reported association with melanonychia striata is systemic lupus erythematosus.[36] Frictional melanonychia resulting from trauma from athletic activities or poorly fitting shoewear may cause nail pigmentation, including pigmentation of the nail fold, especially in dark-skinned persons (pseudo-Hutchinson sign).[32]

Bacterial and Fungal Nail Infections

BACTERIAL PARONYCHIA

Bacterial infection of the nail folds (bacterial paronychia) is usually acute in nature. It is is characterized by swelling, erythema, discomfort, and sometimes purulence. The most common etiologic pathogen is *Staphylococcus aureus*. Treatment requires drainage of a focal abscess, if present, and oral antibiotic therapy.[37]

CHRONIC PARONYCHIA

Chronic paronychia results from persistent or frequently recurrent nail-fold inflammation, which is usually the result of chronic irritant dermatitis and loss of cuticle from trauma or nail-care practices. Secondary candidal infection may occur.[29,38]

Table 1 Oral Antifungal for Toenail Onychomycosis*[46]

Drug	*Dosage*	*Comments*
Griseofulvin tablets or liquid	500 mg – 1 g daily × 12 – 18 mo	Generally not recommended because of limited efficacy and because more effective agents are available; only active against dermatophyte organisms
Itraconazole capsules	Pulse therapy†: 200 mg twice daily × 1 wk/mo for 3 consecutive mo Continuous therapy: 200 mg daily × 3 mo	Contraindications include specific drug interactions and congestive heart failure; potential hepatotoxicity (rare); effective for dermatophytes, *Candida* species, and some nondermatophytic molds; should be administered with food; absorption may be decreased by increased gastric pH (as might result from use of H_2 blockers, antacids, proton pump inhibitors); blood clearance in 1 – 2 wk; therapeutic nail levels 9 mo posttherapy
Terbinafine tablets	250 mg daily × 3 mo	Most active for dermatophytes; some efficacy for certain nondermatophytic molds; limited activity against most *Candida* species; potential hepatotoxicity (rare); sporadic reports of blood dyscrasias (rare); reversible change or loss of taste (< 2%); blood clearance in 1 – 2 mo; therapeutic nail levels 9 mo posttherapy
Fluconazole tablets‡	150 – 300 mg × 9 – 12 mo	Effective against dermatophytes and *Candida* species; potential hepatotoxicity (rare); some significant drug interactions; limited therapeutic drug reservoir in nail posttherapy

*Topical ciclopirox 8% nail lacquer is FDA approved for onychomycosis caused by *Trichophyton rubrum*. Treatment involves application once daily for 12 mo (or until outgrowth of clear nail occurs), combined with debridement/trimming of onycholytic nail plate. Efficacy is lower than that seen with newer oral agents (e.g., itraconazole, terbinafine). No oral or topical agent is currently FDA approved for nondermatophytic onychomycosis (e.g., *Candida* species, molds).

†Pulse itraconazole is FDA approved for fingernail tinea unguium; established efficacy has been demonstrated for toenail disease.

‡Fluconazole is not FDA approved for onychomycosis; established efficacy has been demonstrated for tinea unguium.

Table 2 Selected Dermatologic Disorders Affecting the Nail Unit

Disease State	*Disease Features*	*Nail Findings*
Inflammatory diseases		
Psoriasis	Nail findings in 10% – 50% of patients; 39% of children with psoriasis with nail changes (usually pitting); nail disease present in 50% – 85% of patients with psoriatic arthritis	Proximal matrix involvement: pitting, transverse grooving, deeply ridged plate surface (onychorrhexis) Distal matrix involvement: plate thinning, lunula erythema Nail bed: subungual hyperkeratosis, oil drop sign, splinter hemorrhages Nail folds: cutaneous lesions of psoriasis Phalangeal/joint involvement: psoriatic arthritis
Lichen planus	Nail changes occur in up to 10% of patients with lichen planus; may occur in childhood or adulthood; nail involvement may be present with or without skin or mucosal disease; potentially reversible in early inflammatory stage; irreversible in cicatricial (later stage) of disease; may present as ridged, rough-surfaced, lusterless plates (trachyonychia) or 20-nail dystrophy in children	Matrix involvement: combination of nail-plate ridging, splitting, and progressive uniform thinning; distal-edge splitting, fragility, crumbling, brittleness, nail-plate shedding (onychomadesis) Focal matrix scarring: pterygium formation (scarring bridge between proximal nail fold and subungual epidermis with focal loss of nail plate) Nail-bed involvement: subungual hyperkeratosis, onycholysis Diffuse matrix/nail-bed disease: total nail-plate loss, atrophy, scarring
Alopecia areata	Nail changes in 10% of patints with alopecia areata; nail changes in over 40% of children with alopecia areata; fingernail involvement most common; may present in children as 20-nail dystrophy	Matrix involvement: orderly nail pitting arranged in a crosshatched pattern (glen-plaid sign); roughened nail-plate surface (trachyonychia); fragility; splitting; longitudinal ridging; spotted or red lunula (erythema); nail-plate shedding (onychomadesis)
Nail tumors		
Glomus tumor	75% occur on the hand, usually subungual (nail bed); a benign vascular hamartoma	Visible through plate as a light-red, reddish-blue spot; rarely exceeds 1 cm in size; characteristic symptom of intense or pulsatile pain; pain is spontaneous or provoked by slight trauma or pressure
Digital myxoid (mucus) cyst	A form of focal mucinosis; not a true cyst (no epithelial lining); contains clear, viscous, jellylike fluid; usually seen in adults	Soft, domed, translucent, pink or skin-colored, shiny, soft neoplasm of proximal nail fold or overlying distal interphalangeal joint; those over fold may compress matrix, producing flattening of plate; those over joint may connect to underlying joint space
Subungual exostoses	Outgrowths of calcified cartilage or normal bone; most seen on great toe; most frequent in adolescents and young adults; benign lesions	Emerge from the dorsal digit at distal phalanx; may erode through plate or project from under distal or lateral edge of plate; often painful; may become eroded
Periungual angiofibromas	Arise out of nail fold; often multiple; seen in 50% of cases of tuberous sclerosis (Borneville-Pringle disease); usually arise in early teenage years; benign neoplasm	Small, round, flesh-colored or pink, firm papules with shiny, smooth surface arising from nail-fold region; may partially cover nail plate; usually asymptomatic

ONYCHOMYCOSIS

Onychomycosis, the most common infection of the nail, is a fungal infection characterized by nail-bed and plate involvement. Dermatophyte onychomycosis (tinea unguium) is the most common type of fungal nail infection.[39] It is seen far more commonly in adults than in children and most frequently affects one or more toenails. The mode of fungal invasion usually presents as distal-lateral subungual onychomycosis, occurring as dermatophyte organisms migrate from pedal skin to below the nail plate and invade nail-bed tissue.[40] Tinea pedis and onychomycosis frequently coexist in a patient.[41,42]

The dermatophytes that most commonly cause onychomycosis are *Trichophyton rubrum* and *T. mentagrophytes*.[43] The tendency to harbor dermatophytes (especially *T. rubrum*), predominantly on pedal skin, has been noted in some kindreds. As a result, patients with such a tendency are prone to tinea pedis, tinea unguium, tinea cruris, and diffuse tinea corporis. They may present with dermatophyte infections earlier in life than usually seen and often experience recurrence of dermatophyte infection after completion of initially effective therapy.

The most characteristic clinical features of dermatophyte onychomycosis are distal onycholysis, subungual hyperkeratosis, and a dystrophic, discolored nail plate.[42] Because this combination of features is also seen in persons with nail psoriasis, accurate diagnosis may require performance of a potassium hydroxide (KOH) preparation and fungal culture [*see Figure 5*]. It is important that specimens be obtained from the nail bed [*see Figure 6*] and that culture specimens be transported and plated appropriately, because different culture media are required for identification of dermatophyte and nondermatophyte fungal nail pathogens.[42] Dermatophyte test medium (DTM) may be used as an in-office culture technique that has no special incubation requirements. DTM is inexpensive and accurate in the diagnosis of dermatophyte onychomycosis.[44] The clinical presentation of proximal white subungual onychomycosis, another presentation of dermatophyte onychomycosis, has been reported in association with systemic immunosuppression, including HIV disease.[45]

Candida onychomycosis is far less common than dermatophyte onychomycosis. *Candida* onychomycosis is often associated with immunosuppression (e.g., HIV disease and chronic mucocutaneous candidiasis). The *Candida* organisms may invade

the nail as a secondary pathogen, and they more frequently affect the fingernails.[42] Nondermatophyte molds, including *Aspergillus* species, *Scopulariopsis brevicaulis*, *Fusarium* species, *Scytalidium hyalinum,* and *Scytalidium dimidiatum,* have been reported to cause fingernail or toenail infection; however, such infections are relatively uncommon.[42,46] Associated paronychia may be seen when nondermatophytic fungi cause onychomycosis. Effective therapy for onychomycosis includes the use of an oral antifungal agent [*see Table 1*].[47] Because nails grow slowly, clinical response is delayed.[46] Infections with *Scytalidium* species are rare in the United States, and such infections respond poorly to currently available antifungal agents.

DERMATOLOGIC DISORDERS AFFECTING THE NAIL

Complete reviews of dermatologic, systemic, neoplastic, and exogenous disorders affecting the nail are beyond the scope of this subsection. An overview of selected dermatologic disorders affecting the nail unit and their associated clinical findings is provided [*see Table 2*].

James Q. Del Rosso, D.O., participates in the speakers' bureaus and is a consultant for Allergan, Inc., Janssen Pharmaceutica Products, L.P., Dermik Laboratories, Inc., Novartis Pharmaceuticals Corp., and Medicis Co.

C. Ralph Daniel III, M.D., has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

XV DISORDERS OF PIGMENTATION

Pearl E. Grimes, m.d.

Disorders of Hyperpigmentation

melasma

Definition

Melasma is a common acquired symmetrical hypermelanosis characterized by irregular light-brown to gray-brown macules involving the face. There is a predilection for the cheeks, forehead, upper lips, nose, and chin [*see Figure 1*]. Lesions may occasionally occur in other sun-exposed areas, including the forearms and back.[1-3]

Epidemiology

Melasma is most commonly observed in females. Men constitute only 10% of the cases but usually demonstrate the same clinicopathologic features as women do. The condition affects all racial and ethnic groups but is most prevalent in persons with darker complexions (skin types IV through VI). It is also more common in geographic areas with intense ultraviolet radiation (sunlight), such as tropical and subtropical regions.

Etiology and Pathogenesis

Although the precise cause of melasma is unknown, multiple factors have been implicated in the etiology and pathogenesis of this condition. These factors include genetic influences, intense ultraviolet radiation exposure, pregnancy, oral contraceptive use, hormone replacement therapy, cosmetics, and phototoxic and antiseizure medications.[1]

Endocrinologic studies of patients with melasma have shown varying results. Although a detailed study of nine women with melasma showed significantly increased levels of luteinizing hormone (LH) and low levels of estradiol, suggesting a role for subclinical mild ovarian dysfunction, a study of 26 women found no difference in LH, follicle-stimulating hormone (FSH), and α-melanocyte–stimulating hormone (α-MSH) levels between patients with melasma and control subjects.[3] Another study reported increased expression of α-MSH in the affected skin areas of 10 women with melasma. α-MSH stimulates tyrosinase and melanin synthesis.[4]

Clinically, the light-brown patches are commonly evident on the malar prominences, forehead, chin, nose, and upper lip. The patches may have a malar, centrofacial, or mandibular distribution. Histologically, an epidermal, epidermal-dermal, or dermal pattern of increased pigmentation occurs. Histologic studies document an increase in epidermal pigmentation, increased numbers of melanocytes, and increased activity of melanogenic enzymes.[5] A Wood-light examination enhances the epidermal pattern of pigment deposition. Such epidermal lesions are most amenable to treatment.

The differential diagnosis of melasma includes other conditions that cause facial hyperpigmentation, such as postinflammatory hyperpigmentation, drug-induced hyperpigmentation, lichen planus actinicus, and photosensitivity disorders.

Treatment

Current treatments for melasma include broad-spectrum sunscreens, 2% (over the counter) and 4% (prescription) hydroquinone formulations, azelaic acid, kojic acid formulations, α-hydroxyacid products, retinoic acid, retinol, superficial chemical peels, and microdermabrasion.[1,6-9] A triple-combination product containing 4% hydroquinone, 0.01% fluocinolone, and 0.05% retinoic acid has enhanced efficacy. This product was previously compounded by pharmacists, but it is now available as a commercial preparation (Tri-Luma cream, Galderma Laboratories) that has been approved by the Food and Drug Administration for treatment of melasma. Because the combination contains a fluorinated steroid, treatment should be limited to 8 weeks. Laser therapy offers minimal long-term success and, instead, may worsen the condition. Intense pulsed light therapy may offer some improvement in patients with melasma.[10,11]

Although all of these therapies reduce the severity of melasma, none are curative. Hence, it is essential for patients to rigidly adhere to a regimen of daily sun protection (e.g., using sunscreen or wearing protective clothing) to control the progression of melasma.

postinflammatory hyperpigmentation

Definition

Postinflammatory hyperpigmentation is characterized by an acquired increase in cutaneous pigmentation secondary to an inflammatory process [*see Figure 2*]. Excess pigment deposition may occur in the epidermis or in both the epidermis and the dermis.

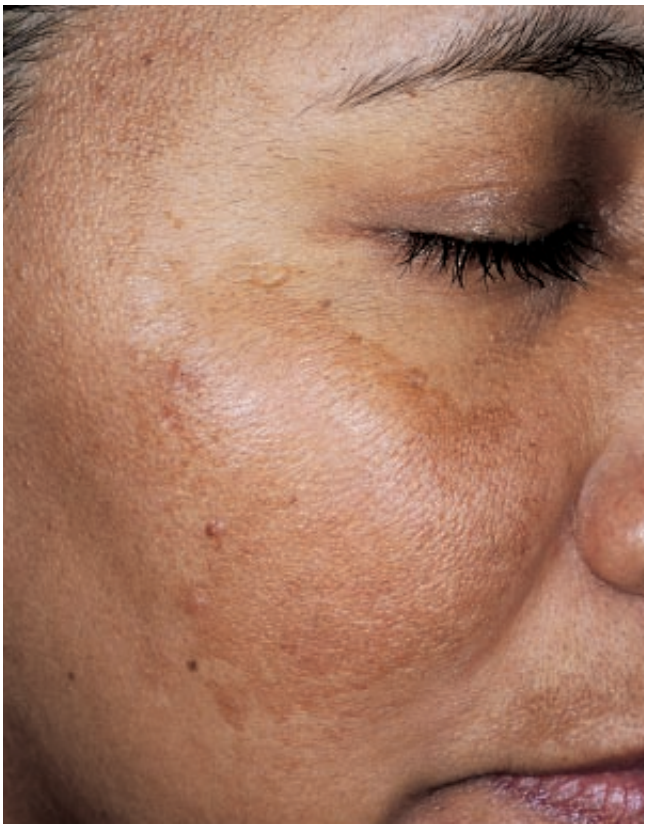

Figure 1 **Melasma is characterized by hyperpigmentation of the cheek, forehead, and upper lip.**

Epidemiology

All racial and ethnic groups are susceptible to postinflammatory hyperpigmentation, but the incidence of the condition is higher in persons with darker complexions. In a diagnostic survey of 2,000 African-American patients seeking dermatologic care, the third most common diagnosis was pigmentary disorders, of which postinflammatory hyperpigmentation was the most prevalent.[1]

Etiology and Pathogenesis

Pigmentary changes may be a result of production of inflammatory mediators and altered cytokine production.[12,13] Such changes may lead to an increase in the number and size of epidermal melanocytes. In addition, hyperpigmentation may be a consequence of pigmentary incontinence, with deposition of pigment in the upper dermis. Postinflammatory hyperpigmentation may be a sequela of conditions such as acne, allergic reactions, drug eruptions, papulosquamous disorders, eczematoid disorders, and vesiculobullous disorders.[14]

Diagnosis

Clinically, postinflammatory pigmentary changes may be localized, circumscribed, or generalized. Lesions range in color from brown to black to ashen gray and usually follow the distribution of the primary dermatosis.

Treatment

Therapies for postinflammatory hyperpigmentation include over-the-counter and prescription hydroquinone preparations. Higher concentrations are indicated for moderate to severe involvement. Other treatments include azelaic acid, kojic acid, retinoic acid [*see* Melasma, *above*], and adapalene.[15]

DRUG-INDUCED HYPERPIGMENTATION

Medications are a common cause of cutaneous hyperpigmentation. Lesions may be localized or generalized. Medications can also cause hyperpigmentation of the oral mucosa and nails. There may be some improvement upon withdrawal of the offending agent; however, drug-induced hyperpigmentation can persist for many years.

Medications causing drug-induced hyperpigmentation include oral contraceptives, hormone replacement therapies, antibiotics, antidepressants, antiviral agents, antimalarials, antihypertensives, and chemotherapeutic agents. Such medications include progesterone, estrogen, zidovudine (AZT), minocycline, tetracycline, bleomycin, hydrochlorothiazide, hydantoin, amiodarone, chlorpromazine, quinacrine, hydroxychloroquine, chloroquine, imipramine, amitriptyline, diltiazem, citalopram, hydroxyurea, doxorubicin, busulfan, daunorubicin, cisplatin, cyclophosphamide, thiotepa, vinblastine, and vincristine.[16-23]

Heavy-metal preparations can also cause hyperpigmentation. These preparations include arsenic, gold, silver, mercury, and bismuth.

Treatment with the Q-switched alexandrite laser has proven to be an effective treatment for drug-induced pigmentation.[19,24]

ERYTHEMA DYSCHROMICUM PERSTANS

Definition

Erythema dyschromicum perstans (EDP, or ashy dermatosis) is an acquired benign condition characterized by slate-gray to violaceous macules. It was first described in 1957.

Figure 2 **Postinflammatory hyperpigmentation of the face may be secondary to acne vulgaris.**

Epidemiology

EDP is reported most commonly in dark-skinned persons. However, cases have been reported globally and in all skin types. The disease appears to have a relatively equal frequency in men and women. It has also been reported in children.

Etiology and Pathogenesis

The precise cause of EDP is unknown. Studies suggest that pollutants, pesticides, hair dyes, chemicals, and drug exposure may play a role in the pathogenesis.[23-28] Findings in light microscopic, ultrastructural, and immunofluorescent studies of EDP have been similar to those in studies of lichen planus, leading some investigators to postulate that EDP may be a variant of lichen planus. Other studies suggest that EDP is a distinct entity. Expression of intercellular adhesion molecule–I (ICAM-I) and major histocompatibility complex (MHC) class II molecules (HLA-DR) has been reported.[29] These findings suggest that aberrant cell-mediated immunity may be involved in the pathogenesis of EDP.

Diagnosis

Clinically, the macules of EDP are ashen and may have an erythematous, slightly raised border during the early stages of the disease. Erythematous macules have also been described during the early stages. Areas of erythema eventually resolve, leaving slate-gray areas of pigmentation. The lesions are usually symmetrically distributed and vary in size from small macules to very large patches. Common sites of involvement include the face, neck, trunk, and upper extremities. Mucous membranes, palms, soles, and nails are usually spared. Light microscopic findings are slight epidermal atrophic changes, spongiosis, lymphocytic exocytosis, and basal vacuolopathy in the epidermis, as well as lymphohistiocytic, lichenoid dermal infiltrates. In later stages, the lesions lack the epidermal changes and show increased deposition of dermal pigment.

Postinflammatory hyperpigmentation, idiopathic eruptive macular pigmentation, pityriasis rosea, lichen planus, fixed drug eruption, Addison disease, pinta, syphilis, macular amyloidosis, hemochromatosis, and argyria must be distinguished from EDP.

Treatment

Therapies for EDP have been minimally effective. They include sunscreens, hydroquinone, topical corticosteroids, systemic steroids, griseofulvin, clofazamine, antibiotics, and antimalarials.[30]

LENTIGINES

Definition

A lentigo is a well-circumscribed, brown to brown-black macule, usually less than 1 cm in size, that appears at birth or in early childhood. Lentigines occur in all skin types and may be found on any cutaneous surface, including the palms, soles, and mucous membranes. They do not darken with sun exposure. Lentigines can be localized and must be distinguished from freckles (ephelides). Clinical differentiating features include the later appearance of freckles (at 4 to 6 years of age) and their predominance on sun-exposed skin and increased frequency in redheads and fair-skinned persons. Freckles also tend to fade in winter and with advancing age.

Epidemiology

Multiple lentigines have been reported in 18.5% of black newborns and 0.04% of white newborns. Solar lentigines have been reported in 90% of whites older than 60 years.

Diagnosis

Several types of lentigines are recognized, including lentigo simplex, solar lentigines, nevus spilus, lentigines induced by psoralens plus ultraviolet A (PUVA), generalized lentiginosis, and syndrome-related lentiginosis.

Lentigo simplex lesions may occur as solitary localized macules or may be numerous and widespread. They often occur during the first decade of life and can be found on any cutaneous surface.

Solar (senile) lentigines, or so-called liver spots, are brown macules that appear late in adult life on chronically sun-exposed skin. These lesions are present in 90% of whites older than 70 years and occur in response to solar exposure. Solar lentigines correlate with the tendency to freckle and with two or more sunburns after 20 years of age.

Nevus spilus, or speckled lentiginous nevus, is a congenital brown patch on which dotted brown macules develop during childhood. Histologically, the brown patch has features of a lentigo, whereas the dotted brown macules most often reveal features of junctional nevi. Zosteriform patterns have also been described. Generalized lentiginosis is characterized by innumerable lentigines unassociated with other abnormalities.

Syndromes characterized by multiple lentiginosis include multiple lentigines (LEOPARD [multiple lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, sensorineural deafness]) syndrome, Moynahan syndrome, centrofacial lentiginosis, Carney complex, Laugier-Hunziker disease, Peutz-Jeghers syndrome, and Bannayan-Ruvalcaba-Riley syndrome.[31,32]

The histopathology of lentiginosis shows elongated rete ridges, increased numbers of basal melanocytes, and increased basal melanization. In contrast, freckles result from hypermelanization of basal melanocytes without a concomitant increase in number.

Lentigo must be distinguished from other flat, pigmented lesions, including freckles, junctional nevi, postinflammatory hyperpigmentation, and pigmented actinic keratoses.

Treatment

The treatment of lentigines includes hydroquinone-containing bleaching agents, cryotherapy, Q-switched neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, and intense pulsed light.[33,34]

CONFLUENT AND RETICULATED PAPILLOMATOSIS OF GOUGEROT AND CARTEAUD

Definition

The eruption of confluent and reticulated papillomatosis was initially described by Gougerot and Carteaud in 1927 and 1932. The condition consists of 2 to 5 mm hyperpigmented papules that have a predilection for the sternal area and midline of the back and neck.

Epidemiology

Confluent and reticulated papillomatosis occurs in equal frequency in men and women and shows no racial or ethnic predilections. The disease usually begins during the third decade of life.

Etiology and Pathogenesis

The precise cause of confluent and reticulated papillomatosis is unknown. Abnormal host response to *Pityrosporum orbiculare* (*Malassezia furfur;* the fungus that causes tinea versicolor), abnormal response to colonization by follicular bacteria, and genetically determined defects of keratinization have been suggested.[35,36] The disease has been associated with Cushing syndrome, diabetes, hypopigmentation, and thyroid disorders.

Diagnosis

Patients present with 2 to 5 mm hyperpigmented, slightly verrucoid papules that have a predilection for the back, scapula, and inframammary areas. The papules become confluent near the midline and possess a reticulated pattern near the periphery. The lesions do not form a true scale but, rather, a mealy deposit that can be easily removed with the fingertips.

Histologically, studies show hyperkeratosis, decreased granular cell layers, papillomatosis, absence of sweat glands, and fragmentation of elastic fibers. Electron microscopic studies have shown increased numbers of transitional cells between the stratum granulosum and stratum corneum. This finding suggests premature keratinization. In addition, increased expression of keratin 16 has been reported, suggesting abnormal proliferation, differentiation, or both.[36]

Other conditions that simulate confluent and reticulated papillomatosis are tinea versicolor and acanthosis nigricans.

Treatment

Minocycline is reportedly beneficial.[37] Other treatments that have shown some efficacy include selenium sulfide shampoo, salicylic acid, urea, vitamin A, corticosteroids, calcipotriol, tetracycline, erythromycin, doxycycline, retinoids, and PUVA.[38-41]

DOWLING-DEGOS DISEASE

Definition

Dowling-Degos disease, or reticulated pigmented anomaly of the flexures, is an autosomal dominant disorder with variable penetrance characterized by brownish-black macules of the flexures that develop in a reticulated pattern. It may be caused by an underlying defect in follicular epithelial proliferation.

Diagnosis

Dowling-Degos disease presents as symmetrical, reticulated hyperpigmentation of the groin, axilla, antecubital area, inframammary areas, and neck.[42] The lesions begin as 1 to 3 mm macules that gradually become confluent, assuming a reticulated lacelike pattern. In addition, perinasal and facial involvement is common. Pigmented pinhead-sized comedones are frequently observed in the affected areas, and perinasal, pitted acneiform scars can occur around the mouth.

Lesions of Dowling-Degos disease begin in early adult life and are slowly progressive. The condition has been reported in association with reticulated acropigmentation of Kitamura and hidradenitis suppurativa,[43] suggesting an underlying defect in follicular epithelial proliferation. In addition, the disease has been reported in a large kindred with reticulate acropigmentation of Kitamura and acropigmentation of Dohi, suggesting an association between and overlap of these conditions.[44] Histologically, thin, pigmented epithelial strands of downgrowth extend from the epidermis and follicular wall in a filiform pattern resembling adenoid seborrheic keratoses.[42,45]

Treatment

In general, there is no effective treatment for Dowling-Degos disease. Adapalene and the erbium:YAG laser have been reported to offer some benefit.[46]

Disorders of Hypopigmentation

VITILIGO

Definition

Vitiligo is a common acquired, idiopathic skin disorder characterized by one or more patches of depigmented skin. The depigmentation results from loss of cutaneous melanocytes. These lesions are cosmetically disfiguring and usually cause emotional trauma in both children and adults [*see Figure 3*].

Epidemiology

Vitiligo affects 1% to 2% of the population. Onset may begin at any age, but peak incidence is in the second or third decade of life. The disease shows no racial or ethnic predilection, but because of the stark contrast between depigmented and darker skin tones, it is more cosmetically disfiguring in darker racial and ethnic groups. Females are affected more often than males. The disease has a familial incidence of 25% to 30%. Genetic studies suggest a polygenic inheritance pattern.

HLA studies have reported increases in a variety of haplotypes of class I and class II antigens in patients with vitiligo. However, results vary significantly by race and ethnicity of the population studied. The reported HLA associations include increased frequencies of HLA A30, CW6, CW7, DR1, DR3, DR4, and DQW3.[47]

Etiology and Pathogenesis

The precise cause of vitiligo is unknown. Multiple theories have been proposed, including genetic, autoimmune, neural, biochemical, and viral mechanisms. Reviews addressing the etiology of vitiligo suggest that vitiligo is probably a heterogeneous disease encompassing multiple etiologies.[47,48]

An immune-mediated pathogenesis is the most popular theory. This theory is predicated on the increased frequency of a plethora of immunologic diseases in patients with vitiligo, including hypothyroidism (Hashimoto thyroiditis), Graves disease, pernicious anemia, diabetes mellitus, and alopecia areata. Thyroid diseases are the most common associated diseases. Other disorders reported in association with vitiligo include Addison disease, atopic dermatitis, asthma, lichen planus, morphea, lichen sclerosus et atrophicus, mucocutaneous candidiasis, biliary cirrhosis, myasthenia gravis, Down syndrome, AIDS, and cutaneous T cell lymphoma.

Figure 3 **Vitiligo is indicated by generalized patches of depigmentation of the trunk.**

Humoral and cell-mediated immunologic defects are a common phenomenon in vitiligo.[47,48] Numerous studies have documented an increased frequency of organ-specific autoantibodies. Antithyroid, gastric antiparietal cell, and antinuclear antibodies are most commonly demonstrated. Patients with positive organ-specific autoantibodies unassociated with autoimmune disease have an increased risk of subsequent subclinical or overt autoimmune disease.

Antimelanocyte antibodies, often demonstrated in the sera of patients with vitiligo, induce the destruction of cultured melanocytes by complement-mediated lysis and antibody-dependent cellular cytotoxicity. The presence and titer of antimelanocyte antibodies correlate with the severity and activity of vitiligo. These antibodies are directed against melanocyte cell surface antigens with molecular weights of 25, 35 to 40, 75, 90, and 150 kd. Studies suggest that the antimelanocyte antibody may mediate the destruction of melanocytes in vitiligo. Tyrosinase antibodies have also been reported in patients with localized and generalized disease.[49]

Cellular immune-mediated defects include diminished contact sensitization and quantitative and qualitative alterations in T cells and natural-killer cells. Skin-homing cytotoxic T cells have also been implicated in the destruction of melanocytes. Immunohistochemical studies have demonstrated abnormal expression of MHC class II and ICAM-I by melanocytes in vitiligo, which may contribute to the aberrant cellular immune response. In addition, there is increased expression of the antiadhesive matrix component tenasin in perilesional and lesional vitiliginous skin. Increased tenasin expression may be a consequence of elevated cytokine production and cellular infiltrates in vitiligo.[47] Studies have documented alterations in cytokine production in patients with vitiligo. Studies of affected skin showed a significantly lower expression of granulocyte-macrophage colony-stimulating factor

(GM-CSF), basic fibroblast growth factor (bFGF), and stem cell factor.[50] In contrast, expression of interleukin 6 (IL-6) and tumor necrosis factor–α (TNF-α) was greater in lesional skin than in perilesional or normal skin. Another study reported increased expression of TNF-α, interferon gamma, and IL-10 in the lesional and adjacent skin of vitiligo patients.[51]

Cytomegalovirus DNA has been demonstrated in the involved and uninvolved skin of patients with vitiligo. No viral DNA was detected in matched control subjects.[52] These findings suggest that in some cases, vitiligo may be triggered by a viral infection.

The neural theory is supported by several clinical, biochemical, and ultrastructural observations. These observations include the occurrence of segmental vitiligo; the demonstration of lesional autonomic dysfunction, such as increased sweating; and the demonstration of nerve ending–melanocyte contact. The last observation is rare in normal skin.

Several studies suggest that oxidative stress may be the initial event in the destruction of melanocytes.[53,54] Defective recycling of tetrahydrobiopterin, increased production of hydrogen peroxide, and decreased catalase have been demonstrated in the skin of patients with vitiligo.[55,56] In addition, lesional catecholamine biosynthesis and release are increased. Thus, abnormal release of catecholamines from autonomic nerve endings and oxidative stress may damage melanocytes by altering the free radical defense of the epidermis.

The self-destruction hypothesis proposes that melanocytes may be destroyed by phenolic compounds formed during the synthesis of melanin. In vivo and in vitro studies have demonstrated the destruction of melanocytes by phenols and catechols. In addition, industrial workers who are exposed to catechols and phenols may experience depigmentation of areas of skin.

A variety of environmentally ubiquitous compounds containing catechols, phenols, and sulfhydryls can induce hypopigmentation, depigmentation, or both. These compounds are most often encountered in industrial chemicals and cleaning agents. Possible mechanisms for altered pigment production by these compounds include melanocyte destruction via free radical formation, inhibition of tyrosinase activity, and interference with the production or transfer of melanosomes.

Diagnosis

Clinical manifestations Vitiliginous lesions are typically asymptomatic depigmented macules without clinical signs of inflammation. However, inflammatory vitiligo with erythematous borders has been reported. Hypopigmented lesions may coexist with depigmented lesions. The patches are occasionally pruritic. Macules frequently begin on sun-exposed or perioral facial skin and either remain localized or disseminate to other cutaneous sites. Areas of depigmentation vary in size from a few millimeters to many centimeters, and their borders are usually distinct. Trichrome lesions are most often observed in darker-complexioned persons. These lesions are characterized by zones of white, light-brown, and normal skin color. Depigmented hairs are often present in lesional skin and do not preclude repigmentation of a lesion. In addition, there is a high incidence of premature graying of scalp hair in patients with vitiligo and in their families. Vitiliginous lesions can remain stable or can slowly progress for years. In some instances, patients undergo almost complete spontaneous depigmentation over a few years.

Vitiligo is subclassified into different types on the basis of the distribution of skin lesions. These subclassifications include the generalized or vulgaris, acral or acrofacial, localized, and segmented types. The generalized pattern is characterized by symmetrical macules or patches occurring in a random distribution. Acral or acrofacial vitiligo consists of depigmented macules confined to the extremities or to the face and extremities, respectively. A subcategory of the acrofacial type is the lip-tip variety, in which lesions are confined to the lips and the tips of the digits. The generalized and acrofacial varieties are the most common. Segmental vitiligo occurs in a dermatomal or quasidermatomal distribution; lesions rarely spread beyond the affected dermatome. This type is the less common variety of vitiligo and most often occurs along the distribution of the trigeminal nerve.

Melanocytes of the eye, ear, and leptomeninges may also be involved in vitiligo. Depigmented areas of the retinal pigment epithelium and choroid have been reported in 39% of patients studied. These lesions usually do not interfere with vision. Vitiligo is also a manifestation of the Vogt-Koyanagi-Harada syndrome, which is characterized by poliosis, chronic uveitis, alopecia, dysacusis, vitiligo, and signs of meningeal irritation. It usually begins in the third decade of life, and although no race is spared, the disease tends to be more severe in darker-complexioned races, especially Asians.

The syndrome has been divided into stages. The first, or meningeal, stage, is associated with headache, nausea, vomiting, fever, confusion, cranial nerve palsies, hemiparesis, and cerebrospinal fluid pleocytosis. Usually, there are a few neurologic sequelae. In the second stage, ophthalmic and auditory changes predominate, including photophobia, ocular pain, visual loss, anterior or posterior uveitis, and sometimes retinal detachment, tinnitus, and dysacusis. Cutaneous lesions are dominant in the third, or convalescent, stage, occurring as the uveitis begins to subside. Common features are vitiligo, which frequently involves the eyelids and periorbital region [*see Figure 4*]; poliosis of the scalp, hair, eyelashes, and eyebrows; and diffuse or patchy alopecia.

Patients with malignant melanoma frequently experience a vitiligolike depigmentation surrounding melanoma lesions and at distant sites. The presence of depigmentation in melanoma patients portends a longer survival.

Laboratory findings Histologically, the predominant finding in vitiligo is an absence of melanocytes in lesional skin. Light microscopy and ultrastructural studies have also revealed vacuolar degeneration of basal and parabasal keratinocytes and revealed epidermal and dermal lymphohistiocytic cell infiltrates.

Figure 4 **A patient with Vogt-Koyanagi-Harada syndrome shows periorbital depigmentation.**

Immunohistochemical staining has confirmed the presence of a predominantly T cell infiltrate in vitiliginous and adjacent skin.

In view of the association of vitiligo with myriad other autoimmune diseases, the routine baseline evaluation of a patient should include a thorough history and physical examination. Recommended laboratory tests include a complete blood count; sedimentation rate; comprehensive metabolic panel, including liver function tests; and autoantibody tests (antinuclear antibody, thyroid peroxidase, and parietal cell antibodies).

Differential Diagnosis

Other disorders characterized by depigmentation may occasionally mimic vitiligo clinically. These include piebaldism, nevus depigmentosus, nevus anemicus, postinflammatory depigmentation or hypopigmentation, pityriasis alba, tinea versicolor, discoid lupus erythematosus, scleroderma, hypopigmented mycosis fungoides, and sarcoidosis. Therefore, in some instances, a skin biopsy may be necessary to substantiate a diagnosis of vitiligo.

Treatment Selection

Therapeutic objectives in vitiligo should include both stabilization of the disease and repigmentation of vitiliginous skin lesions. Repigmentation can be accomplished medically[57-59] or, in patients with localized stable lesions, surgically.[60] The choice of repigmentation therapies should be predicated on the age of the patient, extent of cutaneous surface involvement (severity), and activity or progression of the disease. The disease can be divided into four stages: limited (less than 10% involvement), moderate (10% to 25% involvement), moderately severe (26% to 50% involvement), and severe (greater than 50% involvement) [*see Table 1*].

Table 1 Therapeutic Approaches for Vitiligo

Stages I and II disease*	Topical steroids Topical photochemotherapy PUVA-sol In-office PUVA Bath photochemotherapy Pseudocatalase/UVB UVB phototherapy Narrow band Broad band Excimer laser Topical immunomodulators Tacrolimus Pimecrolimus L-phenylalanine/UV Topical khellin/UVA Melagenina Calcipotriol/PUVA Tar emulsions Vitamin supplementation Autologous melanocyte grafting (stable lesions)
Stages III and IV disease*	Oral photochemotherapy Systemic steroids (oral, I.M.) (for stabilization) Bath photochemotherapy UVB phototherapy Narrow band Broad band Oral khellin/UVA L-phenylalanine/UV Immunomodulators Isoprinosine Levamasole Immunosuppressives Cyclosporine Cyclophosphamide Nitrogen mustard Depigmentation (severe, recalcitrant lesions)

*Stage I, < 10% involvement; stage II, 10%–25% involvement; stage III, 26%–50% involvement; stage IV, > 50% involvement.
PUVA—psoralens plus ultraviolet A UV—ultraviolet UVA—ultraviolet A UVB—ultraviolet B

Medical Treatment

Medical therapies for vitiligo include topical and systemic steroids, topical and systemic PUVA, narrow-band ultraviolet light therapy (UVB), excimer laser therapy, nutritional vitamin supplementation, immunomodulators, calcipotriol, phenylalanine, and khellin.[57-59]

Steroids Mid- to high-potency steroids are indicated in patients with limited involvement. Low-potency topical steroids are usually ineffective. Topical mid- to high-potency steroids can be used safely for 2 to 3 months, then interrupted for 1 month or tapered to low-potency preparations. Patients must be closely monitored for topical steroid side effects, which include skin atrophy, telangiectasias, hypertrichosis, and acneiform eruptions. Since the introduction of topical immunomodulators (tacrolimus and pimecrolimus), topical steroids are used less often in vitiligo patients.

Short courses of oral prednisone for 1 to 2 weeks or intramuscular triamcinolone acetonide injections, 40 mg/month for 2 to 3 months, are often extremely helpful for stabilizing rapidly progressive vitiligo. However, prolonged use of systemic steroids is not indicated.[57-59]

Photochemotherapy Until recently, topical and systemic PUVA therapies were the mainstay for repigmenting vitiliginous lesions.[57,58] However, in the past several years, these therapies have been overshadowed by new ones, including narrow-band UVB phototherapy, lasers, and topical immunomodulators.

Topical photochemotherapy can be administered in the office or outside the office in combination with sunlight. The choice of topical PUVA is predicated on the severity of vitiligo, patient lifestyle, and convenience for the patient. Topical in-office PUVA is appropriate for patients with less than 20% cutaneous surface involvement. A thin coat of 0.01% to 0.1% methoxsalen ointment is applied to affected areas 30 minutes before UVA exposure. Treatments are weekly or twice weekly. For patients with less than 10% involvement, an alternative approach involves the use of 0.001% methoxsalen ointment applied 30 minutes before sunlight exposure. Patients are allowed to expose the affected areas for 10 minutes, gradually increasing exposure time to 30 minutes. Treatments are daily or every other day.

Oral photochemotherapy is indicated in patients with greater than 20% to 25% cutaneous surface involvement. The standard dose of 8-methoxypsoralen (8-MOP) is usually 0.3 to 0.4 mg/kg ingested 1.5 hours before UVA exposure. The treatments are administered twice weekly. Broad-spectrum sunscreen protection is essential after PUVA treatments. In addition, because of the ocular pharmacokinetics of 8-MOP, protective UVA sunglasses should be worn indoors and outdoors for 18 to 24 hours after ingestion of 8-MOP.

Contraindications to oral PUVA treatment include liver disease and photosensitivity disorders. Side effects include headaches, nausea, vomiting, xerosis, pruritus, photoaging, diffuse

hyperpigmentation, and hypertrichosis. Compared with topical PUVA, the major advantages of oral PUVA include its effectiveness in controlling the progression of active disease and its lower frequency of blistering reactions. Oral PUVA therapy has been associated with an increase in nonmelanoma and melanoma skin cancer in patients with psoriasis. However, similar documentation has not been reported in patients with vitiligo.

Factors that portend enhanced PUVA-induced repigmentation include young age (children), patient motivation, maintenance of adequate lesional phototoxicity, and location of lesions. Maximal repigmentation occurs on the face and neck, and minimal responses occur in the hands and feet. Overall, mean repigmentation of 60% to 65% of the affected areas can be achieved.[58]

Narrow-band UVB Recent studies have reported the benefits of narrow-band UVB phototherapy (NB-UVB).[61] NB-UVB treatment was shown to be as effective as topical PUVA, with fewer side effects. In a study of NB-UVB phototherapy versus oral PUVA, 56% of the UVB group had greater than 25% repigmentation, compared with 63% of the oral PUVA group. The difference was not statistically significant. Because of its efficacy and safety profile, NB-UVB has emerged as the therapy of choice for patients with moderate to severe disease.

NB-UVB phototherapy offers several advantages over oral psoralen photochemotherapy, including ease of treatment, lack of need for posttreatment ocular protection, lack of the side effects (e.g., nausea, headaches, and gastritis) associated with oral methoxsalen, and minimal phototoxic reactions. Furthermore, NB-UVB phototherapy can be used to treat young children who have extensive, progressive vitiligo. Disadvantages include the need for more treatments for maximal efficacy (three times weekly for NB-UVB, compared with twice weekly for PUVA) and the lack of data concerning the possible long-term carcinogenic effects of NB-UVB phototherapy.

Dermatologists continue to treat patients with PUVA, and it remains the gold standard despite its inherent difficulties. Patients whose vitiligo does not respond to NB-UVB phototherapy are often switched to oral PUVA.

Repigmentation occurs gradually and requires many treatments: 16 to 24 treatments are usually needed for new pigment to become evident. In general, maximal repigmentation involves 6 to 12 months of NB-UVB or PUVA therapy.

Laser therapy The excimer laser (308 nm UVB), recently approved by the FDA for treatment of psoriasis, also shows promise as a therapy for vitiligo.[62,63] This laser can be used as monotherapy or in combination with other modalities. Laser therapy targets the lesional area and theoretically reduces UV exposure. In addition, because the laser provides a focused, high-intensity dose of NB-UVB, treatment duration, in theory, may be reduced. Long-term, controlled studies are needed to further define the efficacy, risks, and benefits of the excimer laser for treatment of vitiligo.

Pseudocatalase The beneficial effects of pseudocatalase and calcium applied twice daily and UVB exposure twice weekly have also been reported. The rationale for this therapy is derived from previous studies that demonstrated aberrant catalase and calcium homeostasis in patients.[64]

Vitamins Preliminary open-label studies have documented stabilization and repigmentation in vitiligo patients treated with high-dose vitamin supplementation, including daily doses of ascorbic acid (1,000 mg), vitamin B_{12} (1,000 μg), and folic acid (1 to 5 mg).[57]

Topical immunomodulators Abnormalities of both humoral and cell-mediated immunity have been well documented in patients with vitiligo,[47-52] which explains the apparent efficacy of several immunomodulators for this disease. Preliminary investigations have reported repigmentation of vitiliginous lesions with isoprinosine, levamisole, suplatast tosilate, and cyclosporine.[57]

Tacrolimus ointment is a novel topical immunomodulatory drug for treatment of adult and pediatric atopic dermatitis. Tacrolimus exerts its therapeutic effect via inhibition of the production of proinflammatory cytokines. Moderate to excellent repigmentation was reported in five of six patients treated with tacrolimus. Patients ranged in age from 6 to 32 years. Repigmentation responses did not correlate with disease duration.[58,65]

Calcipotriol Several studies have documented the efficacy of calcipotriol for repigmentation of vitiligo. Used in combination with UV exposure, calcipotriol was well tolerated and effective in both children and adults.[58] Melanocytes are thought to express 1α,25-dihydroxyvitamin D_3 receptors, which may play a role in stimulating melanogenesis.

Depigmentation Since the 1950s, monobenzylether of hydroquinone (MBEH, or monobenzene) has been used as a depigmenting agent for patients with extensive vitiligo. In general, MBEH causes permanent destruction of melanocytes and induces depigmentation locally and remotely from the sites of application. Hence, the use of MBEH for other disorders of pigmentation is contraindicated.

Depigmentation is a viable therapeutic alternative in patients with greater than 50% cutaneous depigmentation who have demonstrated recalcitrance to repigmentation or in patients with extensive vitiligo who have no desire to undergo repigmentation therapies.[55,58] The major side effects of MBEH therapy are dermatitis and pruritus, which usually respond to topical and systemic steroids. Other side effects include severe xerosis, alopecia, premature graying, and suppression of lymphoproliferative responses.

Surgical Treatment

Surgical treatment is appropriate for patients with localized, stable areas of vitiligo that have been recalcitrant to medical treatment.[60] Such approaches are contraindicated in patients with keloids or hypertrophic scars. Techniques for surgical grafting include suction blister grafts, punch grafts, sheet grafts, pure melanocyte cultures, and cocultures of melanocytes and keratinocytes. These techniques are indeed beneficial for localized lesions.

Micropigmentation is often associated with the induction of koebnerization; therefore, its use should be limited to treatment of mucous membrane lesions.

ALBINISM

Definition

Albinism is an uncommon, complex congenital disorder characterized by hypopigmentation of the hair, eyes, and skin. Albinism is generally subclassified as oculocutaneous albinism (OCA) and ocular albinism (OA); in the latter, reduction of melanin is limited to the eye.[66-71] Sometimes, different mutations in the same gene can cause OCA or OA.

Epidemiology

OCA has been reported by investigators in all mammalian orders and in all human ethnic groups. It is one of the most widely distributed genetic abnormalities in the animal kingdom. Human albinism has been noted throughout history. OCA is the most common inherited disorder of generalized hypopigmentation.

Etiology and Pathogenesis

Albinism may result from primary defects that are specific for the melanin synthetic pathway or from defects that are not specific for melanin synthesis. Mutations in seven genes have been reported to cause OCA or OA.[67,68] They include the tyrosinase gene (*OCA1* on chromosome 12q1), the oculocutaneous albinism gene (*OCA2*, a missed mutation of the *P* gene on 15q11), the tyrosinase-related protein 1 gene (*OCA3*), the *HPS* gene (Hermansky-Pudlak syndrome at 10q23 and mutations of the β3A-adaptin gene), the *CHS* gene (Chédiak-Higashi syndrome), and the *OA1* gene (X-linked ocular albinism).

Diagnosis

Clinically, the most severe disease is observed in OCA1A, which is OCA resulting from mutations in the tyrosinase gene. It is characterized by absent tyrosinase activity, which results in complete absence of melanin in the eyes, skin, and hair. There is no improvement with age. Affected individuals have marked photophobia, nystagmus, and profound sun sensitivity because of the inability to tan.

OCA1B, or yellow albinism, is less severe. Tyrosinase activity is low or absent, and pigmentation of the hair and skin improves with age. In contrast to OCA1A, pigmented freckles and lentigines develop with age.

OCA1-MP, or minimal-pigment OCA, is characterized by white skin and hair at birth. Iris pigment is present at birth, or it appears during the first decade of life. All reported cases have been in white persons. The tyrosinase gene mutation produces a less active enzyme.

Temperature-sensitive OCA (OCA1-TS) is characterized by white skin and hair and blue eyes at birth and by development of patterned pigmentation by puberty. Darker hair develops in cooler areas (extremities), and white hair is retained in warmer areas (axilla and scalp). The pattern results from a tyrosinase mutation that causes a temperature-sensitive enzyme.

OCA2, tyrosinase-positive OCA with normal tyrosinase activity, is the most common variety. The hair darkens with age, but the skin remains white. Pigmented nevi, lentigines, and freckles develop and are especially pronounced in sun-exposed areas. This type has recently been ascribed to mutation of the *P* gene, which encodes the tyrosinase-transporting membrane protein. The *P* gene is on chromosome 15q.

OCA3 encompasses the Rufous variety and some cases of brown albinism. Clinically, there is minimal pigment reduction in the hair, eyes, and skin.

The secondary varieties of albinism in which the primary defect is not specific for the melanin synthetic pathway include Hermansky-Pudlak syndrome,[71] Chédiak-Higashi syndrome, Cross-McKusick-Breen syndrome, Prader-Willi syndrome, and Angelman syndrome.

The autosomal recessive Hermansky-Pudlak syndrome is characterized by low to absent tyrosinase activity. The *HPS* gene has been mapped to chromosome 10q23.[71-73] Skin and hair color varies from white to light brown. Freckles and lentigines develop with age. Iris pigment correlates with hair and skin pigmentation. Affected individuals experience a hemorrhagic diathesis secondary to a platelet-storage-pool deficiency. Their platelets lack storage granules (i.e., sites of storage for serotonin, calcium, and adenine nucleotides). Ceroidlike deposits are present in macrophages of the bone marrow, lungs, liver, spleen, and gastrointestinal tract. These patients bruise easily and are subject to epistaxis and gingival bleeding. Pulmonary fibrosis and granulomatous colitis develop as a consequence of the ceroid deposits.

Figure 5 **A patient with piebaldism has the classic midextremity areas of depigmentation with islands of hyperpigmentation.**

Chédiak-Higashi syndrome consists of hypopigmentation, recurrent sinopulmonary bacterial infections, peripheral neuropathy, and giant lysosomal granules, with death occurring at an early age as a result of lymphoreticular malignancies. The *CHS* gene locus is on chromosome 1q29. Chédiak-Higashi syndrome must be distinguished from Griscelli syndrome, which is characterized by partial albinism, lymphohistiocytosis, immunodeficiency, neutropenia, and thrombocytopenia. Griscelli syndrome has been mapped to chromosome15q21, around the *myosin-Va* gene. However, the presence of giant lysosomal granules is pathognomonic for Chédiak-Higashi syndrome.[74,75]

Cross-McKusick-Breen syndrome includes hypopigmentation, microphthalmia, nystagmus, and severe mental and physical retardation.

Prader-Willi syndrome is a developmental syndrome characterized by mental retardation, neonatal hypotonia, and poor feeding, followed by hyperphagia and obesity later in life. Short stature, hypogonadism, and inappropriate emotional behavior constitute the syndrome. Fifty percent of patients have a deletion on the long arm of chromosome 15. Patients have ocular abnormalities and skin and hair hypopigmentation consistent with OCA.

Mutation of the *P* gene has been reported in Angelman syndrome and is also characterized by mental retardation, abnormal behavior, and hypopigmentation. The pattern of hypopigmentation is similar to that in Prader-Willi syndrome. In addition, Angelman syndrome is associated with a deletion on chromosome 15. However, in contrast to Prader-Willi syndrome, the deletion occurs on the maternal chromosome.

Treatment

The management of patients with albinism should include genetic counseling and patient education regarding the use of sunscreens and clothing for protection against ultraviolet radiation–induced damage. Magnifiers are beneficial for ocular symptoms.

Complications

The long-term consequences of albinism are solar keratoses and basal and squamous cell carcinomas. Malignant melanoma is uncommon.

PIEBALDISM

Definition

Piebaldism is a rare autosomal dominant congenital disorder of pigmentation. It is a stable leukoderma and is characterized by patches of white skin and white hair. The affected areas are principally the frontal scalp, forehead, ventral chest, abdomen, and extremities. A white forelock occurs in 80% to 90% of patients.

Epidemiology

Although rare, piebaldism occurs in all ethnic groups worldwide. Its estimated occurrence is one in 100,000 persons. It is found with equal frequency in males and females.

Etiology and Pathogenesis

Molecular genetics studies have shown that piebaldism results from mutations of the *KIT* proto-oncogene, which encodes the cell surface receptor tyrosine kinase for mast cell or stem cell factor located on chromosome segment 4q12. Mutations occur in the highly conserved tyrosinase domain of *KIT*. A number of different mutations in the *KIT* gene can cause piebaldism.[76-80] The locations of the *KIT* gene mutation correlates with severity of disease. Mutations of the intracellular tyrosine kinase domain are associated with the most severe phenotypes.[77] Reduced *KIT* function arrests the migration of melanocytes into affected hair follicles and epidermis during embryonal development.[76-78]

In general, patients with piebaldism are healthy and do not have associated systemic abnormalities. However, the disorder occasionally has been associated with heterochromia irides, mental retardation, osteopathia striata, Woolf syndrome, and Hirschsprung disease.

Diagnosis

Cutaneous depigmentation is the only manifestation of piebaldism in 10% to 20% of cases. Amelanotic macules are usually present on the ventral surface of the thorax and abdomen and extend to the back but spare the midline. Characteristic extremity lesions extend from midarm to wrist and occur on the midleg [*see Figure 5*]. White patches of the mucous membranes have also been reported. Hyperpigmented macules may appear within the areas of depigmentation.

Light and electron microscopic studies of the white macules have typically revealed an absence of melanocytes. However, melanocytes have been demonstrated in the white forelock and amelanotic skin of three patients studied.

Differential Diagnosis

Piebaldism is sometimes confused with vitiligo, but in piebaldism, the leukodermic patches are both congenital and relatively static in shape and size.

Treatment

The lesions of piebaldism are usually stable throughout life, although some patients have reported spontaneous repigmentation. In general, therapeutic approaches, including psoralen photochemotherapy and grafting, are unsatisfactory. Autologous melanocyte grafting procedures may offer some benefit for localized or limited areas of involvement.

IDIOPATHIC GUTTATE HYPOMELANOSIS

Definition

Idiopathic guttate hypomelanosis (IGH) is a common asymptomatic disorder characterized by hypopigmentation and depigmented polygonal macules ranging from approximately 2 to 8 mm in diameter.

Epidemiology

IGH appears to be a very common, benign dermatosis. It occurs in all races, with a frequency ranging from 46% to 70%, but is more prevalent in darker-skinned racial and ethnic groups. Macules may begin to appear during the third or fourth decade of life and gradually increase in number thereafter.

Etiology and Pathogenesis

The precise pathogenesis has not been established for IGH. Long-term sun exposure, trauma, genetic influences, and aging, with a gradual loss of melanocytes, have been implicated in the pathogenesis of this disorder.[81]

Diagnosis

The lesions of IGH are macules that are punctate to polygonal in shape, 2 to 8 mm in diameter, and hypopigmented to depigmented. They are most commonly observed on the lower extremities. There is no atrophy or change in the overlying skin. Histologic evaluation of lesions reveals hyperkeratosis, epidermal atrophy, and decreased epidermal melanin. Melanocytes may be normal or decreased. Immunoperoxidase studies show a markedly reduced number of melanocytes. Melanocyte differentiation appears to be unaffected.[82]

Differential Diagnosis

IGH must be differentiated from other hypopigmentary disorders, such as vitiligo, scleroderma, leukodermic guttate parapsoriasis, tinea versicolor, hypopigmented sarcoidosis, pityriasis alba, chemical depigmentation, and postinflammatory hypopigmentation.

Treatment

No definitive treatment is currently available. Patients often need reassurance regarding the banality of lesions. For patients concerned about the cosmetic appearance of lesions, clinicians have used camouflage, intralesional steroids, and topical photochemotherapy. Localized superficial dermabrasion may offer some improvement.[83]

The author has received grants for clinical research from Allergan Inc., Fujisawa Healthcare, Inc., and Galderma Laborotories, L.P., during the past 12 months.

XVI APPROACH TO THE DIAGNOSIS OF SKIN DISEASE

Robert T. Brodell, m.d.
Stephen E. Helms, m.d.

Patients frequently see their primary care physician for skin disease[1]; however, compared with dermatologists, primary care physicians treat substantially fewer patients with common skin conditions, and the types of cutaneous disease they treat tend to be few in number.[2,3] One study reported that dermatologists had 728 and 352 office visits a year for acne and contact dermatitis, respectively; by contrast, internists averaged three and nine visits, a year, respectively, and family physicians averaged eight and 27 visits a year.[2] The relative inexperience with cutaneous presentations gives rise to possible error in the dermatologic care offered by nondermatologists. Some studies have reported that nondermatologists perform poorly in the diagnosis and treatment of skin disease.[4] One area of concern is the apparent low proficiency among nondermatologists in the diagnosis of skin cancer.[5,6] The root of most problems encountered by primary care physicians in the treatment of skin disease rests in establishing the accurate diagnosis of cutaneous presentations.

Diagnosis of a cutaneous disease is most reliably achieved by a stepwise approach to patient evaluation, beginning with an examination of the morphologic features of the skin lesions and frequently culminating in diagnostic testing. This chapter reviews the primary skin lesions that allow categorization of dermatologic disease (e.g., papulosquamous diseases, blistering diseases, nonscaling erythematous and infiltrative diseases, and tumors) and presents a method by which the physician can narrow the possible causes of a specific presentation and arrive at a diagnosis in a cost-effective manner.

Approach to the Patient with a Dermatologic Lesion

Dermatology is a visual specialty, and physical examination is primarily oriented toward observing the skin. Dermatologists approach skin disease in a manner that has been tested over time and perpetuated in the training of medical students and residents. A simple diagnostic evaluation based on the approach preferred by dermatologists allows primary care physicians to narrow the possible causes of a cutaneous presentation and arrive at an accurate diagnosis.

diagnostic evaluation

Diagnostic evaluation of a cutaneous presentation begins with a brief patient history that is directed at the nature of the chief complaint and its onset; factors that aggravate and alleviate symptoms; and responses to over-the-counter or prescription medications. This is followed by careful inspection of the skin. In examining a patient with a rash, the first step is to try to identify primary lesions (i.e., lesions that appear early in the disease process) [*see* Morphologic Classification of Skin Disorders, Primary Lesions, *below*]); these lesions help to categorize the disease and provide the basis for diagnosis. Information derived from the identification of primary lesions is augmented by an examination of primary lesions that have undergone change. Secondary changes to primary lesions may occur naturally or after trauma, such as scratching [*see* Morphologic Classification of Skin Disorders, Secondary Changes, *below*]. The location, distribution, and configuration of primary lesions and their secondary changes are analyzed, and the findings are categorized to promote the development of a differential diagnosis.

After an examination of the lesions, a more complete patient history is obtained, including the patient's family history, social history, and medical history. The expanded patient history is followed by a focused general medical examination. In the context of a detailed patient history, the general medical examination often provides diagnostic clues that further narrow the differential diagnosis.

The final step in a dermatologic examination comprises various forms of testing (e.g., dermatologic testing, skin biopsy, and laboratory tests) [*see* Arriving at a Diagnosis, *below*] to confirm the diagnosis or sufficiently narrow the differential diagnosis to permit selection of the most appropriate treatment. If the diagnosis remains uncertain after testing, consultation with a dermatologist may be useful in establishing the diagnosis. The patient is typically scheduled for a follow-up visit after initiation of treatment. The purpose of the follow-up visit is to assess the response to therapy and to confirm that the proper diagnosis was rendered.

suboptimal methods of diagnosis and management

Errors in dermatologic diagnosis can be classified into several categories. It is worth exploring these problems to avoid falling into predictable traps.

Treating Symptoms Rather than Diseases

Establishing the underlying cause of symptoms is a guiding principle in medicine; however, the treatment of dermatologic presentations frequently focuses on symptom management without addressing the underlying cause. This approach is seldom an efficient or effective form of management. For example, treatment of pruritus with antihistamines is a poor substitute for establishing a definitive diagnosis of the underlying condition that is the cause of the symptom. In the case of a patient with severe itching associated with dermatitis herpetiformis, treatment with a topical corticosteroid may give temporary relief from pruritus; however, a careful examination would most likely reveal grouped papulovesicles on the extensor surfaces of the extremities, and a biopsy would confirm the diagnosis of dermatitis herpetiformis. Treatment of dermatitis herpetiformis with a gluten-free diet and oral dapsone would lead to dramatic, long-lasting remission.

Snapshot Approach to Diagnosis

A snapshot diagnosis is rendered on the basis of physical appearance of a rash or other form of lesion in the absence of any other data. This method of examination is quick; however, it can lead to inaccurate diagnosis and imprecise and inadequate treatment. For example, a patient with widespread scaling, erythema, lichenification, and excoriations may appear to have eczema. On careful examination, the finger webs disclose burrows. The patient reports that itching is more severe at night, and that family members are also experiencing itching. A scabies preparation test discloses the presence of mites, confirming the diagnosis as

Table 1 Primary Lesions: Consensus Definitions of Dermatologic Morphologic Terms[7]

Morphologic Term	*DLP Proposed Definition*
Bulla	A fluid-filled blister greater than 0.5 cm in diameter; fluid can be clear, serous, hemorrhagic, or pus-filled
Comedo	An enlarged hair follicular infundibulum primarily containing keratin and lipids and having a plugged, dilated follicular opening (blackhead) or a clinically unapparent follicular opening (whitehead)
Macule	A flat area of skin or mucous membranes having a color different from the surrounding tissue and a diameter generally less than 0.5 cm; macules may have nonpalpable, fine scales
Nodule	A dermal or subcutaneous firm, well-defined lesion usually greater than 0.5 cm in diameter
Papule	A discrete, solid, elevated body usually less than 0.5 cm in diameter; papules are further classified by shape, size, color, and surface change
Patch	A flat area of skin or mucous membranes having a color different from the surrounding tissue and a diameter generally greater than 0.5 cm; patches may have nonpalpable, fine scales
Plaque	A discrete, solid, elevated body usually broader than it is thick and measuring more than 0.5 cm in diameter; plaques may be further classified by shape, size, color, and surface change
Pustule	A circumscribed elevation that contains pus; pustules are usually less than 0.5 cm in diameter
Vesicle	Fluid-filled cavity or elevation less than 0.5 cm in diameter; fluid may be clear, serous, hemorrhagic, or pus-filled
Wheal	An edematous, transitory papule or plaque

DLP—Dermatology Lexicon Project

scabies infestation. A snap diagnosis of eczema and treatment with topical steroids would have been inappropriate.

Scattershot Management

A suboptimal approach to the management of a dermatologic presentation is touted by physicians who delude themselves into believing that all rashes look alike. This leads to the scattershot approach to management, which advocates increasing the potential for successful treatment of an unknown skin disease by treating all possible causes. For example, the use of a topical steroid/antifungal preparation for a papulosquamous process may seem a prudent treatment of two possible disorders—namely, eczema and superficial fungal infection; however, if the patient has a dermatophyte-induced fungal infection, the topical steroid may decrease local immunity and slow the healing process. This management strategy is expensive, increases the risk of iatrogenic disease, and delays appropriate diagnosis and treatment.

A scattershot approach may also be used in diagnostic evaluation; such an approach entails the ordering of a broad battery of tests in the hope of stumbling upon the correct diagnosis. This inefficient method can lead to false positive results that confuse rather than confirm the diagnosis.

All rashes present physical diagnostic clues that are useful in establishing a diagnosis. A careful evaluation of the lesions' morphologic characteristics, coupled with a thorough patient history and examination, will most likely provide an accurate diagnosis. If the diagnosis remains uncertain, the morphologic condition of the lesion will suggest which specific tests are appropriate for arriving at the diagnosis.

Morphologic Classification of Skin Disorders

PRIMARY LESIONS

The first step in the diagnosis of a rash is to identify primary lesions [*see Table 1*]. Primary lesions are those physical characteristics of skin disease that appear initially and are most useful in developing a differential diagnosis. The characterizing features of primary lesions include whether they are flat or raised, solid or fluid filled, dark or light in color, large or small, smooth or rough. Lesions may be few or numerous, localized or widespread. The newly erupted and undisturbed lesions are most often helpful in categorizing skin conditions in a manner that leads to a correct diagnosis.

Primary skin lesions can be defined simply. Flat lesions are referred to as macules when they are smaller than 0.5 cm and as patches when they are greater than 0.5 cm in diameter [*see Figure 1*].

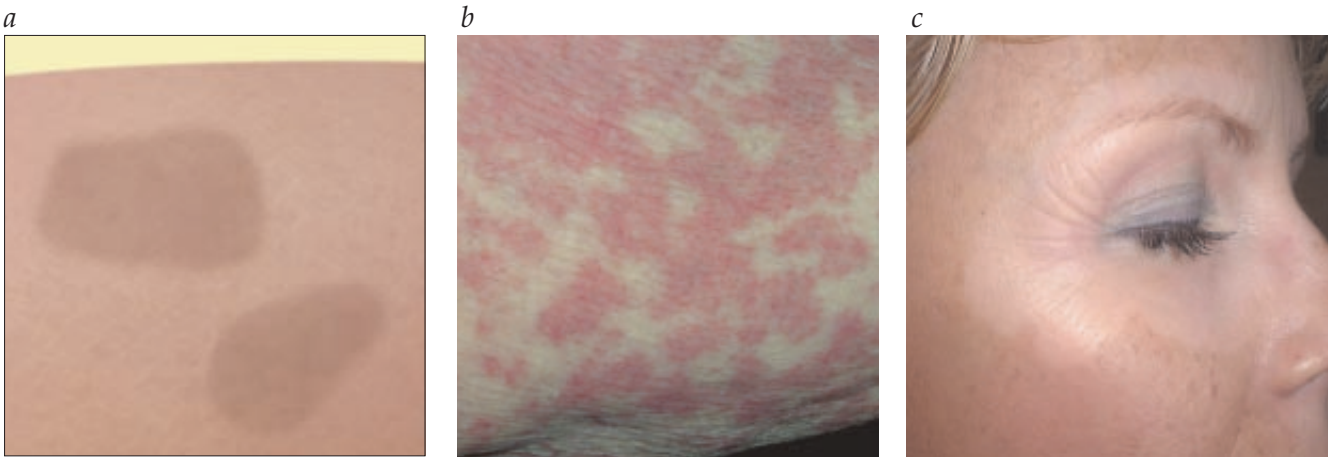

Figure 1 **(*a*) Schematic drawing of macules (lesions < 0.5 cm) or patches (lesions > 0.5 cm). Macules and patches are flat areas of skin for which the color and texture differ from that of the surrounding tissue. (*b*) Nonblanching erythematous macules and patches are present in a patient with a drug eruption. (*c*) Depigmented macules are noted on the face of a patient with vitiligo.**

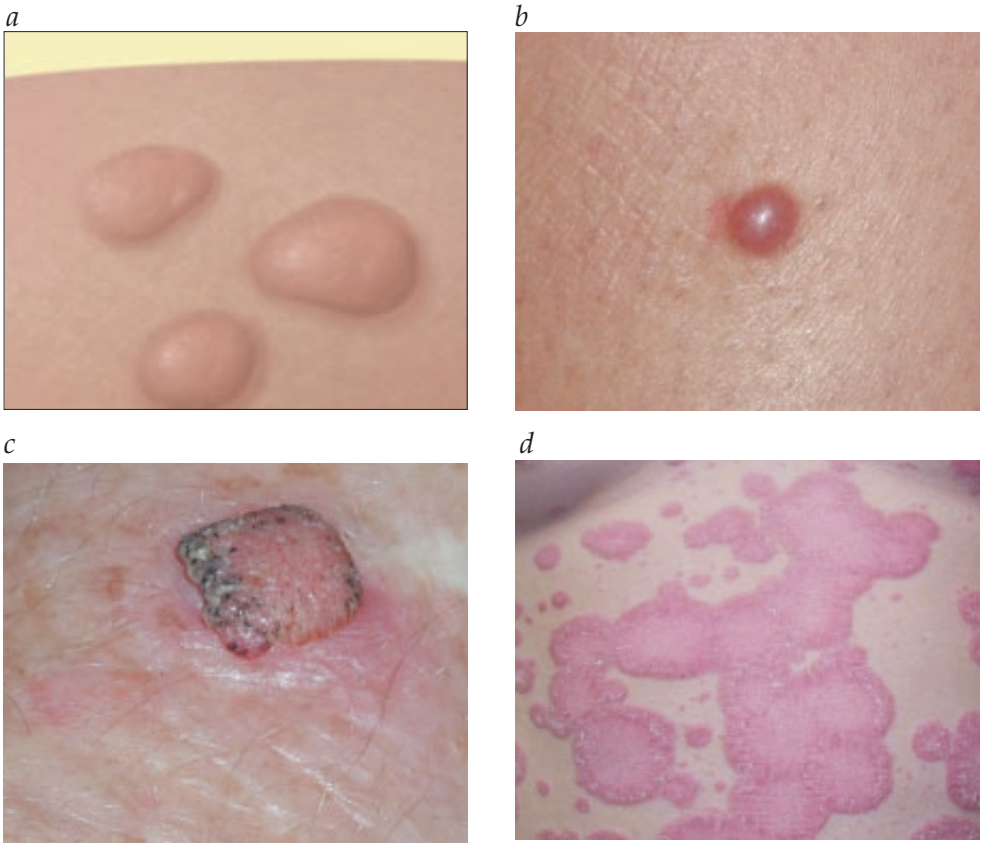

Figure 2 **(*a*) Schematic drawing of papules (lesions < 0.5 cm) or nodules (lesions > 0.5 cm). Papules and nodules are discrete, solid, elevated lesions. (*b*) A raised, dome-shaped, erythematous papule is seen in a case of dermatofibroma. (*c*) A raised, flat-topped, erythematous, and hyperkeratotic nodule with scalloped edges is present in a patient with squamous cell carcinoma. (*d*) Large, erythematous plaques of psoriasis have an annular appearance, owing to their elevated margins.**

Small raised bumps are referred to as papules [*see Figures 2a and b*], and large lesions of this type are referred to as nodules; nodules typically have a deeper dermal component [*see Figure 2c*]. Discrete, broad, raised eruptions are referred to as plaques [*see Figure 2d*]. Raised lesions containing fluid (commonly known as blisters) are referred to as vesicles when smaller than 0.5 cm [*see Figures 3a and b*] and as bullae when larger than 0.5 cm in diameter [*see Figure 3c*]. Vesicles and bullae are usually clear but may be turbid. White or yellow fluid-filled lesions are called pustules. Atrophic lesions exhibit a thinned epidermis that is often depressed; they have a scaly, shiny surface that has the texture of cigarette paper. An edematous transitory papule or plaque is called a wheal [*see Figure 4*].

The shape of primary lesions often provides diagnostic clues. Primary lesions may be round, oval, angular, or irregular; flat-topped or domed; or umbilicated or verrucous. The borders of primary lesions may be well circumscribed or poorly defined; the presence or absence of an elevated border may be a useful finding.

SECONDARY CHANGES

Secondary changes to lesions provide valuable diagnostic information; however, they are not as useful as primary lesions in arriving at a specific diagnosis [*see Table 2*]. Secondary changes may represent a late stage in the natural history of primary lesions, or they may be the result of trauma such as from scratching or rubbing of the skin. Secondary changes to lesions include the following:

- Scales: small flakes of superficial skin.
- Scale crusts: scales combined with serous exudate.
- Excoriations: abrasions resulting from the scratching of elevated lesions.
- Erosions: localized loss of epithelium.
- Ulcers: denuded areas of epidermis and some portion of dermis. Ulcers may be open or covered with a black eschar [*see Figure 5*].
- Scars: raised or depressed fibrous lesions caused by trauma or disease.
- Cutaneous horns: keratotic projections extending from a skin lesion.
- Fissures: cracks that extend through the epidermis into the dermis.

Numerous additional terms are helpful in characterizing the morphologic presentation of skin lesions [*see Table 3*]. It is critical that exacting definitions of descriptive terms be used by all clinicians if a reproducible method of diagnosis is to be promulgated. The Dermatology Lexicon Project (DLP) has provided an expert consensus of definitions for dermatologic terms [*see Tables 1 through 3*].[7]

MORPHOLOGIC PATTERNS OF PRESENTATION

Once the patient has been examined for primary and secondary lesions, the diagnostician must consider the overall presentation of the rash and determine its location, distribution, and configuration—three factors essential in determining a diagnosis.

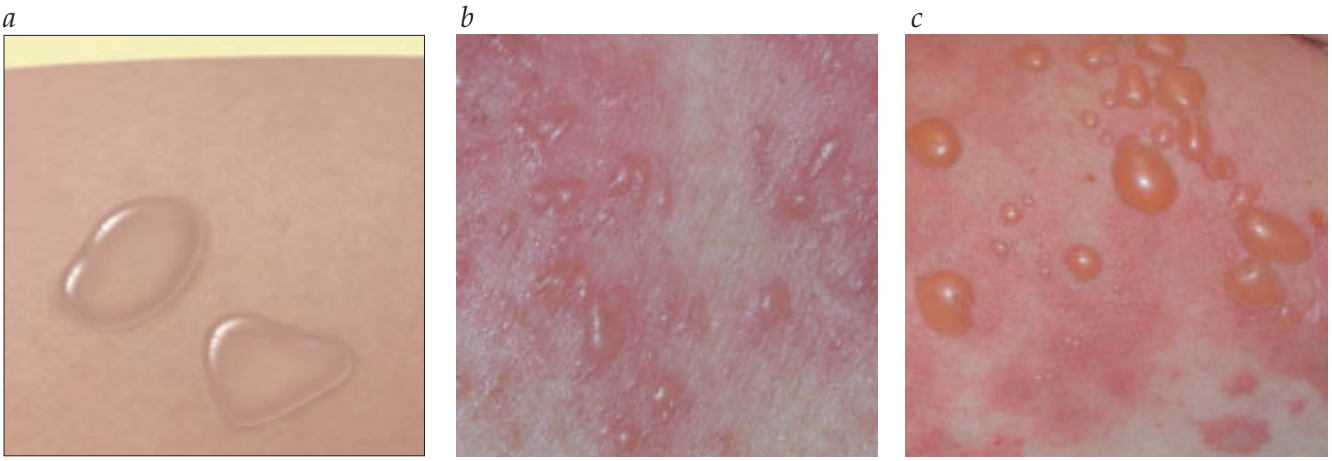

Figure 3 **(*a*) Schematic drawing of a vesicle (lesions < 0.5 cm) or bulla (lesions > 0.5 cm). Vesicles, bullae, and pustules are fluid-filled elevations or cavities in the skin. Vesicles and bullae are clear; pustules are turbid and pus filled. (*b*) Small, clear, fluid-filled vesicles on an erythematous base are present in a patient who has herpes zoster. (*c*) Large, clear, fluid-filled bullae are present in a patient with bullous pemphigoid. The bullae are associated with erythematous patches.**

Location

The location refers to the particular site where the lesion or lesions are found. The location should be carefully defined because some skin diseases target specific anatomic areas. Notation of involved anatomic sites should be as specific as possible, listing not only the involved sites but the affected aspects of those sites. For example, facial lesions may occur in the periorbital or perioral areas; hand lesions may occur on the fingers or palm; and foot lesions may occur on the toes or sole. Lesions might also be found on the upper arm or the forearm, the lower leg or the thigh, and the trunk. It is important to further describe the affected areas as being on the right or left side and on the proximal or distal, medial or lateral, dorsal or ventral, and flexural or extensor surfaces of the involved anatomic sites.

Distribution

The distribution of lesions describes the overall pattern of an eruption in relation to the entire cutaneous surface. The rash may be localized to one area of the body, may involve several areas, or may extend over much of the body surface. Rashes may be symmetrical or asymmetrical, and they may be present primarily on the trunk or on the extremities. Rashes may be present on exposed skin (i.e., skin that is not covered by clothing) or unexposed skin. These characteristics should be carefully noted because a particular distribution will narrow the differential diagnosis.

Configuration

The configuration of lesions refers to the pattern exhibited by multiple lesions within a defined area. Because the configuration of lesions may vary according to the disorder, any detectable pattern may be helpful in arriving at a definitive diagnosis. Some of the more common configurations include the following:

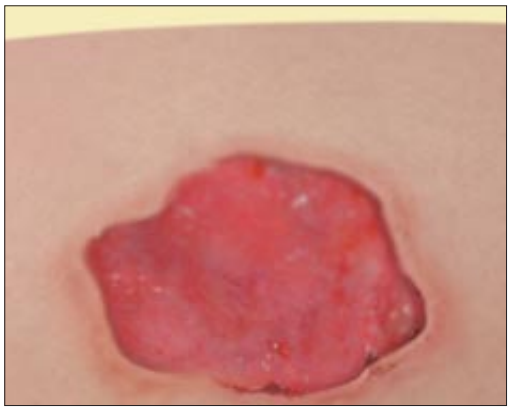
- Grouped or herpetiform configuration: multiple small lesions appearing within a small, defined area [*see Figure 6*].
- Zosteriform configuration: lesions occurring within a dermatone.
- Linear configuration: lesions oriented along a line [*see Figure 7*].
- Annular configuration: lesions appearing in a ringlike pattern.
- Target (iris) configuration: lesions appearing in concentric rings.

Figure 4 **Multiple linear, erythematous wheals secondary to scratching are noted on the back of a patient with chronic urticaria and dermatographism.**

Table 2 Selected Secondary Lesions: Consensus Definitions of Dermatologic Morphologic Terms[7]

Morphologic Term	*DLP Proposed Definition*
Horn	Abnormally keratinized cutaneous projection taller than it is broad
Erosion	A localized loss of the epidermal or mucosal epithelium
Fissure	A linear crack or cleavage within the skin usually found with thickened skin
Ulcer	A circumscribed loss of the epidermis and at least the upper dermis; ulcers are further classified by their depth, border/shape, edge, and tissue at their base

a



b

Figure 5 **(*a*) Schematic drawing of a skin ulceration. A skin ulceration is a circumscribed lesion denuded of epidermis and at least some dermis. (*b*) A well-defined 3.5 by 4.0 cm ulceration with an erythematous granulating base is present in a patient who has early evolving pyoderma gangrenosum.**

- Arcuate configuration: lesions appearing in a semicircular pattern.
- Polycyclic configuration: lesions appearing as interlocking rings.
- Serpiginous configuration: lesions appearing in snakelike whorls.
- Digitate configuration: lesions resembling the size and shape of a fingertip.

When lesions coalesce over large areas, they are termed confluent. Erythroderma describes a widespread confluence of rash covering nearly all of the cutaneous surface.

Color

The color of cutaneous lesions also provides important diagnostic clues. Lesions may be flesh-colored, hyperpigmented or hypopigmented, erythematous, or virtually any color of the rainbow. Purpuric rashes caused by the extravasation of red blood cells show no blanching on diascopy (i.e., a test in which a glass slide or lens is pressed against the skin).

Categories of Skin Diseases

The appearance of individual lesions on the skin (e.g., primary lesions and their secondary changes) classifies a rash or growth within a major category of skin disease. The most common skin diseases and many important rare conditions can be classified into one of five disease categories on the basis of their characteristic lesions. Once the category is determined, the diseases within that category are considered in the differential diagnosis of the presenting disorder [*see Table 4*].

As a clinician's dermatologic knowledge becomes more sophisticated, additional categories can be mastered, including (but not limited to) diseases of the hair, nails, or mucous membranes; photosensitivity diseases; diseases of vascular reactivity; ulcerative skin conditions; and conditions typical of specific distributions, such as diseases of the genitalia, feet and hands, and eyelids. Manuals of differential diagnosis based on the morphology of lesions and other physical features are plentiful and can be quite helpful in determining a diagnosis.

Table 3 Other Important Morphologic Terms: Consensus Definitions of Dermatologic Morphologic Terms[7]

Morphologic Term	*DLP Proposed Definition*
Abscess	A localized accumulation of pus in the dermis or subcutaneous tissue; frequently red, warm, and tender
Atrophy	A thinning of tissue defined by the location (e.g., epidermal atrophy, dermal atrophy, or subcutaneous atrophy)
Burrow	A threadlike linear or serpiginous tunnel in the skin typically made by a parasite
Carbuncle	An inflammatory nodule composed of coalescing furuncles
Ecchymosis	A discoloration of the skin or mucous membranes resulting from extravasation of blood that exhibits color change over time; the characteristic transition is from blue-black to brown-yellow to green
Erythema	Localized, blanchable redness of the skin or mucous membranes
Exfoliation	Desquamation of the superficial epidermis appearing as a fine scaling or as peeling sheets
Furuncle	A follicle-centered nodule caused by a suppurative infection characterized by pain, redness, and perhaps visible pus; usually greater than 1 cm in diameter
Induration	Hardening of the skin beneath the epidermis, usually caused by edema, dermal sclerosis, inflammation, or infiltration
Petechiae	Purpuric nonblanchable macules resulting from tiny hemorrhages, initially measuring 1 to 2 mm
Poikiloderma	An area of variegated pigmentation, atrophy, and telangiectasia
Purpura	Hemorrhaging into skin or mucous membranes that varies in size, color, and duration; types of purpura include palpable purpura, ecchymosis, and petechiae
Telangiectasia	Visible, persistent dilation of small, superficial cutaneous blood vessels

Figure 6 **Close-up view of a herpetiform pattern of vesicles on an erythematous base within a dermatome in a patient with herpes zoster.**

Arriving at a Diagnosis

It is important to begin the assessment of a skin condition with a broad differential diagnosis, noting the presentation as characteristic of one of the categories of skin disease [*see Table 4*]. Using physical findings, patient history, and diagnostic testing, the differential diagnosis is gradually narrowed until a diagnosis is determined. For example, scaling conditions, including rashes composed of both papules and plaques, are characterized as papulosquamous skin diseases; each papulosquamous condition [*see Table 4*] should be considered in the differential diagnosis of a scaling rash. The specific features of each of the papulosquamous conditions are compared with the patient's lesions to systematically identify the disorder. It is critical that the initial differential diagnosis be broadly determined. Jumping to an early conclusion and not systematically considering all of the possible papulosquamous disorders can result in an incorrect diagnosis. In fact, if the actual diagnosis is not among the diseases initially considered, it is much more difficult to determine the correct diagnosis.

Figure 7 **Linear arrangement of papules in a patient with contact dermatitis caused by poison ivy.**

Table 4 Categories of Skin Disease

Papulosquamous diseases (discrete papules or plaques with scaling)	Psoriasis vulgaris Chronic atopic dermatitis Lichen planus Pityriasis rosea Fungal infections Secondary syphilis Mycosis fungoides
Blistering diseases (vesicles, bullae, pustules)	Acute allergic contact dermatitis Bullous pemphigoid Pemphigus vulgaris Dermatitis herpetiformis Herpesvirus infections Bacterial folliculitis
Nonscaling erythematous (macules, patches, wheals) and infiltrative diseases (plaques)	Urticaria Morbilliform drug eruptions Viral exanthems Sarcoidosis Leukemia and lymphoma cutis Amyloidosis
Diseases of pigmentation (macules or patches of various colors)	Vitiligo Tinea versicolor Pityriasis alba Café au lait macules Lentigines
Benign and premalignant tumors (macules, papules, nodules, tumors)	Actinic keratosis Basal cell carcinoma Squamous cell carcinoma Melanoma Acrochordons Dermatofibroma Neurofibroma Melanocytic nevi Adnexal tumors

Diagnosis is almost always more difficult than treatment. Consultation with a dermatologist is recommended when the diagnosis is uncertain, particularly in cases in which treatment may fail or may lead to iatrogenic disease. The dermatologist may help define the primary lesions that permit the accurate categorization of the disease process and, in turn, suggest the diagnosis.

If a diagnosis remains in doubt, a follow-up visit with the patient should be scheduled because, as the disease progresses, the development of primary lesions and lesion distribution may make the diagnosis more apparent. In addition, single, confirmatory tests often prove helpful in the diagnosis of cutaneous presentations; tests used to confirm a diagnosis include a Wood light examination, potassium hydroxide (KOH) preparation, sampling for fungal culture, scabies preparation, Tzanck preparation, patch testing, skin biopsy, dark-field microscopic examination, microscopic hair-shaft analysis, Gram stain, and viral or bacterial cultures.

A Wood light examination is performed by shining a black light on the skin in a dimly lit room. Epidermal pigmentation (e.g., lentigines) is highlighted by this examination, whereas dermal pigmentation (e.g., Mongolian spot) disappears. A search for depigmented spots such as ash-leaf macules in babies with tuberous sclerosis is also aided by the Wood lamp.

A KOH test for fungal infections involves applying KOH to scales of skin or hair shafts to clear the keratin so that fungal hyphae and spores can be identified. For example, scales can be lightly scraped onto a glass slide after placing the slide on the advancing margin of an annular plaque with central clearing. After a coverslip is applied, 2.5% KOH preparation is applied to the slide next to the coverslip. The KOH preparation spreads under the coverslip by capillary action. After gentle heating, excess KOH is blotted away, and the specimen is examined under a microscope. Fungal infections can also be confirmed by obtaining scales by lightly scraping papulosquamous lesions and sprinkling the scales onto Sabouraud dextrose agar. This agar preparation is then incubated at room temperature for several weeks, after which it is analyzed for colony growth, color, and morphology.

A scabies preparation test involves applying oil to excoriated lesions—frequently found on wrists and finger webs—and lightly scraping the burrows to obtain their contents. The scrapings are placed on a slide with coverslip; the test is positive if scabies mites, eggs, or feces are visible on microscopic examination.

Tzanck preparations are smears obtained from the base of intact vesicles and stained with one of a variety of nuclear stains. A finding of multinucleated giant cells suggests a diagnosis of herpes simplex or herpes zoster infection.

Patch testing is performed to objectively elucidate the specific cause of an allergic contact dermatitis. Standard allergens are applied under patches for 24 hours, and the reactions are read 48 hours and 1 week later.

Skin biopsies are helpful in confirming the diagnosis of a variety of inflammatory and neoplastic diseases. Dark-field microscopic examination of serous fluid from genital ulcers identifies spirochetes in lesions of primary syphilis. Hair-shaft analysis is helpful when alopecia is caused by hair-shaft abnormalities. Finally, viral and bacterial cultures using specific swabs can provide laboratory confirmation of a variety of viral and bacterial diseases.

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

I THYROID

Paul W. Ladenson, m.d.

Thyroid disorders are the most common endocrine conditions encountered in clinical practice. Persons of either sex and any age can be affected, although almost all forms of thyroid disease are more frequent in women than in men, and many thyroid ailments increase in frequency with age. The presentation of thyroid conditions can range from clinically obvious to clinically silent. Their consequences can be widespread and serious, even life-threatening. With proper testing, the diagnosis and differential diagnosis can be established with certainty, and effective treatments can be instituted for almost all patients.

Definitions

States of thyroid dysfunction include hypothyroidism and thyrotoxicosis, both of which have ubiquitous metabolic and organ-specific consequences that result in a wide variety of clinical presentations and complications. Thyrotoxicosis is sometimes referred to as hyperthyroidism, but the latter term is more properly limited to forms of thyrotoxicosis in which there is an overproduction of thyroid hormones by the gland.

Both categories of thyroid dysfunction are further classified as overt or mild. In overt thyroid dysfunction, the concentrations of thyrotropin (thyroid-stimulating hormone [TSH]) and one or both thyroid hormones are outside of their normal ranges. In mild thyroid dysfunction, the serum TSH level is abnormal, but the serum thyroid hormone concentrations remain within their reference ranges. Although the terms clinical and subclinical are often used in reference to overt and mild thyroid dysfunction, respectively, these states are actually defined on the basis of biochemical criteria, not of clinical manifestations.

Epidemiology

In the Third National Health and Nutrition Survey (NHANES III), thyroid function tests were assessed in a group of 17,353 persons 12 years of age or older whose makeup reflected the geographic and ethnic diversity of the United States population.[1] Hypothyroidism was identified in 4.6% (0.3% overt and 4.3% mild), and thyrotoxicosis was found in 1.3% (0.5% overt and 0.7% mild) [*see Figure 1*].

thyroid nodules

Thyroid nodules (masses within the gland) are relatively common in adults. In the Framingham Study, 6% of women and 2% of men had palpable thyroid nodules.[2] The prevalence of nonpalpable thyroid nodules incidentally detected by imaging studies such as sonography and CT has been reported to be as high as 27% in adults.[3] Diffuse thyroid gland enlargement (goiter) is declining in prevalence—a tendency that reflects the increase in levels of dietary iodine in the United States. Whereas goiter was identified in 3% of persons in a 10-state United States survey in the 1970s, it was self-reported by less than 0.5% of persons in the more recent NHANES III.[4,5]

thyroid cancer

Thyroid cancer is the 14th most common malignancy in the United States, with an estimated annual incidence of 23,600 new cases and a female-to-male ratio of 3 to 1.[6] However, the epidemiology of thyroid cancer is more important than this incidence ranking would imply, for two reasons. First, thyroid cancer is currently the malignancy with the fastest rising incidence in the United States, with increases of 3.8% annually from 1992 to 2001. Second, because treatment is highly effective, with 95% or more of patients surviving, there may be about 300,000 thyroid cancer survivors in the United States, all of whom require monitoring for recurrent disease.

Hypothyroidism

epidemiology

Hypothyroidism is a common disorder that occurs more commonly in women than in men; in both sexes, the incidence increases during and after middle life.[7] In the NHANES III, 2% of persons 65 years and older had overt hypothyroidism, and 14% had mild hypothyroidism.[1] Prevalences of thyroid dysfunction were also higher in whites and Mexican Americans than in blacks (5%, 4%, and 2%, respectively).

Certain individuals are at higher risk for developing hypothyroidism, including those with a family history of autoimmune thyroid disorders[8]; postpartum women[9]; those with a history of head and neck or thyroid irradiation or surgery; those with certain other autoimmune endocrine conditions[10] (e.g., type 1 diabetes mellitus, adrenal insufficiency, and ovarian failure); and those with certain nonendocrine autoimmune disorders (e.g., celiac disease, vitiligo, pernicious anemia, and Sjögren syndrome). Hypothyroidism also develops more frequently in persons with Down syndrome or Turner syndrome.

etiology and genetics

The causes of hypothyroidism vary, depending on whether the disease is congenital or acquired. In addition, the causes of primary hypothyroidism (i.e., disease of the thyroid gland itself) differ from those of secondary (central) hypothyroidism, which involves deranged hypothalamic-pituitary control of the gland.

Congenital Hypothyroidism

Endemic iodine deficiency remains an important cause of congenital hypothyroidism in certain regions of the world. Even with sufficient dietary iodine, congenital hypothyroidism affects one in 4,000 infants because of thyroid gland dysgenesis (as related, for example, to mutant *PAX8* and *TTF1* genes) or inherited defects in thyroid hormone synthesis (e.g., mutations in the genes that code for thyroid peroxidase, sodium-iodide symporter, and thyroglobulin). Absent or ineffective TSH responsiveness can be the result of mutations in the genes affecting pituitary thyrotrope differentiation (e.g., *POU1F1* and *PROP1*) or the structures of the thyrotropin-releasing hormone (TRH) receptor, the TSH β chain, and the TSH receptor. A mutation in the gene for $G_s\alpha$, which mediates adenylate cyclase activation in thyroid cells, causes hypothyroidism in pseudohypoparathyroidism. Inherited resistance to thyroid hormone can be caused by mutations in the β isoform of the nuclear triiodothyronine (T_3) receptor.

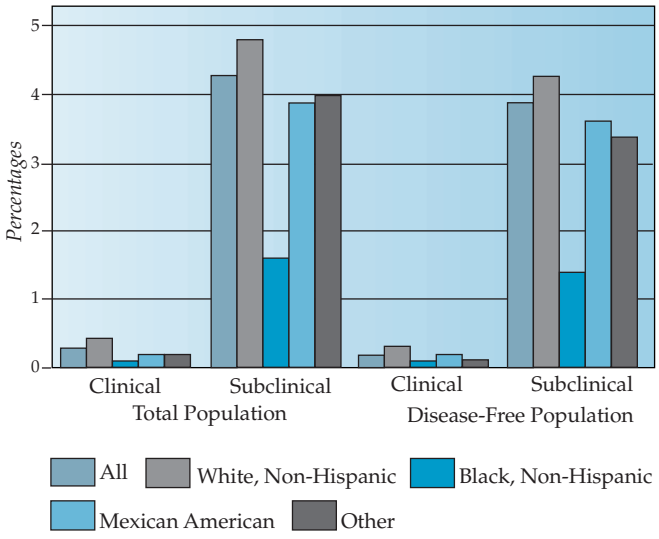

Figure 1 **Prevalences of abnormalities on thyroid function tests in different populations in the third National Health and Nutrition Examination Survey.**

Acquired Hypothyroidism

Autoimmune thyroiditis Autoimmune thyroiditis, also called Hashimoto disease, is far and away the leading cause of hypothyroidism.[11] Its autoimmune pathogenesis is evidenced by the lymphocytic infiltration of the thyroid, the presence of circulating thyroid autoantibodies and activated $CD4^+$ T cells specific for thyroid antigens, and the expression of antigen-presenting major histocompatibility complex (MHC) class II proteins by thyrocytes. There is a genetic predisposition to autoimmune thyroiditis, and a polygenic basis for this predisposition is suggested by linkage to several genetic loci in affected kindreds.[12] Because autoimmune thyroiditis is more common in populations with higher dietary-iodine content, it has been postulated that high levels of dietary iodine cause an increase in thyroglobulin antigenicity. Thyroid autoimmunity can be initiated by interferon-alfa therapy and can cause either hypothyroidism or hyperthyroidism.[13] Discontinuance of immunomodulatory therapy often reverses this effect.

Other causes of thyroid injury Thyroid surgery or thyroid irradiation—whether in the form of radioactive iodine therapy for thyrotoxicosis or external-beam radiotherapy for head and neck malignancies[14]—commonly results in hypothyroidism. In hemochromatosis, iron infiltration of the gland can cause thyroid failure. Transient primary hypothyroidism also occurs with lymphocytic thyroiditis (also known as postpartum or painless thyroiditis) and subacute thyroiditis.

Drug and toxins causing hypothyroidism Long-term administration of iodine in pharmacologic quantities, such as with amiodarone[15] or iodine-containing expectorants, can inhibit thyroid hormone production, particularly in patients with underlying autoimmune thyroiditis. Lithium carbonate interferes with hormone release from the thyroid gland, resulting in transient TSH elevation in one third of patients and sustained hypothyroidism in 10%; those with autoimmune thyroiditis are especially vulnerable.[16] The antiretroviral agent stavudine and the drugs aminoglutethimide and thalidomide have also been reported to cause hypothyroidism. Industrial exposure to polybrominated and polychlorinated biphenyls and resorcinol have been reported to produce hypothyroidism in workers. Although perchlorate is capable of inhibiting thyroid hormone synthesis, this chemical has not been shown to cause hypothyroidism at concentrations reported in contaminated drinking water.[17]

Central (secondary) hypothyroidism Diseases that interfere with TRH production by the hypothalamus or that impair pituitary TSH production can produce central hypothyroidism. The most common causes are pituitary adenomas and the surgical procedures or radiotherapy used to treat them.[18] In addition, tumors impinging on the hypothalamus or pituitary stalk, traumatic transection of the pituitary stalk,[19] and certain infiltrative diseases (e.g., sarcoidosis, hemochromatosis, and Langerhans cell histiocystosis) can interfere with hypothalamic TRH production or delivery. Pituitary thyrotrope dysfunction can be caused by lymphocytic hypophysitis; infection; metastatic disease; apoplexy (e.g., Sheehan syndrome or tumor infarction); and bexarotene, a retinoid X receptor–selective ligand used to treat cutaneous T cell lymphoma.[20]

PATHOGENESIS

Clinical hypothyroidism reflects a widespread lack of thyroid hormone actions at the genomic level in target tissues, where T_3 binds to receptors that are members of the nuclear receptor superfamily.[21] These T_3 receptors are in turn bound to thyroid-response elements located in the regulatory regions of certain genes that increase or decrease their transcription in response to thyroid hormone. Some biochemical and clinical manifestations of hypothyroidism can be explained on the basis of specific deficiencies in molecular actions. For example, reduced expression of the hepatic low-density lipoprotein (LDL) receptor gene decreases LDL cholesterol clearance, causing hypercholesterolemia; decreased expressions of the myocardial α-myosin heavy-chain genes and the sarcoplasmic reticulum adenosine triphosphatase genes impair myocardial systolic and diastolic performance, respectively. Many other clinical aspects of hypothyroidism are not yet understood in terms of specific genomic actions. Some of these may result from putative nongenomic thyroid hormone actions on G protein–coupled membrane receptors and mitochondria.[22]

DIAGNOSIS

Clinical Manifestations

Classic symptoms of hypothyroidism include fatigue, lethargy, cold intolerance, weight gain, constipation, dry skin, hoarseness, slowed mentation, and depressed mood. In a study of patients with short-term hypothyroidism, 38% to 58% of patients had one or more of these clinical findings.[23] However, the diagnostic accuracy of such symptoms is low. Of newly diagnosed hypothyroid patients in a case-control study by Canaris and colleagues, only 30% had any symptoms, and 17% of euthyroid control subjects had one or more of the same nonspecific complaints.[24] As a result, individual symptoms had a positive predictive value of only 8% to 12%.

Inaccuracy in clinical diagnosis of hypothyroidism is attributable to various factors, including the fact that many other disorders produce similar symptoms; the typically gradual onset of thyroid hormone deficiency; and, sometimes, the impaired insight that hypothyroidism produces in some patients. Symptoms that are new or that occur in combination are more likely to rep-

resent hypothyroidism. In the Canaris study, patients with seven or more new symptoms were almost ninefold more likely to be hypothyroid than those with fewer new symptoms. In addition, more hypothyroid patients than euthyroid patients reported that their symptoms had changed from the previous year.[24]

Hypothyroidism can be associated with cognitive deficits, particularly memory problems.[25] Although hypothyroidism is in the differential diagnosis of dementia and is not uncommonly detected in demented elderly patients, thyroid hormone treatment rarely reverses dementia in these patients.[26] Other neurologic findings in hypothyroid patients can include depression, psychosis, ataxia, seizures, and coma. Hypothyroidism is a potentially reversible cause of sleep apnea. It can also cause decreases in the senses of hearing, taste, and smell.

Other special manifestations of hypothyroidism have been reported in children and adolescents. Thyroid hormone deficiency can cause growth failure, delayed or precocious puberty, muscle pseudohypertrophy, and galactorrhea.

Physical Examination

Classic physical signs of hypothyroidism include bradycardia, diastolic hypertension, and hypothermia; coarse, cool, and pale skin; loss of scalp and eyebrow hair; hoarse, slow, and dysarthric speech; distant heart tones; diffuse nonpitting edema; and slowed deep tendon reflexes, particularly during the relaxation phase. However, none of these findings is sufficiently sensitive or specific for diagnosis. Additional signs may be identified when hypothyroid patients present with other unusual features, such as chronic heart failure, pericardial and pleural effusions, ileus and intestinal pseudo-obstruction, or coagulopathy.

In patients with autoimmune thyroiditis, which is the most common type of hypothyroidism, the thyroid gland can be nonpalpable, normal in size, or diffusely enlarged with an irregular contour, firm consistency, and palpable pyramidal lobe. The gland is only rarely painful and tender. There may be signs related to the other endocrine deficiency states associated with the polyendocrine failure syndromes: type 1, which includes hypoparathyroidism (Chvostek and Trousseau signs), adrenal insufficiency (hyperpigmentation), and chronic mucocutaneous candidiasis; and type 2, which includes adrenal insufficiency, type 1 diabetes mellitus, and primary ovarian failure. There can also be evidence of other associated nonendocrine autoimmune disorders, including vitiligo, atrophic gastritis, pernicious anemia, systemic sclerosis, and Sjögren syndrome.

Laboratory Tests

Routine laboratory tests Abnormalities in routine laboratory tests can be the first diagnostic clue suggesting hypothyroidism. Hypercholesterolemia and hyperhomocysteinemia are especially common in hypothyroid patients.[27] In addition, hyponatremia, hyperprolactinemia, hypoglycemia, and elevations in levels of creatine phosphokinase (predominantly MM band) can all be caused by thyroid hormone deficiency.

Serum thyroid function tests Whether it is prompted by clinical or routine laboratory test findings or performed for patient or population screening, measurement of serum TSH should usually be the first test in the diagnosis of hypothyroidism. An elevated serum TSH level identifies patients with primary hypothyroidism regardless of its cause or severity, even those with mild thyroid hormone deficiency and a serum free thyroxine (T_4) concentration within the reference range. Normal serum TSH levels in disease-free populations are typically 0.4 to 4.0 μU/L. However, values are not normally distributed; the mean TSH concentration, 1.5 μU/L, is in the lower half of the reference range.[1] Even a high-normal serum TSH level (e.g., 3.0 μU/L) may reflect very mild thyroid dysfunction, particularly in a patient who has other clinical or laboratory features of autoimmune thyroiditis. As a result, some authorities have recommended lowering the TSH assay's upper limit of normal to 2.5 μU/L.[28]

*Attributable to TSH with reduced biologic-to-immunologic activity ratio.

When an elevation in serum TSH is detected in a potentially hypothyroid patient, the test should be repeated, and the serum free T_4 concentration should be measured. This further testing confirms the diagnosis of hypothyroidism—an important step, because such patients will typically be committed to lifelong thyroid hormone therapy—and more fully defines the severity of hypothyroidism. The serum T_3 concentration has limited sensitivity and specificity and therefore is a poor test for hypothyroidism.

The TSH assay may fail to detect hypothyroidism in a few settings. In patients with central hypothyroidism, the serum TSH level can be low, normal, or even modestly elevated.[29] The absence of an elevation in the TSH level in a patient with a low free T_4 level is attributable to the synthesis of a TSH molecule that has a decreased ratio of biologic to immunologic activity.[30] Central hypothyroidism should be suspected in the absence of TSH elevation if the patient has clinical features of hypothyroidism; has clinical findings suggesting a sellar mass lesion or other anterior pituitary hormone deficiencies; or has a history of head trauma or conditions known to cause hypopituitarism, such as sarcoidosis. In these settings, both the serum free T_4 and TSH concentrations should be measured. Detection of a low serum free T_4 concentration, regardless of the TSH level, indicates the need for further testing, which may include cranial imaging, performance of a TRH stimulation test to assess TSH responsiveness, and other pituitary function testing.

There are also circumstances in which an elevated serum TSH level may not reflect hypothyroidism [*see Table 1*]. Euthyroid patients with renal or adrenal insufficiency may have modest TSH elevations (e.g., levels of 5 to 10 μU/L). Two rare forms of TSH-mediated hyperthyroidism that may present as clinical and biochemical hyperthyroidism with an inappropriately normal or elevated serum TSH are TSH-secreting pituitary tumors[31] and isolated pituitary resistance to thyroid hormone.[32] However, the elevation in levels of serum free T_4, T_3, or both in these patients provides a clue to the diagnosis. Circulating anti-TSH antibodies can yield falsely elevated TSH immunoassay readings.

Effects of nonthyroid illnesses and drugs Distinguishing central hypothyroidism from the thyroid function abnormalities that often accompany severe nonthyroid illnesses can be challenging. Cytokine-mediated TSH suppression can mask mild primary hypothyroidism. Furthermore, certain drugs used to treat severe illness (e.g., glucocorticoids, dopamine, and dobutamine) can normalize elevated serum TSH concentrations in patients with overt primary hypothyroidism. Conversely, false positive transient TSH elevation can be seen in patients recovering from critical illness.[33] Consequently, with severely ill patients, it is best to limit thyroid function testing to those in whom there is a significant clinical suspicion of hypothyroidism; otherwise, abnormal results are much more likely to represent false positive than true positive findings. Similarly, the antiseizure medications phenytoin and carbamazepine can cause decreases in the levels of serum total T_4, free T_4 (as measured by immunoassay), and TSH; these findings can be confused with those of central hypothyroidism.[34] In some patients who are severely ill or who are taking these antiseizure medications, free T_4 measurement by equilibrium dialysis and pituitary imaging may be required to diagnose or exclude central hypothyroidism.

DIFFERENTIAL DIAGNOSIS

Given that the clinical manifestations of hypothyroidism are quite nonspecific and can be caused by myriad other medical conditions and life circumstances, the key to diagnosis is simply for the physician to keep this condition in mind. Once the possibility of hypothyroidism is entertained, serum TSH measurement can confirm or exclude the diagnosis in almost all cases. In a survey of 1,721 primary care physicians, 80% to 90% appreciated the fact that a middle-aged woman presenting with fatigue, impaired memory, or depression might have hypothyroidism and therefore would order a serum TSH concentration for such a patient; however, only half of these physicians would screen for hypothyroidism in a hypercholesterolemic patient.[35]

The cause of primary hypothyroidism may be evident from the history alone; for example, the patient may have previously undergone thyroid surgery or radiation therapy or may currently be taking medications known to cause hypothyroidism. When the history provides no clue, sustained primary hypothyroidism can usually be assumed to be caused by autoimmune thyroiditis. Confirmatory laboratory tests are seldom required. Nonetheless, it is sometimes helpful to confirm this diagnosis by detection of thyroid autoantibodies. Anti–thyroid peroxidase antibody assay is the most sensitive test to confirm the diagnosis of autoimmune thyroiditis. Thyroid autoantibody testing can also be useful in predicting the development of hypothyroidism in patients with mild hypothyroidism and in pregnant and postpartum women.[36-38]

MANAGEMENT

Thyroid Hormone Therapy

Levothyroxine sodium (thyroxine) is the treatment of choice for patients with hypothyroidism. Thyroxine is well absorbed by the proximal small bowel. Thyroxine circulates with a 7-day half-life because of plasma protein binding, and it is metabolized in target tissues, in part by deiodination to T_3. Its long half-life permits a single daily dose; its conversion to T_3 in target tissues mimics normal physiology. The multiple dose strengths available in North America facilitate precise dose titration. Nonetheless, thyroxine and other thyroid hormone preparations have narrow therapeutic indexes and hence have the potential for adverse reactions with even modest overtreatment. Several studies examining the adequacy of thyroid hormone therapy in large populations and in patients in generalist and specialty practices have found that one fifth of patients with treated hypothyroidism are receiving an inadequate dose and one fifth an excessive dose.[39]

Dosing considerations and drug interactions The optimal thyroxine dosage for hypothyroid patients is related to body weight. In adults, this is approximately 1.8 μg/kg/day.[40] Elderly patients, whose metabolic clearance of thyroxine is reduced, have a lower dosage requirement of 0.5 μg/kg/day. The thyroxine dose is usually higher in patients who have undergone thyroidectomy than in patients with autoimmune thyroiditis, who often have residual functioning thyroid tissue. Thyroxine absorption can be decreased in patients with malabsorption from gastrointestinal disorders or previous small bowel bypass surgery. Several mineral supplements, medications, and dietary constituents can interfere with thyroxine absorption; these include iron, calcium carbonate, cholestyramine, aluminum hydroxide gel, sucralfate, soy, and perhaps dietary fiber. Metabolism of thyroxine is accelerated in the nephrotic syndrome, in other severe systemic illnesses, and with the use of phenobarbital, phenytoin, carbamazepine, and rifampin. In 75% of pregnant women, the thyroxine dose requirement is increased by 50% to 100%.[41] Postmenopausal hormone replacement therapy increases the required thyroxine dose in 35% of women.[42]

Patient noncompliance is the most common cause of inadequate thyroxine therapy. Several observations should raise suspicion that a patient is not taking thyroxine faithfully: the apparent thyroxine dose requirement is higher than expected; thyroid function test results vary without correlation with prescribed thyroxine doses; and the serum TSH concentration is elevated, yet the serum free T_4 level is in the mid- to high-normal range, reflecting improved compliance immediately before testing.

Thyroxine treatment should typically start with a dosage at the lower end of the anticipated requirement (e.g., 125 μg/day in a 70 kg adult). In otherwise healthy younger patients, there is no need to titrate the dose upward from a very low starting dose. Laboratory monitoring of treated hypothyroid patients should be performed 4 to 6 weeks after starting a new thyroxine dose or tablet formulation; thereafter, it should be performed annually. It should also be performed whenever a patient's symptoms suggest thyroid hormone deficiency or excess. The goal for most patients is to restore the TSH level to the lower half of the normal range (i.e., 1.0 to 2.0 μU/L). In patients with central hypothyroidism, the serum free T_4 concentration must be monitored; treatment should usually be targeted for a concentration in the upper half of the normal range.

Metabolism of certain other drugs can be affected by the hypothyroid state and by the initiation of thyroxine treatment. Hypothyroid patients may have increased sensitivity to anesthetic and sedative agents. Reduced digoxin clearance and drug distribution volume may predispose patients to toxicity. Sensitivity to warfarin may be decreased because of slowed metabolism of vitamin K–dependent clotting factors, and restoring euthyroidism can increase the required warfarin dose.

Adverse reactions to thyroid hormone therapy Adverse reactions to thyroxine overtreatment include symptomatic thyrotoxicosis and subclinical thyrotoxicosis with increased risks of bone loss and atrial tachyarrhythmias.[43,44] The predisposition to

osteoporosis is principally in postmenopausal women. Atrial fibrillation is more common in patients 60 years of age or older. Both of these complications have been shown to occur when the serum TSH concentration is suppressed to less than 0.1 μU/L.

Complications can also arise from restoring euthyroidism, particularly in patients with underlying ischemic heart disease[45] (see below) and borderline adrenal cortical insufficiency. Concomitant thyroid and adrenal gland failure can occur in hypopituitarism and in the type 2 polyendocrine failure syndrome (Schmidt syndrome), which is marked by autoimmune thyroiditis and idiopathic adrenal insufficiency.

A few patients experience acute sympathomimetic symptoms soon after institution of thyroxine treatment. This syndrome is poorly understood; it can be circumvented by reducing the thyroxine dose to a very low level and advancing it slowly.

Transient scalp hair loss may occur during first few weeks of thyroxine replacement therapy. Patients can be assured that this phenomenon is temporary. Treatment of hypothyroidism sometimes reveals an underlying urticarial disorder, but true allergy to thyroxine formulations has not been well documented.

Special Therapeutic Issues

Hypothyroid patients with ischemic heart disease Because thyroid hormone has positive inotropic and chronotropic effects, thyroid hormone therapy can exacerbate myocardial ischemia in hypothyroid patients with underlying coronary artery disease. In such patients, thyroxine therapy should be initiated at a low dosage (e.g., 25 μg/day) and titrated upward in increments of 12.5 to 25 μg every 4 to 6 weeks. Patients should be monitored vigilantly with clinical assessments and electrocardiography. Deliberate suboptimal dosing, which was previously advocated to limit myocardial oxygen demand, has been shown to actually increase the risk of progressive coronary atherosclerosis. Beta-blocker therapy should sometimes be initiated or intensified when thyroxine therapy is initiated. Hypothyroid patients who experience worsening myocardial ischemia despite these precautions can undergo coronary angioplasty and even surgical bypass grafting with minimal or no increased perioperative risk.[46,47]

Mild hypothyroidism Whether to identify and treat patients with mild hypothyroidism, defined by an elevated serum TSH level with a normal free T_4 level, is controversial. There is agreement that mild hypothyroidism is highly prevalent, particularly in older women, and that clinical diagnosis is inaccurate. Diagnostic serum TSH testing and thyroxine treatment of mild hypothyroidism are clearly effective and are relatively safe and inexpensive. The outstanding issue is whether mild hypothyroidism causes clinical consequences that are important enough to justify widespread screening and therapy.[48] Proponents of detection and treatment argue that it prevents progression to overt hypothyroidism in affected patients, particularly those whose serum TSH concentration is greater than 10 μU/L, who are 65 years of age or older, or who have thyroid autoantibodies, indicating underlying autoimmune thyroiditis. Advocates believe that treatment of mild hypothyroidism may reduce the risk of future atherosclerotic cardiovascular disease. They hold this view on the basis of the following observations: affected patients have higher mean cholesterol levels; most studies have shown that TSH-normalizing thyroxine therapy lowers serum total cholesterol and LDL cholesterol concentrations[49]; and some epidemiologic studies have found that persons with mild hypothyroidism have a higher risk of atherosclerotic cardiovascular disease.[50] Some proponents are persuaded by four small, controlled, double-blind trials that showed that thyroxine therapy was more effective than placebo in improving symptoms and neuropsychologic performance in patients with mild hypothyroidism.[51] On the basis of these studies, two decision and cost-effectiveness models suggested that the cost-effectiveness of screening for and treating mild hypothyroidism is comparable to that of other widely accepted preventive medicine strategies.[52,53] On the other hand, opponents of screening and treatment of mild hypothyroidism point out that these putative benefits have not been rigorously confirmed by large, randomized, controlled trials.[54] When physicians do recommend treatment for patients with mild hypothyroidism, the thyroxine dosage is typically lower than that for overt hypothyroidism—0.5 μg/kg/day.

Residual hypothyroid symptoms and T_3 therapy Compared with euthyroid patients, hypothyroid patients more often have constitutional and neuropsychological complaints, even when serum TSH measurements suggest adequate treatment.[55] This observation may represent only ascertainment bias (i.e., symptomatic patients seeking medical care are more likely to be diagnosed and treated for hypothyroidism). However, it has been postulated that the presence of residual symptoms in thyroxine-treated patients reflects a failure to replace the small amount of T_3 normally secreted by the thyroid gland. Four clinical trials in which a fraction of the thyroxine dose was replaced with a small dose of T_3 failed to confirm an earlier report of significant improvement with combination thyroxine/T_3 therapy.[56] Combination therapy has the disadvantages of a fluctuating and supraphysiologic T_3 level, a greater risk of iatrogenic thyrotoxicosis, and increased complexity and expense. Treatment with desiccated thyroid, a biologic preparation that also contains both T_4 and T_3, has the same disadvantages.

COMPLICATIONS

Severe hypothyroidism (myxedema) can become complicated by multiple organ system failure when it is profound and prolonged, especially in elderly patients who have other cardiac, pulmonary, neurologic, renal, and infectious diseases. Myxedema coma, the most severe expression of hypothyroidism, is associated with substantial mortality. Such complications of thyroid hormone deficiency can be prevented with sustained thyroxine therapy. In newly diagnosed patients, preventive measures also include giving special attention to other potentially provocative medical conditions (e.g., heart failure, renal failure, pneumonia) and medications—particularly sedative, anesthetic, and analgesic medications that suppress ventilatory drive and other central nervous system functions.

Treatment of complicated hypothyroidism includes thyroid hormone replacement and aggressive management of organ system complications that can be present. Two thyroid hormone regimens have proven efficacy for myxedema coma: (1) thyroxine in a full replacement dose (1.8 μg/kg/day), with or without a 500 μg loading dose to replete the normal body thyroxine pool[57]; and (2) T_3 in divided doses, advocated because of the impaired T_4-to-T_3 conversion that occurs in critically ill patients. No trial has rigorously compared these regimens, but one small retrospective study found a higher mortality in T_3-treated patients.[58]

PROGNOSIS

The prognosis for hypothyroid patients who are properly

treated with thyroxine should be excellent. However, discontinuance of thyroid hormone therapy predictably leads to recurrent hypothyroidism, with its potential for serious complications in the elderly. This occurs most often in settings of social neglect, poor access to health care, and associated neuropsychological impairment. Lesser degrees of suboptimal therapy are also associated with long-term risks. Inadequately treated patients may have increased risk of atherosclerotic cardiovascular disease, and iatrogenic thyrotoxicosis can predispose patients to osteoporosis and atrial tachyarrhythmias.

Patients with autoimmune thyroiditis, the most common cause of hypothyroidism, are at risk for certain associated conditions, for which they should be monitored. Pernicious anemia and gastric achlorhydria with consequent iron and calcium malabsorption affect 3% and 25% of autoimmune thyroiditis patients, respectively. Much less commonly, other autoimmune diseases (e.g., Sjögren syndrome and systemic sclerosis), endocrine deficiency states (adrenal insufficiency, type 1 diabetes, hypoparathyroidism, and hypogonadism), and primary thyroid lymphoma can occur.

Thyrotoxicosis

EPIDEMIOLOGY

The alert clinician will diagnose thyrotoxicosis several times each year. NHANES III found thyrotoxicosis in 0.5% of a surveyed cohort that reflected the demographics of the United States adult population.[1] Three disorders account for the majority of cases: diffuse toxic goiter (Graves disease), toxic nodular goiter, and iatrogenic thyrotoxicosis in thyroid hormone–treated patients. The incidence of Graves disease in one United Kingdom community survey was one to two cases per 1,000 population annually; 2.7% of women and 0.2% of men had Graves disease or a history of Graves disease.[59] The highest incidence of Graves disease is in women 30 to 60 years of age, but the disease can affect persons of virtually any age, from neonates to the very elderly. Toxic adenoma and toxic multinodular goiter are more common causes of thyrotoxicosis than Graves disease in regions where dietary iodine deficiency is prevalent; in women; and in older patients.[60] Iatrogenic thyrotoxicosis has been reported in approximately 20% of thyroid hormone–treated patients.[1,39,61]

ETIOLOGY, GENETICS, AND PATHOGENESIS

Thyrotoxicosis can be divided into three etiologic categories: abnormal stimulation of the thyroid gland, thyroid gland autonomy, and gland inflammation with unregulated thyroid hormone release. Each of these categories includes several diseases [*see Table 2*].

Table 2 Etiologic Classification of Thyrotoxicosis

Cause	*Individual Diseases*
Abnormal stimulation of the thyroid gland	Graves disease hCG-mediated thyrotoxicosis TSH-mediated thyrotoxicosis
Thyroid gland autonomy	Toxic adenoma Toxic multinodular goiter Congenital thyrotoxicosis Iodine-induced hyperthyroidism Thyroid cancer–related thyrotoxicosis
Gland inflammation with unregulated thyroid hormone release	Subacute (de Quervain) thyroiditis Lymphocytic thyroiditis Amiodarone-induced thyrotoxicosis, type 2 Acute thyroiditis

hCG—human chorionic gonadotropin

Graves Disease (Diffuse Toxic Goiter)

There is compelling evidence that there is a genetic predisposition to Graves disease, that the incidence is higher in women, that unknown environmental factors are involved in its initiation, and that gland stimulation by antibodies against the TSH receptor is the immediate precipitant of the condition. Identical twins and some families show increased incidences of Graves disease.[62] The condition has been genetically linked to certain MHC components (e.g., HLA-B8 and HLA-DR3), which are on the surface of cells that present antigenic peptide epitopes to T cell receptors. One theory is that certain HLA-DR molecules may be better able to present TSH receptor epitopes, inciting autoimmunity. Another hypothesis is that these HLA-DR recognition sequences are involved in aberrant thymic T cell selection for tolerance. Graves disease has also been linked to polymorphisms in the gene encoding CTLA-4, a T cell receptor important for interaction with antigen-presenting cells.[63] In whites, a susceptibility locus for Graves disease has been identified on chromosome 20q11.

Several environmental factors have been implicated in the initiation of Graves disease. These include stressful life events, smoking, large amounts of dietary iodine, and preceding infection with certain bacterial agents that have been postulated to induce molecular mimicry. Radiation injury to the thyroid gland may increase the risk of the condition, possibly because of increased TSH receptor exposure and immunoreactivity.

Whatever the underlying genetic and environmental factors, the vast majority of Graves disease patients have detectable antibodies that are directed against the TSH receptor and are capable of stimulating it[64] [*see Figure 2*]. Assays using thyroid cells or their membranes can detect circulating TSH receptor autoantibody species in 70% to 90% of patients with Graves disease. These autoantibodies are capable of stimulating intracellular cyclic adenosine monophosphate production (thyroid-stimulating immunoglobulins [TSI]), inhibiting TSH receptor activation (TSH receptor inhibitory immunoglobulins), and inhibiting the binding of TSH to its receptor (TSH receptor–binding inhibitory immunoglobulins [TBII]).

Toxic Adenoma and Toxic Multinodular Goiter

Solitary and multiple thyroid adenomas and diffusely hyperplastic thyroid tissue possess a growth advantage, and their constituent thyrocytes sometimes produce thyroid hormones autonomously (i.e., without regard to TSH regulation). These hyperplastic and neoplastic conditions cause hyperthyroidism when the mass and efficiency of functioning thyroid tissue are great enough to generate hormone excess in target tissues, including suppression of endogenous pituitary TSH production and function of extranodular thyroid tissue.[65] Both genetic and environmental factors are involved in the development of this autonomous function. A twin study showed that genetic factors could account for 82% of the predisposition to nodular goiter, and familial multinodular goiter has been linked to a gene locus on chromosome 14q.[66] At the same time, environmental factors (e.g., dietary iodine deficiency, goitrogens, and radiation exposure) also clearly predispose to the development of autonomous-

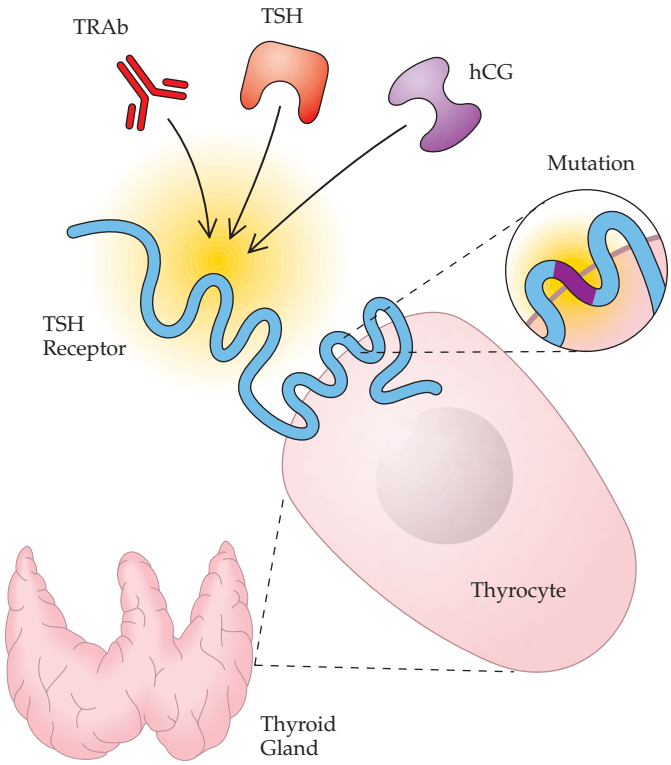

Figure 2 **Certain forms of hyperthyroidism result from deranged physiologic activation of the thyroid-stimulating hormone (TSH) receptor. In Graves disease, TSH receptor autoantibodies (TRAb) bind the TSH receptor. In patients with TSH-secreting pituitary tumors, the autonomously secreted TSH overstimulates the receptor. In molar pregnancy and choriocarcinoma, high concentrations and aberrant forms of human chorionic gonadotropin (hCG) can activate the TSH receptor. In some patients with toxic adenomas, a constitutively activating somatic mutation of the TSH receptor results in autonomous secretion of thyroid hormone.**

ly functioning thyroid tissue. Genetic and environment factors promote thyroid tissue growth by activating intraglandular growth factors (e.g., insulinlike growth factor and epidermal growth factor receptor)[67] and signaling pathway proteins (e.g., $G_s\alpha$ and ras). Constitutively activating somatic mutations of the TSH receptor and $G_s\alpha$ itself have been described in 25% to 80% of toxic adenomas, more commonly in patients from regions where dietary iodine deficiency is prevalent.[68]

Iodine-Induced Hyperthyroidism

Iodine is both a substrate and a physiologic regulator of thyroid hormone synthesis. Excessive iodine intake normally inhibits thyroid hormone production by reducing the trapping of inorganic iodide and its oxidation into an organic form (organification) and by thyroid hormone release. At the same time, exposure to pharmacologic amounts of iodine (typically 1,000-fold more than the physiologic requirement of 150 μg/day) can cause hyperthyroidism, a condition termed the Jod-Basedow effect. Patients with hyperplastic and benign neoplastic thyroid conditions and those with latent Graves disease are particularly vulnerable to iodine-induced hyperthyroidism. Epidemics of thyrotoxicosis have repeatedly been observed when iodine supplementation is instituted in regions of previous dietary iodine deficiency.[69] However, iodine-induced hyperthyroidism can also occur in patients from iodine-sufficient environments whose thyroid glands are apparently normal, especially when excess iodine exposure is substantial and sustained, as it is with long-term amiodarone therapy.[70] The precise molecular and biochemical basis for iodine-induced hyperthyroidism is poorly understood. Iodine-induced hyperthyroidism is typically transient, lasting only a few weeks, but more prolonged thyroid dysfunction can occur when iodine exposure is prolonged, as occurs with the lipid-soluble drug amiodarone and with myelographic radiocontrast agents.

Thyroiditis

Inflammation of thyroid tissue caused by infectious diseases, autoimmune processes, or pharmacologic toxicity can cause thyrocyte death, disruption of follicular architecture, and unregulated leakage of thyroid hormones from the gland into the circulation, resulting in thyrotoxicosis[71] [*see Table 3*]. Thyroiditis-related thyrotoxicosis is typically self-limited, lasting 2 to 8 weeks, with spontaneous resolution once glandular stores of thyroid hormone are exhausted. A comparable period of transient hypothyroidism often follows because of lingering impairment of thyroid hormone synthesis, but most patients ultimately become euthyroid [*see Figure 3*].

Amiodarone-Induced Thyrotoxicosis

The iodine-containing antiarrhythmic agent amiodarone can cause thyrotoxicosis by two mechanisms.[72] Type 1 amiodarone-induced thyrotoxicosis is caused by iodine, whereas type 2 amiodarone-induced thyrotoxicosis is the result of gland inflammation. Both forms can be severe, prolonged, and life-threatening, particularly because affected patients have underlying cardiac disease.

Chorionic Gonadotropin–Mediated Hyperthyroidism

Human chorionic gonadotropin (hCG), which is structurally similar to TSH, can stimulate the TSH receptor and increase thyroid function when circulating in high concentration or when variant forms of either hCG or the TSH receptor increase the affinity of their hormone receptor interaction[73] [*see Figure 3*]. In fact, during the first trimester of normal pregnancy, when a marked physiologic elevation of hCG occurs, a modest rise in the serum free T_4 level and a decline in the serum TSH level are typically seen.[74] An exaggeration of this phenomenon can cause thyrotoxicosis, as can trophoblastic tumors.

Trophoblastic tumors Women with hydatidiform mole and choriocarcinoma, as well as men with metastatic testicular choriocarcinoma, can develop hyperthyroidism as a result of very high concentrations of circulating hCG.[75] Furthermore, these tumors have been shown to produce a variant form of hCG with heightened TSH receptor stimulatory properties.

Gestational transient thyrotoxicosis Mild transient thyrotoxicosis occurs late in the first trimester of pregnancy in 1% to 3% of white women and in as many as 11% of Asian women.[76] The serum hCG level is higher in affected pregnant women than in those who remain euthyroid. Furthermore, gestational thyrotoxicosis appears to be more common in women who have hyperemesis gravidarum or twin pregnancies, both of which are characterized by higher serum hCG concentrations. A rare form of familial gestational thyrotoxicosis has been reported in which a mother and daughter both had recurrent hy-

Table 3 Characteristic Features of Thyroiditis

Form of Thyroiditis	*Presumed Etiology*	*Classic Pattern of Thyroid Dysfunction*	*Other Clinical Manifestations*	*Treatment*
Autoimmune	T cell–mediated autoimmunity	Hypothyroidism	Firm small-to-medium goiter	Thyroxine for hypothyroidism
Lymphocytic (painless, silent, postpartum)	T cell–mediated autoimmunity?	Transient thyrotoxicosis followed by hypothyroidism	Painless small goiter	Observation, beta blockade for thyrotoxicosis, thyroxine for hypothyroidism
Subacute (de Quervain)	Viral infection?	Transient thyrotoxicosis followed by hypothyroidism	Painful and tender hard goiter	NSAID or glucocorticoid, beta blockade for thyrotoxicosis, thyroxine for hypothyroidism
Acute (suppurative)	Bacterial, fungal, and protozoal infections	Thyroid dysfunction (rare)	Painful, tender, and inflamed goiter	Antibiotic therapy, surgical drainage
Amiodarone-induced type 1	Iodine-induced hyperthyroidism	Thyrotoxicosis	Normal-size nontender gland	Thionamide antithyroid medication
Amiodarone-induced type 2	Inflammatory thyroiditis, precise cause unknown	Transient thyrotoxicosis	Normal-size nontender gland	Glucocorticoids
Riedel (invasive fibrous)	Idiopathic fibrosis?, autoimmune?	Hypothyroidism in one third of patients	Enlarging, hard, fixed mass	Surgery, glucocorticoids, tamoxifen

NSAID—nonsteroidal anti-inflammatory drug

perthyroidism during their pregnancies and were found to have a mutant TSH receptor with increased affinity and signaling responsiveness to hCG.[77]

TSH-Mediated (Central) Hyperthyroidism

Hyperthyroidism can be caused by excessive TSH secretion in two rare conditions: TSH-secreting pituitary adenoma and the syndrome of isolated central resistance to thyroid hormone.[78] Excessive and relatively autonomous TSH production by pituitary tumors predictably results in goitrous hyperthyroidism.[79] The TSH produced by TSH-secreting pituitary tumors has increased bioactivity, and normal inhibition of TSH release by dopamine has been shown to be defective in these patients. However, the fundamental cause of these tumors, which often cosecrete other pituitary hormones, is unknown.

Isolated central resistance to thyroid hormone is a rare inherited condition in which impaired negative feedback of thyroid hormone on pituitary thyrotropes leads to TSH hypersecretion and hyperthyroidism.[80] In one patient with isolated central resistance to thyroid hormone, a novel mutation in the thyroid hormone receptor–β gene was identified. In patients with this syndrome, unlike those with generalized resistance to thyroid hormone, other target tissues for thyroid hormone, such as the brain, heart, and liver, respond normally to the resulting thyrotoxicosis.

Exogenous Thyrotoxicosis

Iatrogenic thyrotoxicosis is relatively common, occurring in 20% of thyroid hormone–treated patients.[1,39,61] Possible explanations for this condition include improved patient compliance with therapy, decreased metabolic clearance of thyroid hor-

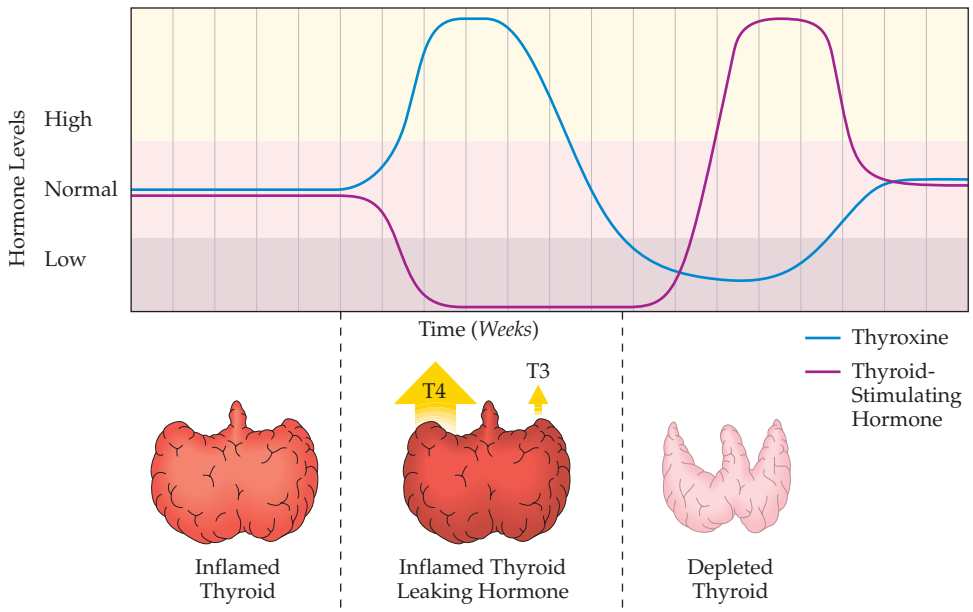

Figure 3 **In acute thyroiditis, inflammation of thyroid tissue leads to unregulated leakage of thyroid hormones from the gland into the circulation. The resulting thyrotoxicosis typically lasts 2 to 8 weeks and ends spontaneously as the glandular hormone stores are exhausted. A comparable period of hypothyroidism often follows, because of impaired thyroid hormone synthesis, but in most patients, the gland gradually returns to normal function.**

mones with aging, a substantial decrease in body weight, an increase in underlying gland function in patients with treated Graves disease or nodular goiter, and discontinuance of medications that interfere with thyroid hormone absorption or that accelerate its metabolism. Factitious thyrotoxicosis is sometimes prompted by a desire to enhance energy and weight loss; it can also occur through the complex psychopathology of Munchausen syndrome. Accidental or suicidal thyroid hormone intoxication can be life-threatening; its clinical manifestations may take 12 to 48 hours to become fully expressed, necessitating close observation even of asymptomatic patients, especially children.[81]

DIAGNOSIS

Clinical Manifestations

The classic symptoms of thyrotoxicosis are familiar to every third-year medical student—weight loss despite good appetite, heat intolerance, tremor, palpitations, and anxiety—yet even experienced clinicians are often slow to make the diagnosis, for several reasons. First, many common symptoms of thyroid hormone excess are nonspecific, such as fatigue, insomnia, dyspnea, and atypical chest pain. Second, patients can present with atypical chief complaints: weight gain; anorexia, nausea, and vomiting; muscle weakness; headache; urticaria; and, in elderly patients, apathy without sympathomimetic symptoms. Severe thyrotoxicosis may also present as heart failure, delirium, or an apparent febrile illness. Third, thyrotoxicosis can occur without the full complement of findings associated with Graves disease (e.g., prominent goiter and ocular findings). For example, thyrotoxicosis can be overlooked in a postpartum woman with weight loss and anxiety from acute lymphocytic thyroiditis, in a middle-aged man with bilateral earache reflecting radiation pain from subacute thyroiditis, and in the older patient with "failure to thrive" related to toxic nodular goiter. Fourth, new thyrotoxic complaints often arise in patients who have been otherwise entirely well and in whom the symptoms can potentially be discounted as a minor intercurrent illness or life stress. Finally, the spectrum of thyrotoxicosis includes entirely asymptomatic disease that nonetheless can have potential health consequences related to mild thyroid hormone excess.

A history of exposure to certain drugs, radiocontrast dye, homeopathic or traditional medicines, and dietary supplements can sometimes be the key to diagnosis. For example, a history of therapy with thyroid hormone, amiodarone, or interferon alfa suggests both the possibility and the likely cause of thyrotoxicosis. A history of recent radiocontrast studies or the recent ingestion of kelp may suggest iodine-induced hyperthyroidism. The family history is also often important in revealing a predisposition to autoimmune thyroid disease, nodular goiter, or, in rare cases, inherited forms of thyrotoxicosis.

Physical Examination

Physical signs related to thyrotoxicosis are often the key to diagnosis and differential diagnosis. Classic signs accompanying thyrotoxicosis can include an anxious, hyperactive demeanor and pressured speech; tachycardia, systolic hypertension, and widened pulse pressure; velvety, warm, and moist skin; onycholysis; flaxen, oily hair; staring gaze and lid lag; prominent apical impulse and systolic flow murmur; and proximal leg muscle weakness and tremor.

Certain findings on physical examination are characteristic of specific etiologies of thyrotoxicosis [*see Table 3*]. In Graves disease, patients typically have a symmetrical, rubbery goiter that is nontender and smooth or subtly lobulated; an audible bruit is sometimes noted. They may also have subtle or prominent eye findings, including episcleral injection, conjunctival swelling, periorbital edema, proptosis, limitation of extraocular motility, and impaired visual acuity or color vision. Less commonly, these patients may have pretibial myxedema, an orange peel–like thickening of the soft tissues of the anterior aspect of the lower leg from subcutaneous mucopolysacharide deposition; rarely, they may have clubbing of the fingers. Graves disease patients may also have physical signs of associated disorders, such as vitiligo and prematurely gray hair, which often escape detection without specific inquiry.

Other findings may suggest other etiologies for thyrotoxicosis. A solitary palpable thyroid nodule or multinodular goiter suggests the possibility of toxic adenoma or toxic multinodular goiter, respectively. Modest thyroid enlargement with an exquisitely tender, wood-hard gland may represent subacute thyroiditis. Thyrotoxic symptoms and signs in a pregnant woman may reflect hCG-related hyperthyroidism or, in a postpartum woman, acute lymphocytic thyroiditis. Signs of an expanding sellar mass lesion or other syndromes of pituitary hormone excess (e.g., acromegaly, Cushing syndrome, or galactorrhea) may suggest the presence of a TSH-secreting pituitary adenoma.

Laboratory Tests

Routine laboratory tests Abnormalities on routine laboratory studies can be the first clue to thyrotoxicosis. Such abnormalities include hypercalcemia, an elevated serum alkaline phosphatase concentration, and a serum total or LDL cholesterol concentration that is either low or that is lower than previously documented for that patient. Serum ferritin, angiotensin-converting enzyme, and testosterone-binding globulin concentrations are all increased in thyrotoxicosis, and such increases may suggest the diagnosis. New significant atrial arrhythmias detected by electrocardiography, particularly atrial fibrillation, mandate testing for thyrotoxicosis.

Serum thyroid function tests Serum TSH measurement is a highly sensitive way to diagnose or exclude all common forms and degrees of thyrotoxicosis.[82] Physiologic inhibition of pituitary thyrotrope function by thyroid hormones results in a serum TSH concentration that is low—almost invariably, less than 0.1 μU/L in patients with thyrotoxicosis. When the TSH assay is employed to diagnose thyrotoxicosis, it must have a detection limit low enough to distinguish normal from low values; a functional sensitivity to less than 0.02 μU/L has been recommended.[83] The serum TSH concentration is so sensitive in detecting thyroid hormone excess that it can be suppressed even when a patient's serum thyroid hormone concentration rises but remains within the reference range for that population—so-called subclinical thyrotoxicosis (see below).

In a few circumstances, however, TSH measurement can be inaccurate in the diagnosis of thyrotoxicosis. First, in patients with rare forms of TSH-mediated thyrotoxicosis (see above), the serum TSH concentration can be elevated, inappropriately normal, or only modestly decreased (i.e., 0.1 to 0.5 μU/L). Second, spurious elevations of the measured TSH level, masking thyrotoxicosis, can occur with rare analytic problems, such as the presence of interfering anti-TSH autoantibodies. Third, there are other causes of a low serum TSH level, including central hypothyroidism and severe nonthyroidal illnesses. Whenever one of

Table 4 Causes of Elevated Serum Total Thyroxine Level

- Thyrotoxicosis
- Increased serum protein binding
  - Increased serum thyroxine-binding globulin concentrations
    - Inherited
    - Estrogen (pregnancy, exogenous, tumor produced)
    - Hepatitis
    - Hepatoma
    - HIV infection
    - Drugs (methadone, heroin, clofibrate, 5-fluorouracil)
  - Familial dysalbuminemic hyperthyroxinemia
  - Increased serum transthyretin binding or concentrations
    - Inherited
    - Carcinoma of the pancreas
    - Hepatoma
- Inhibition of T_4-to-T_3 conversion
  - Medical illnesses
  - Drugs (high-dose propranolol, amiodarone)
- Test artifacts (assay interference from anti-T_4 immunoglobulins)

these circumstances is suspected, serum free T_4 and T_3 levels should be obtained to rule out thyrotoxicosis definitively.

Serum T_4 and T_3 measurements are useful to confirm the diagnosis of thyrotoxicosis, define its severity, and monitor the response to treatment. However, elevated serum total thyroid hormone concentrations are not specific for thyrotoxicosis[84] [*see Table 4*]. Because most of the circulating thyroid hormones are bound to plasma proteins (e.g., thyroxine-binding globulin, transthyretin [thyroxine-binding prealbumin], and albumin), conditions that increase the concentration or binding affinity of these proteins can cause euthyroid hyperthyroxinemia—an increase in the total serum T_4 level without elevation of the small fraction (0.03% for T_4) of biologically active free hormone. The most common such condition is the estrogen-induced increase in thyroxine-binding globulin level that occurs in women who are pregnant or who are taking estrogen preparations. Conversely, a decrease in binding of thyroid hormone by plasma proteins, such as occurs with nephrotic syndrome or androgen use, can mask the diagnosis of thyrotoxicosis on the basis of total T_4 measurement.

The serum free (or unbound) T_4 concentration can help distinguish thyrotoxicosis from euthyroid hyperthyroxinemia. Although equilibrium dialysis is the most accurate approach to free T_4 measurement, it is technically demanding and few laboratories perform it. Free T_4 immunoassays are now widely available and relatively inexpensive. They provide much the same information and have largely supplanted the free T_4 index, which provides an estimate of the unbound T_4 concentration on the basis of partition of radiolabeled thyroid hormone between plasma proteins and a binding resin. Both the free T_4 immunoassay and free T_4 index can reliably differentiate between the hyperthyroxinemia of thyrotoxicosis and that associated with thyroxine-binding globulin elevation.

Certain other conditions causing euthyroid hyperthyroxinemia still cannot be reliably differentiated from thyrotoxicosis with conventional methods of measuring free T_4. For example, free T_4 immunoassays often report falsely elevated values in patients with familial dysalbuminemic hyperthyroxinemia, in which a mutant albumin binds T_4 with increased affinity.[85] Similarly, increased transthyretin binding of thyroxine caused by a mutant transthyretin gene or acquired transthyretin overproduction by hepatic or pancreatic neoplasms can yield deceptively elevated free T_4 immunoassay values.[86] T_4-binding autoantibodies, which occasionally develop in patients with autoimmune thyroiditis, can cause spurious serum T_4 elevation.[87] Hyperthyroxinemia can also occur with disorders and medications that reduce T_4 clearance, including acute systemic illnesses, psychosis, and treatment with amiodarone or high-dose propranolol. Finally, patients with the syndrome of generalized resistance to thyroid hormone typically have elevated serum total and free T_4 and T_3 concentrations.

In summary, hyperthyroxinemia is not pathognomonic of thyrotoxicosis. Clinical information—such as the presence of symptoms and signs of thyrotoxicosis or other conditions or the use of medications associated with hyperthyroxinemia—often permit a straightforward differentiation of thyrotoxicosis from euthyroid hyperthyroxinemia. Serum TSH measurement is invaluable in distinguishing all common forms of thyrotoxicosis, in which serum TSH is low, from euthyroid hyperthyroxinemia, in which serum TSH is usually normal.

Serum total and free T_3 concentrations are elevated in most patients with thyrotoxicosis caused by increased thyroid T_3 production and increased extrathyroid conversion of T_4 to T_3. Less than 5% of hyperthyroid patients have T_3 thyrotoxicosis (i.e., a high serum T_3 concentration and a normal serum T_4 concentration). An elevated serum total T_3 concentration is not entirely specific for thyrotoxicosis, because it can also occur with thyroxine-binding globulin excess, a rare form of familial dysalbuminemic hypertriiodothyroninemia, and anti-T_3 autoantibodies. Serum T_3 assays are useful clinically for fully defining the severity of certain forms of hyperthyroidism, particularly Graves disease; in addition, they are useful, along with the free T_4 concentration, for monitoring the response to treatment of thyrotoxicosis.

DIFFERENTIAL DIAGNOSIS

It is vital for the physician to establish the underlying cause of thyrotoxicosis, because the etiology determines the therapy. In many patients, the history and physical examination alone are sufficient for specific diagnosis. For example, a thyrotoxic woman with a diffuse goiter and exophthalmos almost certainly has Graves disease, whereas a febrile patient with an extremely tender, wood-hard thyroid gland probably has subacute thyroiditis. In other patients, however, the underlying cause may be less certain. For example, a woman with postpartum thyrotoxicosis could have painless (postpartum) thyroiditis, Graves disease, or even factitious thyrotoxicosis—each of which would be treated quite differently. In such patients, further laboratory or radionuclide studies are needed to define the cause and optimal treatment.

The relative degrees of serum T_3 and T_4 elevations can provide a clue to the form of thyrotoxicosis. Predominant T_3 overproduction is common in Graves hyperthyroidism and, to a lesser extent, in toxic nodular goiter (i.e., a serum T_3-to-T_4 [ng/dl:µg/dl] ratio greater than 20). In contrast, T_4-predominant thyrotoxicosis (i.e., a serum T_3-to-T_4 ratio less than 15) suggests thyroiditis (subacute or lymphocytic), iodine-induced thyrotoxicosis, or exogenous T_4 ingestion.

Determining the fractional thyroid uptake of radioactive iodine or pertechnetate and thyroid imaging are required for etiologic diagnosis in some patients. Hyperthyroidism from excessive thyroid hormone synthesis, as in Graves disease, is typically accompanied by increased fractional uptake of the tracer in func-

tioning tissue. In contrast, thyrotoxicosis caused by thyroid inflammation, exogenous thyroid hormone ingestion, and iodine exposure are all associated with a low thyroid uptake. Radionuclide imaging of the thyroid gland often permits differentiation of Graves disease from toxic nodular goiter, because tracer distribution is homogeneous in the former and focal in the latter. Radionuclide imaging can also localize ectopic thyroid tissue that may be hyperfunctioning, such as substernal toxic multinodular goiter and struma ovarii, an ovarian teratoma in which a toxic adenoma can arise.

Anti–TSH receptor immunoglobulin assays have limited clinical uses in differential diagnosis and management.[83] They may be helpful in confirming the diagnosis of Graves disease in clinically and biochemically euthyroid patients who have ophthalmopathy or when differentiation of Graves disease from toxic multinodular goiter is otherwise difficult and important for treatment. In pregnant women with Graves disease, the level of thyroid-stimulating immunoglobulins can predict the likelihood of fetal and neonatal thyrotoxicosis.

Other tests may be helpful in diagnosing certain other causes of thyrotoxicosis. Patients with subacute thyroiditis usually have an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein level, whereas patients with lymphocytic (silent) thyroiditis do not.[88] In patients with thyrotoxicosis caused by thyroid hypersecretion or inflammation, the serum thyroglobulin concentration is high, whereas it is low in patients with factitious thyrotoxicosis. Measurements of the serum glycoprotein hormone α subunit may be useful to confirm the diagnosis of TSH-secreting pituitary adenoma, in which the molar ratio of the α subunit to intact TSH is higher than normal.

Differentiating the two causes of amiodarone-induced thyrotoxicosis is often very difficult, if not impossible. Both the iodine-induced type (type 1) and the inflammatory type (type 2) can be severe; both can be T_4 predominant, and both can be associated with a low thyroid radioiodine uptake. Early reports of higher interleukin-2 levels in the inflammatory form have not been confirmed. Glandular blood flow, as defined by Doppler sonography, is decreased in some patients with the inflammatory form, but this has also proved to be an imperfect distinguishing feature in many affected patients.

MANAGEMENT

Optimal treatment of patients with thyrotoxicosis depends on the underlying cause and severity of their condition and sometimes on the presence of complications that result from hyperthyroidism itself or the patient's other medical disorders. Transient thyrotoxicosis (e.g., exogenous and thyroiditis-related thyrotoxicosis) may require only symptomatic therapy with a beta-adrenergic blocking agent while awaiting spontaneous restoration of euthyroidism. Hyperthyroid Graves disease can be treated with antithyroid medication, radioiodine, or surgery; most of these patients ultimately require an ablative treatment. The hyperthyroidism caused by a toxic adenoma or toxic multinodular goiter will also respond to thionamides (e.g., methimazole and propylthiouracil [PTU]), but it almost never remits spontaneously, so radioiodine or surgery is always required. Fortunately, these three most commonly required therapies are quite comparable with regard to cost-effectiveness, and the vast majority of patients are satisfied with the treatment that they have chosen. Certain special forms of thyrotoxicosis, such as TSH-secreting pituitary adenoma and thyroid hormone intoxication, require other modes of treatment tailored to the responsible cause.

Beta-Adrenergic Blocking Agents

Beta blockers provide prompt relief from some symptoms of thyrotoxicosis, including tremor, palpitations, and anxiety. However, constitutional complaints, such as fatigue and weakness, and hypermetabolic manifestations, such as heat intolerance and weight loss, are unrelieved by beta-adrenergic blockade. These drugs are often valuable for temporary control of symptoms while awaiting a response to more definitive therapies or spontaneous remission of thyrotoxicosis. Beta blockers can be used—optimally, in combination with other drugs—to prepare patients with thyrotoxicosis for surgery. They are also useful for ventricular rate control in patients with thyrotoxic atrial fibrillation (see below). When used judiciously, beta blockers can be a component of treatment for some patients with thyrotoxic heart failure. Some beta blockers, such as propranolol, also partially inhibit extrathyroid T_4-to-T_3 conversion, but these agents do not otherwise address the underlying pathogenesis of thyrotoxicosis.

Antithyroid Drugs

The thionamide antithyroid drugs inhibit iodination and coupling, which are key steps in thyroid hormonogenesis.[89] Consequently, methimazole and PTU are effective treatments for forms of hyperthyroidism caused by excess thyroid hormone production by the gland, such as Graves disease. However, they are ineffective when thyrotoxicosis is caused by unregulated release of hormone from an inflamed gland, such as that which occurs in subacute thyroiditis. Overtreatment with thionamides causes hypothyroidism, so the dose must be titrated or thionamide use must be accompanied by thyroxine replacement. Compared with ablative therapies, antithyroid drugs have the advantage of lowering the long-term incidence of hypothyroidism. However, Graves disease is associated with a 25% long-term incidence of hypothyroidism, which results from the destructive effects of gland inflammation and occurs even with prolonged antithyroid drug treatment.

Thionamide treatment is an appropriate choice for patients with mild Graves disease, in whom the absence of severe manifestations (e.g., a large goiter, a very elevated serum T_4 level, or ophthalmopathy) predicts a higher spontaneous remission rate. Typically, antithyroid drugs are prescribed for 6 to 24 months, after which the dose is tapered to determine whether a remission has occurred. The antithyroid drugs are also useful in four other circumstances: (1) for temporary treatment of patients with Graves disease who are unwilling to accept definitive radioiodine therapy immediately, (2) for preliminary control of hyperthyroidism before definitive radioiodine or surgical treatment, (3) for the management of pregnant women with hyperthyroidism and neonatal Graves disease, and (4) to determine whether nonspecific symptoms are in fact related to mild thyrotoxicosis.

The antithyroid drugs have several limitations. First, they typically take 3 to 8 weeks to restore euthyroidism. Although they inhibit new thyroid hormone synthesis, they do not block the gland's release of existing hormone stores, which can be plentiful in patients with goitrous Graves disease, toxic nodular goiter, and amiodarone-induced thyrotoxicosis. Second, the antithyroid drugs' actions end when the drug is discontinued. As a result, virtually all patients with toxic nodular goiter and the majority of those with Graves disease will experience relapse when the medication is stopped. Third, antithyroid drugs have potential side effects. In addition to hypothyroidism resulting from overtreatment, they cause rash, pruritus, and fever in approxi-

mately 5% of treated patients. Much less commonly, severe adverse reactions can occur, including potentially fatal granulocytosis, vasculitis, or, with PTU, hepatic failure. All thionamide-treated patients must be warned of the symptoms and signs of these problems and be advised that if such manifestations occur, they should report the manifestations and immediately discontinue the medication. The likelihood of another adverse reaction occurring if a patient is switched from one thionamide to another is poorly documented, but such cross-reactivity does occur. Consequently, it is generally advisable in this circumstance to recommend radioiodine or surgery.

For most hyperthyroid patients, methimazole, 10 to 30 mg a day, is more effective and safer than PTU. Methimazole's longer half-life permits a single daily dose, which improves compliance; in contrast, PTU must be given three times daily for sustained effect. Methimazole at dosages of less than 40 mg a day is less likely than PTU to cause agranulocytosis and is not associated with hepatic failure. In certain circumstances, however, PTU, 100 to 200 mg a day in divided doses, may be preferred. In patients with severe and complicated thyrotoxicosis (see below), PTU has the advantage of also blocking extrathyroid T_4-to-T_3 conversion; a benefit in pregnant women is that PTU crosses the placenta less readily than methimazole and therefore has less of an effect on fetal thyroid function.

Radioiodine

Iodine-131 (^{131}I) is a highly effective, safe, and convenient treatment for hyperthyroid patients with hyperthyroid Graves disease, toxic multinodular goiter, and toxic adenoma. This radioisotope of iodine is preferentially concentrated in thyrocytes, where it emits beta particles (electrons) with a short path-length that limits the field of its destructive effects to the thyroid gland. With dosing regimens that are based on estimated gland size and preliminary thyroid radioiodine fractional uptake determinations, or even with empirical doses, a single dose will provide effective treatment for approximately 75% of Graves disease patients and 50% of patients with toxic nodular goiter. Almost all of the remaining patients are cured with a second radioiodine treatment, which is usually best held until the initial dose has proved ineffective after 6 months. For patients with toxic multinodular goiter, there is limited experience with the use of recombinant thyrotropin to increase thyroid uptake of radioiodine—a strategy that might be expected to improve the cure rate and permit a reduction in the administered dose of radioiodine.

Radioiodine has limitations. It takes 1 to 2 months before irradiated thyrocytes die and hyperthyroidism resolves; during this time, patients must often be treated with adjunctive beta-adrenergic blockade, antithyroid drugs, or stable iodide (see below). Approximately 25% of patients develop a transient worsening of thyrotoxicosis 2 to 4 weeks after treatment because of radiation thyroiditis, which can also cause mild and short-lived gland discomfort. The principal side effect of radioiodine is postablative hypothyroidism, which occurs within 3 months in more than half of radioiodine-treated Graves disease patients. Furthermore, in Graves disease patients who remain euthyroid, gland failure continues to occur at a rate of 3% annually, so lifelong follow-up of their thyroid function is essential. In patients with hyperthyroidism resulting from toxic multinodular goiter and toxic adenoma, the incidence of postablative hypothyroidism is lower (approximately 25%) because the suppressed normal extranodular tissue receives much less irradiation. During the more than 65 years that radioiodine has been used to treat hyperthyroidism, the preponderance of evidence has shown no higher long-term incidence of thyroid or other malignancies. In radioiodine-treated women, no higher incidences of subsequent infertility or spontaneous abortion has been found, nor has there been a higher incidence of teratogenesis in their children. In one large follow-up study, radioiodine treatment of children and adolescents was associated with a higher subsequent incidence of benign thyroid nodules. As a result, many experts prefer to treat pediatric patients with antithyroid drugs for several years before resorting to radioiodine. However, radioiodine should not be withheld from children when hyperthyroidism is poorly controlled or side effects occur with thionamide therapy.

Radioiodine is inappropriate in several circumstances. It is absolutely contraindicated in pregnant women. All women of childbearing age should be advised to avoid pregnancy until euthyroidism is restored; this typically requires 3 to 6 months. Radioiodine is not indicated in transient forms of thyrotoxicosis, such as subacute and lymphocytic thyroiditis. Furthermore, it is ineffective in these and other forms of thyrotoxicosis in which the thyroid uptake of radioiodine is decreased, including amiodarone-induced thyrotoxicosis.

Surgery

Thyroidectomy by an experienced surgeon who has a demonstrated low incidence of complications is a highly effective, prompt, and relatively safe alternative. However, transient pain and scarring are universal after thyroidectomy, and postanesthetic symptoms are common. Partial thyroidectomy has an unacceptably high rate of residual hyperthyroidism; thus, gland resection that is extensive enough to ensure success can be expected to result in postsurgical hypothyroidism. Even in the most skilled surgical hands, there is a small risk (approximately 2% to 5%) of hypoparathyroidism or injury to the recurrent laryngeal nerve. Finally, for most patients, surgery is less convenient and entails greater interruption of life commitments than does radioiodine therapy.

Despite its drawbacks, surgery is the best choice in several settings. Pregnant women with severe thionamide side effects have no alternative. In some hyperthyroid patients, other aspects of their condition may make neck surgery necessary (e.g., the patient may have a cytologically suspicious thyroid nodule or hyperparathyroidism). Amiodarone-induced thyrotoxicosis can require surgery when medical treatment is ineffective and the patient's cardiovascular and metabolic status is deteriorating. For some patients, such as those planning prolonged travel in the near future and those who cannot or will not take medications reliably, surgery is attractive because it provides prompt and certain cure. Thyroidectomy is also preferred in countries that require prolonged hospitalization for even low-dose radioiodine therapy.

Other surgical procedures play a role in the treatment of certain rare forms of hyperthyroidism. Transsphenoidal pituitary adenomectomy is typically the first step in treatment of patients with TSH-secreting adenomas, but it is curative in only one third of patients.[90] Oophorectomy is appropriate when hyperthyroidism results from a toxic adenoma arising in teratomatous ovarian tissue in a patient with struma ovarii.

Other Agents

Stable iodide, given as either potassium iodide or Lugol solution in pharmacologic amounts (i.e., 30 mg or more a day), blocks thyroid hormone release from the gland and inhibits organifica-

tion of iodide in patients with Graves disease. When combined with antithyroid drug therapy, iodide can accelerate the decline in circulating thyroid hormone concentrations. However, its effects are only temporary, dissipating after 10 to 14 days, after which hyperthyroidism recurs. Consequently, it is useful in only two settings. First, it can be employed as a short-term measure to prepare patients for thyroidectomy. Second, it can be started several days after radioiodine treatment to accelerate restoration of euthyroidism. In such patients, the irradiated gland is incapable of escaping from iodide's inhibitory effects. Iodide has infrequent side effects of rash, gastritis, and sialadenitis.

Iodinated radiocontrast agents, such as sodium iopanoate, can have two salutary effects in patients with severe thyrotoxicosis. First, they are an abundant source of iodide. Second, they inhibit T_4-to-T_3 conversion.

Lithium carbonate also inhibits hormone release from the thyroid gland. It is used in rare cases to accelerate recovery from severe thyrotoxicosis, as an adjunct to antithyroid medication in type 1 amiodarone-induced thyrotoxicosis, or as a short-term treatment for patients who have experienced severe thionamide side effects. Potassium perchlorate, which blocks iodide uptake by the thyroid, is a rarely used treatment of type 1 amiodarone-induced thyrotoxicosis.

Nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen are first-line agents for controlling thyroid pain and constitutional symptoms in subacute thyroiditis. They do not, however, accelerate recovery of normal thyroid function.

Glucocorticoids (e.g., prednisone, 40 mg/day) can be used to treat thyrotoxicosis under a few specific circumstances. When subacute thyroiditis is resistant to NSAID therapy, steroids are almost invariably effective. However, their side effects and the fact that they may prolong the overall course of subacute thyroiditis make them second-line agents. Glucocorticoid therapy is also useful in the treatment of type 2 amiodarone-induced thyrotoxicosis. Finally, when combined with high-dose antithyroid medication and iodinated radiocontrast agents, glucocorticoids can often be effective in controlling even severe thyrotoxic Graves disease within 1 week after initiation of therapy.

Other agents are employed to treat rare causes of thyrotoxicosis. Cholestyramine can be an adjunct in the treatment of patients with exogenous thyroid hormone intoxication; it interrupts the enterohepatic circulation of thyroid hormones and increases their fecal disposal. Somatostatin analogues are useful in the medical management of patients with inoperable TSH-secreting pituitary tumors or of patients whose tumors were incompletely resected.[91]

COMPLICATIONS

Atrial Fibrillation

Atrial tachyarrhythmias can occur with even mild thyrotoxicosis. Atrial fibrillation is the most common and potentially the most serious of these dysrhythmias; atrial flutter and paroxysmal atrial tachycardia also occur. Thyrotoxic atrial fibrillation occurs more often in older persons and men, as well as in persons with intrinsic cardiac diseases, particularly when these diseases cause left atrial enlargement. Thyrotoxic atrial fibrillation can be complicated by heart failure and thromboembolism. Beta blockers are useful for ventricular rate control; they are less likely to cause hypotension than calcium channel blockers, which remain an alternative. Anticoagulation is generally advisable. Exceptions are in patients in whom thyrotoxic atrial fibrillation has been of short duration and rapidly reverts to sinus rhythm or in those with contraindications to anticoagulation. Cardioversion should generally be deferred until the patient is euthyroid. It should be attempted if spontaneous reversion to sinus rhythm does not occur by 3 months after euthyroidism has been restored[92] [*see 1:IV Atrial Fibrillation*].

Thyrotoxic Heart Failure

When thyrotoxicosis is severe and prolonged or when the patient has intrinsic cardiac disease, heart failure can occur.[93] Contributing factors can include atrial fibrillation; ventricular hypertrophy and dilatation with impaired diastolic function; failure of mitral valve leaflet apposition and resulting regurgitation; and tachycardia-induced cardiomyopathy. Typically, one or more of these factors occurs in the context of increased peripheral tissue demands, vasodilatation, and an expanded blood volume. The left ventricular ejection fraction may be normal at rest but deteriorates with exertion. Therapy includes aggressive treatment of thyrotoxicosis, ventricular rate control, restoration of sinus rhythm when possible, and optimization of blood volume and ventricular filling pressures.

Thyroid Crisis

Thyroid crisis—so-called thyroid storm—refers to the life-threatening constellation of fever; heart failure, often with atrial fibrillation; delirium or psychosis; and fluid and electrolyte depletion resulting from poor oral intake and gastrointestinal losses caused by vomiting or diarrhea.[94] Patients with severe hyperthyroidism, underlying cardiac disease or superimposed infection, and poor access to health care are at increased risk for these complications.[95] Treatment entails medical management of each individual complication and aggressive therapy for thyrotoxicosis, typically with multiple agents appropriate for the underlying cause. Because Graves disease is the most common cause of thyroid storm, treatment typically includes PTU, sodium iopanoate, and glucocorticoids.

Graves Orbitopathy

For some patients with Graves disease, ocular and orbital involvement represents the most disabling aspect of their condition. Exposure keratitis resulting from proptosis, eyelid retraction, and lagophthalmos (inability to close the eye) causes symptoms and can be complicated by infection and ulceration. Treatment includes moistening eyedrops and lubricant ointments, sunglasses, taping the eyelids shut for sleeping, and sometimes blepharoplasty, orbital decompression surgery, and irradiation. Extraocular muscle swelling and fibrosis can cause diplopia, which can require prisms and sometimes corrective surgery. Optic nerve compression can threaten vision; it is treated acutely with high-dose glucocorticoids and definitively by orbital decompression surgery.

PROGNOSIS

Although the short-term morbidity of thyrotoxicosis can be disabling, the long-term outlook is generally bright, given accurate etiologic diagnosis and appropriate therapy targeted to the specific cause. However, many patients with Graves disease ultimately require lifelong treatment of postablative hypothyroidism, and their ophthalmopathy may be an ongoing source of discomfort, cosmetic concern, and, rarely, visual impairment. Mortality and severe long-term disability are rare events that typically result from either cardiovascular complications of thy-

rotoxicosis or side effects of antithyroid medication or thyroid surgery.

Thyroiditis

There are several types of thyroiditis, each of which has distinct causes, clinical manifestations, and treatments [*see Table 3*]. Some types cause thyroid dysfunction. When thyrotoxicosis occurs in these conditions, it is a transient result of the unregulated release of hormone from the gland, whereas hypothyroidism can be transient or permanent. Goiter occurs in some of these disorders (e.g., autoimmune thyroiditis and Reidel thyroiditis), whereas it is not a prominent feature of others. Pain is characteristic of subacute thyroiditis but is an uncommon feature of the other types.

AUTOIMMUNE THYROIDITIS

Autoimmune thyroiditis (Hashimoto disease) is a common condition, particularly in women, who are affected over 10 times more often than men. Its incidence increases with age; during and after middle life, approximately 20% of women have serologic evidence of the condition (i.e., thyroid autoantibodies), and 10% to 15% have an elevated serum TSH level secondary to thyroid hormone insufficiency. Its etiology, genetics, and pathogenesis are discussed elsewhere [*see* Hypothyroidism, *above*].

Clinical manifestations of autoimmune thyroiditis, when present, include hypothyroidism and a goiter. However, most affected patients have either no symptoms or only nonspecific ones, and they do not have significant gland enlargement. When present, the goiter is typically diffuse, modest in size, nontender, and firm with a roughened contour. Patients with the fibrous variant can have more substantial gland enlargement. Pain and tenderness are rarely present.

The presence of thyroid autoantibodies confirms the diagnosis, which can often be established on clinical grounds alone. Immunoassay for antithyroid peroxidase antibodies, which are present in 90% of patients, is the most sensitive single test[96]; antithyroglobulin antibodies are present in only 60% of patients. An elevated serum TSH concentration indicates associated primary hypothyroidism. The differential diagnosis of diffuse goiter includes simple euthyroid goiter, Graves disease, iodine-deficiency goiter, and, rarely, diffusely infiltrating malignancies (i.e., lymphoma, papillary cancer, and anaplastic cancer).

The management of patients with autoimmune thyroiditis includes thyroid hormone replacement for those who are hypothyroid and periodic thyroid function testing for those who are euthyroid but remain at risk for the development of hypothyroidism later in life. Women who have experienced transient hypothyroidism are particularly at risk. Associated goiter rarely requires any treatment, but thyroid hormone replacement sometimes results in partial gland shrinkage. The rare patient with thyroid pain may benefit from NSAIDs. The prognosis for properly treated and monitored patients is excellent. Certain other autoimmune disorders occur more often in affected patients; these can include vitiligo, pernicious anemia, adrenal insufficiency, Sjögren syndrome, and systemic sclerosis. Thyroid lymphoma is more common as well, but it is still a very rare event.

LYMPHOCYTIC THYROIDITIS

Lymphocytic thyroiditis (also known as painless thyroiditis, silent thyroiditis, or postpartum thyroiditis) is believed to be caused by cell-mediated autoimmunity. This belief is based on the fact that the gland is infiltrated with lymphocytes and the condition's incidence is highest postpartum—a time when autoimmune disorders are more common.[97] The condition is relatively common in the postpartum period, affecting approximately 6% of women between 2 and 12 months after delivery or abortion. Women with thyroid autoantibodies, previous episodes of postpartum thyroiditis, or type 1 diabetes mellitus are at markedly increased risk. The condition also occurs during treatment with immunomodulatory agents (see below). Rarely, lymphocytic thyroiditis may present in women or men at other times.

Lymphocytic thyroiditis can cause several patterns of transient thyroid dysfunction: thyrotoxicosis alone, thyrotoxicosis followed by hypothyroidism, hypothyroidism alone, or, rarely, hypothyroidism followed by thyrotoxicosis. The pathogenesis of these derangements is described elsewhere [*see* Thyrotoxicosis, *above*]. In postpartum women, symptoms of thyroid dysfunction can often be overlooked or mistaken for depression. Affected patients have a modest goiter or no goiter.

Serum TSH measurement is the best first-line test to detect thyroid dysfunction in patients with lymphocytic thyroiditis. In thyrotoxic patients, the condition can be differentiated from Graves disease, which can also present postpartum, by the absence of significant goiter or eye involvement; by relatively greater concentration of serum T_4 than of serum T_3 (ratio > 20:1 in μg/dl:ng/dl); and by a low thyroid radioisotope uptake. In hypothyroid patients, postpartum thyroiditis can best be distinguished from autoimmune thyroiditis by whether it remits spontaneously or not. Thyroid autoantibodies are detected in many postpartum thyroiditis patients.

Management can often be expectant, without drug treatment. Symptomatic thyrotoxicosis and hypothyroidism can be treated with temporary beta-adrenergic blockade and thyroxine, respectively. One quarter of affected patients go on to develop typical autoimmune thyroiditis and permanent hypothyroidism.

SUBACUTE THYROIDITIS (DE QUERVAIN OR GRANULOMATOUS THYROIDITIS)

Subacute thyroiditis is believed to be the result of a viral infection, because of its association with prodromal symptoms, the presence of circulating viral antibody titers, and electron microscopic evidence of viral particles. Classically, episodes of subacute thyroiditis have three clinical components. First are the systemic manifestations: symptoms suggesting a viral upper respiratory tract infection, followed by malaise, fever, and chills. The second is a painful goiter, which is characteristically moderate in size, wood-hard, and extremely tender. The third is transient thyrotoxicosis, which can be quite severe. The thyrotoxicosis lasts for 2 to 8 weeks and is typically followed by transient hypothyroidism. Although the clinical features of subacute thyroiditis are usually sufficient to suggest the diagnosis, constitutional symptoms (especially high fever) can mimic other infections, and thyroid pain radiating to the ears can be confused with otitis. Thyrotoxicosis is confirmed by a low serum TSH and a high serum T_4 concentration. Marked elevation of the ESR is detectable during the acute phase of the illness. Other causes of painful thyroid enlargement include hemorrhage into a thyroid nodule, which is usually asymmetrical; acute thyroiditis (see below); thyroid lymphoma or anaplastic thyroid cancer; and, very rarely, autoimmune thyroiditis or Graves disease.

Management of subacute thyroiditis entails prescription of an NSAID in high dosage. In approximately 20% of patients, this provides inadequate relief of pain and constitutional symptoms;

these patients can be treated with glucocorticoid therapy (e.g., prednisone, 40 mg/day with a slow taper over 3 to 8 weeks). Transient thyrotoxic symptoms are treated with beta blockers; transient hypothyroid symptoms are treated with thyroxine. In more than 80% of cases, normal thyroid function returns and the condition does not recur.

ACUTE THYROIDITIS (SUPPURATIVE THYROIDITIS)

Acute or suppurative thyroiditis is a rare condition caused by either untreated bacterial infections of the upper respiratory tract or cervical soft tissues or by opportunistic agents in immunocompromised hosts. Hematogenous spread to the thyroid of fungal, mycobacterial, and parasitic infections have all been reported. Piriform sinus fistula, multinodular goiter, or autoimmune thyroiditis may predispose patients to acute thyroiditis.

Patients with suppurative infections typically are extremely ill, with high fever; a painful, tender, swollen thyroid gland; and erythema and warmth of overlying soft tissues. Glands infected with opportunistic pathogens (e.g., *Pneumocystis jiroveci*) may have more subtle signs of gland infection. Treatment requires aggressive, often parenteral, antibiotic therapy and sometimes surgical drainage.

DRUG-INDUCED THYROIDITIS

Several drugs have been associated with painless thyroiditis and thyroid dysfunction, including amiodarone (see above). Treatment of hepatitis C with interferon alfa and interleukin-2 causes thyroid dysfunction in as many as 15% of patients; such dysfunction includes transient thyrotoxicosis with or without subsequent hypothyroidism, as well as persistent hypothyroidism and persistent hyperthyroidism (i.e., Graves disease). Lithium carbonate can exacerbate thyroid dysfunction and cause hypothyroidism in patients with underlying autoimmune thyroiditis. Rarely, pharmacologic doses of iodide can cause transient thyroiditis.

REIDEL THYROIDITIS

Reidel thyroiditis is an extremely rare form of invasive fibrous thyroiditis that can cause substantial goiter with compression and infiltration of adjacent structures. Some patients with this idiopathic disorder also develop hypothyroidism. It may be encountered in patients with retroperitoneal and mediastinal fibrosis. Treatment options are limited. Surgery is challenging and is limited to palliation of obstructive complications. There are reports of effective drug treatment with glucocorticoids and tamoxifen.[98]

Goiter, Thyroid Nodules, and Thyroid Cancer

GOITER

Epidemiology

The prevalence of goiter in populations varies inversely with dietary iodine intake. There are estimated to be 100 million persons with dietary iodine deficiency and one billion with borderline iodine sufficiency. Consequently, in some regions, goiter is almost universal, particularly in women, whereas in regions with an adequate iodine intake, goiter affects less than 5% of the population.

Etiology and Pathogenesis

Worldwide, dietary iodine deficiency is the most common cause of thyroid gland enlargement. In addition, populations have been described in which exposure to goitrogens in drinking water or dietary substances has caused endemic goiter.[99] Although modest thyroid gland enlargement occurs during pregnancy, the so-called goiter of pregnancy is largely restricted to women with associated dietary iodine deficiency. Tobacco smoking has been associated with goiter development, especially in populations without ample dietary iodine. Mutations in genes encoding key proteins involved in thyroid hormone synthesis (e.g., thyroglobulin and thyroid peroxidase), can result in a compensatory goiter. Activation of the TSH receptor by TSH predictably causes diffuse goiter, as occurs in a variety of conditions, including primary hypothyroidism from autoimmune thyroiditis or drugs, TSH-secreting pituitary adenoma, and resistance to thyroid hormone. The TSH receptor can be aberrantly stimulated when thyroid-stimulating immunoglobulins or high levels of hCG bind to it or when a mutation in the TSH receptor gene itself leads to constitutive activation. For the majority of patients with hyperplastic thyroid glands arising despite sufficient dietary iodine—a condition that is sometimes apparently inherited and sometimes sporadic—the precise molecular cause remains unknown. Activation of the biochemical pathways signaling thyrocyte growth or abnormal local levels or activity of intrathyroid growth factors seems likely to be involved. Goiter can also be the result of gland infiltration with inflammatory cells (e.g., leukocytes and multinucleated giant cells in subacute thyroiditis) or tumor cells (e.g., anaplastic or diffusely infiltrating papillary thyroid cancers).

In summary, goiter can be associated with hypothyroidism, euthyroidism (nontoxic goiter), or hyperthyroidism (toxic goiter). It can be a manifestation of benign hyperplastic or neoplastic conditions, malignancy, and inflammation. In many of these disorders, thyroid gland enlargement is initially diffuse, but with time, the thyroid becomes multinodular, and it may become asymmetrical.

Diagnosis and Differential Diagnosis

For the clinician evaluating a patient with a goiter, three pragmatic questions are typically more important than the specific etiologic diagnosis. First, is the enlarged thyroid gland producing pain or other local symptoms as a result of obstruction or invasion of adjacent structures, or is it so large as to be unsightly? Second, is the goiter a manifestation of a disorder causing hypothyroidism or hyperthyroidism that requires treatment? Third, is the gland enlarged because of malignancy?

Clinical manifestations Symptoms related to a goiter reflect gland impingement on adjacent structures. A sensation of cervical fullness, tightness, or pain can occur when the enlarging gland stretches its capsule, which has sensory innervation, and compresses adjacent tissues and structures. Thyroid pain can radiate to the jaw or ears. Tracheal compression can cause cough and difficulty clearing mucus; tracheal invasion from thyroid malignancy can cause hemoptysis. Esophageal compression can produce dysphagia and, rarely, odynophagia. Compression of the recurrent laryngeal nerve results in hoarseness, a weak voice, and dysphagia for fluids; bilateral nerve dysfunction can also cause dyspnea from airway obstruction.

Physical examination Inspection during deglutition often provides the first clue to the presence of a goiter. In addition, it helps distinguish true enlargement of the thyroid, which moves cephalad with swallowing, whereas subcutaneous fat does not.

Any tracheal deviation, cervical vein engorgement, or visible adenopathy should also be noted. On palpation, the dimensions of the gland and its symmetry, contour, consistency, mobility, and tenderness should all be noted.

Other physical findings can provide important information. A bruit suggests either a hypervascular Graves disease gland or compression of cervical blood vessels. Venous engorgement and facial plethora that develops when the patient touches the hands together above the head (Pemberton sign) implies near obstruction of the thoracic outlet by a goiter. Signs of hypothyroidism or hyperthyroidism should, of course, be sought.

Laboratory tests and imaging studies In all patients with goiter, the serum TSH and free T_4 concentrations should be measured to assess gland function. Serologic testing for thyroid autoantibodies, especially anti–thyroid peroxidase antibody, can help establish the diagnosis of autoimmune thyroiditis, the most common cause of diffuse goiter in populations with sufficient dietary iodine.

Ultrasonography can be useful in confirming that a neck mass is, in fact, a goiter. It can define the gland size; determine whether there is diffuse heterogeneity typical of autoimmune thyroiditis or discrete nodules; and identify potentially related cervical adenopathy. A chest and lower cervical x-ray can show tracheal deviation and suggest mediastinal extension of a goiter, but computed tomography or magnetic resonance imaging provides a fuller depiction of the gland's substernal extent and its relationship to the trachea and intrathoracic structures. The decision whether or not to use iodinated radiocontrast agents with CT imaging should be thoughtfully addressed, because these agents can precipitate hyperthyroidism in patients with multinodular goiter and can interfere with subsequent postoperative radioiodine therapy in patients who prove to have thyroid cancer. Radionuclide imaging is seldom required in the initial assessment of patients with goiter, but it can confirm that a superior mediastinal mass concentrating radioiodine is thyroidal in origin. Radioiodine fractional uptakes and imaging can be useful in the differential diagnosis of goitrous thyrotoxicosis (see above). Assessment of ventilatory flow-volume loops can be useful in determining whether dyspnea in a patient with goitrous tracheal compression is caused by the thyroid condition. Although cytologic evaluation plays a central role in the differential diagnosis of thyroid nodules, it is required in only a small minority of patients with diffuse goiters that cannot be readily characterized with clinical, laboratory, and imaging findings.

Management

Management of goiter addresses three key clinical issues: size, function, and potential malignancy. Treatment for thyroid dysfunction or thyroid cancer is the same as in patients without goiter. Large nontoxic, multinodular goiters causing obstructive symptoms or cosmetic concerns can be surgically excised or, if obstruction is not severe, treated with radioiodine.[100] Surgery provides more prompt relief and excludes cancer with certainty, but it is associated with greater short-term morbidity than radioiodine therapy. Even goiters with substantial substernal extension can often be removed through a cervical incision. Recombinant thyrotropin can successfully augment ^{131}I concentration by nodular goiters, which typically have only a normal fractional radioiodine uptake.[101] TSH-suppressive thyroxine therapy has limited value in the treatment of most patients with goiters of significant dimensions. Published experience shows that no more than half of patients have a response, which is often only partial.[102] Furthermore, long-term TSH suppression is associated with risks of bone loss and atrial fibrillation.

Complications and Prognosis

The type and probability of complications in patients with goiter depend on the underlying cause. Most patients with gland enlargement of benign cause never suffer local compressive symptoms and require treatment only if they have associated thyroid dysfunction (i.e., hypothyroidism in patients with autoimmune thyroiditis or hyperthyroidism in patients with multinodular goiter). However, large multinodular goiters can cause dyspnea from tracheal narrowing or dysphagia from esophageal compression. Recurrent laryngeal nerve impingement and dysfunction is very unusual and should raise concern of malignancy. Rarely, thyroid substernal goiter extension can cause superior vena cava obstruction. Goiter from papillary or anaplastic thyroid cancer or lymphoma can cause all of the complications associated with goiters from benign causes, as well as pain from invasion of adjacent structures, hemoptysis from tracheal invasion, and vocal cord paresis from recurrent laryngeal nerve involvement.

THYROID NODULES

Epidemiology and Etiology

Thyroid nodules are palpable in 6% of women and 2% of men.[2] Nonpalpable thyroid nodules can be detected by sonography in one third of women. The prevalence of nodules increases with age. The genetic and environmental factors associated with thyroid nodule development are essentially the same as those for goiter. Nodules may represent solid tissue composed of thyroid cells or colloid or represent cysts from accumulated serous fluid or blood, often from hemorrhage within a solid nodule in the gland. The majority of thyroid nodules are benign; in adults, 5% to 10% of thyroid nodules are cancerous.

Diagnosis

Three clinical issues must be addressed in patients with thyroid nodules: the nodule's size and the resulting potential for local complications, the possibility of associated thyroid dysfunction, and malignancy.[103] The same principles and approach apply to palpable thyroid nodules as to incidentally detected nodules (so-called thyroid incidentalomas) that are greater than 1.0 to 1.5 cm in diameter.[104] After proper assessment, the majority of patients will be found to have none of these three problems, and they can be monitored conservatively.

Clinical Manifestations

Thyroid nodules are usually detected incidentally by asymptomatic patients themselves or by their physicians. Rapidly enlarging or invasive nodules may cause pain in the anterior neck, jaw, or ear. Tracheal or esophageal compression can cause cough or dysphagia, respectively. Invasion of the trachea or recurrent laryngeal nerve by tumor can produce the worrisome symptoms of hemoptysis or hoarseness, respectively. Symptoms of thyrotoxicosis suggest the possibility of toxic adenoma, whereas complaints consistent with hypothyroidism may reflect autoimmune thyroiditis and an asymmetrical goiter that is mimicking a true nodule.

The presence of pulmonary, skeletal, or neurologic symptoms suggesting metastatic disease increases concern about a primary

thyroid cancer. An increased risk of thyroid cancer is also suggested by a history of childhood or adolescent irradiation; irradiation was employed until the early 1950s for thymic enlargement, tonsillitis, adenoiditis, cutaneous hemangiomas, and acne. A family history of thyroid cancer is also an indication for thorough assessment, especially if the familial disease is medullary or papillary thyroid cancer. A history of hyperparathyroidism or pheochromocytoma raises the possibility of the multiple endocrine neoplasia type II (MEN II) syndrome, which includes these disorders and medullary thyroid cancer.[105] Hypercalcitoninemia in patients with metastatic medullary thyroid cancer can cause flushing, pruritus, and diarrhea.

Physical Examination

Nodules that are fixed or associated with ipsilateral cervical adenopathy are worrisome for thyroid cancer. Nodule size and consistency are not reliable features for distinguishing benign from malignant lesions. Although multiple thyroid nodules are typical of benign multinodular goiter, a nodule that is larger, that is growing more rapidly, or that is more symptomatic than others in the gland requires the same assessment as a solitary thyroid nodule. Signs of hyperthyroidism or hypothyroidism suggest toxic adenoma or autoimmune thyroiditis, respectively. Patients with the MEN IIB (or MEN III) syndrome, which includes medullary thyroid cancer and pheochromocytoma, can have a Marfanoid body habitus and submucosal neuromas that are visible as lumps beneath the buccal mucosa and conjunctivae.

Laboratory Tests

The serum TSH concentration should be measured: a low serum TSH suggests a possible toxic adenoma; a high TSH, autoimmune thyroiditis. Antithyroid antibody screening can corroborate the diagnosis of autoimmune thyroiditis in patients who actually have diffuse but asymmetrical thyroid gland enlargement. Serum calcitonin should be measured in patients with clinical features that suggest hypercalcitoninemia or the MEN II syndrome. The serum thyroglobulin assay is not helpful in distinguishing benign from malignant thyroid nodules.

For most thyroid nodules, the definitive diagnostic procedure is fine-needle aspiration to provide cytologic material for examination by an experienced pathologist. Sonographic guidance of aspiration can be useful when nodules are poorly localized by palpation or for the assessment of lesions that have a cystic component; in addition, it can sometimes be useful in identifying additional nonpalpable nodules requiring assessment.[106] Radionuclide imaging currently has only a secondary role in thyroid nodule assessment. In thyroid nodule patients whose serum TSH concentration is low, a iodine-123 or technetium-99m pertechnetate scan that indicates that the nodule is "hot" (i.e., that shows a concentration of tracer in the nodule, with suppression of uptake in the remainder of the gland) provides assurance that the nodule is benign. CT and MRI have no role in the evaluation of the typical patient with a thyroid nodule unless there is substernal extension of a nodular goiter.

Differential Diagnosis

Clinical features of thyroid nodules are sometimes helpful but seldom provide definitive diagnosis. Sonography can confirm that an ambiguous neck mass is thyroidal. Radionuclide imaging should be limited to patients with a suppressed serum TSH concentration. The sensitivity and specificity of cytologic assessment of thyroid nodules are 97% and 95%, respectively. However, approximately 20% of nodules are cytologically indeterminate, among which approximately 15% are malignant.[107] Some thyroid nodules can ultimately be definitively diagnosed only by surgical excision and histopathologic examination.

Management, Complications, and Prognosis

Most cytologically benign thyroid nodules can be managed with observation only, unless the lesion is so large as to cause discomfort, other local compressive complications, or cosmetic concern. Because cytology is not 100% sensitive for cancer exclusion, patients should be followed up for 12 to 24 months. For palpable lesions, follow-up should consist of physical examination; for nonpalpable lesions, sonography is usually advisable. Toxic adenomas diagnosed on the basis of a low serum TSH level and radionuclide confirmation of hot-nodule status can usually be assumed to be benign; treatment of associated thyrotoxicosis is, of course, indicated. Patients with cytologically malignant nodules should undergo thyroidectomy unless their general medical condition contraindicates it. Most patients with cytologically indeterminate nodules require surgery for definitive diagnosis, although if the suspicion of cancer is low, thyroid lobectomy may be worth considering. A subset of patients with cytologically indeterminate thyroid nodules (e.g., older women with multinodular goiter and no clinical features suggesting malignancy) can be followed with sonographic monitoring of the nodules' dimensions.

THYROID CANCER

Epidemiology

Thyroid cancers represent approximately 2% of clinically detected malignancies.[108] The most common tumor types, arising from follicular epithelium (i.e., papillary, follicular, and Hürthle cell cancers), occur three times more often in women and increase in incidence with age. Medullary thyroid cancer arising from parafollicular C cells represents less than 10% of all thyroid cancers but has special importance because of its common familial occurrence. In the United States, the reported incidence of thyroid cancer is rising, perhaps because these tumors are being detected more easily with contemporary diagnostic tools.[109]

Etiology and Pathogenesis

The cause of most thyroid cancers is unknown. Genetic predisposition to papillary thyroid cancer is seen in the familial syndromes of familial adenomatous polyposis (*APC* gene mutation) and Cowden syndrome (*PTEN* gene mutations). It can also occur as familial isolated papillary thyroid cancer. Overall, however, familial cases represent less than 10% of all thyroid cancers.[110] Thyroid irradiation from external sources and accidental radioiodine exposure predisposes to the development of malignant and benign thyroid tumors, as has been observed after radiotherapy (e.g., for recurrent tonsillitis and lymphoma) and after exposure to radioactive iodine fallout from a nuclear-weapon detonation or nuclear-reactor accident. Radioiodine exposure has been shown to produce a characteristic chromosomal rearrangement that creates the *RET/PTC* oncogene.

Progression and clinical aggressiveness of thyroid malignancies have been associated with a sequence of molecular events, including *BRAF* gene mutation and loss of the *p53* tumor suppressor gene.[111] Controversy surrounds evidence relating the development of thyroid cancer to preexisting benign thyroid conditions; to parity and estrogen therapy in women; to previous therapeutic radioiodine exposure; and to dietary factors, includ-

ing iodine intake. Dietary iodine does clearly influence the distribution of thyroid cancer types, with more papillary cancers in populations with generous dietary iodine content.

Diagnosis

Clinical manifestations and physical examination Most thyroid cancers present as a thyroid nodule in an otherwise asymptomatic and euthyroid patient. Enlargement of the mass over weeks or months is more suspicious for cancer than long-standing stable size or very rapid appearance, which can represent hemorrhage into a preexisting benign nodule. Less commonly, patients develop complaints related to local invasion (e.g., pain, hoarseness, or hemoptysis) or distant metastatic disease (e.g., dyspnea, bone pain, or neurologic symptoms). On physical examination, nodule fixation or ipsilateral cervical adenopathy suggests thyroid cancer.

Laboratory tests Cytologic diagnosis of thyroid cancer can often be established from material obtained by fine-needle aspiration of suspicious thyroid nodules [*see* Thyroid Nodules, *above*]. Patients with cytologically indeterminate lesions usually require surgery for definitive diagnosis. Novel molecular markers, such as *BRAF* in papillary thyroid cancers, may in the future permit more accurate preoperative diagnosis and exclusion of cancer in these lesions. In thyroid cancer patients who present with metastatic disease in cervical nodes, lungs, bone, and other sites, biopsy of the identified lesion often establishes the diagnosis, which can be confirmed by thyroglobulin immunostaining. Subsequent careful examination and sonographic imaging of the thyroid gland typically reveal a nodule that can then itself be subject to biopsy.

Management

The therapeutic modalities commonly employed to treat patients with epithelial thyroid cancers are surgical thyroidectomy, radioiodine, and TSH-suppressive thyroid hormone therapy. Physicians and surgeons face the challenge of determining how aggressively these treatments should be applied to these patients, who exhibit a wide spectrum of disease behavior.[112]

When the diagnosis has been made preoperatively, total or near-total thyroidectomy is the procedure of choice. The rationale for bilateral thyroid excision is that papillary cancer, the most common thyroid malignancy, is often multifocal, involving the contralateral lobe in at least 20% of cases. Bilateral surgery has been shown to be associated with a lower papillary cancer recurrence rate.[113] In addition, removal of all, or nearly all, normal thyroid tissue positions patients for more accurate long-term monitoring with serum thyroglobulin measurement and radioiodine imaging. When thyroid cancer is unexpectedly diagnosed after lobectomy, these potential benefits must be balanced against the risks and inconvenience of completion thyroidectomy. For patients with microscopic papillary and minimally invasive follicular cancers, unilateral surgery may be deemed to have been adequate.[114] Unless regional node metastases are recognized before thyroidectomy, selective central neck compartment node excision is generally advisable, although modified radical neck dissection is justifiable when extensive nodal involvement is identified before or at the time of initial surgery.

Postoperatively, ^{131}I is often recommended for patients with epithelial thyroid cancers, with the rationale of eradicating residual disease and ablating remnant thyroid tissue that will otherwise limit the accuracy of long-term monitoring with serum thyroglobulin and radioiodine scans. The value of adjunctive radioiodine treatment to reduce risk of tumor recurrence has been shown in retrospective and observational trials for patients with more advanced stages of disease.[115] The principal factors related to an increased risk of recurrence are older patient age, larger tumor size, extrathyroidal invasion, incomplete tumor resection, and extensive and nodal metastases. In addition, certain histologic subtypes of thyroid cancer are more likely to recur, including the tall cell, columnar cell, and insular variants of papillary thyroid cancer, as well as follicular cancers with vascular invasion. Traditionally, patients have been withdrawn from thyroid hormone therapy postoperatively to effect a rise in endogenous TSH and to facilitate radioiodine uptake by residual thyroid tissue. This is effective but predictably causes clinical hypothyroidism. It has now been shown that radioiodine therapy can also be effective in euthyroid patients who are given recombinant thyrotropin.[116]

Patients with epithelial thyroid carcinoma require long-term thyroxine therapy both to replace thyroid hormone and to suppress TSH to reduce the risk of tumor recurrence. Typically, the thyroxine dose is increased until the lowest dosage capable of suppressing the serum TSH concentration to less than 0.1 μU/L is identified. In patients with symptoms of thyrotoxicosis or patients at low risk for tumor recurrence, the target TSH concentration may adjusted to the 0.1 to 0.5 μU/L range.

Patients treated for epithelial thyroid cancers require long-term follow-up to detect recurrent disease, which can present years after initial therapy. Serum thyroglobulin measurement has become the first-line choice for tumor detection.[117] This thyroid-specific protein should be undetectable in the blood of patients who have no residual thyroid cancer and who have undergone complete ablation of normal thyroid tissue. When circulating thyroglobulin is detected—whether during thyroid hormone therapy or after TSH stimulation by either thyroid hormone withdrawal or recombinant TSH administration—imaging techniques should be employed to localize the residual disease. Cervical sonography and fine-needle aspiration of suspicious adenopathy is the most productive initial step, followed by CT of the chest and, in patients with a serum thyroglobulin concentration greater than 10 ng/ml, 18-fluorodeoxyglucose positron emission tomography. Radioiodine scanning with ^{123}I or ^{131}I is another monitoring technique that is particularly helpful in identifying residual normal thyroid tissue as the source of circulating thyroglobulin and in localizing iodine-avid residual cancer tissue that may be amenable to radioiodine therapy. Radioiodine imaging also requires TSH stimulation by thyroid hormone withdrawal or recombinant TSH administration.[118]

Additional treatment modalities may be required for patients with advanced epithelial thyroid cancers.[119] Radioiodine can be employed for iodine-avid metastatic disease that is nonresectable, such as pulmonary metastases in younger patients with papillary thyroid cancer and metastatic follicular thyroid cancer in older patients. Repeat surgery may be indicated to excise recurrent cervical disease and, occasionally, other distant metastatic lesions that are solitary or that threaten to cause complications. External-beam radiotherapy can be used to treat nonresectable cervical disease, painful bone lesions, or pulmonary metastases causing airway obstruction or hemoptysis. Chemotherapy for these tumors has only a partial response rate; moreover, the response rate is relatively low, and the risk of side effects is significant. Nonetheless, chemotherapy may be offered when other alternatives have been exhausted.

Less common and more aggressive thyroid malignancies are managed with some of the same therapeutic modalities. Medullary thyroid cancer is treated with initial thyroidectomy.[120] Thyroid hormone therapy for replacement, but not TSH suppression, is then prescribed. Patients are followed with serial calcitonin and carcinoembryonic antigen measurements. Repeat surgery, external-beam radiotherapy, and chemotherapy (which is relatively ineffective) are sometimes employed. Thyroid lymphoma, which is primary to the thyroid gland in half of cases, is diagnosable with tissue biopsy and is treated, sometimes rather effectively, with combined chemotherapy and radiation therapy. Anaplastic thyroid cancer is typically nonresectable and is also treated with combined external-beam radiotherapy and chemotherapy.[121] Only in exceptional cases, however, do these interventions significantly alter the grim prognosis.

Complications

Complications can occur in thyroid cancer patients as a result of the malignancy or its treatment. Local cervical invasion of the recurrent laryngeal nerve can cause temporary or permanent hoarseness, dysphagia, and dyspnea. Progression of tumor in the neck can lead to strangulation or esophageal obstruction and malnutrition. Pulmonary failure can occur with pulmonary metastases, fractures with bony involvement, paraparesis with paraspinal lesions, and other neurologic consequences with brain dissemination. Functioning metastases can cause thyrotoxicosis in patients with follicular cancer and, rarely, in patients with papillary carcinoma.

Thyroidectomy may be complicated by recurrent laryngeal nerve injury or hypoparathyroidism. Radioiodine treatment can cause gastritis with short-term symptoms, and it can cause sialadenitis, whose symptoms are dry mouth, loss of taste, and dental caries. High cumulative doses of therapeutic ^{131}I have been associated with an increase in the risk of leukemia. External-beam radiotherapy and chemotherapy have their usual potential for adverse reactions.

Prognosis

The indolent growth of most thyroid tumors and the efficacy of available therapies result in a low mortality, with survival rates of 98% for papillary, 92% for follicular, and 80% for medullary cancers.[122] Clinical recurrence is common, however; for example, almost one third of papillary thyroid cancers recur. Extracervical medullary cancer is incurable but generally follows a slowly progressive course. Poorly differentiated epithelial cell thyroid cancers and anaplastic thyroid cancers unfortunately can be among the most aggressive and treatment-resistant malignancies known.

The author has received grants for clinical research or educational activities from or served as advisor or consultant to Abbott Laboratories and Genzyme Corporation during the past year.

Recombinant thyroid-stimulating hormone has not been approved by the FDA for treatment of nodular goiter and postoperative ablation of thyroid gland remnant tissue.

II TESTES AND TESTICULAR DISORDERS

Peter J. Snyder, m.d.

The testes begin to function early in utero and continue to function into senescence, but the consequences of their function differ at different stages of life. Diseases that affect testicular function, therefore, also have different consequences at different stages of life. Testicular function can be affected by diseases of the hypothalamus and pituitary, as well as by diseases of the testes themselves. The diseases may be either congenital or acquired [*see Tables 1 and 2*].

Normal Testicular Function

The testes have two functions, the secretion of testosterone by the Leydig cells and the production of sperm by the seminiferous tubules. The cumulative effect of testosterone is to produce and maintain a phenotypic male. Testicular function is stimulated by the gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which are secreted by the gonadotroph cells of the pituitary gland, which in turn are stimulated by gonadotropin-releasing hormone (GnRH) from the hypothalamus.

gonadotropin synthesis and secretion

GnRH is a decapeptide cleaved from a larger precursor peptide that is synthesized in the arcuate nucleus of the hypothalamus. FSH and LH are synthesized in the gonadotroph cells of the pituitary. Each is a heterodimeric glycopeptide consisting of a common α subunit and a unique β subunit.

GnRH travels via the hypothalamic-pituitary portal circulation to the pituitary, where it binds to G protein–coupled receptors on the surface of the gonadotroph cell. This triggers a cascade of intracellular signaling pathways and stimulates LH and FSH release. Although GnRH cannot be measured readily in the portal or peripheral circulation of humans, its secretion is thought to be pulsatile, because LH secretion is pulsatile. In addition, administration of GnRH to men who have GnRH deficiency increases LH secretion to normal only if GnRH is administered in pulses.[1]

Table 1 Causes of Primary Hypogonadism

Congenital	Chromosomal abnormalities

	AIDS

testosterone

Synthesis and Secretion

LH stimulates testosterone synthesis by binding to a surface receptor on the Leydig cells and activating a cyclic adenosine monophosphate–mediated mechanism that increases cholesterol side-chain cleavage and conversion to pregnenolone and eventually to testosterone. Testosterone is synthesized at a rate of 5 to 7 mg a day. Testosterone secretion is episodic, like that of LH, and follows a diurnal pattern. In normal young men, the highest concentrations of testosterone occur at about 8 A.M.; the lowest, at about 8 P.M.[2]

Plasma Binding

Circulating testosterone is 98% to 99% bound. About 40% is bound to sex hormone–binding globulin (SHBG) with high affinity; 60% is bound to albumin with low affinity. Testosterone bound to SHBG is not available to tissues, but that bound to albumin probably is available. SHBG synthesis is stimulated by estrogens and decreased by androgens and obesity.

Actions

Testosterone has many different effects in many different tissues, at least partly because it can act on a cellular level as three

Table 2 Causes of Secondary Hypogonadism

Congenital	Isolated gonadotropin deficiency
	Isolated gonadotropin-releasing hormone (GnRH) deficiency

	Isolated acquired GnRH deficiency

distinct hormones: testosterone itself and its two metabolites, dihydrotestosterone (DHT) and estradiol. Both testosterone and DHT act by binding to the androgen receptor, which is encoded by a gene that is located on the X chromosome and belongs to the steroid-retinoid-thyroid hormone superfamily of receptors.[3] Although there is only one androgen receptor, the presence of coactivators or corepressors of transcription in certain types of cells could explain why the effects of testosterone vary in different tissues.[4]

The direct effect of testosterone on cells is mediated by its passive diffusion into cells, its binding to the androgen receptor, the binding of the testosterone–androgen receptor complex to DNA, and subsequent stimulation of messenger RNA (mRNA) and protein synthesis. This mechanism appears to be responsible for testosterone's stimulation of the wolffian ducts to become the male internal genitalia during embryonic development[5] and for testosterone's inhibition of gonadotropin secretion. Testosterone has a probable role in the stimulation of erythropoiesis; the growth of muscle; an increase in linear bone growth; and, to some degree, an increase in bone mineral density.

In tissues that express the enzyme 5α-reductase, testosterone is irreversibly converted to DHT in the target cell cytoplasm. Two forms of 5α-reductase have been identified: type 1, which is found predominantly in nongenital skin and the liver; and type 2, which is found predominantly in urogenital tissue in both men and women. DHT binds to the androgen receptor with greater affinity than does testosterone and so has a greater effect than testosterone. After DHT binds to the androgen receptor, the DHT-receptor complex binds to DNA, stimulating mRNA and protein synthesis. This mechanism appears to be responsible for male differentiation of the external genitalia in utero,[5] enlargement of the male external genitalia during puberty, and the development of sexual hair during puberty.

In tissues that express the enzyme complex aromatase—especially some hypothalamic nuclei, adipose tissue, liver, and perhaps bone—testosterone is converted to estradiol, which binds to an estrogen receptor. This mechanism appears to mediate several effects of testosterone. One effect is on bone: in males who have mutations of the gene coding for the estrogen receptor[6] or the aromatase enzyme,[7] the epiphyses do not close and the bones are osteoporotic. Another effect is on libido, as suggested by the case report of a man who lacked aromatase and had poor libido until he was treated with estradiol.[8] Aromatase appears to partially mediate the inhibition of LH secretion by testosterone and to entirely mediate the inhibition of FSH secretion by testosterone.[9]

SPERMATOGENESIS

Spermatogenesis occurs in the seminiferous tubules, stimulated principally by testosterone. The concentration of testosterone within the testes is 100 times that in the peripheral circulation. This high concentration, which is essential for spermatogenesis, probably results from both the LH-stimulated production of testosterone in the nearby Leydig cells and the FSH-stimulated binding of testosterone by androgen-binding protein, produced by the Sertoli cells of the seminiferous tubules. FSH also stimulates the Sertoli cells to secrete activin, which stimulates spermatogenesis. In addition, the Sertoli cells secrete inhibin, which inhibits FSH secretion by the pituitary.

Spermatogenesis takes approximately 3 months. Maturation of a spermatogonium to a mature spermatozoon takes approximately 75 days; passage through the epididymis, where motility is acquired, takes another 14 days.

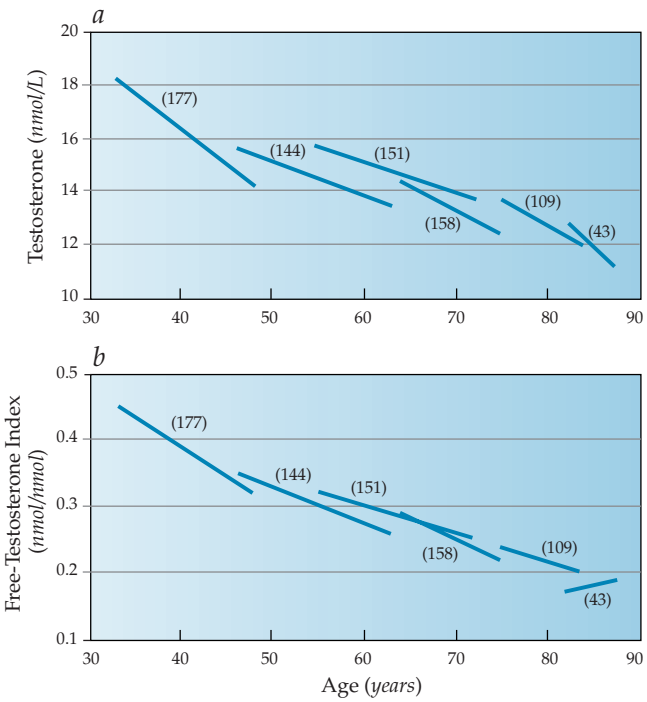

Figure 1 **Serum concentration of testosterone (*a*) and the free-testosterone index (*b*) versus age in healthy men who were followed longitudinally.[12] Each line represents the mean for a cohort of men, and the numbers in parentheses represent the number of men in each cohort.**

TESTICULAR FUNCTION THROUGHOUT LIFE

Testicular function begins in utero, increases briefly in the first few months of infancy, develops fully during puberty, and declines gradually during adulthood.

In Utero

Sexual differentiation occurs during the first trimester in utero.[10] In the presence of the *SRY* gene, which is the sex-determining region of the Y chromosome, the undifferentiated gonads become testes. The Sertoli cells of the testes secrete antimüllerian hormone, which suppresses the müllerian ducts, thereby preventing the development of female internal genitalia.[11] Human chorionic gonadotropin (hCG) from the placenta stimulates the Leydig cells of the testes to secrete testosterone, which in turn stimulates the nearby wolffian ducts to become the male internal genitalia—the vas deferens and seminal vesicles. In addition, testosterone is converted to DHT by the anlage of the external genitalia, and DHT influences the anlage to become the penis, scrotum, and prostate. During the third trimester, LH from the fetal pituitary stimulates the fetal testes to secrete testosterone, which results in penile growth. During the first few months post partum, there is a third testosterone elevation, to levels approximating that of a midpubertal boy. The consequences of this elevation are not known. Thereafter, the serum testosterone concentration falls to relatively low values until puberty.

Puberty

Puberty in boys begins with an increase in the secretion of LH and FSH by the pituitary, which is presumably stimulated by an increase in GnRH secretion by the hypothalamus. This takes place at a mean age of 11.4 years (with a standard deviation of ± 1.1 years). The initial consequence is an increase in testicular volume, from 2 ml toward its adult volume of 20 to 25 ml. Rising levels of circulating testosterone cause an increase in the size of the phallus and promote the growth of pubic, axillary, and eventually body and facial hair, along with regression of temporal scalp hair. Testosterone also causes an increase in long bone growth and body height, thickening of the vocal cords and lowering of the voice, and an increase in hemoglobin concentration. Most of these changes are completed within 4 to 5 years, but full development of body hair and beard may take several more years, and temporal scalp hair regression continues for decades.

Senescence

As men age, their serum total testosterone concentration decreases [*see Figure 1*].[12-14] The decrease in the serum concentration of total testosterone is very gradual and of relatively small magnitude. SHBG, however, increases with increasing age, so the free-testosterone concentration decreases to a greater degree than the total. By 80 years of age, according to cross-sectional studies, the free-testosterone concentration is one half to one third that at 20 years of age.[15,16] The decrease in testosterone appears to result from both decreased LH secretion and decreased responsiveness of the Leydig cells.[17] The parallels between male senescence and male hypogonadism—both of which are marked by decreases in libido, energy, muscle mass and strength, and bone mineral density—suggest that testosterone deficiency could be a cause of the changes in male senescence.[17] Serum estradiol concentration also decreases with increasing age, however. Several studies show a better correlation of some consequences of aging, such as the decrease in bone mineral density, with the estradiol level than with the testosterone level. Nevertheless, there is preliminary evidence that increasing the serum testosterone concentration of elderly men to that of young men increases bone mineral density[18] and muscle mass and decreases fat mass,[19] which supports the notion that the decrease in testosterone does have adverse consequences.

Male Hypogonadism

ETIOLOGY

Male hypogonadism can occur as a consequence of a disease of the testes (primary hypogonadism) or as a consequence of a disease of the pituitary or hypothalamus (secondary hypogonadism). Certain clinical findings suggest hypogonadism, but these are usually nonspecific, so the diagnosis must be confirmed by laboratory tests.

DIAGNOSIS

Clinical Findings

The clinical findings of hypogonadism result from either decreased spermatogenesis or decreased testosterone secretion. The sole clinical finding of decreased spermatogenesis is infertility. In contrast, decreased testosterone secretion causes a wide variety of clinical findings; specific findings depend on the stage of life in which the deficiency occurs. When testosterone deficiency occurs in the first trimester in utero, male sexual differentiation is incomplete. Complete lack of testosterone during this period results in female external genitalia (i.e., clitoris and labia). Incomplete testosterone deficiency causes partial virilization, ranging from posterior labial fusion when testosterone deficiency is severe to hypospadias when testosterone deficiency is mild. Testosterone deficiency that begins in the third trimester in utero results in normal male sexual differentiation but microphallus at birth. When testosterone deficiency occurs in childhood but before puberty, the result is incomplete puberty. When testosterone deficiency develops after puberty, some pubertal changes regress; such changes usually occur slowly, and the effects can occur at different rates. Energy and libido diminish within days to weeks of the fall in testosterone, and the hemoglobin concentration and hematocrit decline within a few months. Decreases in sexual hair, muscle mass, and bone mineral density are usually not recognized for several years.

Physical Examination

The physical examination focuses primarily on whether sexual development is consistent with the patient's age. If the patient is an adult, he should have facial, chest, and other body hair; temporal scalp hair should be receding appropriately for the patient's age and family pattern; and pubic hair should be dense and in a diamond pattern. The voice should be appropriately deep. Musculature should be normal for a man. Subcutaneous fat should be less than that of a boy or a woman. The testes should be 4 to 7 cm in length (20 to 25 ml in volume). If the patient is an adolescent, development should be appropriate for his age. If the patient is a child, the testes should be descended, and no hypospadias should be present.

The physical examination should also include evaluation for possible eunuchoid proportions and gynecomastia. An adult male usually has an upper body segment approximately equal to his lower segment and an arm span equal to his height. The absence of testosterone and the continued presence of growth hormone during puberty, as occurs in primary hypogonadism and isolated secondary hypogonadism, causes a delay in epiphyseal closure and an increase in the length of the long bones. In such patients, the lower body segment becomes longer than the upper and the arms become longer than the legs—a relationship known as eunuchoid proportions. This relationship persists even after testosterone treatment. Consequently, a man of any age who has a heel-to-pubis measurement more than 2 cm longer than his pubis-to-crown measurement and an arm span more than 2 cm longer than his height was probably hypogonadal during adolescence. Gynecomastia often occurs in hypogonadism; it is especially common in patients with primary hypogonadism.

Laboratory Findings

Once the diagnosis of hypogonadism has been suspected on the basis of symptoms and signs, the diagnosis must be confirmed by documenting decreased production of sperm or testosterone. If hypogonadism is confirmed, the next step is to measure LH and FSH. Elevated serum concentrations of LH and FSH indicate primary hypogonadism, whereas subnormal or normal values indicate secondary hypogonadism.

Spermatogenesis Sperm production can be assessed most readily by counting the sperm in an ejaculated semen specimen. Generally accepted normal values for ejaculated sperm are a density of greater than 20×10^6 sperm/ml of ejaculate and a total

count of more than 40×10^6 sperm/ejaculate. More than 60% of the sperm should be motile, and more than 30% should be normal in morphology. A recent study of the male partners in 765 infertile couples and 696 fertile couples showed that fertility was associated with a sperm density of greater than 48×10^6 sperm/ml, sperm motility of greater than 63%, and normal morphology in more than 12% of sperm.[20] Low fertility was associated with a sperm density of less than 13.5×10^6 sperm/ml, sperm motility of less than 32%, and normal morphology in less than 9%. Indeterminate fertility was associated with intermediate values. A severely subnormal sperm count (e.g., $< 5 \times 10^6$ sperm/specimen) can result from either primary or secondary hypogonadism. A normal or mildly subnormal sperm count (e.g., 35×10^6 sperm/specimen) associated with markedly abnormal sperm motility more likely indicates a primary spermatogenic abnormality and less likely indicates secondary hypogonadism.

Testicular biopsy usually provides no more information about spermatogenesis than a semen analysis, because the variety of histologic responses to testicular injury is very limited. Testicular biopsy is likely to be helpful only when the ejaculated semen contains no sperm but the testicular size is normal and the serum concentrations of testosterone, LH, and FSH are normal. Such a patient may have obstruction of the ejaculatory outflow, or he may have suffered damage to the seminiferous tubules sufficient to impair spermatogenesis but not sufficient to cause an elevation in the serum FSH concentration. A testicular biopsy showing normal seminiferous tubules would favor the former diagnosis.

Testosterone concentration Testosterone secretion is best evaluated by measuring the serum concentration of total testosterone, because the total testosterone level is usually an accurate reflection of the free-testosterone level. Also, most of the current assay techniques for free testosterone are not as accurate as those for total testosterone. Testosterone is secreted into the circulation episodically, in a diurnal pattern; the serum testosterone concentration is highest at about 8 A.M. and lowest at about 8 P.M.[2] Therefore, the serum testosterone concentration should be measured at 8 A.M. If the result is low or borderline, the test should be repeated. Measurement of free testosterone and SHBG may be helpful in situations in which the total testosterone level does not accurately reflect the free-testosterone level, such as would be the case with obese patients. If free testosterone is measured, the assay method should be equilibrium dialysis.

Gonadotropins If the testosterone concentration is low, serum LH and FSH concentrations should be measured. If those values are high, the patient has primary hypogonadism; otherwise, he has secondary hypogonadism. In a patient with a distinctly subnormal sperm count but a normal serum testosterone concentration, the combination of an elevated FSH concentration and a normal LH concentration indicates that there has been damage to the seminiferous tubules but that the Leydig cells have not been affected.

In patients with secondary hypogonadism, magnetic resonance imaging of the sellar region is indicated. The MRI scan will show whether the patient has a mass lesion and, if so, whether it is in the pituitary, the hypothalamus, or the parasellar region. Pituitary and hypothalamic lesions cannot be distinguished on the basis of the LH response to a single dose of exogenous GnRH. Administration of repeated doses of exogenous GnRH, however, will result in a normal LH response to an individual dose of GnRH in patients who have hypothalamic disease, but not in patients who have pituitary disease. In patients with hypothalamic disease, the length of time required for LH response to become normal varies widely.

DISEASES THAT CAUSE HYPOGONADISM

Overall, primary hypogonadism [*see Table 1*] is more common than secondary hypogonadism [*see Table 2*]. Once a patient's hypogonadism has been identified as primary or secondary, the specific etiology can be sought.

Primary Hypogonadism

Primary hypogonadism may be congenital or acquired. Many cases of primary hypogonadism have no identifiable cause, however. Presumably, many causes are yet unknown.

Congenital Of the congenital abnormalities that cause primary hypogonadism, the most common is Klinefelter syndrome,[21] which occurs in approximately 0.2% of newborns. It is the phenotypic presentation of a male with more than one X chromosome. The most common genotype is 47 XXY, but additional X chromosomes (e.g., 48 XXXY) and mosaics (e.g., 46 XY/47 XXY) have also been reported. The 47 XXY genotype results from nondisjunction of the sex chromosomes of either parent during meiotic division. Mosaicism probably results from nondisjunctive mitotic division after conception. The severity of the phenotypic consequences usually increases with the number of extra X chromosomes. The gonadal consequences are usually severe damage to the seminiferous tubules and variable damage (minimal to severe) to the Leydig cells. Consequently, men with Klinefelter syndrome usually have very small testes, no sperm in their ejaculate, infertility, and markedly high serum FSH concentrations. Their serum testosterone concentrations vary from normal to subnormal; correspondingly, their virilization varies from normal to low and their serum LH concentrations vary from normal to elevated. Klinefelter syndrome is also usually marked by abnormalities of behavior and of the long bones. These abnormalities are not directly related to the gonadal abnormalities. The behavioral abnormality is manifested as difficulty in social interactions that is recognized in childhood, and it leads to problems in school and eventually in work. The long-bone abnormality is increased length of the legs but not the arms; this abnormality occurs independently of increased length of both the arms and legs as a result of testosterone deficiency.

The diagnosis of Klinefelter syndrome can usually be made by determining the karyotype of the peripheral leukocytes. Testosterone deficiency, if present, can be treated with testosterone replacement (see below). The behavioral abnormality cannot be treated satisfactorily, but a support group can be helpful for the patient's family, and school counselors should be advised of the diagnosis.

Cryptorchidism, or undescended testes, is also associated with damage to the testes and with greater damage to the seminiferous tubules than to the Leydig cells. More than one mechanism may be involved: testosterone deficiency in utero may inhibit descent, and the heat of the abdomen may cause further damage to the undescended testis. The clinical consequences depend partly on whether one or both testes are undescended. If only one testis is undescended, there is a 25% to 33% likelihood that the sperm count will be subnormal and the serum FSH level slightly high.[22] If both testes are undescended, the sperm count will likely be severely subnormal and the patient infertile; the

serum testosterone concentration may be subnormal, and the patient may be undervirilized as well. Neoplasms are two to five times more likely to develop in cryptorchid testes.[23] The diagnosis is made in patients younger than 1 year by failure to palpate a testis that either is within the scrotum or can be manipulated manually from the inguinal canal into the scrotum.

Varicocele—a varicosity of the venous plexus within the scrotum—has for decades been considered a possible cause of infertility. The proposed mechanism is that varicocele causes an increase in blood flow, which impairs spermatogenesis by raising scrotal temperature above normal. However, scrotal temperatures are similar in infertile men with and without varicoceles, and varicoceles are not much more common in infertile than fertile men, so it is not certain that varicocele can cause infertility. More important, in a randomized trial of the surgical treatment of varicocele in men who were infertile, fertility was not found to be improved as a result of treatment.[24] Therefore, surgical treatment of a varicocele cannot be recommended as a means of improving fertility.

Congenital deficiency of testosterone production can also result from mutations of genes that encode enzymes necessary for androgen biosynthesis. These disorders are rare. The cholesterol side-chain cleavage enzymes 3β-hydroxysteroid dehydrogenase and 17α-hydroxylase occur in the adrenal as well as in the testes, so deficiencies of either of these enzymes lead to deficient cortisol secretion as well. Deficiency of 17β-hydroxysteroid oxidoreductase affects only the testes. All of these disorders result in deficient testosterone secretion, beginning in the first trimester in utero, and subsequent incomplete virilization. The degree of incompleteness, especially of phallic development, influences whether these babies are raised as boys or girls. The testosterone deficiency itself can be treated in the same way as testosterone deficiency from any other cause.

Deletions on the long arm of the Y chromosome appear to be associated with infertility. Azoospermia is more common than oligospermia in such cases.[25]

Acquired Many acquired illnesses can cause primary hypogonadism. These include infections—notably, mumps orchitis. Orchitis is an uncommon complication of mumps and may be unilateral. In bilateral cases, both testes initially become markedly swollen and severely painful, then gradually atrophy. Diminished sperm production is common; decreased testosterone secretion is less common. The diagnosis is made by eliciting a history of painful swelling of the testes during systemic mumps infection.

Treatment of neoplasms with chemotherapeutic drugs (especially alkylating agents) or with radiation therapy to the inguinal lymph nodes often damages the seminiferous tubules; less often, it damages the Leydig cells. Radiation causes damage despite shielding of the testes, because of radiation scatter. The degree of damage is usually proportionate to the radiation dose. In cases of less extensive treatment, the damage may be reversible. No specific remedy for such damage is available, however.

Medications and drugs of abuse can produce hypogonadism. The antifungal agent ketoconazole impairs testosterone production. Heavy alcohol ingestion damages the testes.

HIV infection and AIDS wasting are commonly associated with hypogonadism.[26] Several mechanisms appear to be involved in these cases. Some men with HIV infection and subnormal serum testosterone concentrations have inappropriately low serum concentrations of LH. This may be the result of conditions such as malnutrition, opiate abuse, and megestrol acetate administration, all of which are known to cause secondary hypogonadism. Other men with HIV infection lack known risk factors for secondary hypogonadism but have elevated serum concentrations of LH, indicating primary hypogonadism. Hypogonadism in HIV-infected men has been observed less commonly since the introduction of retroviral therapy.

Testicular torsion can cause permanent damage if not treated promptly. Trauma to the testes can sometimes be sufficiently severe to damage them.

Hypogonadism may be induced (surgically or chemically) as a therapeutic strategy in cases of advanced prostate cancer [*see 12:IX Prostate Cancer*]. Bilateral orchiectomy is used as a treatment for bilateral testicular cancer. In testicular cancer patients, however—unlike those treated with castration for prostate cancer—there is no reason to withhold testosterone replacement.

Secondary Hypogonadism

Like primary hypogonadism, secondary hypogonadism (also called hypogonadotropic hypogonadism) has both congenital and acquired causes in men [*see Table 2*]. Unlike primary hypogonadism, secondary hypogonadism often has a cause that is amenable to specific treatment. For that reason, finding the cause carries particular importance. Pituitary adenomas, other benign tumors and cysts of the sellar area, and malignancies that arise in the sellar region or metastasize there can usually be detected by MRI. Infiltrative diseases (e.g., sarcoidosis, hemochromatosis) usually produce manifestations in other organ systems that suggest the diagnosis. Tumors, cysts, and infiltrative lesions are often accompanied by deficiencies of other hypothalamic or pituitary hormones.

Some cases of secondary hypogonadism are not associated with any other hormonal abnormalities and are called isolated. Some cases appear to be caused by a deficiency of GnRH secretion by the hypothalamus; such cases can be congenital or acquired. When congenital, they may or may not be a part of Kallmann syndrome.[27] Patients with Kallmann syndrome have deficient GnRH secretion, variably associated with anosmia, cryptorchidism, red-green color blindness, and long-bone and urogenital tract abnormalities. Kallmann syndrome may occur sporadically or in families; familial cases can be inherited in an autosomal dominant pattern, with expression mostly limited to males, or in an X-linked recessive pattern. The genetic defect responsible both for the deficiency in GnRH secretion and for anosmia in some patients who have the X-linked recessive form of Kallmann syndrome is a mutation in the *KAL-1* gene, which encodes a neural cell adhesion protein, anosmin. When this protein is not present during embryogenesis, GnRH-secreting neurons do not migrate from the olfactory placode to the olfactory bulb and then to the hypothalamus, resulting in both anosmia and hypogonadotropic hypogonadism.

Another cause of isolated secondary hypogonadism is a mutation of the GnRH receptor. In these cases, GnRH is secreted by the hypothalamus but does not stimulate LH secretion by the pituitary. A third cause is a mutation of the *DAX-1* gene, which leads to hypogonadotropic hypogonadism and to adrenal hypoplasia congenita.

Gonadotropin secretion can be reversibly inhibited by any systemic illness or by hyperprolactinemia. Inhibition from medications, such as glucocorticoids, suramin, and opiates, is also reversible. Since the introduction and widespread use of controlled-release forms of opioids for chronic-pain management,

hypogonadism from these medications has become more common.[28] Heroin addicts may experience hypogonadism by the same mechanism. Damage to the pituitary from surgery or radiation, in contrast, usually results in permanent inhibition of gonadotropin secretion.

Delayed puberty is diagnosed in any boy whose pubertal development does not begin by more than two standard deviations past the mean age. In some cases, this delay represents a normal variant; these patients eventually enter puberty spontaneously. In other cases, the delay is caused by secondary hypogonadism. Distinguishing a normal variant from pathologic delay can be difficult. The degree of hypogonadism is usually not helpful in making this distinction, nor is any biochemical test. A family history of delayed puberty or constitutional short stature increases the likelihood of physiologic delayed puberty. Anosmia, symptoms of a chiasmal lesion, or other signs of a specific hypothalamic or pituitary disease increase the likelihood of an organic lesion as the cause. In many cases, the diagnosis can be made only by continued observation.

In an otherwise healthy elderly man, an unequivocally subnormal serum testosterone concentration, along with an LH concentration that is not elevated, can be considered a form of secondary hypogonadism.

TREATMENT

Testosterone Replacement

Testosterone can be replaced whether the hypogonadism is primary or secondary. Unlike estrogen, testosterone itself is not suitable for oral replacement, because it is catabolized rapidly during its first pass through the liver. Derivatives of testosterone that are alkylated in the 17α position do not undergo this rapid hepatic catabolism; however, these agents appear to lack the full virilizing effect of testosterone, and they may cause hepatic toxicity, including cholestatic jaundice, a cystic condition of the liver called peliosis, and, possibly, hepatocellular carcinoma. Consequently, the 17α-alkylated androgens should not be used to treat testosterone deficiency.

Currently, replacement therapy is instead delivered by the intramuscular or transdermal routes. The intramuscular formulations, testosterone enanthate and testosterone cypionate, are long-acting esters of testosterone produced by esterifying the hydroxyl group in the 17β position with a fatty acid. These do produce full virilization. They are usually administered in doses of 150 to 200 mg by deep intramuscular injection every 2 weeks. With this regimen, serum testosterone values peak within 1 to 2 days after the injection and fall to a nadir just before the next injection [*see Figure 2*].[29] These fluctuations are noticed by some patients as fluctuations in energy, mood, and libido.

Transdermal testosterone is now available in both patch[30] and gel[31] form [*see Figure 2*]. In most hypogonadal men, these preparations usually produce serum testosterone concentrations that are within the normal range and that fluctuate no more than physiologically, resulting in reasonable stability of energy, mood, and libido. The relatively physiologic pattern of serum testosterone concentrations and the infrequency of side effects make transdermal preparations the best means of testosterone replacement for most hypogonadal men.

During replacement therapy, clinicians should monitor patients for the efficacy and side effects of testosterone. Efficacy is determined by measurement of the serum testosterone concentration, which should be in the middle of the normal range midway between injections of testosterone esters and at any time after application of a transdermal preparation. Serum testosterone concentrations can vary with any of these preparations, however, so testosterone should be measured more than once to determine whether the initial dose is optimal. Serum testosterone should be measured again after a dose is changed and then once or twice a year. If the serum testosterone concentration is maintained within the normal range, the patient should experience reversal of the consequences of testosterone deficiency. Specifically, energy, libido, hemoglobin concentration, muscle mass, and bone density will increase.[32]

Men older than 40 years who are receiving testosterone replacement should be monitored for testosterone-dependent diseases, such as prostate cancer, benign prostatic hyperplasia, and erythrocytosis. However, there is as yet no evidence that exogenous testosterone is more likely to exacerbate any of these conditions than is endogenous testosterone.

Stimulation of Spermatogenesis

When sperm production is impaired by damage to the seminiferous tubules, no treatment can improve fertility. However, if some mature sperm are produced, they may be used for in vitro fertilization. When the sperm count is low because of pituitary or hypothalamic disease, sperm production can often be stimulated to within the normal range by administration of exogenous gonadotropins. If the hypogonadism occurred postpubertally, usually only LH need be replaced. If the hypogonadism occurred prepubertally, usually both LH and FSH need to be replaced.[33] In hypogonadism secondary to hypothalamic disease, spermatogenesis can also be stimulated by pulsatile administration of GnRH.

Androgen Insensitivity

Generalized tissue insensitivity to the action of androgens results in abnormalities similar to those of testosterone deficiency. Such insensitivity can be caused by abnormalities of either the androgen receptor [34] or 5α-reductase type 2 enzyme.[35] Both conditions result from genetic mutations, both are rare, and both result in incomplete virilization of the external genitalia.

Many different mutations of the androgen receptor gene have been described. Some of these mutations interfere with binding of androgen to the receptor, and others interfere with binding of the androgen-receptor complex to the DNA of the androgen-responsive cell.

The clinical presentations of the different receptor abnormalities also vary. In the most severe clinical presentation, called complete androgen insensitivity, the affected person is born with testes in the inguinal canals, no internal genitalia, and female external genitalia. At puberty, the serum testosterone concentration increases to a high-normal or slightly above-normal value, but sexual hair does not develop. Breasts do develop, because testosterone can still be converted to estradiol. In incomplete androgen insensitivity, there is variable partial fusion of the labial folds: a lesser degree of fusion results in genitalia that are still more female than male, and a greater degree results in genitalia that are more, but still incompletely, male. The least severe form of androgen resistance is manifested only by infertility and sometimes gynecomastia. Serum testosterone and LH concentrations are high normal to slightly high in all of these forms of androgen resistance.

Kennedy disease consists of a relatively mild form of androgen insensitivity but progressively severe spinal bulbar neuropa-

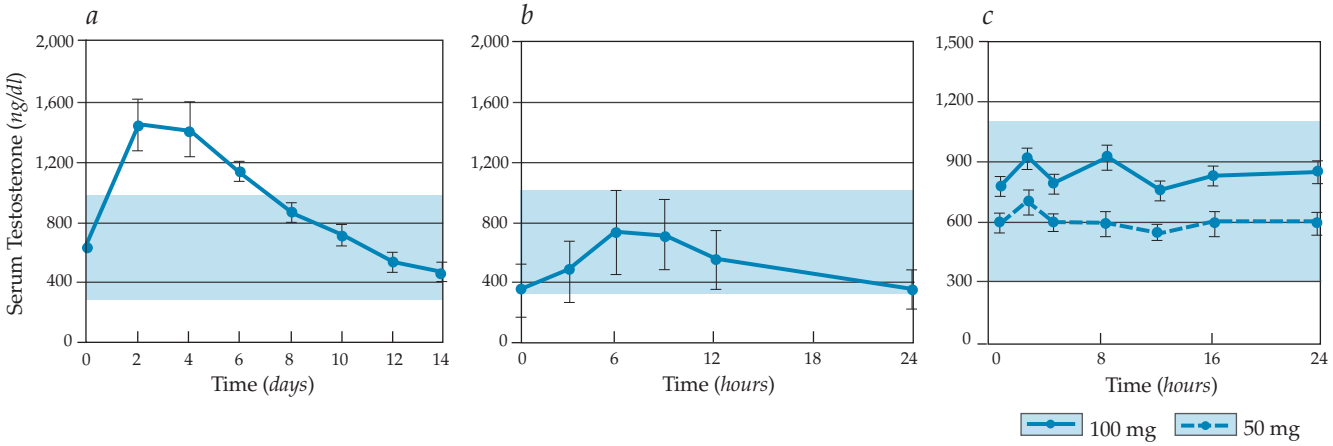

Figure 2 **Serum testosterone concentrations during the course of chronic administration of three different testosterone preparations to hypogonadal men. (*a*) Concentrations during 14 days after the injection of 200 mg of testosterone enanthate.[29] (*b*) Concentrations during the 24 hours after application of a testosterone patch that delivers approximately 5 mg of testosterone.[41] (*c*) Concentrations during the 24 hours after application of a testosterone gel containing 50 or 100 mg of testosterone.[31]**

thy. It is caused by a mutation leading to doubling of the number of N-terminal glutamines in the androgen receptor.

Other mutations of the androgen receptor have been described in metastatic prostate cancer that has become resistant to androgen deprivation. These mutations may allow ligands other than testosterone to bind to the receptor and stimulate receptor-dependent functions even in the absence of testosterone.

Mutations of the 5α-reductase type 2 gene also lead to incomplete virilization of the external genitalia because virilization requires conversion of testosterone to DHT by this enzyme.[35] At birth, most males with 5α-reductase type 2 deficiency have external genitalia that are predominantly female, so the sex of rearing is usually female. At puberty, the serum testosterone concentration increases and overcomes the lack of DHT to some degree; binding of testosterone to the androgen receptor causes phallic enlargement and hair growth in an adult male pattern. If the patient is being raised as a female, the testes can be removed before puberty to prevent these events.

Gynecomastia

Gynecomastia is the development of glandular breast tissue in a man. In most cases of gynecomastia, the stimulation of glandular tissue appears to result from an increased ratio of estrogen to androgen.

EPIDEMIOLOGY

Gynecomastia is common at all ages of life but is more common in infancy, puberty, and from middle age on. In most large series, gynecomastia can be detected in 10% to 20% of midpubertal boys and in more than 50% of men older than 50 years. These high rates probably reflect the hormonal changes that typically occur at those ages and do not represent disease.

ETIOLOGY AND PATHOGENESIS

The common mechanism for gynecomastia appears to be an increased estrogen-to-androgen effect on the breast. This may involve an increase in estrogen effect or a decrease in androgen effect, or both, and may result from changes in hormonal production or in hormonal action at the cellular level. Normally, most of the estrogen in the peripheral circulation in men is produced by the conversion of testosterone to estradiol or of androstenedione to estrone by the enzyme complex aromatase, which is concentrated in adipose tissue and the liver.

Exposure to Exogenous Estrogen

Gynecomastia from exogenous estrogens is uncommon. Reported cases have involved exposure to a partner's vaginal cream, application of antibalding creams, dietary intake, and occupational exposure.

Increased Estrogen Secretion

The most common cause of increased endogenous estrogen secretion is increased gonadotropin stimulation of the testes, which increases intratesticular aromatase levels and thereby increases the amount of estradiol secreted relative to testosterone. This is the likely mechanism by which gynecomastia occurs in normal males during puberty; with refeeding after starvation; and after successful treatment of severe illness, such as chronic cardiac, hepatic, or renal disease. In these situations, a period of secondary hypogonadism is followed by normal gonadotropin secretion. Increased gonadotropin (specifically, LH) secretion is also the cause of gynecomastia in primary hypogonadism. Increased secretion of hCG is the cause in patients who have tumors of the testes or liver. Administration of hCG therapeutically (e.g., to stimulate spermatogenesis) acts similarly, especially when the dose is excessive.

Increased Peripheral Conversion of Androgens to Estrogens

Increased peripheral conversion of testosterone to estradiol or of androstenedione to estrone can occur via several mechanisms: (1) an increased rate of conversion, as in hyperthyroidism or cirrhosis of the liver; (2) an increase in the amount of aromatase, as occurs in obesity; and (3) an increased substrate for aromatization, as occurs when an adrenal carcinoma secretes large amounts of androstenedione or when an aromatizable androgen, such as a long-acting testosterone ester, is administered in excessive doses.

Inhibition of Androgen Binding

Many drugs that cause gynecomastia appear to do so by binding to the androgen receptor and thereby blocking endogenous testosterone. As a consequence, endogenous androgens have

less androgenic action but are still converted to estrogens. Drugs that can block the androgen receptor include spironolactone, cimetidine, flutamide, bicalutamide, and cyproterone acetate. Inherited disorders of the androgen receptor produce similar results, although in these cases, the inhibition of binding is, of course, irreversible.

DIAGNOSIS

The diagnosis of gynecomastia is confirmed by physical examination. The examiner places a spread thumb and forefinger above and below the patient's nipple and draws them together, like calipers, toward the nipple, hugging the chest wall. Subcutaneous tissue feels soft as the fingers are drawn together, whereas gynecomastia feels firm. The diameter of the gynecomastia can be measured with a ruler. Mammography is usually unnecessary. Gynecomastia is generally bilateral, although it is occasionally unilateral. It is often asymmetrical. If the tissue is tender, the gynecomastia is more likely to be of recent origin.

Having confirmed that gynecomastia exists, the clinician then needs to find the cause. This involves inquiring about medications and searching for diseases known to cause gynecomastia [*see* Etiology and Pathogenesis, *above*].[36]

DIFFERENTIAL DIAGNOSIS

Gynecomastia must be distinguished from carcinoma of the male breast, which is rare, and from adiposity, which is common. Breast cancer should be suspected when the breast enlargement is unilateral, nontender, not centered directly under the nipple, and hard. The diagnosis can be confirmed by mammography. Breast adiposity is bilateral and can usually be distinguished from gynecomastia by the absence of palpable glandular tissue on physical examination.

TREATMENT

Gynecomastia is not physically harmful, and it usually regresses once the cause has been removed, although regression may take many years. Therefore, treatment is indicated only if the gynecomastia is causing psychological distress. The only accepted treatment is surgical removal, which is best performed by a plastic surgeon. Small series suggest that the antiestrogen drug tamoxifen and the aromatase inhibitor testolactone can reduce gynecomastia. Anastrozole is a more potent aromatase inhibitor than testolactone, but no results of its efficacy in treating gynecomastia have been published. None of these drugs have been approved by the Food and Drug Administration for this purpose.

Erectile Dysfunction

Erectile dysfunction is the inability to achieve or maintain an erection sufficient for intercourse. Although occasional erectile dysfunction does not indicate disease, its occurrence on most attempts to engage in sexual activity may indicate disease and is usually very troubling to the patient and his partner. Erectile dysfunction is not the same as a decrease in libido, which is decreased sexual interest. The two usually have different causes and, therefore, different treatments.

EPIDEMIOLOGY

In a cross-sectional survey of noninstitutionalized men 40 to 70 years of age, all degrees of erectile dysfunction, from minimal to complete, occurred in 50% of men. Older men were more commonly affected, however. For example, impotence occurred in 5% of 40-year-old men and in 15% of 70-year-old men.[37] When men from the same population were followed longitudinally, the incidence of new cases was 2.5% a year.[38]

PATHOPHYSIOLOGY

Development of an erection requires intact psychological, neurologic, and vascular mechanisms.[39,40] Erotic stimuli result in neural impulses that are carried from the cerebral cortex to the penis via the spinal cord, and stimulation of the penis results in neural impulses that loop to the spinal cord and back to the penis via parasympathetic nerves. These stimuli trigger blood flow into the corpora cavernosa. The inflow of blood is mediated by relaxation of arteriolar smooth muscle under the influence of nitric oxide, the production of which is catalyzed by the enzyme nitric oxide synthetase. Nitric oxide, in turn, promotes the production of cyclic guanosine monophosphate (cGMP), which also relaxes arteriolar smooth muscle and increases blood flow. Outflow of blood from the engorged corpora cavernosa is impeded by an increase in venous resistance.

Disruption of any of these steps can lead to erectile dysfunction. The neural mechanisms can be disrupted mechanically (such as by radical prostatectomy, surgery for an abdominal aortic aneurysm, or spinal cord trauma) or pathologically (such as by diabetic autonomic neuropathy or autonomic insufficiency syndromes). They also can be disrupted functionally, such as by drugs. The vascular mechanism can be disrupted by large vessel (atherosclerotic) or small vessel (diabetic) disease. The mechanism by which hyperprolactinemia causes impotence is not known, although it does not appear to be via hypogonadism.

DIAGNOSIS

History, physical examination, and laboratory testing all contribute to finding the cause of erectile dysfunction. From the history, the physician can determine whether the patient is taking a drug or has a disease associated with this disorder. Several drugs that are used to treat hypertension may occasionally cause erectile dysfunction; these include thiazide diuretics and alpha- and beta-blocking agents. Other drugs include tranquilizers and antidepressants. Excessive alcohol ingestion can also cause erectile dysfunction. The physician should ask about a history of diabetes of long duration, including other manifestations of diabetic neuropathy, and explore psychogenic factors, including depression, anxiety, fatigue, interpersonal stresses, and chronic illness. It is useful to ask whether the patient can obtain an erection under any circumstances. If the patient has an erection on awakening in the morning or can get an erection on some occasions but not others, the cause is more likely to be psychogenic than organic.

On physical examination, the absence of peripheral pulses and the presence of femoral bruits indicate vascular disease. Neurologic disease is indicated by diminished touch sensation and proprioception and a diminished cremasteric reflex (retraction of the testis on stroking of the ipsilateral inner thigh).

Laboratory evaluation should include measurement of the serum prolactin concentration, because hyperprolactinemia can be detected in no other way. The serum testosterone concentration should be measured in a man who has decreased libido as well as erectile dysfunction, but it will rarely be helpful in a man who has erectile dysfunction but normal libido.

DIFFERENTIAL DIAGNOSIS

Erectile dysfunction should be differentiated from decreased libido, if possible, because they often have different causes and

different treatments. The two conditions may occur together, however. Decreased libido is decreased sexual interest, of which the principal hormonal cause is hypogonadism. Hypogonadism does not by itself impair erectile ability. A man who has a normal libido but has difficulty getting an erection probably does not have hypogonadism, whereas a man who has decreased libido and potency should be evaluated for hypogonadism as well as erectile dysfunction.

TREATMENT

Treatment of erectile dysfunction depends on the cause. If a medication is the source of the problem, it may be possible to substitute a drug that does not affect erectile function. For example, if the patient is being treated for hypertension with a thiazide diuretic, it might be replaced with an angiotensin-converting enzyme inhibitor or a calcium channel blocker—agents that do not seem to interfere with erectile function.

Underlying disorders should be corrected whenever possible. Hyperprolactinemia can be treated with a dopamine agonist (e.g., cabergoline).

The most effective treatment for erectile dysfunction of psychogenic, vascular, or neurologic origin is sildenafil. This agent inhibits phosphodiesterase, the enzyme that degrades cGMP, and therefore enhances smooth muscle relaxation in the corpora cavernosa, increasing arteriolar blood flow and promoting erection. In one randomized study of 329 men with erectile dysfunction who were randomized to receive either sildenafil or placebo, the men who took sildenafil were eventually able to get an erection on 69% of attempts, compared with 22% of attempts in men who received placebo.[39,40]

Other treatments include intraurethral instillation of alprostadil, intracavernous injection of alprostadil or prostaglandin E_1, and application of a vacuum pump to the penis. These are more cumbersome and therefore less popular than sildenafil, even when they are effective.

The author has received research support from, and has been a consultant to, Solvay Pharmaceuticals, Inc., during the past year.

IV THE ADRENAL

D. Lynn Loriaux, m.d., ph.d.

Anatomy

There are two adrenal glands, which are adjacent to the rostral pole of each kidney. The glands weigh 3 to 5 g each and are about 5 cm in largest dimension. They are the shape of a flattened sphere, with one side invaginated. Hence, on tomographic views, the gland has an upside-down Y shape, with a trunk and two limbs [*see Figure 1*]. The thickness of the gland in a given person should be no greater than that of the ipsilateral crus of the diaphragm.

Histologically, the adrenal gland is composed of a cortex and a medulla. The cortex has three zones [*see Figure 2*]. From the capsule inward, these zones are the glomerulosa, the fasciculata, and the reticularis. The glomerulosa is a thin, discontinuous zone in which the cells are arranged in a fashion similar to that of glomeruli. In the process of fixation, lipid is lost from these cells disproportionately; as a result, they are histologically clear. The glomerulosa accounts for about 5% of the cortical volume. The cells of the fasciculata are arranged in linear fashion, vertically, similar to that of the fascicles of pages in the spine of a book. The fasciculata accounts for about 70% of the volume of the adrenal cortex. The reticularis is intensely eosinophilic, with cells arranged in a poorly organized netlike fashion. This zone of the cortex is referred to as the x-zone in fetal life, when it accounts for most of the cortical volume. The reticularis disappears in childhood and then reappears at the time of adrenarche, which usually takes place 2 to 3 years before the onset of puberty. In the mature adrenal cortex, the reticularis accounts for 10% to 20% of the volume of the gland. The innermost zone of the adrenal gland is the medulla. Its structure is analogous to that of a sympathetic ganglion, being composed of chromaffin cells innervated by presynaptic sympathetic axons.

Physiology

The adrenal gland makes three principal hormones: hydrocortisone, or cortisol, which is necessary for life; aldosterone, which promotes salt retention and thereby permits maintenance of salt balance in a salt-poor environment; and adrenaline, or epinephrine, which features prominently in the fight-or-flight response (etymologically, the two terms are identical, with the former deriving from the Latin *ad renal* and the latter from the Greek *epi nephros*). Additionally, the adrenal gland secretes small amounts of estrogen and androgen, as well as two androgen precursor steroids, androstenedione and dehydroepiandrosterone (DHEA). These hormones and prohormones are products of distinct zones of the gland: aldosterone from the glomerulosa, cortisol from the fasciculata, DHEA from the reticularis, and epinephrine from the medulla.

Cortisol levels are regulated by a feedback loop [*see Figure 3*]. The synthesis and secretion of cortisol are stimulated by adrenocorticotropic hormone (ACTH) from the pituitary gland. Once in the bloodstream, cortisol levels rapidly regulate the synthesis and secretion of ACTH by the pituitary. ACTH release is also dependent on corticotropin-releasing hormone (CRH) from the hypothalamus. CRH is also regulated by cortisol, but at a much slower tempo.

Aldosterone levels are also regulated by feedback loops [*see Figure 3*]. Renin, a polypeptide hormone secreted by the juxtaglomerular cells of the kidney, is converted to angiotensin II, notably in the lungs, and stimulates adrenal aldosterone synthesis and secretion. Aldosterone acts on the thick ascending limb of the loop of Henle to enhance salt retention and thus expand vascular volume. The juxtaglomerular cells monitor vascular volume in the afferent artery of the glomerulosa and decrease renin secretion in response to expanded volume. DHEA and epinephrine have no known feedback regulation. All the adrenal hormones can now be measured specifically and accurately by radioimmunoassay, greatly facilitating the study of adrenal physiology and pathophysiology.

Diseases of the adrenal gland can be conveniently categorized as conditions associated with increased or decreased activity of the key hormones: hypercortisolism and hypocortisolism, hyperaldosteronism and hypoaldosteronism, virilization and feminization from sex hormone secretion, and catecholamine excess or deficiency.

Hypercortisolism (Cushing syndrome)

Cortisol is normally secreted at a rate of 6.5 mg/m^2/day.[1] Secretion of cortisol in excess of this rate can, with time, lead to Cushing syndrome. Harvey Cushing described this syndrome in his book *The Pituitary Body and Its Disorders*, published in 1919.[2] The classic clinical presentation of Cushing syndrome includes central obesity, striae, moon facies, supraclavicular fat pads, diabetes mellitus, hypertension, hirsutism and oligomenorrhea in women, and erectile dysfunction in men [*see Table 1*].[3]

The causes of cortisol excess can best be categorized as ACTH dependent or ACTH independent. The two categories can be distinguished by the measurement of ACTH in the blood. ACTH-dependent causes account for about 90% of cases of noniatrogenic Cushing syndrome, and they most often result from

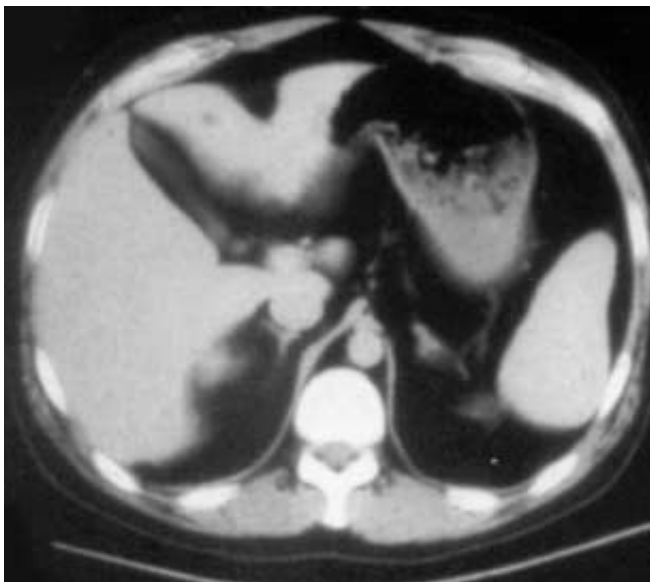

Figure 1 **A computed tomographic image shows a normal adrenal gland.**

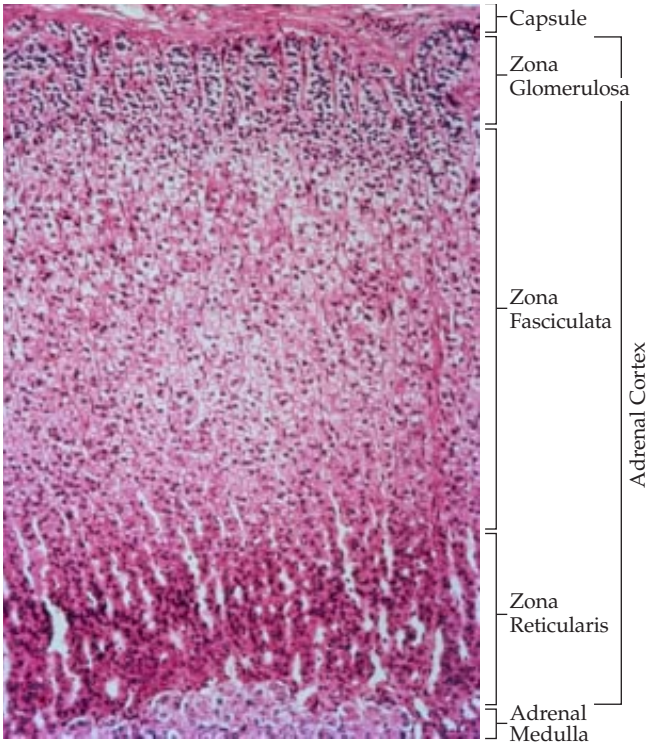

Figure 2 **Hematoxylin and eosin staining distinguishes the zones of the adrenal cortex.**

ACTH secretion by a pituitary microadenoma that is relatively insensitive to the feedback effects of cortisol (i.e., Cushing disease). The most common cause of ACTH-independent Cushing syndrome is iatrogenic long-term glucocorticoid administration. The most common naturally occurring cause of ACTH-independent Cushing syndrome is cortisol secretion from a benign adrenal adenoma [*see Table 2*].

DIAGNOSIS

The diagnosis of Cushing syndrome is principally clinical. The more signs and symptoms of the syndrome that are present, the more confident of the diagnosis the physician can be. The firmer the clinical diagnosis, the less important is biochemical confirmation. Typically, patients will have some, but not all, of the clinical manifestations of Cushing syndrome, and the diagnosis will require confirmation by demonstrating an elevated urinary free cortisol excretion on 24-hour urine testing, which is the single best biochemical marker of Cushing syndrome. The upper limit of the normal range of urinary free cortisol in unstressed persons is generally agreed to be about 100 μg/day as measured in commercial laboratories. If the patient has florid signs of Cushing syndrome, the diagnosis can be made even in the absence of convincing biochemical confirmation. On the other hand, if the patient has few clinical signs of Cushing syndrome, the urinary free cortisol must be greater than 300 μg/day to permit the diagnosis on that basis alone.

Taken together, the number of clinical manifestations and the level of urinary free cortisol define three general categories of Cushing disease: atypical, anorexia-associated, and classic [*see Figure 4*]. Atypical Cushing syndrome is characterized by low levels of urinary free cortisol but many clinical manifestations. Anorexia-associated Cushing syndrome is characterized by high levels of urinary free cortisol and few clinical manifestations. Classic Cushing syndrome is characterized by high levels of urinary free cortisol and many clinical manifestations.

Each of these general categories of Cushing syndrome has an associated differential diagnosis. The most common cause of atypical Cushing syndrome is glucocorticoid use, whether iatrogenic or factitious, and that of anorexia-associated Cushing syndrome is small cell carcinoma of the lung. The most powerful tool in the identification of these less common causes of Cushing syndrome is the clinical history.

In patients with classic Cushing syndrome, a search for the cause should not be undertaken unless the diagnosis is secure. Once that is accomplished, the first step in the differential diagnosis is to determine whether the condition is ACTH dependent or ACTH independent. This is most easily done by measuring the level of circulating plasma ACTH. There is no need to perform dexamethasone suppression testing.[4]

Although an ACTH level greater than 10 pg/ml indicates ACTH dependence, this threshold will fail to identify 5% of ACTH-dependent cases. Consequently, patients with a random plasma ACTH level of less than 10 pg/ml should undergo a CRH challenge. In this test, ACTH levels are measured 10 to 30 minutes after injection of an intravenous bolus of CRH.[5] If the plasma ACTH is less than 10 pg/ml after a CRH challenge and if the urinary free cortisol level is normal or high, the disorder is adrenal in origin; in other words, it is ACTH independent. Either CT or MRI scans will reveal these lesions with a high degree of accuracy. If no tumor is found on adrenal imaging studies, micronodular adrenal dysplasia should be suspected.[6] The familial form of micronodular adrenal dysplasia, Carney syndrome, is an autosomal dominant disorder characterized by pigmented lentigines, blue nevi, and multiple tumors.

ACTH-secreting pituitary microadenomas are often too small to be visible on MRI scans [*see 3:V Pituitary*]. Consequently, patients with ACTH-dependent Cushing syndrome and a normal pituitary MRI should undergo an inferior petrosal sampling procedure to search for a gradient in ACTH levels between blood draining the pituitary gland (inferior petrosal sinus blood) and peripheral antecubital blood. An ACTH gradient greater than 3 between simultaneously sampled central and peripheral blood confirms a pituitary etiology for Cushing syndrome.[7] If the gradient is less than 3, the search for an ectopic source of ACTH should be undertaken. Chest CT and MRI scans (with CT scans typically performed first) are central to this investigation, because 95% of these tumors are intrathoracic. The most common offending tumor is a bronchial carcinoid.

TREATMENT

Except for atypical Cushing syndrome, in which the treatment is to discontinue exogenous glucocorticoid, all treatments for Cushing syndrome are surgical. ACTH-independent cases should be treated with adrenal tumor resection or, in the case of micronodular adrenal dysplasia, bilateral adrenalectomy. ACTH-dependent cases should be treated with transsphenoidal microadenomectomy or ablation of the ectopic ACTH-secreting tumor. When an ectopic source for ACTH cannot be identified, the patient can be treated temporarily with a cortisol synthesis inhibitor, most commonly ketoconazole, until the lesion is found. If it is not found within 18 to 24 months, bilateral adrenalectomy should be performed.

Effective surgery for an ACTH-secreting tumor renders the patient adrenally insufficient. This is documented by measurement of the plasma cortisol level on the morning after surgery. If the

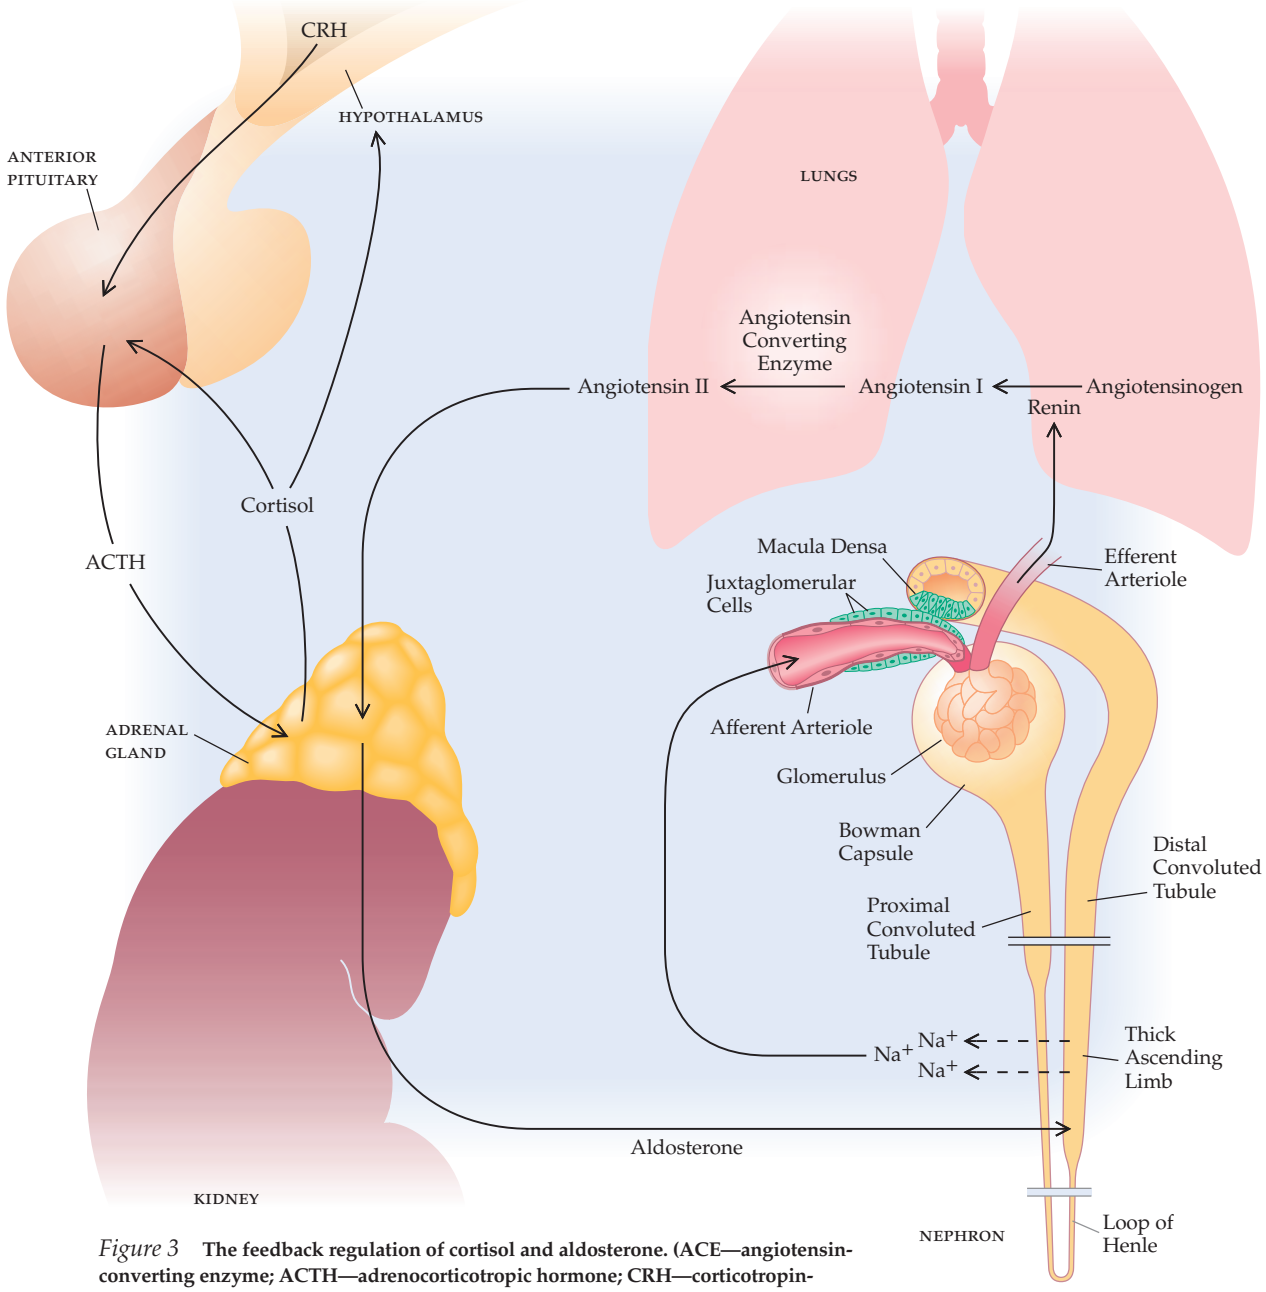

Figure 3 **The feedback regulation of cortisol and aldosterone. (ACE—angiotensin-converting enzyme; ACTH—adrenocorticotropic hormone; CRH—corticotropin-releasing hormone)**

level is greater than 20 μg/dl, the operation has not been successful and no cortisol therapy is indicated. If the plasma cortisol level is below the normal range (i.e., less than 5 μg/dl), the operation has been successful, and steroid replacement therapy will be required until the hypothalamic-pituitary-adrenal (HPA) axis can recover—possibly 1 year or longer. During this period, the patient should be treated with hydrocortisone at a rate of 12 mg/m^2 in a single daily dose with breakfast. Adrenal function is tested with a synthetic ACTH (cosyntropin) stimulation test at 3-month intervals. In patients with cortisol values between 5 and 20 μg/dl after cosyntropin stimulation, cortisol replacement therapy can be withdrawn; but 3-month testing should continue, and cortisol replacement therapy should be reinstituted if signs and symptoms of adrenal insufficiency appear. As soon as the cortisol level reaches 20 μg/dl or greater after cosyntropin stimulation, discontinuance of cortisol replacement without continued testing is safe.

If the operation has not been curative, Cushing syndrome will reappear with time. In addition to cortisol replacement, patients who have undergone bilateral adrenal resection will also require aldosterone replacement in the form of fludrocortisone, 0.1 mg each morning.

Without treatment, Cushing syndrome is fatal. Except for adrenal cancer, however, all causes of Cushing syndrome can be cured. Successful treatment restores normal life expectancy.

Adrenal Cancer

Adrenocortical cancer is a rare disease, with an annual incidence of 1 in 600,000.[8] Thus, about 500 new cases are diagnosed in the United States each year. This disease usually presents clinically as a combination of steroid hormone excess syndromes, the most common being Cushing syndrome with virilization.

Table 1 Sensitivity and Specificity of Selected Findings in Cushing Syndrome

Finding	*Sensitivity (%)*	*Specificity (%)*
Central obesity	90	71
Glucose intolerance	88	23
Plethora	82	69
Proximal muscle weakness	65	93
Striae	40	78
Hyperkalemia	25	96
Osteoporosis	64	97

Differential diagnostic tests will generally show ACTH-independent Cushing syndrome associated with increased serum testosterone levels in hirsute or virilized women. Occasionally, increased serum estradiol levels will be found in feminized men with Cushing syndrome. In rare instances, patients will present with virilization or feminization only, and some will have hypertension caused by tumor secretion of aldosterone precursors. CT or MRI scans usually show a large unilateral adrenal mass. Masses greater than 6 cm have a greater chance of being malignant. These tumors tend to be large when first discovered because the adrenal steroidogenic cells, in the course of dedifferentiation, become less efficient in cortisol synthesis. As a result, the tumor burden has to be large to yield the same clinical effect as a small, highly differentiated, benign adenoma.

The treatment of adrenocortical cancers is surgical. The first operation should focus on complete resection with clear margins. However, the incidence of surgical cure is unknown and is believed to be low, perhaps zero. With recurrence, each subsequent operation should focus on removing all visible disease, including accessible metastases. If left untreated, about half the patients with adrenocortical cancer will die in a few months. With aggressive surgery, their survival can be extended to about 48 months. When surgery is no longer feasible, treatment with steroid hormone synthesis blockers is indicated. Ketoconazole is typically used for this purpose. In addition, ortho,para'-DDD (mitotane) can be considered. At full dosages (> 2 g/day in divided doses), mitotane can produce remission in about 25% of patients. The average remission is 7 months long. Lengthened life span has not been demonstrated, and mitotane has severe side effects—nausea, vomiting, lethargy, and vertigo—so some physicians argue that the cost-to-benefit ratio (quality of life versus days of life gained) does not justify the use of this drug. Other chemotherapeutic regimens are under development, and patients with this rare disease are best served by referral to a center engaged in this research.[9]

Table 2 Differential Diagnosis of Cushing Syndrome

Incidental Adrenal Masses

About 300,000 abdominal CT and MRI procedures are done annually in the United States for indications unrelated to the adrenals. An incidental adrenal mass (incidentaloma) is found in about 4% of these procedures, or 12,000 newly discovered masses each year.[10] Assuming that this is the incidence in the general population, there would be roughly 12 million such masses in the United States population. Assuming that adrenal cancers are detectable by MRI 6 years before they become clinically evident, the prevalence of adrenal cancer would be about 1 in 3,000 population. Therefore, 1 in 4,000 incidentally discovered adrenal masses will be an adrenal cancer.

Measurement of serum potassium and bicarbonate levels is appropriate in patients with an incidentaloma. Plasma free metanephrine measurement may disclose a pheochromocytoma. Dexamethasone suppression testing has been advocated,[10] but its predictive value is only 0.5—no better than tossing a coin.

The central question in the management of the incidental adrenal mass is whether surgical removal is indicated. Certainly, the tumor should be removed if it is metabolically functional, as manifested by Cushing syndrome, the syndrome of mineralocorticoid excess, or virilization or feminization for which there is no other explanation. If there is no evidence of functionality, the tumor should be studied with a CT contrast washout study. Benign adrenal adenomas are lipid rich, whereas malignant ones tend to contain much more cellular and intercellular water. Thus, water-soluble contrast agents tend to wash out of benign lesions much faster than they do from malignant ones. The accuracy of this procedure in experienced hands is very high, with greater than 90% specificity and sensitivity.[11,12]

A mass that displays slow washout can be assumed to be a metastasis. If the patient has a known malignancy, the adrenal mass can be treated as part of the primary process. If there is no known primary malignancy, the mass could be the first manifestation of metastasis or a rare nascent adrenocortical carcinoma. Percutaneous needle biopsy can readily differentiate between these two possibilities, but it does involve risks, such as pneumothorax and tumor seeding. Alternatively, the mass can be removed laparoscopically and a pathologic analysis done.

In most series, 5% to 6% of incidental adrenal masses are pheochromocytomas.[13] This possibility should be excluded before biopsy or operation so as to avoid the hypertensive crises that can be associated with surgery. The safest course is to assume that the lesion is a pheochromocytoma and to prepare all such patients for surgery with adequate alpha blockade [*see* Pheochromocytoma, *below*].

Adrenal Insufficiency

Adrenal insufficiency (Addison disease) is categorized as primary or secondary. Primary adrenal insufficiency results from destruction of the adrenal cortex. There is a long list of causes of primary adrenal insufficiency [*see Table 3*]; worldwide, tuberculosis is the most common cause, and in the industrialized nations, idiopathic or autoimmune adrenal destruction is the most common cause. Secondary adrenal insufficiency results from disruption of

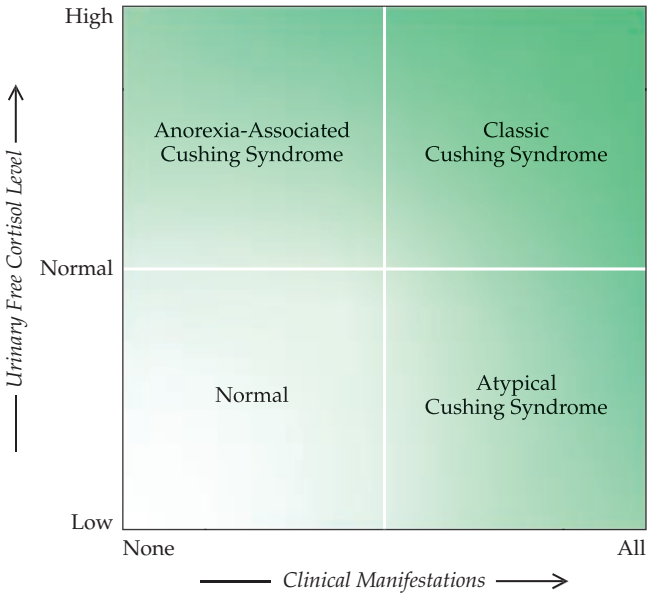

Figure 4 **The severity of the clinical manifestations and the level of urinary free cortisol can be used to define three categories of Cushing syndrome: classic, atypical, and anorexia associated.**

pituitary secretion of ACTH, which by far is most commonly caused by prolonged treatment with exogenous glucocorticoids. With time, doses of exogenous glucocorticoids sufficient to suppress ACTH secretion will lead to dysfunction of CRH-secreting neurons and attendant ACTH deficiency; subsequent withdrawal of glucocorticoids, for whatever reason, will then unmask the deficiency. Recovery of function may require a year or more. A far less common cause of disrupted ACTH secretion is destructive lesions in and around the pituitary gland and hypothalamus [*see Table 4*].

The symptoms and signs of adrenal insufficiency can be grouped into chronic and acute syndromes. The chronic syndrome is characterized by anorexia, weight loss, fatigue, and orthostatic hypotension. In patients with primary disease, the predominant signs are weight loss and hyperpigmentation of the skin, especially of the sun-exposed areas and extensor surfaces. The acute syndrome is closely analogous to cardiogenic or septic shock, with reduced cardiac output into a dilated and unresponsive vascular system. Symptoms include prostration and all of the signs and symptoms of the shock syndrome. Shock in this setting tends to be unresponsive to volume replacement and vasoconstrictor therapy.

With both chronic and acute syndromes, the diagnosis should be suspected on clinical grounds, but it requires laboratory confirmation. The critical test for the diagnosis of chronic adrenal insufficiency is the cosyntropin stimulation test. Synthetic ACTH (cosyntropin) is administered in a 250 μg intravenous bolus, and plasma cortisol levels are then measured after 45 and 60 minutes. Values greater than 20 μg/dl exclude adrenal insufficiency as a cause of the clinical findings. Values less than 20 μg/dl suggest that adrenal compromise could be a contributing factor. In this situation, treatment with glucocorticoids is mandatory until the clinical situation is clarified with more precision.

In acute adrenal insufficiency, the most useful test is measurement of the plasma cortisol level. Cosyntropin stimulation testing is not necessary; the illness, which is sufficiently severe to merit admission to an intensive care unit, represents an endogenous source of maximal physiologic stress. Plasma cortisol levels in acute adrenal insufficiency are greater than 20 μg/dl, with the only exception being in patients who have a low plasma albumin concentration, which lowers the total cortisol concentration.[14] Unfortunately, there are no published data on the interpretation of plasma cortisol values in patients with low albumin concentrations, so most clinicians adhere to the 20 μg/dl standard. Currently, if the cortisol value is less than 20 μg/dl, it should be confirmed with a standard cosyntropin stimulation test.

The differential diagnosis of adrenal insufficiency requires the discrimination of primary and secondary causes; the most useful test is measurement of the circulating plasma ACTH level. ACTH levels greater than normal define primary disease; values in the normal range or below define secondary disease.

Patients with primary adrenal disease should have the adrenal glands imaged with CT or MRI. Infectious, malignant, and vascular causes of adrenal insufficiency all result in enlargement of the adrenal glands. In idiopathic or autoimmune adrenal insufficiency, the glands are normal or small in size. Patients with secondary adrenal insufficiency should first be assessed for exogenous glucocorticoid use. If that can be eliminated as a cause, they should undergo CT or MRI scanning of the hypothalamus and pituitary gland to exclude destructive lesions in this area.

TREATMENT

The goal in treating adrenal insufficiency is to replace the

Table 5 Differential Diagnosis of Pheochromocytoma

Toxemia of pregnancy
Selective serotonin reuptake inhibitors

missing hydrocortisone and aldosterone in quantities calibrated to the clinical situation. Hydrocortisone can be replaced with oral or intravenous hydrocortisone. Aldosterone is replaced with oral fludrocortisone. Exogenous hydrocortisone and fludrocortisone are both equipotent with the endogenously secreted hormone. Unstressed persons secrete hydrocortisone at a rate of 6.5 mg/m^2 daily. In the face of stress, such as a surgical procedure or serious trauma, hydrocortisone secretion can rise more than 10-fold. The secretion rate of aldosterone is 100 μg/day in persons consuming large amounts of sodium (i.e., a typical United States diet).

Primary chronic adrenal insufficiency is treated with oral hydrocortisone, 12 to 15 mg/m^2/day. This is roughly double the amount of hydrocortisone that is normally secreted; the added amount is needed to compensate for first-pass hepatic metabolism. Hydrocortisone is best given as a single daily dose with breakfast. Fludrocortisone is given at a dose of 0.1 mg/day. When moderate stress is anticipated (e.g., a root canal procedure), the dose of hydrocortisone is temporarily doubled, beginning the day before the stress and continuing until 2 days afterward. It is not necessary to alter the fludrocortisone dose. With anticipated major stress (e.g., appendectomy with general anesthesia), the hydrocortisone dosage is increased to 100 mg every 6 hours from the day before the procedure until 2 days afterward. Hydrocortisone dosage increases are not required for periods of psychological stress, such as major depression, psychosis, or grief.

These replacement regimens roughly reproduce the patterns of cortisol and aldosterone secretion in persons with normal adrenal function. The need for these temporary dosage increases has not been clearly established, on either clinical or biologic grounds, but this has become the standard of practice and is not likely to change. Chronic secondary adrenal insufficiency is treated in the same way as chronic primary disease but with replacement of hydrocortisone only, not aldosterone.

Patients with acute adrenal insufficiency are treated in the same fashion as those with chronic adrenal insufficiency who are experiencing major stress. Treatment is monitored clinically. Signs of Cushing syndrome indicate overtreatment; hyponatremia, orthostasis, and anorexia indicate undertreatment. There is no good clinical evidence to suggest that the dosage regimens ever need to be exceeded. If a patient on recommended replacement doses of hydrocortisone and fludrocortisone fails to do as well as expected, the reason is something other than the adrenal replacement regimen.

All patients with adrenal insufficiency should wear a medical-alert bracelet imprinted with the words "adrenal insufficiency" and carry a similar wallet card at all times.

Pheochromocytoma

The adrenal medulla accounts for about 10% of the weight of the adrenal gland. It is composed primarily of chromaffin cells, which are named for the yellow-brown color they take on when stained with chromatic salts. The cells of the medulla are directly innervated by preganglionic sympathetic nerve cells. Hence, these epinephrine-secreting cells are analogous to the postganglionic neurons in the other areas of the sympathetic nervous system. These cells are not neurons, however, and have no dendrites or axons. In addition, the primary secretory product of the adrenal medulla is epinephrine, whereas the remainder of the sympathetic nervous system employs norepinephrine as the neurotransmitter. The reason for this difference is that the blood supply to the adrenal medulla is derived from the capillary plexus draining the adrenal cortex. This capillary blood is extremely rich in cortisol—perhaps the highest concentration of cortisol in the human body is in the adrenal medulla—and cortisol induces catechol-O-methyl transferase, the enzyme that converts norepinephrine to epinephrine. The primary disease of the adrenal medulla is pheochromocytoma; 90% of pheochromocytomas occur in the adrenal medulla. Extra-adrenal tumors of the chromaffin cell are known as paraganglions or chemodectomas, depending on the location. All have similar clinical presentations, and all are treated in the same way (see below).

The main clinical manifestation of pheochromocytomas is hypertension. The hypertension can be sustained or episodic; the two forms occur with equal frequency. Paroxysmal hypertension is associated with tachycardia, diaphoresis, anxiety, and a sense of foreboding. Patients also complain of nausea and abdominal pain. The association of headache, palpitations, and sweating with hypertension has a high (> 90%) sensitivity and specificity for pheochromocytoma. The differential diagnosis for pheochromocytoma is extensive and includes anxiety and panic attacks, thyrotoxicosis, amphetamine and cocaine use, and use of over-the-counter cold medicines that depend upon catecholamines for effect, such as atomizers for nasal congestion [*see Table 5*]. Pheochromocytomas are usually benign (90%) and usually unilateral (90%). The incidence of pheochromocytoma is markedly increased in several genetic syndromes: multiple endocrine neoplasia types 2a and 2b and the phakomatoses, including neurofibromatosis, cerebelloretinal hemangioblastosis, tuberous sclerosis, and Sturge-Weber syndrome.

DIAGNOSIS

The traditional tests for diagnosing pheochromocytoma are measurements of the urinary fractionated catecholamines and urinary metanephrine excretion in 24-hour urine samples. Total catecholamine excretion is normally less than 100 μg/day, with no more than 25% being epinephrine. Urinary metanephrine excretion is normally less than 1.3 mg/day. The urine for these tests must be collected in an acid medium (laboratories typically provide appropriate containers) and need not be refrigerated. Creatinine should also be measured, as an indicator of completeness of collection. The patient should be taken off all medications when possible. If the hypertension must be treated, diuretics, vasodila-

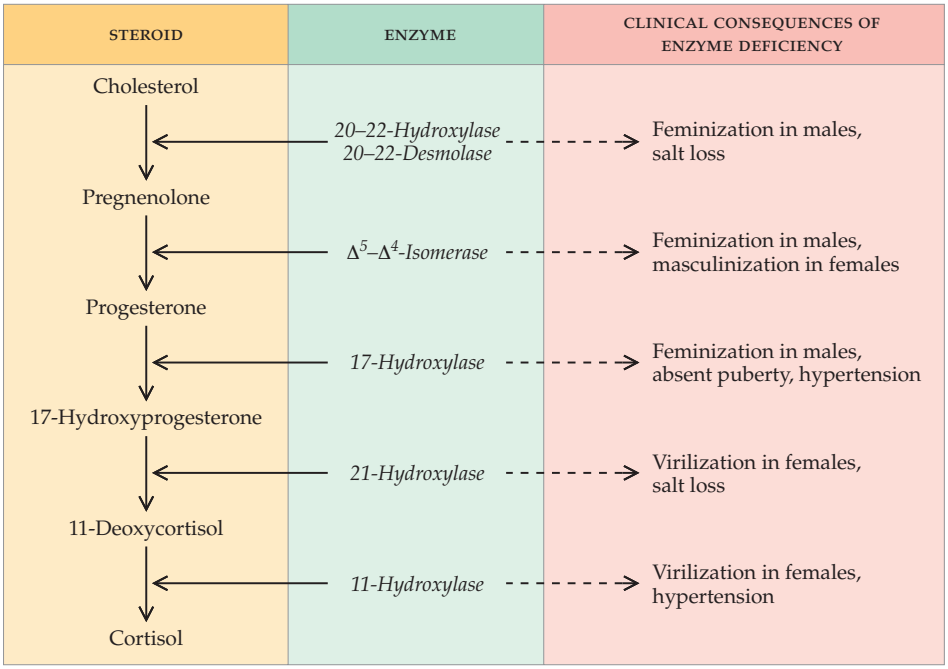

Figure 5 **Congenital adrenal hyperplasia may result from mutations that inactivate any of the six enzymatic steps in the biosynthesis of cortisol from cholesterol. The clinical manifestations of the disorder vary with the enzyme deficiency.**

tors, calcium channel blockers, and angiotensin-converting enzyme (ACE) inhibitors interfere minimally with the assays. When there is concordance between the clinical picture and the biochemical tests, CT or MRI scans should be employed to localize the tumor. MRI is particularly useful because these tumors almost always "brighten" with T_2-weighted images. If CT and MRI fail to reveal an adrenal tumor, radiolabeled meta-iodobenzylguanidine (MIBG) can be a useful scanning technique for locating tumors outside of the adrenal gland, such as those in the carotid body, heart, urinary bladder, and the organ of Zuckerkandl.

TREATMENT

The treatment of pheochromocytoma is surgical. The surgery should be undertaken only by a team experienced and skilled in the management of pheochromocytoma. Before the surgical procedure, complete alpha blockade should be induced to avoid intraoperative hypertensive crisis. Preparation should begin 7 days before the planned procedure, using phenoxybenzamine at an initial dosage of 10 mg by mouth twice daily. The dose should be increased daily, and by the seventh day, the patient should be taking at least 1 mg/kg/day in three divided doses. Adequate blockade is associated with reduced blood pressure and reduced orthostatic hypotension as the vascular volume is restored.

Malignant pheochromocytoma should be treated with surgical debulking, ongoing alpha blockade with phenoxybenzamine, and comanagement with an oncologist. Radiation therapy is useful for bone pain, and some success has been achieved with combination chemotherapy, including cyclophosphamide, vincristine, and dacarbazine.

Congenital Adrenal Hyperplasia

There are six enzymatic steps in the biosynthesis of cortisol from cholesterol, and all can be affected by inactivating mutations [*see Figure 5*]. Because cortisol is essential for life, cortisol concentrations are maintained in the normal range at the expense of adrenal hypertrophy and increased adrenal secretion of the steroid biosynthetic intermediate in the step immediately before the affected enzyme. Depending on which enzyme is blocked, the increased concentrations of the steroid biosynthetic intermediate can lead to virilization in females and to hypertension. In some cases, primarily because of reduced androgen secretion in utero—a time when there is no feedback regulation of testosterone—male fetuses can be feminized.

The most common underlying disorder in congenital adrenal hyperplasia is 21-hydroxylase deficiency. The virilizing form of this disease is thought to be the most common autosomal recessive disorder.

21-Hydroxylase deficiency is categorized according to two clinical distinctions: (1) the classic form, which can be salt losing or non–salt losing, and (2) the nonclassic form.

The degree to which a person with 21-hydroxylase deficiency loses salt in a salt-poor environment correlates with the degree of expression of the enzyme defect in the zona glomerulosa. In persons with mild expression, salt loss is sufficiently minimal that a standard United States diet will maintain a normal salt balance.

The classic form of the disease is usually diagnosed in the neonatal period and is characterized by failure to thrive as a result of the salt loss and by male pseudohermaphroditism in female infants. The nonclassic form of the disease, which is sometimes referred to as adult onset or attenuated, usually becomes clinically apparent in adolescence. It is manifested by a slightly earlier age at puberty (approximately 1 year) and, in females, oligomenorrhea and androgen-mediated hirsutism. Adults who present with the classic form of 21-hydroxylase deficiency usually have a well-documented diagnosis since infancy, have a gender assignment, and have completed a series of genital reconstructive plastic surgical procedures. The usual clinical questions are whether ongoing treatment is necessary and, if so, whether the current regimen is appropriate.

The typical adult patient with the nonclassic or attenuated form is a young woman with oligomenorrhea, infertility, and hirsutism. The most common confounding diagnosis is the polycystic ovary syndrome [*see 16:V Polycystic Ovary Syndrome*].

The diagnostic test for 21-hydroxylase deficiency is a cosyntropin stimulation test: synthetic ACTH is administered in a 250 μg intravenous bolus, and plasma levels of 17-hydroxyprogesterone are measured after 45 and 60 minutes. 17-Hydroxyprogesterone is the steroid biosynthetic intermediate immediately proximal to the enzyme defect. In normal patients, 17-hydroxyprogesterone levels will rise to no higher than 340 ng/dl after cosyntropin stimulation; in patients with 21-hydroxylase deficiency, 17-hydroxyprogesterone levels will be no lower than 1,000 ng/dl. CT or MRI scanning in these patients will show that the adrenal glands are larger than normal and, in some cases, nodular.

TREATMENT

All patients with 21-hydroxylase deficiency should be considered to have some degree of salt loss. Fludrocortisone, 0.2 mg every morning, should be the first therapy. Hydrocortisone, 12 to 15 mg/m^2 as a single morning dose, should be initiated several days later. After 2 weeks of combined therapy, a morning 17-hydroxyprogesterone level should be measured. If the target level of 400 to 600 ng/dl is achieved, the fludrocortisone dose can be reduced by half. Two weeks later, the 17-hydroxyprogesterone should be measured again; if it is still below 600 ng/dl, that establishes the fludrocortisone dose as the patient's maintenance dose. If the 17-hydroxyprogesterone level has risen above 600 ng/dl, the fludrocortisone dose should be restored to the initial 0.2 mg/day, which likely will be the maintenance dose. Reduction of 17-hydroxyprogesterone levels to within the normal range is not recommended. Achieving this level often requires doses of fludrocortisone that produce adrenal suppression and lead to Cushing syndrome.

Lifelong treatment is required in patients with 21-hydroxylase deficiency to prevent the appearance of adrenal rest tumors, which are nodules of ectopic adrenal tissue that become hypertrophic because of ongoing ACTH stimulation. These tumors are usually found in the broad ligament in women and in the testes in men. In women, hemorrhage or necrosis of adrenal rest tumors occasionally necessitates emergency pelvic surgery; in men, these tumors can result in testicular pain, testicular masses, and infertility. Testicular pain may be so severe and intractable that castration is required.

Hyperaldosteronism

Hyperaldosteronism can be primary or secondary. In primary hyperaldosteronism, there is disordered function of the renin-aldosterone feedback axis; in secondary hyperaldosteronism, the renin-aldosterone axis is responding normally to chronic intravascular volume deficiency, which may result from such conditions as heart failure or ascites associated with cirrhosis of the liver.

Aldosterone acts on the epithelial cells of the renal collecting tubule to promote reabsorption of sodium and excretion of potassium and hydrogen. Other tissues similarly affected include sweat glands, salivary glands, and intestinal epithelium. Clinically, the result of excess aldosterone is the so-called mineralocorticoid excess syndrome, characterized by hypokalemia, metabolic alkalosis, and, sometimes, hypertension.

PRIMARY HYPERALDOSTERONISM

Primary hyperaldosteronism is caused by benign adrenal adenomas, which are typically unilateral, are usually less than 2.5 cm in diameter, and secrete aldosterone independently of renin-angiotensin stimulation. Patients with primary hyperaldosteronism present with hypertension; in fact, primary adrenal hypersecretion of aldosterone is thought to account for about 2% of cases of hypertension. Laboratory testing shows hypokalemia and metabolic alkalosis, with a serum sodium level that is usually in the high-normal range [*see Figure 6*]. Diagnosis of this disorder is confirmed by demonstrating normal or elevated plasma aldosterone levels (> 14 ng/dl) along with suppression of stimulated plasma renin activity (PRA) to less than 2 ng/ml/hr. Stimulated PRA is determined by measuring the plasma renin activity level after 2 hours of upright posture (standing or walking).

The differential diagnosis of primary hyperaldosteronism also includes dexamethasone-suppressible hyperaldosteronism, in which aldosterone is secreted in response to ACTH rather than angiotensin [*see* Dexamethasone-Suppressible Hyperaldosteronism, *below*], and idiopathic bilateral adrenal hyperplasia, in which the hypertrophic zona glomerulosa secretes aldosterone independent of renin-angiotensin stimulation [*see* Idiopathic Bilateral Adrenal Hyperplasia, *below*]. Dexamethasone-suppressible hyperaldosteronism is confirmed by the suppression of aldosterone levels with dexamethasone administration, 2 mg/day in divided doses for 7 days. In most cases, aldosterone levels decrease by the third day of treatment. If dexamethasone fails to suppress plasma aldosterone levels and to ameliorate the associated hypertension, CT or MRI should be employed to search for an adrenal adenoma. If an adenoma is not found by CT or MRI, simultaneous adrenal venous sampling for the measurement of aldosterone and cortisol will be needed to define the source of aldosterone secretion.[15] If the venous sampling identifies unilateral aldosterone secretion, the patient should be treated as if primary adrenal hypoaldosteronism is present, despite the absence of a visible adenoma. The surgeon, at the time of operation, can define unilateral versus bilateral disease.

The treatment of primary adrenal hyperaldosteronism is unilateral adrenalectomy, preferably by a laparoscopic procedure. The cure rate, defined as correction of hyperaldosteronism and hypertension, is about 75%.[16] Patients whose blood pressure remains elevated postoperatively will require ongoing antihypertensive therapy, which is managed as if essential hypertension were present.

Idiopathic Bilateral Adrenal Hyperplasia

The clinical presentation of idiopathic bilateral adrenal hyperplasia is indistinguishable from that of primary hyperaldosteronism caused by an adrenal adenoma. However, patients with idiopathic bilateral adrenal hyperplasia have no dominant adrenal adenoma, and aldosterone secretion from both adrenal glands can be documented by bilateral adrenal venous sampling. Adrenalectomy in these patients does not correct the hypertension. Thus, treatment is directed at the hypertension. Interestingly, antagonizing aldosterone activity with spironolactone is usually ineffective. Calcium channel blockers, however, are effective antihypertensive agents in these patients, as are ACE inhibitors. If hypokalemia persists during the treatment of hypertension, it can usually be managed by the addition of a potassium-sparing diuretic.

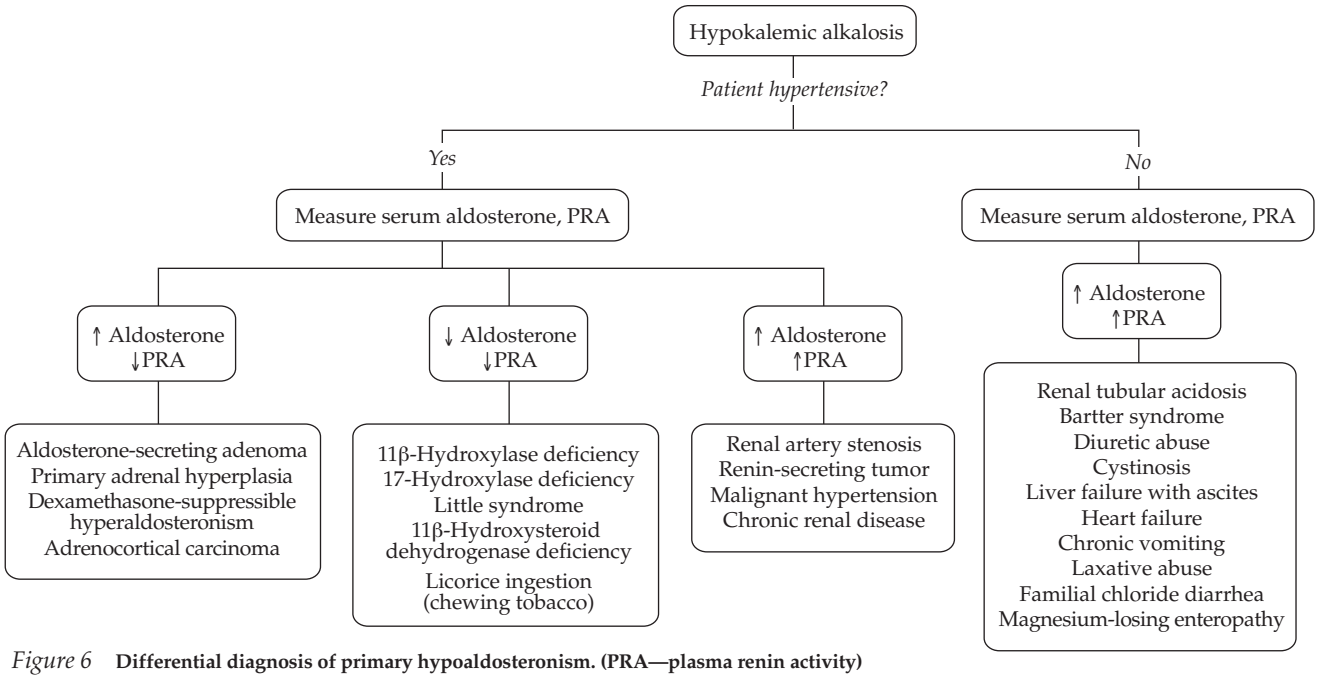

Figure 6 **Differential diagnosis of primary hypoaldosteronism. (PRA—plasma renin activity)**

Dexamethasone-Suppressible Hyperaldosteronism

Dexamethasone-suppressible hyperaldosteronism is a rare familial cause of hyperaldosteronism and is transmitted as an autosomal dominant trait. The cause of the disorder is a fusion gene in which the coding region for ACTH-responsive regulation of 11-β hydrolase is coupled with the coding region for aldosterone synthase. Thus, aldosterone secretion becomes entrained to ACTH secretion and is "blind" to renin-angiotensin levels. Because ACTH secretion is not modulated by aldosterone, aldosterone secretion becomes independent of salt balance, blood potassium levels, and vascular volume.

Treatment for this disorder starts with the use of a potassium-sparing diuretic such as amiloride or triamterene. This regimen has the advantage of not suppressing the HPA axis. If it is unsuccessful, ACTH secretion can be suppressed with dexamethasone, usually 0.5 mg in a single daily dose.

SECONDARY HYPERALDOSTERONISM

Secondary hyperaldosteronism may or may not be associated with hypertension. Patients with hypertension usually have underlying renal pathology, including renal artery stenosis, renin-secreting tumors, and chronic renal failure. Both plasma renin activity and aldosterone are elevated in such cases. Treatment should be directed at the underlying cause.

Secondary hyperaldosteronism that is not associated with hypertension occurs in disorders characterized by decreased vascular volume. Renal causes include chronic nephritis, renal tubular acidosis, and calcium- and magnesium-losing nephropathies. Chronic diuretic abuse also is a cause. Gastrointestinal causes include chronic vomiting, laxative abuse, and chronic diarrhea of any kind. Probably the most common causes are chronic heart failure and cirrhosis of the liver with ascites. Again, treatment is best directed at the underlying disorder.

Finally, there are two forms of congenital adrenal hyperplasia in which overproduction of mineralocorticoids other than aldosterone leads to the syndrome of mineralocorticoid excess. These two disorders are 11-hydroxylase deficiency and 17-hydroxylase deficiency. Both renin and aldosterone levels are low in these disorders. Treatment is the same as that for 21-hydroxylase deficiency (see above), but without fludrocortisone.

Bartter syndrome is associated with hypokalemic alkalosis, hyperreninemia, and hyperaldosteronism, with normal blood pressure. This pattern can be seen in a number of disorders causing secondary hyperaldosteronism. Bartter syndrome is caused by a deficit in chloride transport in the thick ascending limb of the loop of Henle. Diagnosis is difficult because the pattern of electrolyte abnormalities mimics that seen in diuretic abuse. A more detailed discussion of Bartter syndrome is provided elsewhere [*see 10:II Disorders of Acid-Base and Potassium Balance*].

Hypoaldosteronism

PRIMARY HYPOALDOSTERONISM

Primary hypoaldosteronism is defined as aldosterone deficiency of adrenal cause. Hypoaldosteronism manifests as an inability to conserve sodium, leading to a negative salt balance in a salt-poor environment. This leads to hypotension, hyperkalemia, dehydration, and volume depletion associated with a mild metabolic acidosis. The disorder can be corrected by a high-salt diet or by replacement of aldosterone with fludrocortisone.

Primary adrenal insufficiency is the most common cause of primary hypoaldosteronism. Diagnosis and treatment are the same as those for adrenal insufficiency (see above). Two rare autosomal recessive disorders, corticosterone methyl oxidase (CMO) deficiency types I and II, can result in markedly reduced adrenal secretion of aldosterone. CMO deficiency type I is recognized by the syndrome of mineralocorticoid deficiency and low aldosterone levels associated with high plasma corticosterone concentration. CMO deficiency type II is similar, except that high levels of 18-hydroxycorticosterone will be associated with low levels of aldosterone. These are primarily diseases of childhood, becoming less severe with age and free access to salt.

SECONDARY HYPOALDOSTERONISM

The syndrome of hyporeninemic hypoaldosteronism is the most common form of secondary hypoaldosteronism. The disorder is often referred to as renal tubular acidosis type 4. It has been described in almost every disorder of renal function. Chronic renal disease is present in 80% of patients with the disorder. The clinical picture is that of hyperkalemia, hyponatremia, and metabolic acidosis in association with a low plasma renin activity and a low plasma aldosterone level. The most direct and rational therapy for this syndrome is replacement of aldosterone with fludrocortisone at a dosage of 0.1 to 0.2 mg/day.

PSEUDOHYPOALDOSTERONISM (MINERALOCORTICOID RESISTANCE)

Pseudohypoaldosteronism type I and type II are syndromes of end-organ resistance to the effects of aldosterone. Type I is caused by an inactivating mutation in the mineralocorticoid receptor, and type 2 is ascribed to an ill-defined defect in aldosterone action distal to its binding to the mineralocorticoid receptor. Pseudohypoaldosteronism type 1 is characterized by salt wasting that is resistant to mineralocorticoid replacement. It is best treated with a high-salt diet, 10 to 40 mEq/kg/day. Pseudohypoaldosteronism type II (Gordon syndrome) is a non–salt-wasting disorder that can be associated with hypertension, metabolic acidosis, and hyperkalemia. Plasma renin activity and aldosterone are both low, and administration of mineralocorticoid fails to correct the hyperkalemia and acidosis. The basic defect is thought to be a chloride shunt disorder in the nephron. Treatment is with a potassium-wasting diuretic; hydrochlorothiazide and furosemide are most often used.

Glucocorticoid Therapy

Glucocorticoids can be valuable, even lifesaving, in the treatment of many inflammatory and neoplastic diseases. Although cortisol accounts for about half of the mineralocorticoid effect produced by the adrenal gland, the synthetic steroids that are customarily used for glucocorticoid therapy (e.g., prednisone and dexamethasone) have virtually no salt-retaining activity and, therefore, do not cause unacceptable salt retention. On the other hand, their glucocorticoid effect is far more powerful than that of cortisol. Gram for gram, prednisone has four times the glucocorticoid potency of cortisol; dexamethasone has about 25 times the potency.

The target tissues in glucocorticoid-responsive diseases are glucocorticoid resistant. The basis for this resistance remains unknown, but the prevailing hypothesis is that the chaperone proteins produced in stressed cells, particularly the heat shock proteins, in some way attenuate glucocorticoid action. Overcoming glucocorticoid resistance may require dosages of prednisone as high as 100 mg/day and dosages of dexamethasone as high as 20 mg/day. These high doses expose the rest of the tissues in the patient's body, which have normal responsiveness to glucocorticoid, to an extremely enhanced glucocorticoid effect. Over time, this leads to Cushing syndrome, whose potentially lethal effects may force the tapering or even discontinuance of glucocorticoid therapy.

An invariable aspect of Cushing syndrome induced by exogenous glucocorticoid is suppression of ACTH secretion. In contrast to the recovery of pituitary secretion of other hormones, such as thyroid-stimulating hormone or luteinizing hormone and follicle-stimulating hormone, recovery of ACTH secretion is very slow; the return to normal may require a year or more. Thus, the physician must ensure that the HPA axis is intact before completely withdrawing long-term glucocorticoids.

Pharmacologic glucocorticoid therapy is typically initiated at a high dose (e.g., prednisone, 60 mg daily in divided doses). As soon as the disease process is controlled, the dose is reduced in 5% increments weekly in an attempt to find the lowest effective dose as quickly as possible. The ultimate goal is to taper to normal replacement doses of the glucocorticoid. When the glucocorticoid dose approximates the replacement level, the preparation is changed to an equivalent dose of hydrocortisone given at a dosage of 12 mg/m^2 once a day in the morning. This dose remains unchanged until it is safe to withdraw glucocorticoid therapy completely or until the disease reactivates, in which case the process is begun anew. Patients receiving hydrocortisone at the replacement dose should undergo cosyntropin stimulation testing every 3 months. When the plasma cortisol response to cosyntropin exceeds 20 μg/dl, hydrocortisone can be discontinued safely. In the event that the dose cannot be lowered to replacement levels because of recurrent disease activity, alternative and adjunctive non–glucocorticoid-based therapies must be aggressively pursued in the hope that they might permit tapering of the glucocorticoid to replacement dose before the ravages of Cushing syndrome demand cessation of glucocorticoid treatment in the setting of an uncontrolled inflammatory or neoplastic illness.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

V PITUITARY

Shlomo Melmed, m.d.

Functional Anatomy of the Pituitary

The pituitary gland regulates the critical hormonal functions of growth, development, reproduction, stress homeostasis, and metabolic control. Because of its prominent role in these processes, the pituitary has been termed the master gland.

The pituitary is situated within the sella turcica at the base of the brain and weighs about 600 mg. It comprises functionally distinct anterior and posterior lobes. The blood supply to the anterior pituitary is predominantly derived from the hypothalamic-pituitary portal vessels. The posterior lobe is supplied directly by the systemic inferior hypophyseal arteries.

Anatomically and functionally, the pituitary is closely linked with the hypothalamus [*see Figure 1 and Table 1*]. Neural cell bodies in the hypothalamus synthesize releasing and inhibiting hormones that control pituitary hormone secretion. These hypothalamic hormones are secreted into the portal vessels of the pituitary stalk and are transported to the anterior pituitary cell surface receptors.

The anterior pituitary synthesizes and secretes adrenocorticotropic hormone (ACTH), growth hormone (GH), prolactin (PRL), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH).[1,2] The posterior pituitary secretes vasopressin (also known as antidiuretic hormone [ADH]) and oxytocin, both of which are synthesized in the hypothalamus.

Pituitary tropic hormones elicit responses from their respec-

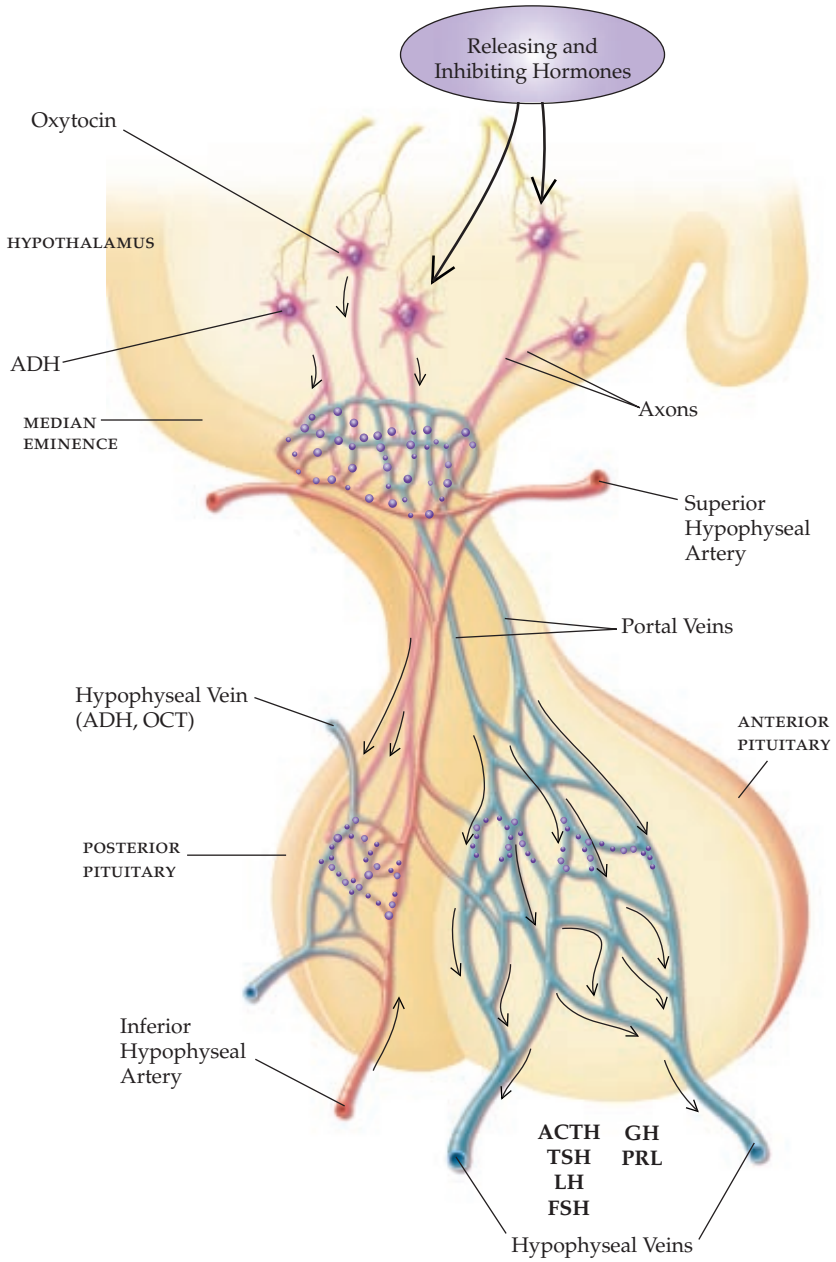

Figure 1 **The anterior pituitary and the hypothalamus are connected by the hypophyseal portal vasculature. Releasing or inhibiting hormones secreted by hypothalamic neurons enter the primary plexus of the hypophyseal portal vasculature. They flow down the long portal veins in the pituitary stalk to the secondary plexus, a capillary network that enmeshes the cells of the anterior pituitary. The anterior pituitary cells secrete their hormones in response to the releasing hormones. Because neither the hypothalamus nor the anterior pituitary is isolated by the blood-brain barrier, feedback signals have direct access to both sites of regulation. The posterior pituitary is made up of the terminal portions of neurons whose origin is the hypothalamus. (ACTH—adrenocorticotropic hormone; ADH—antidiuretic hormone; FSH—follicle-stimulating hormone; GH—growth hormone; LH—luteinizing hormone; PRL—prolactin; TSH—thyroid-stimulating hormone)**

Table 1 Hypothalamic and Related Pituitary Hormones

Hypothalamic Hormones	*Pituitary Hormones*
Growth hormone–releasing hormone	Growth hormone (GH)
Growth hormone release–inhibiting hormone (somatostatin)	GH
Prolactin release inhibitory factor (dopamine)	Prolactin
Gonadotropin-releasing hormone	Follicle-stimulating hormone Luteinizing hormone
Corticotropin-releasing hormone Vasopressin (arginine vasopressin; antidiuretic hormone)	Adrenocorticotropic hormone (corticotropin)
Thyrotropin-releasing hormone	Thyrotropin (thyroid-stimulating hormone)

tive target glands; the latter secrete endocrine hormones that activate specific tissue receptors. Circulating levels of these peripheral hormones influence secretion of their respective pituitary tropic hormone by negative feedback [*see Table 2*].

Pituitary Masses

LOCAL MASS EFFECTS

Pituitary masses can cause symptoms by secreting hormones, by impinging on adjacent structures, or both. These masses may also compress adjacent normal pituitary tissue, leading to pituitary failure. Expanding intrasellar lesions can exert significant compressive effects on surrounding vascular and neurologic structures, including the cavernous sinuses, cranial nerves, and optic chiasm. Intrasellar lesions may invade contiguous local structures and may compress central structures, depending on their anatomic location [*see Figure 2*]. The sellar roof presents the least resistance to soft tissue expansion from within the confines of the bony sella; this accounts for the vulnerability of the optic chiasm to sellar mass expansion. Small changes in intrasellar pressure may stretch the dural plate and cause headache, the severity of which does not necessarily correlate with mass size or extension. Chiasmic pressure can result in bilateral or unilateral visual defects. Pituitary stalk compression encroaches on the portal vessels, with resultant hyperprolactinemia and concurrent failure of other pituitary tropic hormones. Cavernous sinus invasion may lead to palsies of the third, fourth, and sixth cranial nerves, as well as lesions of the ophthalmic and maxillary branches of the fifth cranial nerve. Inferior extension through the bony sellar floor involves the sphenoid sinus; further extension into the palate roof may result in nasopharyngeal invasion and, rarely, cerebrospinal fluid leakage. Tumor invasion of the temporal or frontal lobe can cause seizures and personality disorders. Hypothalamic encroachment by an invasive pituitary mass may have metabolic sequelae, including precocious puberty or hypogonadism, diabetes insipidus, dysthermia, appetite disorders, and sleep disturbances.

PITUITARY TUMORS

Pituitary Adenomas

Pituitary adenomas account for about 15% of all intracranial neoplasms. They arise from one of the specific anterior pituitary cell types as benign monoclonal expansions. Loss of heterozygosity of regions of chromosome 11q13, 13, and 9 occurs in up to 20% of larger sporadic pituitary tumors, suggesting the presence of tumor suppressor genes at these loci. Other factors involved in initiation and promotion of pituitary adenoma growth include loss of negative feedback inhibition, as seen with thyroidal or gonadal failure; intrapituitary paracrine growth factors (angiogenesis factors), mainly mediated by estrogen; and activation of any of several oncogenes.

Pituitary adenomas are usually diagnosed when they hypersecrete pituitary hormones or compress adjacent structures. Tumors arising from lactotroph, somatotroph, corticotroph, and thyrotroph cells hypersecrete PRL, GH, ACTH, or TSH, respectively [*see Table 3*]. Functional tumors exhibit autonomous tropic hormone secretion, leading to hyperprolactinemia, acromegaly, Cushing disease, or, rarely, TSH hypersecretion. Plurihormonal tumors may produce mixed clinical features. About one third of adenomas do not actively secrete hormones and are clinically nonfunctional. On autopsy, up to one quarter of patients are found to harbor an unsuspected microadenoma (diameter < 10 mm) with no apparent clinical sequelae. Rarely, ectopic secre-

Table 2 Pituitary Hormones, Their Mediators, and Their Effects

Pituitary Hormones	*Stimulators*	*Inhibitors*	*Target Glands*	*Tropic Effects*
Gonadotropins: follicle-stimulating hormone, luteinizing hormone	Gonadotropin-releasing hormone	Sex steroids, inhibin	Ovary, testis	Sex steroid production, reproductive activity
Thyroid-stimulating hormone	Thyrotropin-releasing hormone (TRH)	Triiodothyronine (T_3), thyroxine (T_4), dopamine, somatostatin, glucocorticoids	Thyroid	T_3, T_4 synthesis and secretion
Prolactin	Estrogen, TRH	Dopamine	Breast, other tissues	Milk production
Growth hormone (GH)	GH-releasing hormone, GH secretagogue	Somatostatin, insulinlike growth factor (IGF)	Liver, bones, other tissues	IGF-1 production, growth induction, insulin antagonism

tion of GH-releasing hormone (GHRH) or corticotropin-releasing hormone (CRH) elaborated by abdominal or chest tumors results in hyperplasia of the cells that secrete GH or ACTH; these patients may present with pituitary hyperplasia and acromegaly or Cushing syndrome.

Genetic Syndromes Associated with Pituitary Adenomas

Multiple endocrine neoplasia type I Multiple endocrine neoplasia type I (MEN I) is an autosomal dominant syndrome caused by an inactivating mutation in the coding region of *menin*, a tumor suppressor gene located at the q13 locus of chromosome 11. The syndrome comprises parathyroid, pancreatic, and pituitary adenomas, including prolactinomas, and may present as acromegaly or Cushing syndrome.

Carney syndrome Carney syndrome is an autosomal dominant syndrome associated with activated protein kinase activity. It comprises spotty skin pigmentation; myxomas; and testicular, adrenal, and pituitary adenomas.

McCune-Albright syndrome The McCune-Albright syndrome is associated with chromosome 20q13.2 mosaicism and constitutive activation of cyclic adenosine monophosphate (cAMP). This syndrome manifests as polyostotic fibrous dysplasia (cancellous bone is replaced with immature woven bone and fibrous tissue), pigmented skin patches, precocious puberty, and acromegaly.

Familial acromegaly Affected persons with this rare syn-

Table 3 Effects of Pituitary Adenomas

General Effect	*Adenoma Cell Origin*	*Hormone Product*	*Clinical Syndrome*
Hormone hypersecretion	Lactotroph	PRL	Hypogonadism, galactorrhea
	Somatotroph	GH	Acromegaly/gigantism
	Corticotroph	ACTH	Cushing disease
	Mixed growth hormone and prolactin cell	GH, PRL	Acromegaly, hypogonadism, galactorrhea
	Acidophil stem cell, mammosomatotroph	PRL, GH	Hypogonadism, acromegaly
	Thyrotroph	TSH	Hyperthyrotoxinemia
	Other plurihormonal cell	Any	Mixed
Hypopituitarism	Gonadotroph	FSH, LH, subunits	Silent or hypogonadism
	Null cell	None	Pituitary failure from mass effect
	Oncocytoma	None	Pituitary failure from mass effect

drome have acromegaly or gigantism and exhibit loss of heterozygosity at an 11q13 chromosomal locus distinct from that of *menin*.

Anterior Pituitary Hormones and Associated Disorders

PROLACTIN

Synthesis

Lactotrophs comprise about 20% of the anterior pituitary cells. Estrogen causes lactotroph cell hyperplasia, which occurs transiently during pregnancy and lactation. Central inhibitory control of PRL secretion is mediated predominantly by dopamine from the hypothalamus. Physiologic, pharmacologic, or pathologic alterations in dopamine availability or action disrupt PRL regulation. For example, if the hypophyseal-portal system is disrupted by pituitary compression or pituitary stalk damage and the flow of hypothalamic dopamine to the anterior pituitary is compromised, the resulting loss of lactotroph inhibition leads to PRL hypersecretion.[3]

Secretion

Normal serum PRL levels are 10 to 25 µg/L. The PRL level rises approximately 10-fold during pregnancy, as does the estrogen level. The PRL level declines rapidly within 2 weeks after delivery and returns to normal during the subsequent 3 months. Basal levels remain elevated during breastfeeding, and suckling induces a transient (approximately 30 minutes) reflex rise in PRL level.

Actions

PRL induces and maintains puerperal lactation. It also attenuates reproductive function, thus helping to ensure that lactation is not interrupted by pregnancy. In the primed puerperal breast, integration of multihormonal signals—from PRL, placental lactogens, progesterone, and local paracrine growth factors—leads to lactation. PRL also enhances milk production by improving calcium absorption and mobilization.

Hyperprolactinemia

Etiology Hyperprolactinemia has many possible causes; it may be physiologic, pathologic, or iatrogenic in origin [*see Table 4*]. Pregnancy, lactation, nipple stimulation, and chest wall lesions (including surgical incisions and herpes zoster) are associated with hyperprolactinemia. PRL-secreting pituitary adenomas (prolactinomas) produce the highest elevations of serum PRL levels (*see* Prolactinomas, *below*). Medications, compromised pituitary stalk function, hypothyroidism, and renal failure typically produce lesser elevations in PRL level [*see Table 1*]. Hypothalamic dopamine delivery may be disrupted by hypothalamic tumors, cysts, infiltrations, and radiation-induced damage. Plurihormonal tumors commonly hypersecrete PRL, and clinically nonfunctioning pituitary tumors may also compromise stalk integrity and cause hyperprolactinemia.

Table 4 Causes of Hyperprolactinemia[39]

Physiologic hypersecretion	Pregnancy Lactation Chest wall lesions Sleep Stress
Hypothalamic-pituitary damage	Masses Craniopharyngioma Suprasellar pituitary mass extension Rathke cyst Meningioma Dysgerminoma Metastases Granulomas Infiltration Lymphocytic hypophysitis Trauma Pituitary stalk section Suprasellar surgery Cranial irradiation
Pituitary hypersecretion	Prolactinoma Acromegaly Empty sella syndrome
Systemic disorders	Chronic renal failure Hypothyroidism Cirrhosis Epileptic seizures
Drug-induced hypersecretion	Dopamine receptor blockers Phenothiazines (e.g., chlorpromazine, perphenazine) Butyrophenones (e.g., haloperidol) Thioxanthenes Metoclopramide Dopamine synthesis inhibitor α-Methyldopa Catecholamine depletor Reserpine Opiates H_2 antagonists (e.g., cimetidine, ranitidine) Imipramines Amitriptyline, amoxapine Selective serotonin reuptake inhibitors (e.g., fluoxetine) Calcium channel blockers (e.g., verapamil) Hormones Estrogens Antiandrogens

Diagnosis The clinical features of hyperprolactinemia vary by the sex of the patient. In males, PRL attenuates LH secretion, leading to low testosterone levels. Men with hyperprolactinemia present with diminished libido and diminished sexual potency, oligospermia, and lowered ejaculate volume; up to about 30% may have galactorrhea. In women, hyperprolactinemia leads to loss of pulsatile LH secretion, blunting of the LH peak, hypoestrogenism, and anovulation [*see Figure 3*]. Women with hyperprolactinemia develop oligomenorrhea and amenorrhea. Anovulation and estrogen deprivation result in vaginal dryness, dyspareunia, loss of libido, and infertility. Hyperprolactinemia is also associated with enhanced risk of bone loss, which is further exacerbated by associated hypoestrogenemia.

In patients with clinical complaints consistent with hyperprolactinemia, a careful history and physical examination may reveal the source of the problem. Laboratory studies are indicated to exclude hypothyroidism, which can cause hyperprolactin-

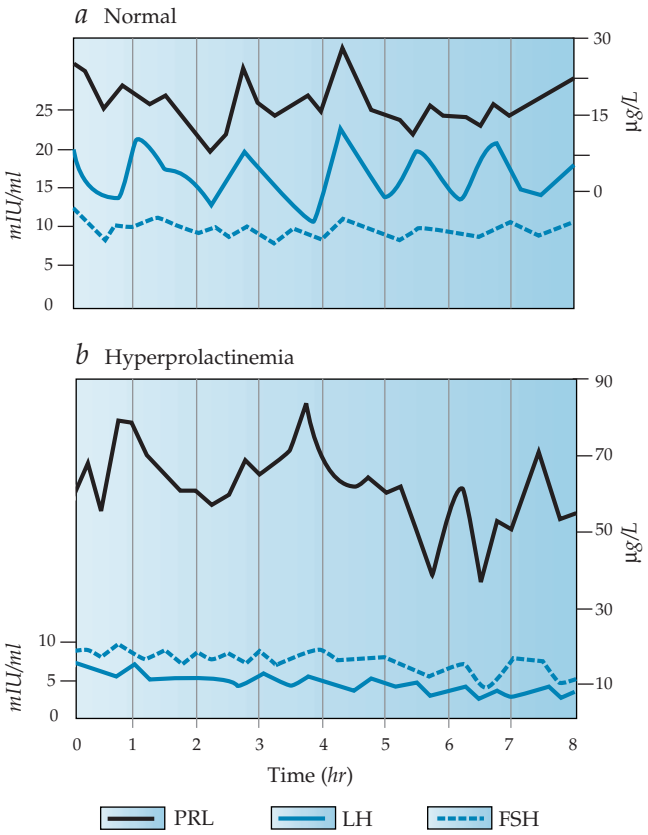

Figure 3 **In women, hyperprolactinemia results in loss of pulsatile luteinizing hormone (LH) secretion and lowering of follicle-stimulating hormone (FSH) levels.[39] (PRL—prolactin)**

emia. Alternatively, hypothyroidism and hyperprolactinemia can result from pituitary disease.

The degree of PRL elevation may offer a clue to the source of the prolactinemia. Prolactinomas account for most elevations of prolactin level higher than 100 µg/L; serum prolactin levels greater than 200 µg/L almost invariably indicate a prolactinoma.

All patients with symptoms of hyperprolactinemia and PRL levels above 30 µg/L should undergo MRI imaging of the pituitary. Small microadenomas (< 2 mm), which are undetectable on MRI scanning, may account for most cases of idiopathic hyperprolactinemia.

Treatment Treatment of hyperprolactinemia is aimed at normalizing PRL levels, alleviating gonadal dysfunction and galactorrhea, and preserving bone mineral density. Medications known to alter PRL levels should be discontinued, if possible. Dose titration of critical neuroleptic drugs with a dopamine agonist can normalize serum PRL levels and alleviate reproductive dysfunction. Hyperprolactinemia usually resolves after thyroid hormone replacement in hypothyroid patients and after renal transplantation in patients with chronic renal failure who are on dialysis. Hypothalamic or nonadenomatous sellar mass lesions should be removed surgically. Spontaneous resolution of hyperprolactinemia occurs in up to 30% of patients, whether or not they have a visible pituitary microadenoma.

Prolactinoma

Prolactinomas arising from lactotrophs are the most common functional pituitary tumors, with an annual incidence of about three per 100,000 population. Microadenomas are less than 1 cm in diameter and do not invade the parasellar region. Macroadenomas are more than 1 cm in diameter, are locally invasive, and may compress vital structures, leading to symptoms such as headaches and visual defects. Microprolactinomas have a female preponderance (20:1). Macroadenomas occur equally in both sexes, although men usually present with larger tumors. Tumor size correlates with PRL concentrations—serum PRL values above 200 µg/L are invariably associated with larger adenomas.

Diagnosis Prolactinoma should be suspected in patients with clinical signs of hyperprolactinemia (see above) and high random PRL levels. Men with prolactinomas tend to have relatively higher PRL levels than do women with prolactinomas. Diagnosis is confirmed by visualizing a pituitary adenoma on MRI.

Treatment Prolactinomas can be treated medically, with cabergoline or bromocriptine [*see Table 5*], or, rarely, surgically.

Cabergoline is a long-acting dopamine agonist that suppresses prolactin for more than 14 days after a single oral dose and shrinks prolactinomas in most patients.[4] The dosage is 0.5 to 1.0 mg twice weekly. Normal serum prolactin levels are achieved in about 80% of patients with microadenomas; normal gonadal function is restored and galactorrhea improves or resolves in 90% of patients. In patients with macroadenomas, cabergoline normalizes prolactin levels and shrinks the tumor in about 70% of cases. Cabergoline may be more effective in patients resistant to bromocriptine. Adverse effects and drug intolerance are less commonly encountered with cabergoline than with bromocriptine.

Bromocriptine mesylate is a D_2 dopamine receptor agonist that normalizes prolactin secretion in up to 70% of patients with microadenomas; it decreases tumor size and restores gonadal function. Prolactin levels normalize in 70% of patients with macroadenomas, and tumor mass shrinkage of 50% or more is achieved in about 50% of patients. Headaches and visual disorders usually improve or resolve within days, and sexual function improves. Therapy is initiated with 0.625 to 1.25 mg given at bedtime with a

Table 5 Dopamine Agonists in the Treatment of Prolactinomas

Treatment Response	*Bromocriptine Patient Response (%)**	*Cabergoline Patient Response (%)†*
Microadenomas		
Prolactin level normalized	70	80
Menses resumed	70	80
Macroadenomas		
Prolactin level normalized	65	70
Menses resumed	85	80
Tumor shrinkage		
≥ 50%	40	25
< 50%	40	55
None	20	20
Visual-field improvement	90	70
Drug intolerance	15	5

*2.5–7.5 mg/day; bromocriptine is preferred for infertility because it is short acting and can be discontinued immediately on pregnancy confirmation.
†0.5–1 mg twice weekly; cabergoline offers better compliance because it is long acting and has fewer gastrointestinal side effects.

snack, and the dosage is gradually increased. Successful control is usually achieved with a daily dose of less than 7.5 mg (i.e., 2.5 mg t.i.d.). About 20% of patients are resistant to the drug.

Side effects of dopamine agonists include transient nausea, vomiting, and postural hypotension with faintness; these symptoms occur in about 25% of patients. Other side effects include reversible constipation, nasal stuffiness, nightmares, and insomnia. For women who cannot tolerate orally administered agonists, intravaginal administration of bromocriptine tablets is often effective.

Indications for surgical resection of prolactinomas include resistance to or intolerance of pharmacologic treatment and the presence of an invasive macroadenoma that causes compromised vision and that fails to rapidly improve with dopamine agonists.[5] Initial attempts at resection lead to normalization of prolactin levels in about 70% of patients with microprolactinomas but only 30% of patients with macroadenomas. Prolactinomas recur in up to 20% of patients within the first year after surgery; long-term recurrence rates for macroadenomas exceed 50%.

Therapeutic goals in patients with prolactinomas include control of hyperprolactinemia; reduction of tumor size; resolution of galactorrhea; and restoration of menses, fertility, or both [*see Figure 4*].[6] Dopamine agonists suppress PRL secretion and synthesis and lactotroph cell proliferation. Patients are monitored with measurement of serum PRL levels, pituitary MRI scans, and visual field examinations. Once controlled, PRL levels can be measured every 6 months and MRI can be performed every 2 years. Medication doses are titrated to the lowest levels required to normalize PRL levels, restore reproductive function, and shrink the tumor mass.

If fertility is not desired, no treatment of microprolactinoma may be needed. Such patients should be monitored through regular serial PRL measurements, pituitary MRI scans, and assessment of bone mineral density. For patients with macroadenomas, visual field testing is performed before initiating dopamine agonists. MRI results and visual fields should be assessed serially until the mass shrinks, and annually thereafter. Reduction in PRL levels invariably precedes radiographically evident tumor shrinkage, and failure to lower PRL levels usually portends lack of tumor shrinkage. Radiotherapy is reserved for the rare patients with aggressive tumors that do not respond to maximally tolerated dopamine agonists or surgery.

Prolactinomas and pregnancy Women with prolactinomas who wish to become pregnant should receive bromocriptine and use barrier methods of contraception until they have had regular menses for 3 months; this will permit accurate conception dating. Contraception may then be discontinued. When pregnancy is confirmed, bromocriptine should be discontinued and PRL levels followed serially. The patient should be carefully monitored for headaches or visual field disturbance. Cabergoline is not approved for restoration of fertility.

During pregnancy, the pituitary swells and there is an increased risk of prolactinoma growth; in particular, up to 30% of macroadenomas may grow during pregnancy. In women harboring macroadenomas, bromocriptine is restarted if visual field defects develop. Although pituitary MRI is considered safe during pregnancy, it is reserved for patients who develop severe headache or documented visual field defects. In the rare cases in which vision is threatened during the third trimester, surgical decompression may be indicated. Bromocriptine can be safely restarted during pregnancy. Comprehensive surveillance data do not indicate an adverse impact on the fetus; nevertheless, this approach should be undertaken cautiously, and only with the patient's informed consent.

GROWTH HORMONE

Synthesis and Secretion

GH is the most abundant anterior pituitary hormone; GH-secreting somatotroph cells constitute about 50% of the pituitary cell population. GH is encoded by five distinct genes situated on chromosome 17q22. The pituitary GH gene gives rise to a circulating form of GH that is 22 kilodaltons in size, and to a less abundant, cleaved 20-kd GH molecule. Placental syncytiotrophoblast cells express a GH variant, as well as chorionic somatotrophin. Somatotroph development and pituitary GH expression are largely determined by the Pit-1 nuclear transcription factor, whose mutations may also account for rare cases of hereditary pituitary failure.

GH secretion is controlled by complex hypothalamic and peripheral factors. Hypothalamic GHRH and somatostatin release-inhibitor factor (SRIF) stimulate and inhibit GH secretion, respectively. Ghrelin is synthesized predominantly in the gastrointestinal tract and stimulates GH secretion by binding to a specific pituitary GH secretagogue receptor.[7] SRIF is also expressed in extrahypothalamic tissues, including the GI tract and the pancreas. SRIF binds to five distinct receptor subtypes (SSTR1 to SSTR5), of which SSTR2 and SSTR5 are expressed on the surface membranes of pituitary cells. Signaling through the SSTR2 and SSTR5 subtypes preferentially suppresses secretion of GH (and also TSH). Insulinlike growth factor–1 (IGF-1), the peripheral target hormone for GH, inhibits GH via negative feedback.

GH secretion occurs in pulsatile peaks, interspersed by periods during which GH may be undetectable.[8] GH secretion peaks during puberty and declines by middle age, in parallel with age-related decline in muscle mass. Mean integrated nocturnal GH levels are at least twice that of daytime levels. GH levels rise within 1 hour after onset of deep sleep, as well as after exercise and trauma. GH secretion is low in the elderly and the obese and is higher in women; GH secretion is enhanced by estrogen replacement therapy. Increased GH pulse frequency and peak amplitudes occur with chronic malnutrition and prolonged fasting. Glucose loading suppresses GH to below 0.7 µg/L in women and below 0.07 µg/L in men. A complex interaction of nutritional factors and hypothalamic appetite-regulating peptides, including leptin, mediate GH secretion. Therefore, random measurements of GH levels do not readily identify adult patients with GH deficiency.[9] Differences in linear growth patterns in males and females may reflect differences in GH pulsatility. Higher GH pulses observed in males, as compared with the relatively continuous GH secretion patterns in females, may determine liver enzyme induction and postreceptor activity levels of GH-signaling molecules.

Actions

Peripheral GH receptors are most abundant in the liver. The extracellular domain of GH receptors is a soluble form—GH binding protein (GHBP)—which circulates in the blood. Binding of GH to its receptor induces intracellular signaling that is mediated by a phosphorylation cascade involving the Janus kinase-signal transducer and activator of transcription (JAK/STAT) pathway.[10]

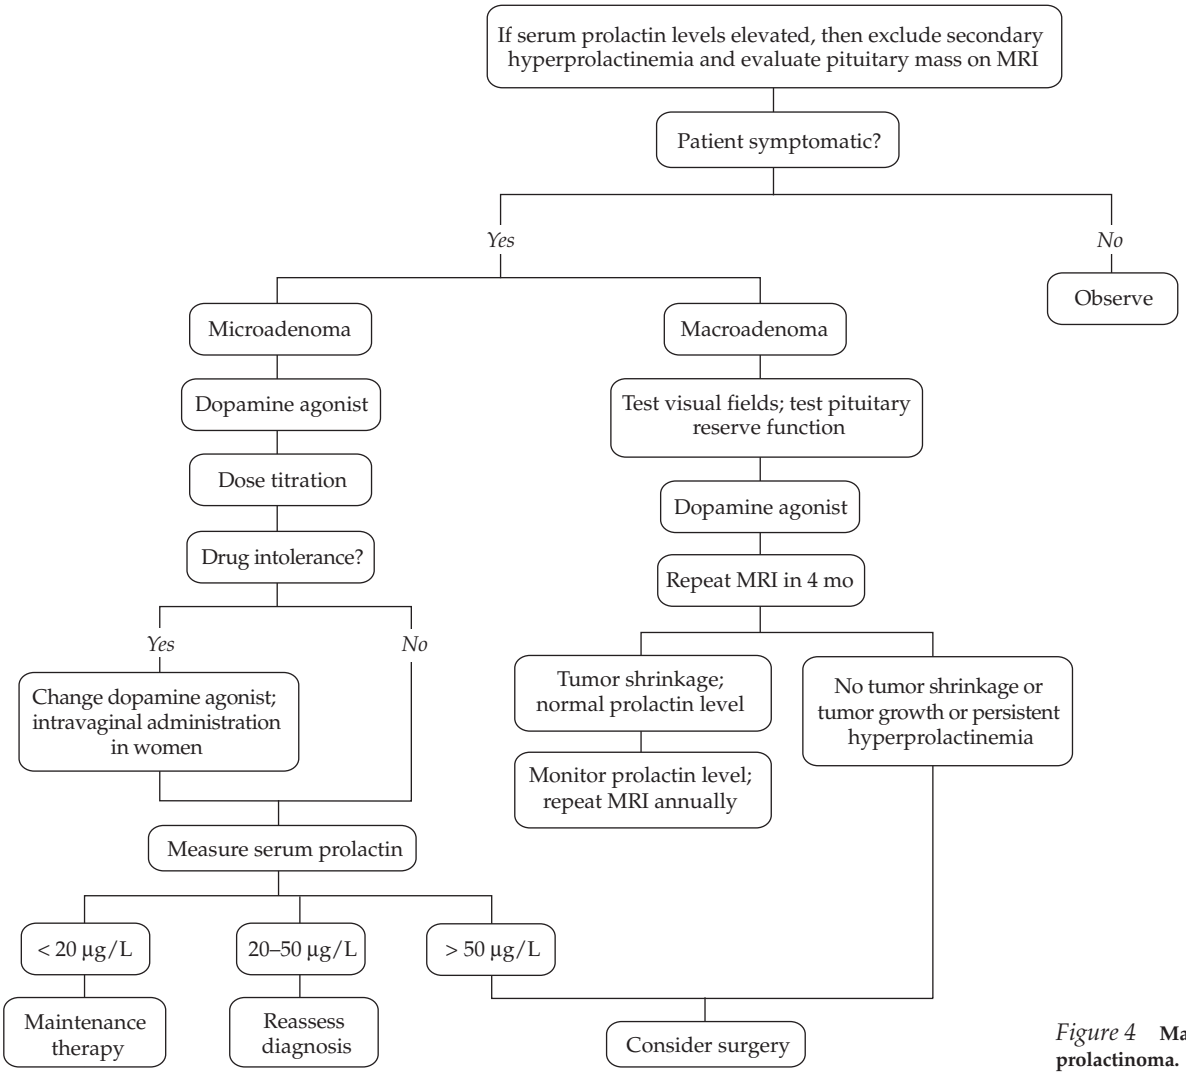

Figure 4 **Management of prolactinoma.**

In children and adolescents, GH stimulates the differentiation of epiphyseal prechondrocytes into IGF-1–responsive cells. GH also induces local IGF-1 and chondrocyte expansion. Linear growth is maintained by complex endocrine and paracrine mechanisms. In persons of all ages, GH antagonizes insulin action, impairs glucose tolerance, induces protein synthesis, enhances lipolysis, and increases lipid oxidation.

Insulinlike growth factors The IGF family of polypeptide growth factors comprises IGF-1, IGF-2, and proinsulin. IGF-1 in peripheral tissue exerts local paracrine actions, which are both GH dependent and independent. GH induces increases in circulating levels and tissue levels of IGF-1. Both IGF-1 and IGF-2 are bound to one of six high-affinity circulating IGF binding proteins (IGFBPs) that also regulate IGF bioactivity. IGFBP3 is GH dependent and is the major carrier protein for circulating IGF-1. GH deficiency, GH insensitivity, and malnutrition are associated with low IGFBP3 levels. Serum IGF-1 levels increase throughout puberty, peak at 16 years of age, and decline thereafter. Concentrations are higher in female subjects, especially during puberty. IGF-1 levels are lower in patients with GH deficiency, cachexia, malnutrition, or sepsis; they are invariably high in patients with acromegaly.

Adult GH Deficiency

Somatotroph damage and the subsequent development of pituitary tropic hormone deficiency follows a sequential pattern in which loss of adequate GH reserve usually foreshadows subsequent deficits of other pituitary hormones. The presence of central hypogonadism, hypothyroidism, or hypoadrenalism invariably implies concomitant GH deficiency. About half of all patients with pituitary insufficiency will already manifest GH deficiency if specifically tested.

Diagnosis Clinically, GH deficiency in adults is marked by impaired quality of life, body composition changes, and decreased exercise capacity [*see Table 6*]. Cardiovascular risk factors increase in patients with GH deficiency; indeed, the increase in mortality associated with adult hypopituitarism, and, possibly, GH deficiency in particular, is primarily from cardiovascular and cerebrovascular disease.[11] Because adult GH deficiency is rare and its symptoms are largely nonspecific, patients should be carefully selected for evaluation on the basis of well-defined risk criteria. These criteria include a history of pituitary surgery; pituitary or hypothalamic mass lesions; cranial irradiation; the need for GH replacement therapy in childhood, or the finding of a low IGF-1 level, as compared to the age- and sex-

Table 6 Findings in Adult Growth Hormone Deficiency[39]

Clinical Manifestations
- Impaired quality of life
  - Decreased energy and drive
  - Poor concentration
  - Low self-esteem
  - Social isolation
- Body-composition changes
  - Increased body fat mass
  - Abdominal fat
  - Increased waist-hip ratio
  - Decreased lean body mass

Imaging Studies
- Pituitary: mass or structural damage
- Bone: reduced density
- Abdomen: excess omental adiposity

Laboratory Tests
- Evoked GH level < 3 ng/ml
- IGF-1 and IGFBP3 levels low or normal
- Lipid disorders
- Concomitant deficits in gonadotropin, TSH, or ACTH reserve

Reduced Exercise Capacity
- Reduced maximum O_2 uptake
- Impaired cardiac function
- Reduced muscle mass

Cardiovascular Risk Factors
- Impaired cardiac structure and function
- Abnormal lipid profile
- Decreased fibrinolytic activity
- Atherosclerosis
- Omental obesity

ACTH—adrenocorticotropic hormone GH—growth hormone
IGF—insulinlike growth factor TSH—thyroid-stimulating hormone

matched population.[12] A subnormal evoked GH response (i.e., < 3 µg/ml) to a standard GH stimulation test establishes the diagnosis of adult GH deficiency. If other pituitary tropic hormone deficits are present, GH deficiency will be an inevitable concomitant finding; for that reason, some experts have recommended that GH testing not be required in this setting.[13] About 25% of GH-deficient adults have normal IGF-1 levels.

Treatment GH replacement is indicated for adult patients with unequivocal GH deficiency.[14] The decision to treat is also determined by informed patient perception of therapeutic benefits, including prevention of future ischemic heart disease and skeletal fractures, improved exercise capacity and energy levels, and enriched quality of life. For replacement therapy, GH is started at a dosage of 0.15 to 0.2 mg/day and titrated to a maximum of 1.25 mg/day, to maintain midrange age- and sex-matched IGF-1 levels. Women require higher GH doses than men, and elderly patients require lower doses.[15]

Contraindications to therapy include the presence of an active neoplasm or both uncontrolled diabetes and retinopathy. The risks of pituitary tumor regrowth are currently being assessed in long-term surveillance studies.

The side effects of GH replacement include reversible dose-related fluid retention, joint pain, and myalgia and parethesia associated with carpal tunnel syndrome. These side effects occur in up to 30% of patients.[16] Patients with type 2 (non–insulin-dependent) diabetes mellitus will initially experience increased insulin resistance. However, glycemic control may improve in association with sustained loss of abdominal fat during long-term GH replacement.

If after 6 months there is no clinical response to GH replacement, treatment should be discontinued. In patients who show a response, GH replacement is continued in conjunction with regular monitoring of IGF-1 levels, lipids, and bone density.

GH is not indicated for adults with intact pituitary function, except for those with AIDS-related cachexia. The hormone should not be used for nonapproved indications, because the risk of side effects—especially glucose intolerance and fluid retention—outweigh potential benefits ascribed to improved muscle energy and anti-aging properties. Results of prospective controlled trials for these potential indications are not yet at hand.

Acromegaly

Etiology GH hypersecretion usually results from a GH-secreting pituitary adenoma [*see Table 7*]. Occasionally, patients with partially empty sella may harbor a small GH-secreting adenoma within the compressed rim of pituitary tissue. Rarely, GH is secreted ectopically by abdominal or chest tumors. GHRH may be elaborated by hypothalamic tumors or carcinoid tumors in the chest or abdomen, causing acromegaly through chronic somatotroph overstimulation.

Diagnosis The manifestations of GH and IGF-1 hypersecretion are protean and develop slowly; they are often not diagnosed for 10 years or more [*see Table 8*]. Acral bony overgrowth results in frontal bossing, increased hand and foot size, and mandibular enlargement with prognathism and a widening of incisor spaces. GH hypersecretion that occurs before epiphyseal long-bone closure causes pituitary gigantism. Soft tissue swelling results in coarse facial features; increased heel pad thickness; and enlargement of the feet and hands, evidenced by increased shoe or glove size and ring tightening. Hyperhidrosis; oily skin; a deepening of the voice; arthropathy; kyphosis; carpal tunnel syndrome; proximal muscle weakness and fatigue; skin tags; and visceromegaly, including macroglossia, cardiomegaly, thyroid, and salivary gland enlargement, may be encountered. About 30% of patients develop coronary artery disease, cardiomyopathy with arrhythmias, left ventricular hypertrophy, decreased diastolic function, or hypertension. Sleep apnea, caused by soft tissue laryngeal airway obstruction or central sleep dysfunction, is an important comorbidity. Diabetes develops in 25% of patients, because GH is a potent insulin an-

Table 7 Causes of Acromegaly

- Excess growth hormone (GH) secretion
  - Pituitary (~98% of cases)
    - GH cell adenoma
    - Mixed GH cell and prolactin cell adenoma
    - Mammosomatotroph cell adenoma
    - Plurihormonal adenoma
    - GH cell carcinoma or metastases
    - Multiple endocrine neoplasia type 1 (GH cell adenoma)
    - McCune-Albright syndrome (rarely, adenoma)
    - Ectopic sphenoid or parapharyngeal sinus pituitary adenoma
  - Extrapituitary tumor (< 1% of cases)
    - Pancreatic islet cell tumor
- Excess GH-releasing hormone secretion
  - Central (< 1% of cases)
    - Hypothalamic hamartoma, choristoma, ganglioneuroma
  - Peripheral (~1% of cases)
    - Bronchial carcinoid
    - Pancreatic islet cell tumor
    - Small cell lung cancer
    - Adrenal adenoma
    - Medullary thyroid carcinoma
    - Pheochromocytoma

Table 8 Features of Acromegaly

Enlarged hands and feet	Profuse sweating/hot
Coarsening of facial features/prognathism	Headache
Bite problems	Carpal tunnel syndrome
Skin tags	Arthritis/arthralgias
Frontal bossing	Hypertension and heart disease
Cystic acne	Sleep apnea and snoring
Colonic polyps	Glucose intolerance
Deepening of voice	Hyperprolactinemia
Oily skin	Visual problems
	Sexual dysfunction

tagonist; most patients with elevated GH levels are intolerant of glucose. Colon polyps are present in up to one third of patients. Overall mortality is enhanced about threefold, primarily as a result of cardiovascular and cerebrovascular disorders and respiratory disease. Unless GH levels are tightly controlled, survival is reduced by an average of 10 years compared with an age-matched control population.

Measurement of serum IGF-1 can be used for case finding in patients with possible acromegaly; in patients with GH hypersecretion, IGF-1 levels are invariably elevated, as compared with the levels in the age- and sex-matched population. Single random GH measurements are not useful for diagnosis. Instead, diagnosis is confirmed by demonstrating a failure to suppress GH levels to below 1 μg/L within 1 to 2 hours after an oral glucose load (75 g); about 20% of patients exhibit a paradoxical glucose-induced rise in GH. PRL levels are elevated in about 25% of patients. Thyroid function studies and assays of gonadotropin and sex steroid levels may show attenuation, which is the result of the compressive effects of an expanding pituitary mass.

Treatment Control of acromegaly can be achieved by a judicious application of multimodal therapeutic approaches.[17,18] Therapeutic interventions include surgery, somatostatin analogues, and dopamine agonists. Transsphenoidal surgical resection by an experienced surgeon is indicated for both microadenomas and macroadenomas. Resection results in control of disease in about 70% of patients with microadenomas but in less than 50% of patients with macroadenomas. GH levels fall rapidly after tumor resection, and IGF-1 levels return to normal within 3 to 4 days. The disorder recurs in about 10% of patients, and pituitary failure develops in up to 15% of patients after surgery. Persistent postoperative GH hypersecretion necessitates adjuvant therapy, typically with somatostatin analogues.

Octreotide acetate is an 8–amino acid synthetic somatostatin analogue that binds mainly to SSTR2 receptors and effectively controls GH hypersecretion.[19] Octreotide is given in a dosage of 50 to 400 μg subcutaneously every 8 hours. Within an hour of receiving an injection, most patients experience an 80% reduction in GH level. About 10% of patients show no response. Rapid relief of headache and soft tissue swelling occurs, with amelioration of excessive perspiration, obstructive apnea, and cardiac failure. Significant pituitary tumor shrinkage occurs in about 40% of patients.[20] A long-acting octreotide formulation, Sandostatin LAR Depot, provides sustained GH suppression, with effects lasting for up to 6 weeks after a 30 mg intramuscular injection. Long-term treatment with monthly injections of 20 to 40 mg maintains GH and IGF-1 suppression in about 70% of patients, and pituitary tumor size is controlled. Because it is effective, and well tolerated and is less inconvenient for the patient than subcutaneous preparations, the long-acting formulation is the medical treatment choice for these patients.[21,22]

Side effects of somatostatin analogues are typically minor and transient; they are mostly related to suppression of GI motility and secretion. Nausea, abdominal discomfort, diarrhea, and flatulence occur in one third of patients but usually remit within 2 weeks. In the United States, up to 30% of patients receiving long-term treatment develop echogenic gallbladder sludge or asymptomatic cholesterol gallstones. Mild glucose intolerance, hypothyroxinemia, asymptomatic bradycardia, and local pain at the injection site have been reported.

Bromocriptine may suppress GH secretion in some patients. High doses (i.e., 20 mg/day or more) are usually required. About 10% of patients receiving bromocriptine have normalized IGF-1 levels. Cabergoline suppresses GH when given at a relatively high dosage (i.e., 0.5 mg/day). Combination treatment with octreotide plus cabergoline offers additive biochemical control compared with either drug alone.

GH antagonists have been developed. These new GH analogues antagonize GH action by blocking peripheral GH receptor binding. Pegvisomant, administered in daily subcutaneous injections, lowers serum IGF-1 levels and so may block the deleterious peripheral effects of GH. GH levels may remain elevated, but the excess hormone is effectively inactive. Long-term monitoring of pituitary adenoma size and liver function testing are suggested. The drug is particularly useful in those patients with persistently elevated IGF-1 levels and controlled GH levels.

External radiation therapy or high-energy radiosurgery suppresses GH levels to below 5 μg/L, although 50% of patients require at least 8 years of therapy for this outcome.[23] Interim medical therapy is required in the years before patients attain maximal radiation benefits. Most patients also develop gonadotropin, ACTH, or TSH deficiency within 10 years of therapy. Rarely, visual deficits, brain necrosis, or new tumor formation are encountered. Stereotactic ablation of GH-secreting adenomas by gamma-knife radiosurgery is promising, but compelling long-term results are not yet available, and long-term side-effect profiles have not been established.

The initial treatment option for well-circumscribed GH-secreting tumors is surgical resection. Somatostatin analogues reduce GH hypersecretion and are used for preoperative shrinkage of large, invasive macroadenomas; for immediate relief of debilitating symptoms in frail patients experiencing morbidity; for patients who decline surgery; and for patients in whom surgery fails to result in biochemical control, as is inevitable in cases of invasive adenoma.[24] Irradiation or repeat surgery is indicated for patients for whom medical therapy fails. The main disadvantages of radiotherapy are the slow rate of biochemical response (i.e., 5 to 15 years) and the high rate of hypopituitarism. Comorbid features of acromegaly, including cardiovascular disease, diabetes, and arthritis, should be aggressively treated. Maxillofacial surgery may be indicated for mandibular repair.

Adrenocorticotropic Hormone Synthesis

Up to 20% of the pituitary consists of ACTH-secreting corticotroph cells. These cells express products of the *POMC* (pro-opiomelanocortin) gene, which include 1-39 ACTH, β-lipotropin, and endorphins. β-Lipotropin gives rise to α-lipotropin and β-endorphin; the latter contains the sequence for met-enkephalin. The *POMC* gene, located on chromosome 2, possesses different promot-

er regions that determine pituitary-specific and peripheral tissue–specific POMC expression, respectively. Ectopic ACTH/POMC transcripts are expressed in gonads, placenta, GI tissues, kidney, adrenal medulla, lung, and lymphocytes; POMC products also arise from peripheral neuroendocrine tumors.

Secretion ACTH synthesis and release are stimulated by CRH. In addition, ACTH release is induced by vasopressin, cytokines, physical stress, exercise, acute illness, and hypoglycemia.

ACTH secretion is pulsatile and follows a circadian rhythm that is highest in early morning and declines at night. This rhythm is paralleled by a diurnal pattern of adrenal glucocorticoid secretion. ACTH levels peak at 6 A.M., with values ranging from 8 to 25 pg/ml; peak values are approximately fourfold higher than the nadir levels measured between 11 P.M. and 3 A.M. Glucocorticoids suppress CRH and ACTH release. The loss of cortisol inhibition that occurs with primary adrenal failure results in extremely high compensatory ACTH levels.

Actions

The hypothalamic-pituitary-adrenal (HPA) axis maintains metabolic homeostasis and mediates the neuroendocrine stress response. The pituitary affects the pattern and quantity of adrenal cortisol secretion by integrating peripheral and central signals. The neuroendocrine stress response reflects the net result of sensitively integrated hypothalamic, intrapituitary, and peripheral hormone and cytokine signals, resulting in cortisol production. The HPA axis is triggered by acute inflammatory or septic insults that mediate release of inflammatory cytokines, bacterial toxins, and neural signals. ACTH stimulates steroidogenesis by maintaining adrenal cell proliferation and function. Cortisol elevation curtails the inflammatory response and provides host protection.

Pro-opiomelanocortin peptides and appetite control Several lines of experimental and clinical evidence implicate the POMC system in appetite control. The melanocortin receptor family comprises important regulators of central appetite control. Inactivation of MC-2 receptors leads to obesity, hypoadrenalism, and red hair pigmentation. Disruption of MC4 receptors is associated with childhood obesity and elevations in the level of circulating leptins; disruption is also genetically linked to the POMC gene locus [*see 3:III Obesity*].

HPA Axis Testing

Insulin-induced hypoglycemia and cortisol levels Intravenous administration of insulin (0.05 to 0.3 U/kg) lowers blood glucose levels to 50% of baseline within 30 minutes. This evokes plasma cortisol increases of 7 mg/dl or greater; peak cortisol levels of at least 20 μg/dl are evoked within 30 to 45 minutes of nadir blood glucose levels and indicate intact pituitary ACTH reserve production.

Metyrapone The pituitary response to a decrease in the serum cortisol level can be assessed with metyrapone testing. A 3 g oral dose of metyrapone administered at 11 P.M. with a snack blocks conversion of the cortisol precursor 11-deoxycortisol (compound S) to cortisol. The resulting fall in serum cortisol level normally stimulates ACTH secretion, raising the compound S level to above 8 μg/dl at 8 A.M. the next morning. Cortisol inhibition by metyrapone can be confirmed by finding that the plasma cortisol level is less than 5 μg/dl.

Synthetic ACTH Injection of synthetic ACTH (Cortrosyn) at a dose of 250 μg intravenously or intramuscularly evokes adrenal cortisol reserve after 30 and 60 minutes. Cortisol levels should rise to at least twice the baseline value, rise at least 7 μg/dl, or peak at above 20 μg/dl; any one of those three reactions indicates normal reserve. Blunted cortisol responses to ACTH reflect compromised pituitary ACTH reserve, primary adrenal failure, or steroid ingestion.

CRH Intravenous CRH, 1 μg/kg, directly stimulates ACTH secretion during the 60 minutes after injection. Pituitary damage prevents an evoked response. Patients with Cushing disease associated with an ACTH-secreting corticotroph cell adenoma often have exaggerated ACTH responses to CRH. CRH injection does not stimulate a further rise in ACTH secretion by ectopic ACTH-secreting tumors.

ACTH Deficiency

Diagnosis Clinically, pituitary ACTH deficiency results in secondary hypocortisolism with tiredness, weakness, anorexia, nausea, and vomiting; occasionally, hypoglycemia results from diminished counterregulation of insulin. Stressful acute illness may unmask the presence of partial ACTH deficiency and cause life-threatening hypocortisolism.

On laboratory testing, ACTH deficiency is characterized by inappropriately low ACTH levels in conjunction with low cortisol levels. Low basal serum cortisol levels or blunted cortisol responses to provocative ACTH stimulation reflect diminished adrenal reserve caused by prolonged insufficient ACTH tropic action on the adrenal cortex.

Treatment Hydrocortisone replacement reverses most clinical and biochemical features of cortisol deficiency. Hydrocortisone is given two or three times daily. The total daily dose should usually not exceed 20 mg. Doses should be increased severalfold during periods of acute illness or stress.

ACTH-Secreting Adenoma (Cushing Disease)

ACTH-producing adenomas account for about 10% to 15% of all pituitary adenomas and are usually well-differentiated microadenomas. Cushing syndrome is also caused by ectopic ACTH production by tumors, including small-cell lung carcinomas and bronchial and thymic carcinoids. In contrast to ACTH secretion by pituitary tumors, which can be suppressed by high-dose glucocorticoids, ectopic ACTH secretion by neoplasms is usually not suppressible, a fact that highlights the unrestrained malignant gene expression.

Diagnosis Unrestrained ACTH secretion causes hypercortisolemia, which results in thin, brittle skin; central obesity; hypertension; plethoric moon facies; purple striae and susceptibility to bruising; glucose intolerance or diabetes; gonadal dysfunction; osteoporosis; proximal muscle weakness; acne; hirsutism; and labile depression, mania, or psychosis [*see Table 9*]. Leukocytosis, lymphopenia, and eosinopenia also may develop. In young women, osteoporosis may be particularly prominent. Cardiovascular disease is the primary cause of death.

The differential diagnosis of ACTH-secreting pituitary tumor includes other causes of hypercortisolism: iatrogenic glucocorticoid administration, ectopic ACTH-secreting tumor, and cortisol-secreting adrenal tumor. In ectopic Cushing syndrome, manifestations usually develop acutely: patients present with

Table 9 Clinical Features of Cushing Syndrome[40]

Symptoms and Signs	*Frequency (%)*
Obesity or weight gain (>115% ideal body weight)	80
Thin skin	80
Moon facies	75
Hypertension	75
Purple skin striae	65
Hirsutism	65
Abnormal glucose tolerance	55
Impotence	55
Menstrual disorders (usually amenorrhea)	60
Proximal muscle weakness	50
Truncal obesity	50
Acne	45
Bruising	45
Mental changes	45
Osteoporosis	40
Edema of lower extremities	30
Hyperpigmentation	20
Hypokalemic alkalosis	15
Diabetes	15

Note: manifestations seen in patients of all ages.

florid skin hyperpigmentation, severe myopathy, hypertension, hypokalemic alkalosis, glucose intolerance, and edema. Serum potassium levels are below 3.3 mmol/L in most patients with ectopic ACTH secretion.

The diagnosis of pituitary Cushing disease requires documentation of hypercortisolism in the presence of pituitary-derived ACTH elevation. Reproducible markers for hypercortisolism include the failure to experience suppression of the cortisol level after a dose of dexamethasone and an elevation in 24-hour urinary free cortisol level. Urinary cortisol levels greater than 300 μg/day indicate the presence of Cushing syndrome. Urinary 17-hydroxysteroid levels reflect secretion of cortisol metabolites.

In general, ACTH-secreting pituitary tumors retain feedback responsiveness to circulating glucocorticoids. Basal ACTH levels are usually about eightfold higher in patients with ectopic ACTH secretion, but considerable overlap with pituitary adenoma–derived ACTH may preclude an accurate biochemical distinction of the two disorders. In patients with endogenous (adrenal) or exogenous (iatrogenic) Cushing syndrome, ACTH levels are suppressed. Elevated concentrations of circulating ACTH and cortisol measured at midnight usually indicate the presence of Cushing syndrome.

Dynamic testing should be undertaken when hypercortisolemia has been rigorously documented.[25] Dexamethasone suppression of ACTH and ultimately of cortisol levels is the standard test for diagnosis of ACTH-dependent Cushing disease. Ingestion of 1 mg oral dexamethasone at 11 P.M. should result in suppression of serum cortisol levels to below 7 μg/dl at 8 A.M. the next morning, unless obesity, chronic depression, or alcoholism is present. In patients with ACTH-secreting pituitary adenomas or ectopic tumors, overnight dexamethasone does not suppress plasma ACTH or serum cortisol levels, and longer-term dexamethasone suppression testing is required. Baseline pretesting of 24-hour urinary free cortisol and 17-ketosteroids or 17-hydroxysteroid values is followed by administration of low-dose dexamethasone (0.5 mg every 6 hours) for 2 days. Plasma ACTH, serum cortisol, and 24-hour urinary free cortisol levels remain elevated in patients with Cushing disease. High-dose dexamethasone (2 mg every 6 hours) for the subsequent 2 days will usually suppress 17-hydroxysteroid levels by 50% or less and suppress urinary free cortisol to less than 90% of baseline in patients with pituitary ACTH-secreting tumors, but this result will be seen in only 10% of those patients with ectopic ACTH secretion.

MRI scanning is indicated for patients with documented hypercortisolemia and nonsuppressed ACTH levels. If a pituitary mass is clearly visible on MRI, transsphenoidal surgical resection should be undertaken after rigorous biochemical confirmation of pituitary-derived ACTH hypersecretion. However, most ACTH-secreting tumors are less than 5 mm in diameter; about half are less than 2 mm in diameter, and so are undetectable even by sensitive MRI. Therefore, MRI has only limited ability to visualize ACTH-secreting pituitary tumors. Bilateral inferior petrosal sinus ACTH sampling before and after CRH administration may distinguish pituitary from ectopic ACTH hypersecretion.[26] Because most ectopic ACTH-secreting tumors are located in the chest or abdomen, imaging studies of those areas are indicated for diagnosis. The diagnosis of ectopic ACTH secretion is ultimately confirmed by four measures: (1) rigorous exclusion of a pituitary lesion; (2) demonstration of an arteriovenous ACTH gradient over the tumor bed; (3) resolution of hypercortisolism with excision of the tumor; and (4) confirmation of *POMC* gene expression in excised tumor tissue.

Adrenal imaging is indicated when suppressed ACTH levels point to an adrenal origin of hypercorticolism. Bilateral adrenal hyperplasia with cortical thickening usually indicates tropic effects of ACTH hypersecretion. Adrenal adenomas causing Cushing syndrome are usually clearly visible, and adrenal carcinomas are larger than adenomas (> 2 cm). The contralateral gland may be normal or atrophic. Adrenal nodularity may occur unilaterally or bilaterally, with approximately 50% of glands appearing normal [*see 3:IV The Adrenal*].

Treatment Selective transsphenoidal resection after careful preoperative localization is the preferred treatment for ACTH-secreting pituitary adenomas.[27] Remission rates are about 80% for microadenomas but less than 50% for the less common ACTH-secreting macroadenomas. After successful surgery, patients may experience a period of compensatory adrenal insufficiency for up to 6 months and may require low-dose cortisol replacement during that time. Within 5 years of the operation, approximately 5% of patients in whom surgery was initially successful will experience biochemical recurrence.

Patients with ACTH hypersecretion that is not controlled by surgery require pituitary irradiation. Cortisol-lowering agents (i.e., mitotane, ketoconozole, or aminoglutethimide) are administered after irradiation to achieve earlier biochemical remission. Rarely, all these measures fail, and bilateral adrenalectomy is required.

FOLLICLE-STIMULATING HORMONE AND LUTEINIZING HORMONE

Synthesis

Gonadotroph cells comprise up to 10% of anterior pituitary cells. The gonadotropins FSH and LH (along with TSH and human chorionic gonadotropin) are glycoprotein hormones comprising a common α and a specific β subunit. Gonadotroph cells exhibit cytoplasmic immunostaining for both FSH and LH β

subunits, as well as for the common α subunit. Primary gonadal failure, resulting from gonadal damage, is associated with hyperplastic gonadotroph cells with accumulation of hormone secretory granules, reflecting loss of negative feedback by peripheral sex steroids.

Hypothalamic gonadotropin-releasing hormone (GnRH) regulates both LH and FSH secretion. GnRH, under positive feedback control by peripheral estrogens, is secreted in a pulsatile fashion every 60 to 120 minutes; it regulates the complex reproductive cycles. Activins also induce gonadotropins, whereas inhibins suppress their secretion.

ACTIONS

Gonadotropins interact with their respective cell surface receptors on the ovary and testis, thereby controlling the development and maturation of germ cells and the synthesis of steroid hormones. In women, LH mediates ovulation and the maintenance of the corpus luteum, and FSH mediates ovarian follicle development and induces ovarian estrogen production. In men, LH induces testosterone secretion by the Leydig cells, and FSH regulates seminiferous tubule development and stimulates spermatogenesis.

Gonadotropin Deficiency

Gonadotropin secretion is sensitive to pituitary damage, and hypogonadism is the most common presenting feature of adult hypopituitarism. Congenital or acquired central hypogonadotropic hypogonadism results from a pituitary or hypothalamic disorder that disrupts GnRH availability. Hypothalamic defects causing hypogonadism include Kallmann syndrome and a mutation in the *DAX-1* gene that is associated with deficient GnRH and pituitary gonadotropin synthesis. Inactivating mutations in the LH and FSH β-subunit gene cause hypogonadism by disrupting gonadotropin formation and function.

Diagnosis Clinical features of hypogonadism depend on the age at onset of the disorder. Primary amenorrhea, immature internal and external genitalia, absent secondary sex characteristics, and eunuchoidal body proportions occur in adolescent girls. In premenopausal women, decreased ovarian function presents as oligomenorrhea or amenorrhea, infertility, decreased vaginal secretions, decreased libido, breast atrophy, and hot flushes [*see 3:III Ovary*]. The onset of hypogonadotropism during male adolescence results in sexual infantilism, with a smooth scrotum and small penis, diminished or absent postpubertal sex drive, absent secondary sexual characteracteristics, central obesity, eunuchoid proportions, delayed epiphyseal closure, and a characteristic high-pitched prepubertal voice. In men, testicular failure is associated with decreased libido and potency, infertility, decreased muscle mass with weakness, attenuated beard and body hair growth, soft testes, and fine facial wrinkles [*see 3:II Testes and Testicular Disorders*]. Prolonged hypogonadism results in osteoporosis in both females and males.

Central hypogonadism is diagnosed by a finding of low-normal or low serum gonadotropin levels and low sex hormone concentrations (testosterone in males, estradiol in females). Male patients have abnormal results on semen analysis. Normal values for circulating FSH and LH in menstruating women are 4 to 20 mIU/ml, depending on the menstrual phase; levels rise considerably with menopause. FSH and LH levels in men are 1 to 12 mIU/ml. Normal total testosterone levels in men are above 280 ng/100 ml; the serum testosterone concentration should be measured at about 8 A.M., when it is at its peak [*see 3:II Testes and Testicular Disorders*]. In women, circulating estradiol levels vary with the menstrual cycle.

Pituitary gonadotropin deficiency can sometimes be confirmed with GnRH stimulation testing. Gonadotrophs are stimulated by intravenous injection of 100 μg GnRH; evoked LH levels peak within 30 minutes, and FSH plateaus during the subsequent 60 minutes. Normal responses vary with the age and sex of the subject and, in women, the menstrual cycle stage. However, a robust gonadotropin response does not necessarily exclude pituitary gonadotroph damage, and the absence of a response does not reliably distinguish pituitary from hypothalamic causes of hypogonadism. In patients with documented central hypogonadism, pituitary MRI and pituitary function testing are required.

Treatment In premenopausal women, estrogen and progesterone replacement therapy results in the maintaining of secondary sexual characteristics and genitourinary tract integrity and prevents osteoporosis. Gonadotropin therapy is used for ovulation induction. Pulsatile GnRH is effective for treating hypothalamic hypogonadism [*see 3:III Ovary*]. In women who exercise vigorously and maintain a low body mass index (e.g., athletes and ballet dancers), caloric replacement may restore menses. In males, testosterone replacement therapy will result in the attaining and maintaining of growth and development of the external genitalia and secondary sexual characteristics, and patients will maintain libido, muscle mass, and bone density [*see 3:II Testes and Testicular Disorders*].

Nonfunctioning Pituitary Adenomas

So-called nonsecreting adenomas arising from gonadotroph cells are the most common pituitary adenomas. Because these adenomas are clinically nonfunctional, they usually produce no distinct hypersecretory syndrome.[28] Some adenomas express gonadotropin α-subunits but not intact FSH or LH molecules, and administration of thyrotropin-releasing hormone (TRH) may inappropriately evoke gonadotropins or subunit secretion. Clinically inactive, asymptomatic pituitary microadenomas are commonly encountered as incidental findings on MRI; these are termed pituitary incidentalomas.

Diagnosis Nonsecreting adenomas may be incidentally discovered on an MRI performed for another indication. Mass effects, including optic chiasm pressure and other neurologic symptoms, are the usual initial presenting symptoms of large tumors. Gradual onset of visual defects with progressive bitemporal field defects, scotoma, or impaired acuity may occur. Compression of surrounding pituitary tissue by an adenoma may disrupt gonadotropin secretion, resulting in hypogonadism. Amenorrhea and infertility occur in women, whereas men present with progressively decreased potency and low testosterone levels. Rarely, excess FSH or LH secretion results in ovarian hyperstimulation or the downregulation of the reproductive axis.

On laboratory testing, circulating gonadotropin α-subunit levels are elevated in about 15% of male patients. TRH administration evokes LH β-subunit levels in most patients of both sexes. The serum prolactin level should be measured: an elevation suggests a prolactinoma; a PRL level below 100 μg/L in a hypogonadal patient harboring a pituitary mass suggests pituitary stalk compression by a nonfunctioning adenoma. In postmenopausal women, physiologic elevations of FSH concentra-

tions may be difficult to distinguish from tumor-derived FSH elevations. Primary ovarian or testicular failure may lead to compensatory gonadotroph cell hyperplasia and uniformly elevated LH and FSH levels.

Treatment Nonfunctioning microadenomas have a benign natural history. They are slow-growing and can safely be followed with annual imaging and visual testing, as long as the patient remains asymptomatic. Nonfunctioning pituitary masses greater than 1 cm in diameter should be resected. These larger masses should be distinguished from nonadenomatous lesions by MRI characteristics and histologic evaluation of resected tissue.[29] After resection, the tissue diagnosis of a clinically nonsecreting gonadotroph adenoma should be confirmed.[30] Visual improvement occurs in 70% of patients with preoperative visual field defects. Hypopituitarism resulting from compression of normal pituitary tissue improves and may resolve completely. Early complications of surgery include diabetes insipidus, inappropriate antidiuretic hormone secretion, or both. Approximately 15% of tumors recur within 5 to 6 years after initially successful surgical resection.[31] Adjuvant pituitary radiotherapy after transsphenoidal surgery has been advocated to prevent future tumor regrowth in patients with residual adenoma tissue.[32]

THYROID-STIMULATING HORMONE

Synthesis

TSH-secreting thyrotroph cells constitute 5% of the anterior pituitary cell population. Hypothalamic TRH stimulates TSH synthesis and secretion. TRH also stimulates lactotroph cells to secrete PRL. Thyroid hormones, dopamine, SRIF, and glucocorticoids suppress TSH and override TRH induction. Thyroid damage, including surgical thyroidectomy, radiation-induced hypothyroidism, chronic thyroiditis, or prolonged goitrogen exposure are associated with reversible thyrotroph hypertrophy and hyperplasia with prominent TSH secretory granules and sellar enlargement. Thyrotroph cells regress with thyroid hormone treatment and hormone-mediated TSH suppression.

TSH Deficiency

Hypothyroidism from TSH deficiency has the same clinical features as primary hypothyroidism [*see 3:I Thyroid*]. On thyroid function testing, however, patients with pituitary hypothyroidism have low levels of both TSH and thyroxine (T_4). Patients with hypothyroidism of hypothalamic origin have normal, low, or slightly elevated TSH levels and low T_4 values.

Testing of TSH reserve is used to confirm the diagnosis of central hypothyroidism. Twofold to threefold increases in TSH levels occur within 30 minutes of an intravenous injection of TRH (200 μg) in normal patients. Primary hypothyroidism is associated with an exaggerated TSH response to TRH because of release of the thyrotroph from negative feedback inhibition. Hyperthyroidism, exogenously administered thyroid hormone, and pituitary damage result in blunted TSH responses to TRH.

Thyrotropin-Secreting Adenomas

TSH-producing pituitary adenomas are very rare. Patients with these tumors usually present with a goiter and mild or frank hyperthyroidism.[33] The diagnosis is made by demonstrating elevated serum T_4 levels, inappropriately high TSH or α-subunit secretion, and evidence of a pituitary adenoma on MRI. These tumors are usually large and locally invasive. Administration of thyroid hormone fails to suppress TSH secretion, wheras administration of TRH evokes a blunted TSH response. In such cases, it is important to exclude thyroid hormone resistance, which can produce abnormalities in TSH and T_4 levels identical to those seen with TSH-producing adenomas.

Treatment TSH-producing pituitary adenomas are debulked surgically. Total resection is often not achieved because most of these tumors are large and locally invasive. Postoperative treatment with a somatostatin analogue controls residual TSH and α-subunit hypersecretion, shrinks the tumor mass in approximately 50% of patients, and improves visual fields in about 75% of patients.

Posterior Pituitary Hormones and Associated Disorders

Vasopressin and oxytocin are stored in the posterior pituitary and released in response to appropriate stimuli. Serum vasopressin levels (and, thus, urinary concentrations) vary in response to changes in serum osmolality. The sensitivity and, to a lesser extent, the threshold of vasopressin response to a change in tonicity show considerable variability from one person to another; at least part of this variation is hereditary. Chronic heart failure lowers the osmotic threshold for vasopressin release, whereas aging and other factors reduce sensitivity of vasopressin release (i.e., the rate of vasopressin release per unit change in osmolality). Shifts in blood volume and pressure of greater than 10% affect vasopressin release significantly. Hypotension and hypovolemia stimulate vasopressin release by lowering the osmotic threshold; hypertension and hypervolemia inhibit release by raising the threshold. These influences are mediated by baroreceptor pathways that have left atrial afferents.

Nausea, but not vomiting, is a powerful stimulus to vasopressin release; it raises the serum vasopressin up to 1,000 times the level required for maximal antidiuresis. Pain, however, is not an important stimulant of vasopressin release. Many neural pathways influence vasopressin release in response to nonosmotic stimuli. In general, alpha-adrenergic pathways stimulate and beta-adrenergic pathways inhibit vasopressin release.

The principal disorders of vasopressin secretion consist of partial or complete deficiency (diabetes insipidus) and the syndrome of inappropriate antidiuretic hormone (SIADH) excess [*see 10:I Renal Function and Disorders of Water and Sodium Balance*].

DIABETES INSIPIDUS

Polyuria is a common clinical problem. A patient passing large quantities of urine generally has one of three abnormalities: an osmotic diuresis (e.g., from glycosuria), resistance to vasopressin, or deficient vasopressin secretion. Resistance to vasopressin (i.e., nephrogenic diabetes insipidus) is discussed elsewhere [*see 10:I Renal Function and Disorders of Water and Sodium Balance*]. Deficiency of vasopressin (i.e., neurogenic diabetes insipidus) reflects either functional or structural disease of the supraoptic hypothalamic neurons that secrete the hormone. Brain tumors, craniopharyngiomas, metastatic cancer, hypothalamic-pituitary surgery or trauma, pituitary stalk damage, histiocytosis, and lymphocytic hypophysitis account for most cases. Rare familial polyuric syndromes may also present as hypothalamic diabetes insipidus.

Diagnosis

Two clinical clues suggest vasopressin deficiency: sudden

onset of polyuria and a preference for iced beverages. However, neurogenic diabetes insipidus must be distinguished from primary polydipsia, because overdrinking also results in polyuria and suppressed vasopressin secretion.

Neurogenic and nephrogenic diabetes insipidus can usually be differentiated by means of clinical testing. After confirmation that the blood glucose level is normal, the patient is deprived of water until 3% to 5% of body weight is lost and the serum tonicity is higher than 295 mOsm/kg. If polyuria disappears and the urine concentration rises above 500 mOsm/kg, vasopressin secretion is adequate. If polyuria and dilute urine (< 300 mOsm/kg) persist, then 20 mg desmopressin acetate (DDAVP), a synthetic vasopressin analogue, is given intranasally; alternatively, 300 μU of DDAVP can be administered intravenously. If urine flow decreases and urine concentration rises, vasopressin deficiency can be inferred. If, however, the serum becomes concentrated and the urine remains dilute despite administration of DDAVP, the patient has nephrogenic diabetes insipidus.

Some cautions should be kept in mind when conducting dehydration tests. First, the term partial diabetes insipidus describes a patient who, when deprived of water, achieves a urine concentration greater than the serum osmolality but less than that obtained after administration of vasopressin. Functional testing can be misleading in patients with neurogenic or nephrogenic partial diabetes insipidus. In such patients, who have a urine concentration between 300 and 500 mOsm/kg, measurement of the serum vasopressin level can be extremely helpful. A high vasopressin level in the presence of concentrated serum and relatively dilute urine points to nephrogenic diabetes insipidus; a low value points to hormone deficiency. Conversely, partial resistance to vasopressin can result from chronic overdrinking, with secondary dilution of the medullary concentration in the kidney. If such patients control their excess water intake, they recover a normal renal medullary concentration and, at the same rate, a normal response to vasopressin. Finally, water deprivation appears to produce less thirst in older men than in younger men. Men older than 80 years must be watched carefully after testing to ensure that they resume appropriate water intake.

Granulomas, trauma, infection, and other infiltrations can all produce diabetes insipidus. Metastatic tumor seldom produces insufficiency in other endocrine glands, but secondary tumors arising from lung, breast, and other organs can all produce insufficiency in the posterior pituitary. The sensitivity of MRI has considerably refined the approach to the diagnosis of diabetes insipidus.

Diabetes insipidus can develop suddenly after neurosurgery or external trauma. Cases that develop after neurosurgery may be marked by a triphasic sequence of vasopressin deficiency, vasopressin excess, and vasopressin deficiency. In postoperative or posttraumatic diabetes insipidus, a dilute polyuria with a serum sodium level greater than 145 mEq/L allows a presumptive diagnosis, and parenteral DDAVP should be given immediately. Conversely, hyponatremia from increased vasopressin secretion after transsphenoidal surgery should also be anticipated by following serum sodium levels. Explosive and fatal central diabetes mellitus and diabetes insipidus have been reported in young women with postoperative hyponatremia that was not aggressively treated. The pathogenesis of the disorder is not understood, but the pathologic sequence included cerebral edema and herniation, compression of the third cranial nerve, hypoxic infarction of the pituitary and hypothalamus, respiratory arrest, and coma. The rapidity of deterioration in these patients indicates that the hyponatremia in such cases should be promptly corrected, even though fixed pupillary dilatation, secondary to compression of the oculomotor nerve, may suggest brain death.

Treatment

There are several approaches to the treatment of diabetes insipidus. If the polyuria is mild and does not interfere with sleep, no treatment may be needed. Chlorpropamide potentiates the effect of vasopressin on renal concentrating ability and can be used to treat partial diabetes insipidus. It is given in a dosage of 250 to 375 mg once a day and usually does not produce hypoglycemia in normal persons. However, if patients do not eat regularly or if they have unsuspected anterior pituitary insufficiency, chlorpropamide can be hazardous.

For patients with severe diabetes insipidus, intranasal or oral DDAVP provides excellent control of polyuria and polydipsia. Intranasal DDAVP is effective, nontoxic, and nonirritating. Tablets of DDAVP are given in a dose of 0.1 or 0.2 mg, taken one to three times daily. All patients with diabetes insipidus should be warned that in circumstances of extreme water loss or unconsciousness, they are exposed to added risk unless they are under the care of a physician who is aware of the diagnosis.

Pituitary Failure

Attenuated pituitary secretory reserve can develop as a result of impingement and compression of an expanding mass on adjacent functioning pituitary cells or because of acquired or inherited pituitary cell damage.[34] Tropic hormone failure associated with pituitary compression or destruction usually occurs sequentially, with GH; then FSH, LH, and TSH; and finally ACTH. In childhood, growth retardation is often the presenting feature; in adults, hypogonadism is the earliest symptom. Pressure effects may impair synthesis or secretion of hypothalamic hormones, with pituitary failure [*see Table 10*].

DEVELOPMENTAL PITUITARY DYSFUNCTION

Developmental pituitary dysfunction occurs with aplastic, hypoplastic, or ectopic pituitary gland development. Midline craniofacial disorders may be associated with structural pituitary dysplasia. Birth trauma—including cranial hemorrhage, asphyxia, and breech delivery—can cause acquired pituitary failure in the newborn.

Transcription Factor Mutations

Tissue-specific transcription factors, including Pit-1 and PROP-1, determine tissue-specific development and expression of pituitary hormones and are critical for maintaining anterior pituitary cell function. Hereditary transcription factor mutations may result in disruption of pituitary function, which may manifest during infancy, childhood, puberty, or early adulthood. Autosomal dominant or recessive Pit-1 mutations result in combined deficiency of GH, PRL, and TSH. Pituitary imaging may reveal a normal or hypoplastic gland. PROP-1 is an early transcription factor that appears to be necessary for Pit-1 function. PROP-1 mutations result in combined deficiency of GH, TSH, gonadotropins, and sometimes ACTH. Most afflicted patients have growth retardation and do not enter puberty spontaneously. By adulthood, most patients are deficient in TSH and gonadotropins, and some have an enlarged pituitary gland. *T-Pit* mutations result in isolated ACTH deficiency.

Dysgenesis of the septum pellucidum or corpus callosum

Table 10 Causes of Pituitary Failure[39]

Development/ structural	Transcription factor defect Pituitary dysplasia/aplasia Congenital central nervous system masses, encephalocele Primary empty sella Congenital hypothalamic disorders (e.g., septo-optic dysplasia, Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, Kallmann syndrome)
Traumatic	Surgical resection Radiation damage Accidental
Neoplastic	Pituitary adenoma Parasellar mass (meningioma, germinoma, ependymoma, glioma) Rathke cyst Craniopharyngioma Hypothalamic hamartoma, gangliocytoma Pituitary metastases Lymphoma and leukemia Meningioma
Infiltrative/ inflammatory	Lymphocytic hypophysitis Sarcoidosis Histiocytosis X Hemochromatosis Granulomatous hypophysitis
Vascular	Pituitary apoplexy Pregnancy-related infarction Sickle cell disease Arteritis
Infections	Fungal (histoplasmosis) Parasitic (toxoplasmosis) Tuberculosis *Pneumocystis carinii*

may lead to hypothalamic dysfunction and hypopituitarism, with manifestations that include diabetes insipidus, GH deficiency, and, occasionally, TSH deficiency. Affected children harbor a mutation in the *HESX-1* gene. Clinical features include cleft palate, syndactyly, ear deformities, and hypertelorism.

ACQUIRED PITUITARY FAILURE

Rarely, infiltration of the hypothalamus by diseases such as sarcoidosis, histiocytosis X, amyloidosis, or hemochromatosis may disrupt hypothalamic and pituitary function.[35] This hypothalamic infiltration may result in diabetes insipidus and, if GH attenuation occurs before pubertal bone closure, in growth retardation. Hypogonadotropic hypogonadism and, rarely, hyperprolactinemia occur with disrupted gonadotropin secretion. Pituitary damage may be directly caused by accidental or neurosurgical trauma; pituitary or hypothalamic neoplasms, including pituitary adenomas, craniopharyngioma, Rathke cysts, chordomas, or metastatic deposits; inflammatory disease, such as lymphocytic hypophysitis; or pituitary irradiation. Tuberculosis, opportunistic fungal infections associated with HIV infection, and tertiary syphilis may destroy pituitary tissue.

Cranial Irradiation

Cranial irradiation results in long-term compromise of hypothalamic and pituitary function. Children and adolescents who have undergone therapeutic irradiation of the brain or head and neck are at especially high risk. The resulting hormonal abnormalities correlate strongly with radiation dosage, as well as the time elapsed since completion of radiotherapy. By 10 to 15 years after therapy, GH deficiency invariably occurs, whereas central hypogonadism and ACTH deficiency less commonly occur. Anterior pituitary function should be tested in previously irradiated patients, and replacement therapy instituted when required.

Lymphocytic Hypophysitis

Lymphocytic hypophysitis usually occurs in pregnant or postpartum women. It presents as hyperprolactinemia and a pituitary mass resembling an adenoma on MRI; PRL levels are often mildly elevated.[36] Transient pituitary failure and symptoms of progressive sellar compression, such as headache and visual disturbance, may occur, and the erythrocyte sedimentation rate may be elevated. Because its appearance on MRI may be indistinguishable from that of a pituitary adenoma, lymphocytic hypophysitis should be excluded in a postpartum woman with a newly diagnosed pituitary mass. Pituitary surgery is unnecessary in such cases: glucocorticoid treatment usually restores pituitary function within 6 months, and the mass invariably resolves.

Pituitary Apoplexy

Acute intrapituitary hemorrhage may result in catastrophic vascular compression of parasellar structures.[37] Hemorrhage may occur in a preexisting adenoma, often in association with diabetes or hypertension, or in the postpartum period (Sheehan syndrome). During pregnancy, swelling of the pituitary increases the risk of intrapituitary hemorrhage and infarction. Hypoglycemia, hypotension, shock, apoplexy, and death may follow. Severe headache with signs of meningeal irritation, visual loss, dynamically changing ophthalmoplegia, cardiovascular collapse, and loss of consciousness portend acutely progressive intrasellar bleeding. Pituitary imaging may reveal signs of intratumoral or sellar hemorrhage, with deviation of vital structures, including compression of noninvolved pituitary tissue. If vision is intact and consciousness is unimpaired, patients can be treated conservatively with observation and high-dose steroid infusions. Visual loss or decreased consciousness is an indication for urgent surgical decompression. Subsequent pituitary hormone replacement will be required for the inevitable pituitary damage.

Empty Sella Syndrome

Clinically silent pituitary mass infarction may result in development of a partially or totally empty sella. CSF fills the dural herniation. Pituitary function often remains intact, because the surrounding tissue is fully functional. Hypopituitarism may develop insidiously, however. A partially or apparently totally empty sella is usually an incidental MRI finding. Rarely, small functional pituitary adenomas may arise within the rim.

DIAGNOSIS

Pituitary failure is characterized by the clinical impact of single or multiple tropic hormone loss. Growth disorders and abnormal body composition result from GH loss in children and adults, respectively; menstrual disorders and infertility in women and decreased sexual function, infertility, and loss of secondary sexual characteristics in men are caused by gonadotropin deficits; hypothyroidism is caused by TSH loss; hypocortisolism with hypoglycemia is caused by ACTH loss; and failed lactation is caused by PRL loss. Polyuria and poly-

Table 11 Replacement Therapy for Hypopituitarism in Adults

Tropic Hormone Deficit	*Hormone Replacement*
ACTH	Hydrocortisone, 10–15 mg q. A.M., 5 mg q. P.M. Cortisone acetate, 25 mg q. A.M., 12.5 mg q. P.M.
TSH	Levothyroxine, 0.075–0.15 mg daily
FSH/LH	Males Testosterone enanthate, 200 mg I.M. q. 2 wk Testosterone skin patch, 5–7.5 mg/day Females Conjugated estrogen, 0.65–1.25 mg daily for 25 days Ethinyl estradiol, 0.02–0.05 mg Progesterone on days 16–25 to facilitate uterine shedding Estradiol skin patch, 4–8 mg, twice weekly
GH	Somatotropin, 0.15–1.0 mg S.C. daily
Vasopressin	Desmopressin Intranasal: 5–20 μg, b.i.d. Oral: 300–600 μg, q.d.

Note: Doses should be individualized and should be reassessed during stress, surgery, or pregnancy. Treatment for infertility (gonadotropins or gonadotropin-releasing hormone) should be individualized.
ACTH—adrenocorticotropic hormone FSH—follicle-stimulating hormone GH—growth hormone LH—luteinizing hormone TSH—thyroid-stimulating hormone

dipsia reflect loss of ADH secretion. These features may occur selectively or may be sequential and ultimately result in panhypopituitarism. Enhanced mortality in patients with long-standing pituitary damage is caused mainly by increased cardiovascular and cerebrovascular disease.[38]

On laboratory tests, patients with pituitary insufficiency demonstrate lack of normal hormonal feedback responses, with low tropic hormone levels in conjunction with low target hormone concentrations. Provocative tests confirm lack of pituitary hormone reserve.

TREATMENT

Replacement of pituitary hormones or their respective target hormones usually results in clinical homeostasis with few side effects [*see Table 11*]. Hormone replacement therapy for pituitary failure includes glucocorticoids, thyroid hormone, sex steroids, GH, and vasopressin. Rational replacement regimens ensure a normal and safe quality of life. Patients receiving glucocorticoid replacement require dose increases during stressful events, including dental procedures, trauma, and hospitalizations for acute illness.

The author has received research support and been a scientific consultant for Eli Lilly and Co. and Novartis Pharmaceuticals Corp. for the past 12 months.

VI DISEASES OF CALCIUM METABOLISM AND METABOLIC BONE DISEASE

ELIZABETH H. HOLT, M.D., PH.D.
SILVIO E. INZUCCHI, M.D.

Calcium Metabolism

The precise regulation of body calcium stores and of the calcium concentration in both extracellular and intracellular compartments is critically important, for the following reasons: calcium is the chief mineral component of the skeleton; calcium serves major roles in neurologic transmission, muscle contraction, and blood coagulation; and it is a ubiquitous intracellular signal. A typical laboratory range for serum calcium concentration is between 8.8 and 10.5 mg/dl; 50% to 60% of the calcium in the blood is bound to plasma proteins or is complexed with citrate and phosphate. The remaining ionized (free) calcium controls physiologic actions. The body regulates not only ionized calcium concentrations but also the entry and exit of calcium into its main storage site, bone, through the activity of parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D_3 (1,25-$(OH)_2D_3$) [*see Figure 1*]. PTH, secreted by the parathyroid glands, is an 84–amino acid peptide with a very short plasma half-life (2 to 4 minutes). Cholecalciferol (vitamin D_3) is generated by the skin, upon exposure to ultraviolet light; it is also supplied by dietary sources (chiefly fortified liquid milk products). In the liver, vitamin D_3 is hydroxylated to 25-$(OH)D_3$, which is in turn hydroxylated in the kidney to 1,25-$(OH)_2D_3$ (calcitriol), markedly increasing its potency. In concert, this hormonal system expresses its action at the level of the gastrointestinal tract, bone, and the kidney and maintains circulating ionized calcium concentrations under extremely tight control (variation < 0.1 mg/dl), despite significant variations in calcium supply.

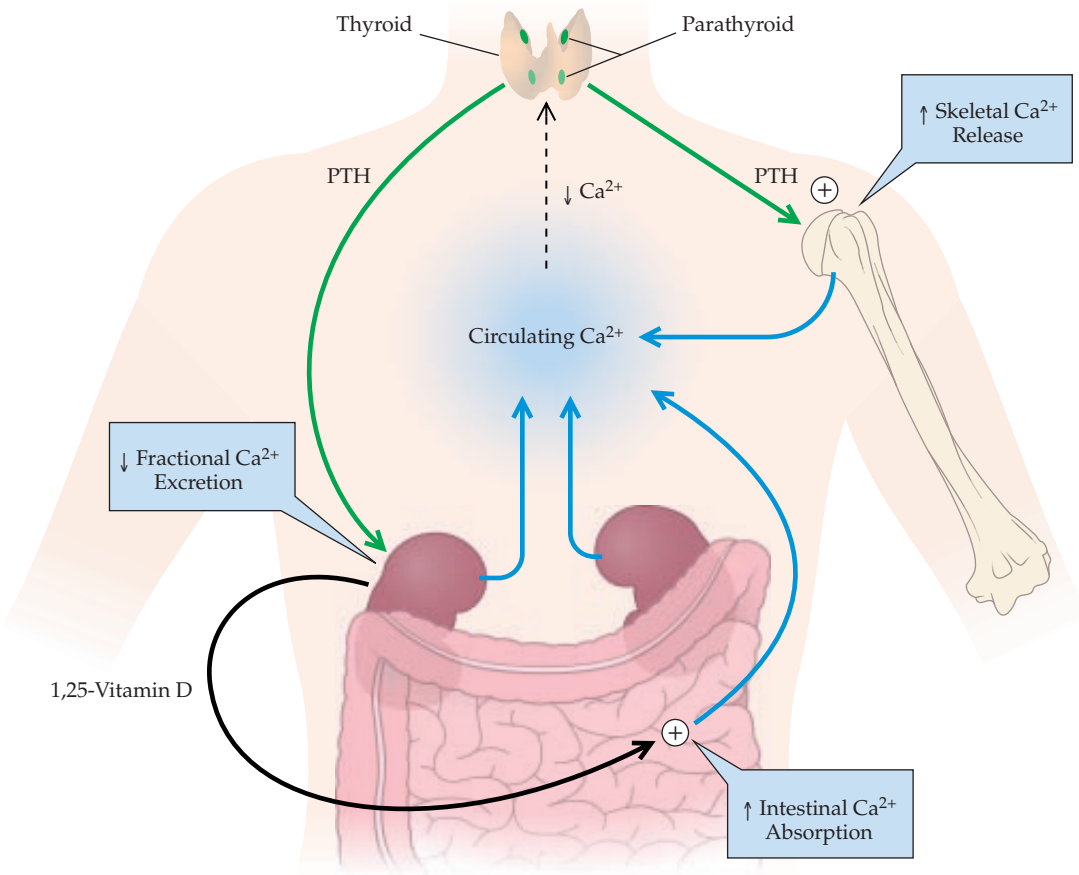

Figure 1 **Circulating concentrations of ionized calcium are maintained under extremely tight control by parathyroid hormone (PTH) and the vitamin D axis. Absorption of dietary calcium by the gastrointestinal tract, reduction of calcium excretion by the kidneys, and release of stored calcium from bones serve as sources for circulating calcium. Decreases in circulating calcium trigger the release of PTH, which promotes release of calcium into the extracellular space by increasing bone resorption; the release of PTH also causes an increase in calcium reabsorption in the distal nephron, resulting in a decrease in urinary calcium loss. PTH also augments renal production of 1,25-dihydroxyvitamin D, which secondarily increases calcium absorption in the gut.**

Under normal conditions, despite ranges in dietary calcium consumption that can vary from 400 to 2,000 mg daily, net calcium absorption from the GI tract averages about 150 to 200 mg/day. In steady state, this equals the amount of calcium excreted by the kidneys. Ongoing remodeling of bone results in the consumption and release of approximately 500 mg of calcium a day. Through humoral regulation, this calcium reservoir can be exploited to maintain extracellular calcium levels in a narrow range despite increased physiologic need or decreased intake, such as results from severe curtailment of the dietary calcium supply or from impairment of intestinal calcium absorption.

Changes in the extracellular ionized calcium concentration are registered by parathyroid cells via the cell surface calcium-sensing receptor (CaSR).[1] Interaction of calcium ions with the extracellular domain of the CaSR triggers a series of intracellular signaling events, which ultimately govern PTH secretion. As circulating concentrations of calcium fall, PTH secretion rises, and vice versa.

PTH increases bone resorption and distal nephron calcium reabsorption, the former promoting calcium release into the extracellular space and the latter decreasing urinary calcium losses. PTH also augments renal production of calcitriol, which then increases fractional calcium absorption in the gut. If calcium intake increases beyond the body's needs, PTH secretion decreases, leading to decreased calcitriol production and decreased calcium absorption by the gut. If calcium is absorbed in excess of requirements, it will be promptly excreted. In this elegant manner, circulating ionized calcium concentration is guarded closely, albeit sometimes at the expense of skeletal calcium stores. Disturbances of PTH, vitamin D action, or both are most often manifested by altered serum calcium or phosphate concentration and by abnormal bone turnover. In some cases, bone mineral density (BMD) is decreased.

Measurement of Calcium

Diagnosis of a calcium disorder depends first on accurate measurement of serum or ionized calcium or both. Serum measurements are usually performed by spectrophotometry or by atomic absorption spectrophotometry, which yields more accurate measurements. Spurious readings may occur with tourniquet stasis (i.e., if the tourniquet is in place too long before the

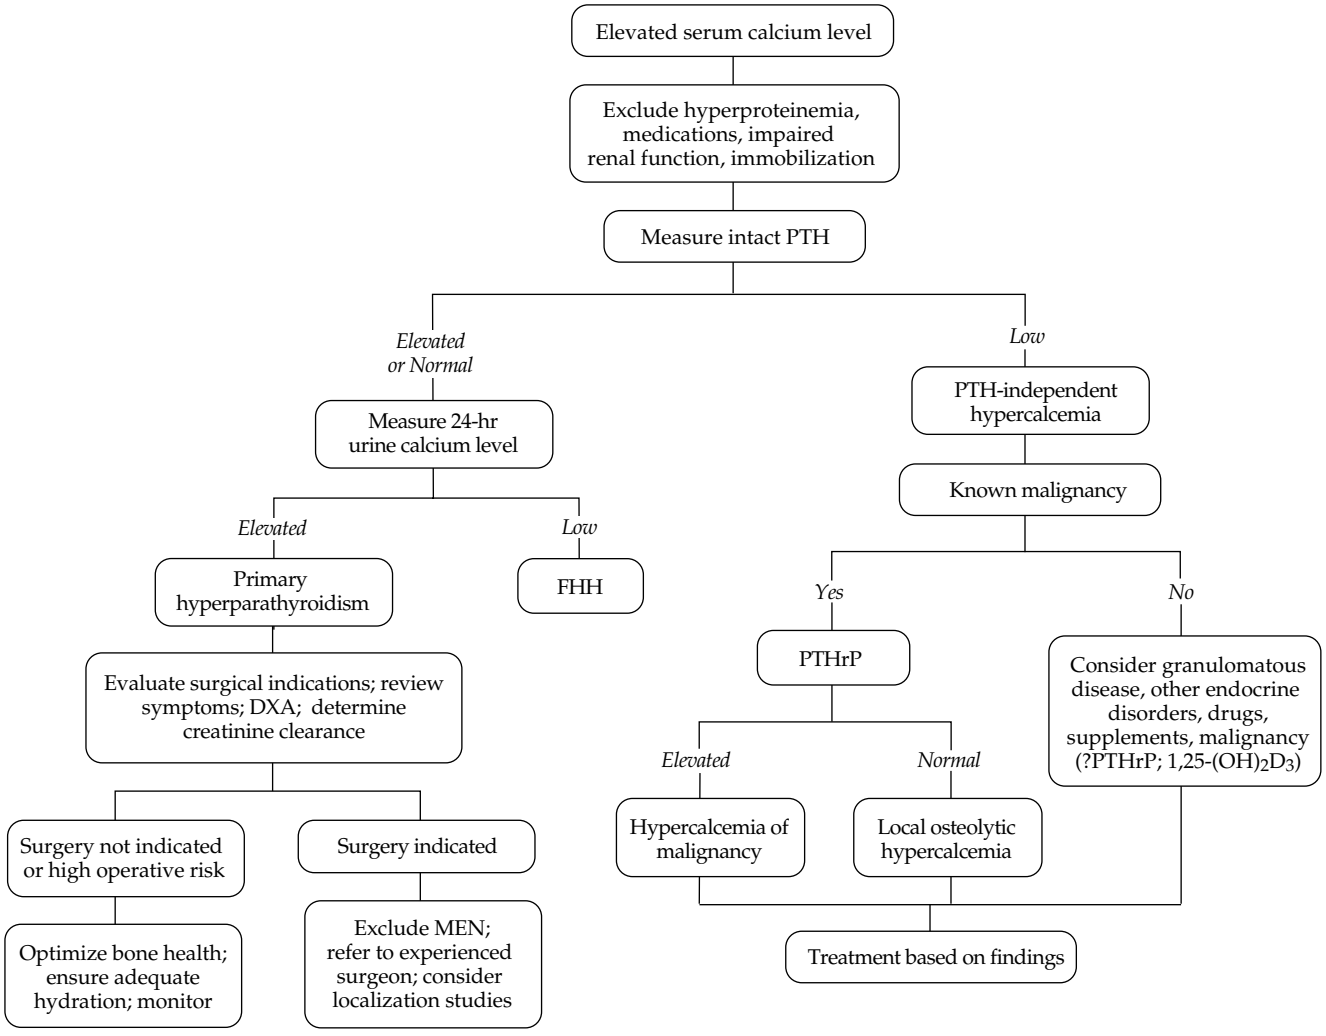

Figure 2 **Evaluation and management of hypercalcemia. (DXA—dual-energy x-ray absorptiometry; FHH—familial hypocalciuric hypercalcemia; MEN—multiple endocrine neoplasia; PTH—parathyroid hormone; PTHrP— parathyroid hormone–related protein)**

Table 1 Differential Diagnosis of Hypercalcemia

blood is drawn), which can elevate serum calcium values by up to 1 mg/dl. Dilution of blood by drawing samples from indwelling intravenous catheters is a common error that leads to spuriously low calcium readings. Ionized calcium measurements should be considered accurate only when performed on samples collected anaerobically (i.e., in a blood gas syringe) and placed on ice, with immediate analysis.

Hypercalcemia

Hypercalcemia is a common metabolic abnormality. Signs and symptoms of hypercalcemia vary significantly from patient to patient and correlate somewhat with the degree of calcium elevation and its rate of change. The diagnostic workup of hypercalcemia is straightforward [*see Figure 2*].[2] The etiology of hypercalcemia is usually discovered after a comprehensive history, physical examination, focused laboratory assessment, and, occasionally, diagnostic imaging studies.[3]

CLINICAL MANIFESTATIONS

Most patients with mild hypercalcemia (serum calcium level < 11 mg/dl) are asymptomatic, although some may experience mild fatigue, vague changes in cognitive function, depression, or polyuria and polydipsia (from decreased urine concentrating ability caused by a high calcium level). Those with moderate hypercalcemia (serum calcium levels of 11 to 14 mg/dl) are more likely to be symptomatic. The likelihood of classic manifestations of hypercalcemia increases sharply when calcium levels rise to 12 to 14 mg/dl. These symptoms include anorexia, nausea, vomiting, abdominal pain, constipation, muscle weakness, and altered mental status. Severe hypercalcemia (i.e., serum calcium levels greater than 14 mg/dl) may cause progressive lethargy, disorientation, and even coma.

In addition to the degree of elevation, the rate of increase in serum calcium may influence the clinical picture. Chronically hypercalcemic patients can function and feel reasonably well with serum calcium values even as high as 15 to 16 mg/dl. In contrast, patients whose calcium level has risen abruptly will often experience symptoms at lesser calcium elevations. Elderly or debilitated patients are also more likely to be symptomatic.

HISTORY AND PHYSICAL EXAMINATION

The history and physical examination are directed at uncovering signs or symptoms of hypercalcemia, as well as signs of the most common causes of hypercalcemia: hyperparathyroidism, malignancy, granulomatous diseases, and certain endocrinopathies. Evidence of any related condition, such as osteoporosis or urinary tract stones, should also be sought. The medical record should be reviewed to determine the duration of the hypercalcemia. The most common cause of hypercalcemia, primary hyperparathyroidism, presents as stable or gradually progressive elevation of the serum calcium level over a period of years. In contrast, malignancy typically causes a more acute rise in serum calcium. All recent medications, foods, and nutritional supplements should be thoroughly reviewed for possible culprits. A careful family history should be performed to identify disorders of calcium metabolism; renal stones; fragility fractures; and any related endocrinopathies, such as diseases of the pituitary, adrenal, thyroid, or endocrine pancreas.

Aside from mental status deficits and signs of dehydration, physical examination findings are generally normal in patients with hypercalcemia, especially if calcium levels are only mildly to moderately elevated. Rarely, severe and prolonged hypercalcemia results in a visible horizontal calcium deposit on the cornea, a condition known as band keratopathy. Other signs and symptoms depend on the etiology of the elevation [*see Table 1*]. Patients with hyperparathyroidism classically have osteopenia, bone pain, or nephrolithiasis. Currently, however, most cases of primary hyperparathyroidism are identified before the patient becomes symptomatic. Patients whose hyperparathyroidism is associated with multiple endocrine neoplasia (MEN) syndromes may have specific manifestations of the other conditions that are part of these syndromes. Patients with sarcoidosis may present with fever, lymphadenopathy, skin rashes, or pulmonary symptoms. Hypercalcemia of malignancy develops only when a substantial tumor burden is present; consequently, most of these patients have an established cancer diagnosis and

clinical features associated with the specific tumor type and extent of disease.

LABORATORY STUDIES

The first step in the laboratory assessment is to exclude factitious hypercalcemia, which may result from an increase in circulating concentrations of plasma proteins. About 50% to 60% of circulating calcium is bound to these proteins, so elevation in their concentrations (as occurs in HIV infection, chronic viral hepatitis, and multiple myeloma) will produce a proportionate rise in the total calcium concentration. The ionized calcium concentration, however, remains normal. To adjust for elevations in plasma protein, the serum calcium level should be lowered by 0.8 mg/dl for every 1 g/dl of albumin (or protein) above the normal range. When performed correctly, ionized calcium measurement is more accurate than adjusted total calcium. Because acute renal failure may occasionally lead to hypercalcemia, renal function should also be assessed.

Once hypercalcemia is confirmed, the next step is measurement of the serum PTH concentration. This is the most important test for determining the cause of hypercalcemia.[3] Several PTH assays are commercially available. The most commonly utilized is the two-site immunochemiluminometric assay (ICMA, or so-called bio-intact PTH). Earlier assays could not distinguish between full-length PTH and inactive molecular fragments that circulate in significant concentrations. The ICMA measures only the intact PTH molecule and is therefore the preferred test in most instances, especially in patients whose serum creatinine level is elevated.

Other helpful tests include measurement of serum creatinine and alkaline phosphatase, as well as inorganic phosphorus assays and an electrolyte panel. Assessment of 24-hour urinary calcium excretion is usually performed. Serum creatinine may be elevated in patients with nephrocalcinosis secondary to prolonged hypercalcemia. The alkaline phosphatase level may be elevated in patients with hypercalcemic states involving increased bone turnover. Patients with hypercalcemia caused by malignancy may demonstrate biochemical or hematologic findings consistent with the site of neoplasia and the degree of its dissemination. Most causes of hypercalcemia are also accompanied by hypercalciuria (24-hour urinary calcium excretion > 4 mg/kg/day), which may lead to nephrocalcinosis or renal stone formation. A serum calcium × phosphate product greater than 70 suggests the patient is at risk for calciphylaxis, and efforts to lower the serum phosphate level (e.g., with phosphate binders) should accompany the interventions to lower serum calcium.

Other diagnostic studies may be dictated by clinical circumstances. Electrocardiographic abnormalities of severe hypercalcemia include shortening of the QT_c interval and, rarely, atrioventricular blocks. In addition, many hypercalcemic conditions cause a decrease in BMD, which may be noted on plain x-rays but is best quantified by measurement of bone density (see below). Abdominal x-rays may identify renal stones or nephrocalcinosis. Specific bone radiographic findings are few, and in primary hyperaparathyroidism, specific bony abnormalities are now rare, thanks to early detection of hypercalcemia.

DIFFERENTIAL DIAGNOSIS

The results of PTH measurement indicate whether hypercalcemia is or is not mediated by PTH and thus provide a broad indication of the cause of hypercalcemia [*see Table 1*]. When PTH levels are high or, in some cases, inappropriately normal, the hypercalcemia is PTH mediated; this is commonly referred to as hyperparathyroidism. When PTH levels are suppressed, the hypercalcemia is said to be non–PTH mediated, or PTH independent. In turn, this distinction guides subsequent patient assessment.

HYPERPARATHYROIDISM (PTH-MEDIATED HYPERCALCEMIA)

Classification

Primary hyperparathyroidism Primary hyperparathyroidism is the most common cause of hypercalcemia in outpatients. Current estimates place the annual incidence at approximately four per 100,000 population; the incidence peaks in the fifth to sixth decade of life, and there is a female-to-male ratio of 3:2.[4] The most common clinical presentation is that of asymptomatic mild hypercalcemia. Pathologically, a solitary parathyroid adenoma is present in 80% to 85% of cases; hyperplasia involving multiple glands is found in 15% to 20% of cases, and parathyroid carcinoma is found in less than 1%. Occasionally, double adenomas are found. Patients with type I MEN (MEN I) or MEN II usually have parathyroid hyperplasia.[5]

Lithium therapy can change the set point for the calcium-sensing receptor such that a higher serum calcium concentration is needed to inhibit PTH secretion. This can lead to biochemical abnormalities (e.g., high levels of calcium and high-normal to elevated PTH levels) that mimic primary hyperparathyroidism. Patients on lithium will often have very low urinary calcium excretion.

Secondary hyperparathyroidism Conditions that tend to decrease serum calcium increase PTH secretion as a corrective measure. This increase of PTH secretion is termed secondary hyperparathyroidism. Once circulating PTH is elevated, the serum calcium may return to normal or remain low. Common causes of secondary hyperparathyroidism include chronic renal insufficiency, vitamin D deficiency, intestinal malabsorption, renal calcium losses, and severe dietary inadequacy. Correction of the underlying calcium abnormality will return serum PTH concentrations to normal.

Familial hypocalciuric hypercalcemia Familial hypocalciuric hypercalcemia (FHH), also referred to as benign familial hypercalcemia, is a rare inherited condition caused by various inactivating mutations in the CaSR. This results in inappropriately increased PTH secretion and a higher set point for the extracellular ionized calcium concentration. Patients with FHH have chronic asymptomatic hypercalcemia associated with relatively depressed urinary calcium excretion.

Tertiary hyperparathyroidism In some patients with prolonged secondary hyperparathyroidism, hyperplasia or neoplasia of the parathyroid glands develops. These parathyroids no longer respond appropriately to serum calcium; instead, they produce excess PTH at all times, leading to chronic hypercalcemia. This is most often seen in patients with chronic kidney disease. More than one parathyroid gland is usually affected.

Diagnosis

Clinical manifestations The clinical manifestations of hyperparathyroidism depend, in part, on the severity of the hypercalcemia. When hyperparathyroidism was first described more than 50 years ago, most patients presented with late-stage com-

plications of prolonged and severe hypercalcemia, such as abnormalities of bone (osteitis fibrosa cystica)[6] or kidneys (nephrocalcinosis, renal failure). Since the development more than 30 years ago of laboratory equipment for measuring serum chemistry, hyperparathyroidism is often diagnosed by routine blood testing, before the development of symptoms. It also may be uncovered during the evaluation of osteoporosis or during the workup of renal stone disease.

When symptomatic, patients with hyperparathyroidism demonstrate clinical manifestations of hypercalcemia (see above).

Physical examination In general, parathyroid tumors are too small to be palpable. Indeed, a palpable parathyroid tumor should be suspected as a malignancy until proved otherwise. Evidence of the consequences of hyperparathyroidism should be sought, such as osteoporosis (kyphosis) or nephrolithiasis (costovertebral angle tenderness).

Laboratory tests Currently, most patients with hyperparathyroidism have a serum calcium concentration of less than 12 mg/dl (unless coexisting volume contraction is present), and they may have mild to moderate hypophosphatemia and a non–anion gap metabolic acidosis (from renal tubular acidosis). Urinary calcium excretion is often increased; in these patients, the reduction of fractional calcium excretion by PTH is overcome by the high filtered calcium load. This may result in nephrocalcinosis or nephrolithiasis.

Renal stones in patients with hyperparathyroidism are usually composed of calcium oxalate and tend to occur bilaterally, especially when urinary calcium excretion is high. Rarely, nephrocalcinosis and azotemia develop, usually in those with the most severe and protracted hypercalcemia, especially if dehydration or other renal insult is superimposed. Because PTH increases both osteoclast and osteoblast activity, there are increases in serum and urinary concentrations of biochemical markers of bone turnover, including bone alkaline phosphatase.

Elevation of both the serum calcium and the PTH concentrations (in the absence of low urinary calcium excretion) supports a diagnosis of primary hyperparathyroidism. PTH levels are usually increased to less than five times the upper limit of normal. In certain mild cases, the calcium level is only slightly high, and the PTH is minimally elevated or inappropriately normal. Rarely, patients with primary hyperparathyroidism have serum calcium levels in only the high-normal range. In fact, most such patients have elevated serum ionized calcium values and therefore are not actually normocalcemic. The diagnosis in such patients can be extremely challenging.

When the PTH level is normal or mildly elevated and the 24-hour urinary calcium level is low, consideration should be given to the possibility of FHH.[7] The relatively low urinary calcium output seen in FHH may help distinguish this condition from primary hyperparathyroidism, although low urinary calcium excretion may also occur in hyperparathyroidism.

The possibility of FHH is raised when there is a strong family history of symptomatic, stable hypercalcemia, especially in patients younger than 40 years; when family members have undergone unsuccessful parathyroid surgery; or when the patient's urinary calcium output is unexpectedly low. When this diagnosis is suspected, further evaluation is necessary, such as the screening of other family members. Unfortunately, specific genetic testing is not currently widely available from commercial laboratories. In some cases, FHH cannot be distinguished confidently from primary hyperparathyroidism. However, in most such patients, expectant management is safe and avoids unnecessary parathyroid exploration. When there is trouble distinguishing between primary hyperparathyroidism and FHH, parathyroid imaging is sometimes useful. In primary hyperparathyroidism, enlarged parathyroid glands are easily found, whereas parathyroid size is usually normal in FHH.

Once the diagnosis of primary hyperparathyroidism is secured, it will usually already be apparent whether the patient is a candidate for parathyroidectomy. If the patient does not meet criteria for surgery on the basis of age, renal function, urinary calcium excretion, history of fractures, or renal stones/nephrocalcinosis, then measurement of bone density with a dual-energy x-ray absorptiometry (DXA) scan may be useful. In addition to the standard left hip and lumbar spine measurements, assessment at the distal radius may be particularly helpful, because hyperparathyroidism may affect this predominantly cortical site more than the other locations, which have a greater percentage of trabecular bone.[6]

Other diagnostic studies are usually not necessary. Consideration should also be given to the possibility of one of the MEN syndromes, particularly if the patient is young or has a personal or family history of a related endocrinopathy.[5] This information will be helpful to the surgeon, because the patient with primary hyperparathyroidism in the setting of a MEN syndrome usually has multigland parathyroid hyperplasia, and in such patients a surgical procedure beyond a single parathyroidectomy is necessary. If MEN II is suspected, medullary thyroid cancer should be considered, and pheochromocytoma must be excluded before the patient goes to surgery.

Treatment

Previous controversy over which patients with hyperparathyroidism require surgical intervention has been largely resolved. Those without symptoms or complications clearly related to hyperparathyroidism can be followed safely for long periods. Treatment of the patient with primary hyperparathyroidism must take into account the degree of the hypercalcemia, the presence of symptoms, and the severity of any end-organ damage.[8] Understandably, it is widely agreed that patients with symptoms clearly attributable to hypercalcemia should undergo surgery.

Guidelines for surgical intervention in patients with primary hyperparathyroidism were developed at a National Institutes of Health workshop in 2002.[9] The indications for surgical intervention are as follows:

1. Significant bone, renal, gastrointestinal, or neuromuscular symptoms typical of primary hyperparathyroidism.
2. Elevation of serum calcium by 1 mg/dl or more above the normal range (i.e., ≥ 11.5 mg/dl in most laboratories).
3. Marked elevation of 24-hour urine calcium excretion (e.g., > 400 mg).
4. Decreased creatinine clearance (i.e., reduced by ≥ 30% compared with age-matched normal persons.
5. Significant reduction in bone density (i.e., > 2.5 standard deviations below peak bone mass [T score < –2.5 at the lumbar spine, proximal femur, or distal radius]).
6. Consistent follow-up is not possible or is undesirable because of coexisting medical conditions.
7. Age younger than 50 years.

Those patients with mild hypercalcemia who are truly asymptomatic can be followed clinically for the subsequent de-

velopment of surgical indications. Most will likely remain asymptomatic and will not require intervention.[9]

Preoperative localization Imaging studies to locate parathyroid adenomas have become more widely used, particularly as more centers have started offering minimally invasive surgery with intraoperative PTH assays (see below).[10,11] In most cases of adenoma in a single gland, precise knowledge of the location of the adenoma may decrease operative time by allowing the surgeon to direct attention to the area of suspicion. It is important to remember, however, that in good hands, parathyroidectomy for primary hyperparathyroidism has a cure rate in the range of 90% to 95%, even without such localization studies. Thus, it is unlikely that preoperative localization will ever be demonstrated to improve overall surgical outcomes. Localization studies are mandatory before minimally invasive parathyroidectomy, in the setting of a second neck exploration for persistent or recurrent hyperparathyroidism, or if previous thyroid surgery has been performed. The localization test of choice is technetium-99m sestamibi scintigraphy.[12,13] This is often followed by a neck ultrasound of the region demonstrating scintigraphic activity to confirm the location of an enlarged parathyroid gland. An additional benefit of ultrasound at this stage in the evaluation is to provide the opportunity for any coexisting thyroid abnormalities to be addressed.

Surgical management The surgical procedure required in patients with hyperparathyroidism resulting from a solitary parathyroid adenoma is resection of that gland. If intraoperative PTH assays show a drop in the PTH level by more than 50% a few minutes after resection, no further neck exploration is required. Intraoperative measurement of PTH is considered by some experts to be critical in the case of ectopic parathyroid adenoma (which would not be easily found during routine neck exploration) and in reoperations. If an intraoperative PTH assay is not used, the other three glands must be directly inspected to ensure that a second adenoma or generalized hyperplasia is not present.[14] If a second adenoma is found, it too should be excised. If hyperplasia is encountered, the surgeon performs a subtotal parathyroidectomy: removal of approximately three to three and one half glands. In some centers, this is followed by autotransplantation of remaining parathyroid tissue to the forearm, which may simplify follow-up surgical exploration in the event of recurrent hypercalcemia. Additional parathyroid tissue may be frozen in case future need develops. Parathyroid autotransplantation is a controversial treatment, because some patients experience aggressive regrowth of parathyroid tissue within the forearm muscles. This can require challenging and disfiguring surgery to correct.

At certain centers, so-called minimally invasive parathyroidectomy is being offered in conjunction with intraoperative PTH measurements.[11] This approach is best suited for a good surgical candidate in whom both history and preoperative imaging studies suggest a single adenoma (which is, in fact, the most common situation in primary hyperparathyroidism). With information from scintigraphy and ultrasound already in hand, the diseased gland can be excised through a smaller, unilateral incision, under local nerve block, in an ambulatory setting. Success is gauged by the drop in PTH levels intraoperatively. This approach usually provides a better cosmetic result, quicker recovery time, and a lower incidence of postoperative hypocalcemia. Minimally invasive surgery may not be appropriate in suboptimal surgical candidates, in patients who may have multigland disease, and in reoperative cases. However, it is quite likely that the majority of parathyroidectomies will be performed in this fashion in the future.

Table 2 2002 NIH Working Group Recommendations Regarding Follow-up Testing for Patients with Primary Hyperparathyroidism Who Do Not Undergo Surgery[9]

Measurement	*Frequency*
Serum calcium	Biannually
24-hour urine calcium	At initial evaluation only
Creatinine clearance	At initial evaluation only
Serum creatinine	Annually*
Bone mineral density	Annually (lumbar spine, femur, and forearm)
Abdominal radiograph (or ultrasound)	At initial evaluation only

* If the serum creatinine suggests a change in renal function, measurement of creatinine clearance is recommended.

Hyperparathyroidism occasionally persists after operative intervention, usually because of failure to identify the culprit gland, occasionally because of undiagnosed multigland hyperplasia, and rarely because of undiagnosed parathyroid carcinoma.[15-17] Scar tissue and the sometimes unexpected location of remaining pathologic parathyroid tissue make second surgeries notoriously more challenging and prone to complications. Consequently, preoperative imaging studies are invaluable in patients undergoing repeat surgery for persistent hyperparathyroidism. Catheterization studies with venous sampling may also be helpful in certain difficult cases. The identity of putative parathyroid glands can be confirmed by fine-needle aspiration with real-time PTH assay.

Nonsurgical management Although there is as yet no recognized medical therapy for primary hyperparathyroidism, patients who do not meet the criteria for surgical intervention or who refuse surgery can be followed expectantly. This involves periodic monitoring of serum and urine calcium levels, renal function, and BMD, as well as evaluation for nephrocalcinosis or nephrolithiasis. The extent and frequency of this monitoring should be tailored to the individual patient's disease and comorbidities. [*see Table 2*].[9] Drugs that have a tendency to raise serum calcium levels, such as thiazides and lithium, should be avoided. Calcium and excessive vitamin D supplementation should generally be avoided. Dietary calcium should not be restricted, because such restriction may lead to further elevation of PTH and may possibly have detrimental effects on bone mass. Vitamin D deficiency should be identified and treated with gradual supplementation, because vitamin D deficiency will enhance the adverse effects of hyperparathyroidism on bone. Good hydration should be maintained at all times to avoid the development of renal insufficiency and renal stones, especially in patients with hypercalciuria. In patients with low BMD, a bisphosphonate will help to slow bone loss. In patients who are very hypercalcemic but cannot or will not have surgery, calcimimetic agents have been used to control hypercalcemia, although they

are not approved by the Food and Drug Administration for use in this particular setting. For example, the calcimimetic agent cinacalcet is approved for the treatment of secondary hyperparathyroidism in patients with chronic kidney disease who are on dialysis, as well as for the treatment of hypercalcemia in patients with parathyroid cancer. Calcimimetic agents activate the CaSR and thus diminish PTH production. The high cost of these agents and the relative ease of parathyroid surgery make their widespread use in the future unlikely.[18]

PTH-INDEPENDENT HYPERCALCEMIA

Cancer remains the most common cause of PTH-independent, persistent, substantial hypercalcemia and is most frequently to blame when an acutely elevated calcium level is discovered in a hospitalized patient. Other causes include sarcoidosis, certain endocrine disorders, and various drugs and supplements.

Etiology

Malignancy Malignancy-associated hypercalcemia has two forms: humoral hypercalcemia of malignancy (HHM) and local osteolytic hypercalcemia (LOH).

HHM results from the elaboration by the tumor of a circulating factor that has systemic effects on skeletal calcium release, renal calcium handling, or GI calcium absorption. Rarely, it can be caused by the unregulated production of calcitriol (usually by B cell lymphomas). However, the best-recognized mediator responsible for HHM is parathyroid hormone–related protein (PTHrP).[19] Normally, PTHrP appears to serve as a paracrine factor in a variety of tissues (e.g., bone, skin, breast, uterus, and blood vessels); it is involved in cellular calcium handling, smooth muscle contraction, and growth and development. The amino terminus of PTHrP is homologous with that of PTH, and they share a common receptor. When PTHrP circulates in supraphysiologic concentrations, it induces most of the metabolic effects of PTH, such as osteoclast activation, decreased renal calcium output, and increased renal phosphate clearance.

Tumors that produce HHM by secreting PTHrP are usually squamous cell carcinomas (e.g., lung, esophageal, laryngeal, oropharyngeal, nasopharyngeal, or cervical carcinomas).[20] Other tumor types that occasionally produce PTHrP include adenocarcinoma of the breast and ovary, renal cell carcinoma, transitional cell carcinoma of the bladder, islet cell tumors of the pancreas, T cell lymphomas, and pheochromocytoma. All tumors that elaborate PTHrP do so in relatively small amounts; thus, the syndrome typically develops in patients with a large tumor burden. It is also unusual for HHM to be the presenting feature of the cancer.

LOH occurs when a tumor growing within bone itself causes the local release of calcium through the production of cytokines that activate osteoclasts; there is no production of a systemic factor in these cases. The classic tumor associated with this syndrome is multiple myeloma, although other neoplasms, such as adenocarcinoma of the breast and various lymphomas, may also cause LOH. Local factors produced by bone cells may further enhance the growth of such tumors; this results in the skeleton inadvertently working in concert with the tumor to promote progressive bone resorption and calcium release and further advancement of the cancer. (This is the basis of the success of bisphosphonates in the treatment of multiple myeloma.)

Other causes PTH-independent hypercalcemia may be caused by sarcoidosis and other granulomatous diseases, such as tuberculosis, in which granulomas produce calcitriol. Endocrine conditions that may occasionally lead to hypercalcemia include hyperthyroidism (which stimulates bone turnover) and Addison disease (in which volume contraction reduces calcium clearance). Immobilization may increase calcium levels, usually in persons with active bone turnover, such as adolescents or those with previously unrecognized hyperparathyroidism or Paget disease of bone (see below). Use of drugs and dietary supplements (e.g., vitamin D and vitamin A) may be associated with hypercalcemia. The association of thiazides with hypercalcemia is now thought to occur when a thiazide-induced reduction in calcium excretion unmasks previously unrecognized primary hyperparathyroidism. Although only rarely encountered today, the so-called milk-alkali syndrome results from the long-term consumption of large quantities of milk and antacids; milk and antacids were the standard treatment of peptic ulcers in the days before the development of H_2 receptor blockers and proton pump inhibitors.

Diagnosis

If the serum calcium concentration is elevated but the PTH level is very low, the patient has PTH-independent hypercalcemia. Possible causes include malignancy, granulomatous disease, thyrotoxicosis, and vitamin D intoxication. These cases require further laboratory assessment, with the choice of tests depending on the clinical situation.

In malignancy-associated hypercalcemia, the degree of calcium elevation is usually moderate or severe. Evidence of significant volume depletion and generalized debility may dominate the clinical picture, along with other cancer-related symptoms. Typically, the diagnosis of malignancy has already been established. The diagnosis of malignancy-associated hypercalcemia should be suspected in cancer patients with hypercalcemia who have abnormally low PTH concentrations. In patients with tumors associated with HHM, measurement of PTHrP is indicated. Radioimmunoassays for PTHrP are commercially available; an elevation of PTHrP concentration will essentially confirm the diagnosis of most cases of HHM. Special care should be taken to ensure that blood for PTHrP levels is drawn and handled correctly to avoid spuriously low results. In HHM from B cell lymphomas, circulating plasma concentrations of calcitriol are increased. In local osteolytic disease, PTHrP and calcitriol are within normal ranges, and there is definitive evidence of bony metastases.

When the PTH is low and the patient is not known to have a malignancy, diagnostic possibilities include granulomatous diseases, other endocrine disorders, drugs or dietary supplements, and immobilization. Possible laboratory studies in such patients might include measurement of vitamin D metabolites, thyroid hormone levels, or 24-hour urine calcium excretion. If investigation of these diagnoses proves unrewarding, the very rare possibility of unrecognized malignancy may be considered, especially if measurement of PTHrP is performed and shows elevated values. Further imaging studies are indicated in such cases, including a plain chest radiograph or a computed tomographic scan of the thorax as the initial study. If the results are negative, consideration should be given to a comprehensive otolaryngoscopic examination, esophagoscopy, or CT of the abdomen. Should such further assessment be unrevealing, radiographic or endoscopic assessment of the genitourinary tract should be considered.

Treatment

Acute hypercalcemia A nonparathyroid disorder, often a malignancy, is responsible for most cases of acute hypercalcemia [*see Table 1*]. When the serum calcium level is substantially elevated, treatment includes attempts to increase renal calcium excretion while simultaneously attenuating either bone resorption or intestinal calcium absorption, depending on which is the primary source of calcium. Because most patients have at least moderate volume contraction, which further exacerbates their ability to excrete calcium, the initial intervention should be expansion of the intravascular volume with an intravenous infusion of normal saline [*see Table 3*]. This will augment the delivery of sodium and water to the distal nephron, both of which will, in turn, increase urinary calcium excretion. Once the intravascular volume is repleted, adding a loop diuretic such as furosemide will allow continued aggressive saline hydration and may further increase calcium excretion. If the serum calcium concentration does not normalize quickly with intravenous fluid and diuresis, pharmacologic therapy is indicated.[21] Because almost all causes of severe hypercalcemia involve some degree of increased osteoclast activation, drugs that decrease bone turnover are favored. The treatment of choice is a bisphosphonate, such as pamidronate or zoledronic acid, both of which are available for intravenous infusion. Pamidronate is given in a dosage of 60 to 90 mg intravenously over several hours; it is generally well tolerated. Typically, serum calcium levels begin to decrease within 24 to 48 hours of the infusion, although the peak effect may not occur for several days. The action of pamidronate may persist for up to several weeks; treatment can be repeated as needed if renal function will allow. Zoledronic acid is given at a dosage of 4 mg intravenously over no less than 15 minutes. It appears to have a higher potency and an even longer duration of action than pamidronate. A repeat dose may be provided after 7 days. Use of intravenous bisphophonates, especially zoledronic acid, is often associated with an acute-phase response after the first dose, with flulike symptoms. Caution should be employed with these agents in the setting of renal dysfunction. In addition, if parathyroidectomy is planned, use of bisphosphonates should be considered carefully, because they may make postoperative hypocalcemia management more difficult. When more rapid action is desired, subcutaneous injection of calcitonin can be tried, either alone or in conjunction with a bisphosphonate. Calcitonin is given at a dosage of 4 IU/kg twice daily. Calcitonin is a relatively weak hypocalcemic agent; tachyphylaxis to the effects of calcitonin is common and limits its use to a few days. Other possible therapies are plicamycin and gallium nitrate, although certain toxicities limit their use as first-line agents. In severe or refractory cases, hemodialysis against a low-calcium bath may also be undertaken.

In the more unusual situation of hypercalcemia resulting from an increase in gut calcium absorption, such as in vitamin D intoxication or granulomatous diseases, glucocorticoid therapy may have an integral role. Glucocorticoids directly impede intestinal calcium transport and also decrease renal or granulomatous 1α-hydroxylase activity, which results in a decrease in concentrations of calcitriol. In patients with lymphoma, steroids may also have an antineoplastic effect.

Contributing factors to hypercalcemia, such as the use of oral calcium or vitamin D supplements, diuretic therapy, or immobilization, should be corrected, if possible.

In malignancy-associated hypercalcemia, effective surgery, chemotherapy, or radiotherapy targeted at the tumor itself will reduce the hypercalcemia. However, because hypercalcemia is often an end-stage complication, further chemotherapy or radiotherapy may be neither possible nor desired.

Table 3 Therapy for Acute Hypercalcemia

- Fluids
  - 0.9% NaCl I.V.
  - Loop diuretic (forced diuresis)
- Medications
  - Bisphosphonates
    - Pamidronate (60–90 mg I.V.)
    - Zolendronic acid (4 mg I.V.)
  - Calcitonin (4 IU/kg S.C. q. 12 hr)
  - Plicamycin (15–25 μg/kg I.V.)
  - Gallium nitrate (200 mg/m²/day continuous infusion for 5 days)
  - Glucocorticoids (20–100 mg of prednisone a day)
- Other
  - Primary therapy directed at tumor
    - Surgery
    - Chemotherapy
    - Radiation
  - Decrease calcium and vitamin D intake
  - Maintain adequate hydration
  - Mobilize patient

Hypocalcemia

Hypocalcemia is defined as a serum calcium level below the reference range for the laboratory. As with hypercalcemia, an ionized calcium determination on a correctly collected sample is the best way to confirm hypocalcemia.

ETIOLOGY

An abnormally low level of serum calcium on laboratory testing is most often factitious, resulting from a decrease in plasma protein concentration secondary to decreased protein synthesis or hemodilution. Because circulating calcium is so highly protein bound, decreases in serum albumin concentrations—such as occurs with malnourishment, liver disease, or nephrotic syndrome—produce proportionate reductions in total serum calcium. In such situations, the serum calcium level may be corrected by adding 0.8 mg/dl for each 1 g/dl reduction in the serum albumin level below 4 g/dl. An accurate ionized calcium measurement will circumvent many of these pitfalls.

True hypocalcemia is most often related to vitamin D deficiency or impaired parathyroid gland function. Removal of or vascular injury to the parathyroids during neck surgery can result in hypoparathyroidism, which is manifested by hypocalcemia, hyperphosphatemia, and inappropriately low concentrations of PTH. However, unless all four parathyroids are removed or their blood supply is severely impaired, hypocalcemia after parathyroidectomy is usually a transient phenomenon. Normal parathyroid function typically returns after a period of several days to weeks. Patients who experience prolonged, severe primary hyperparathyroidism and significant bone resorption before undergoing parathyroidectomy may experience protracted hypocalcemia and hypophosphatemia after surgery, as a result of the deposition of large quantities of mineral into the skeleton. This is referred to as the "hungry bone syndrome."

Automimmune destruction of the parathyroid glands may be

seen in certain conditions, including autoimmune polyglandular syndrome type 1, a condition marked by hypoparathyroidism, premature ovarian failure, Addison disease, and mucocutaneous candidiasis.[22] Certain infiltrative diseases, such as hemochromatosis, may also adversely affect parathyroid function, as may external-beam irradiation of the neck. Functional hypoparathyroidism may also result from hypomagnesemia, because magnesium is necessary for both PTH release and PTH action. This is often seen in hospitalized alcoholic patients. Pseudohypoparathyroidism is caused by inherited PTH resistance, which results in hypocalcemia and secondary marked elevations of PTH levels.

Because vitamin D ultimately regulates intestinal calcium absorption, disorders of its supply, production, or activity may lead to hypocalcemia**.** In such conditions, serum calcium concentrations are usually not severely affected, thanks to compensatory increases in PTH levels. Indeed, the primary clinical manifestations are in the skeleton (e.g., rickets in children and osteomalacia in adults). Dietary vitamin D deficiency in the elderly is common, but it is often overlooked.[23] At-risk adults include the elderly and darker-skinned persons with poor dietary habits who avoid liquid milk products and have little sun exposure, particularly in northern climates. However, recent reports suggest that vitamin D deficiency may be more frequent than traditionally considered, even in persons not previously thought to be at risk.[24]

Hypocalcemia may occur in patients with acute pancreatitis, when fatty acids released through the action of pancreatic lipase complex with calcium. The complexing of phosphate with calcium also occurs in severely hyperphosphatemic states, such as acute renal failure, rhabdomyolysis, and the tumor lysis syndrome, and it may result in a decrease in serum calcium concentrations. Hypocalcemia may also be caused by large-volume blood transfusions using red blood cells to which calcium chelators have been added to prevent clotting.

Table 4 Differential Diagnosis of Hypocalcemia

Abnormal supply or action of parathyroid hormone	Hypoparathyroidism Surgical External-beam irradiation (to neck) Autoimmune Polyendocrine syndromes Congenital Infiltrative Hemochromatosis Thalassemia Wilson disease Magnesium deficiency DiGeorge syndrome PTH resistance Pseudohypoparathyroidism
Abnormal supply or action of vitamin D	Vitamin D–dependent rickets (VDDR)/ osteomalacia Nutritional deficiency Malabsorption Altered vitamin D metabolism Cirrhosis Renal failure Anticonvulsant medications Vitamin D pseudodeficiency (VDDR I) Abnormal vitamin D receptor (VDDR II) Vitamin D–resistant hypophosphatemic rickets/osteomalacia Oncogenic osteomalacia
Medications/ supplements	Phosphate Calcitonin Bisphosphonates Plicamycin
Other conditions	Hypoalbuminemia (factitious) Acute pancreatitis Rhabdomyolysis Calcium malabsorption Hyperphosphatemia Large transfusions of citrate-containing blood products Osteoblastic metastases (prostatic or breast carcinoma)

DIAGNOSIS

Chronic mild to moderate hypocalcemia is usually well tolerated. However, when the serum calcium level falls below 7.5 to 8 mg/dl (assuming that plasma protein levels are normal), the patient may develop symptoms of neuromuscular irritability, such as tremor, muscle spasms, or paresthesias. On examination, Chvostek and Trousseau signs may be present. If the serum calcium level drops further, tetany or seizures may result. Prolongation of the QT_C interval may also occur, predisposing the patient to cardiac arrhythmias.

As with hypercalcemia, the cause of hypocalcemia can usually be discerned after a careful history (including a review of medications, previous surgeries, and dietary and social habits) and by the measurement of the circulating concentrations of calcium, phosphorus, PTH, and 25-$(OH)D_3$. The differential diagnosis consists principally of conditions that result in an abnormal supply or the abnormal action of PTH or vitamin D, but the use of medications or supplements and the presence of other conditions must be considered [*see Table 4*].

TREATMENT

In patients with symptoms of marked hypocalcemia (e.g., neuromuscular irritability), calcium should be infused slowly (e.g., as calcium gluconate) to raise the serum calcium level until symptoms are relieved. Individual boluses of intravenous calcium will not achieve this effect. Concurrently, any deficiency in magnesium stores should be corrected. In severe cases, hypocalcemia may recur quickly after discontinuance of calcium infusion, so oral calcium should be administered concurrently. In less severe cases, calcium can be administered orally as calcium carbonate or calcium citrate in doses of 1,000 to 2,000 mg of elemental calcium daily in divided doses. If appropriate, vitamin D should also be provided. If dietary deficiency of vitamin D is suspected, cholecalciferol (vitamin D_3) or, if cholecalciferol is unavailable, ergocalciferol (vitamin D_2), may be adequate. Because hydroxylation of cholecalciferol may take several days, however, a brief course of calcitriol may also be necessary. In cases of hypoparathyroidism, long-term administration of calcitriol is needed, because renal 1α-hydroxylase may not be active in the absence of PTH. In hypoparathyroid patients, it is important to not fully normalize the serum calcium level, because this often results in hypercalciuria and hyperphosphaturia, increasing the risk of nephrocalcinosis or renal stones. Instead, serum calcium should be kept around the lower limit of the normal range, at a level sufficient to relieve symptoms and reverse tetanic signs (e.g., Trousseau sign). Periodic monitoring for nephrocalcinosis in these patients may be appropriate.

OSTEOPOROSIS

Osteoporosis is defined as a loss of bone mass, including loss of trabecular bone microarchitecture and connectivity and a thinning of cortical bone, leading to an increased risk of fracture. Clinically, osteoporosis is usually diagnosed by measuring BMD, which reflects the bone calcium content and is a surrogate for bone mass. The diagnostic criteria of the World Health Organization are based on the results of standardized bone density measurements: osteoporosis is present when the BMD is more than 2.5 standard deviations (SDs) below that of a normal, young adult control population (in whom bone density is at its peak). Osteopenia is present when the BMD falls between –1.0 and –2.5 SDs from peak bone density.

Epidemiology

Peak bone mass occurs in persons who are in their late 20s or early 30s; after this age, bone density decreases slowly. Consequently, the incidence of osteoporosis increases with age, becoming most common in persons older than 60 years. Because peak bone mass is lower in women than in men, women generally have lower bone density at each succeeding stage of life.[25] Therefore, women experience higher rates of fracture. The most common sites of so-called fragility fractures are the hip, the distal forearm, and vertebrae.

The lifetime risk of experiencing any fragility fracture for white women is 40%, whereas for white men it is 13%. By site, the respective risks for women and men are as follows: 18% and 6% for hip fracture, 16% and 3% for distal radius fracture, and 18% and 6% for vertebral fracture.[26] The incidence of hip fracture in women and men aged 65 years is approximately 300 and 150 per 100,000 person-years, respectively. These rates increase to approximately 3,000 and 2,000 per 100,000, respectively, by 85 years of age.[25] African Americans generally have higher BMD and are at lower risk for fracture than their white, Hispanic, or Asian counterparts.

Osteoporosis produces enormous burdens, both for patients and for society at large. In the United States, the direct costs of treatment of osteoporotic fractures alone are estimated to be $10 billion to $15 billion annually. Hip fracture carries the highest morbidity and mortality of all fractures. Deaths may occur from associated complications, such as pulmonary embolism or pneumonia. Only one third of patients with hip fracture return to their previous level of functioning. Of the remainder, one third will be placed in long-term nursing care facilities. Rates of depression and anxiety also increase after osteoporotic fracture.[10] Because of the high cost to patients and the insurance system, prevention of hip fracture has been a major focus of osteoporosis prevention and treatment.

Pathogenesis

Bone remodeling occurs continuously in adults; at any given time, as much as 5% to 10% of the skeleton is in a state of turnover. The cells involved in this remodeling process are the osteoclasts, which resorb bone, and the osteoblasts, which form new bone. A cycle of bone remodeling begins with the recruitment of osteoclasts. Osteoclast-mediated resorption of bone from the site releases mineral and collagen breakdown products into the circulation. Through local osteoclast-derived cytokine signals, osteoblasts are then recruited to the site and create new bone matrix to fill the resorption pit left behind by the osteoclasts. The matrix is then mineralized through the physiochemical crystallization of hydroxyapatite. Each bone turnover cycle lasts approximately 3 months.

Through the process of bone remodeling, the skeleton is constantly rejuvenated. In an accelerated form, the bone remodeling process allows for the healing of fractures. In addition, the massive mineral stores of the skeleton are continuously made available to the body for systemic needs, especially during times of decreased calcium supply.

With advancing age, slightly less bone is formed than was resorbed during each remodeling cycle, presumably because of a gradual decline in osteoblast activity. As a result, net bone loss occurs with each cycle, resulting in the gradual decline in bone mass with aging. Therefore, bone loss is to some degree linked to the rate of bone turnover. Any process that increases bone resorption without increasing bone formation will result in a decrease in bone mass and in a concomitant increase in the risk of fracture.

Bone mass accumulates during the first 2 decades of life, achieves its peak in the late third or early fourth decade, stabilizes during the next 1 or 2 decades, and then declines slowly. The age-related decline in bone mass occurs at a rate of approximately 0.1% to 0.5% a year in both sexes. In women, however, the rate of bone loss accelerates during the relatively abrupt loss of gonadal steroids during menopause, especially just before and during the first 6 or 7 years after the cessation of menses. During this period, bone mass may actually fall by up to 4% a year. Thus, by the end of this period, a woman may have lost one quarter to one third of her total skeletal mass.[26,27] Subsequently, bone loss tends to slow to a rate similar to that seen in aging men.

Risk Factors and Pathologic Causes

The most important risk factors for decreased bone density and osteoporotic fracture are advanced age, female gender, postmenopausal status, white or Asian race, personal or family history of fragility fracture, and low body weight.[28,29] These risk factors assist in identifying patients who are at increased risk for bone loss and consequent fracture. Those patients warrant prophylactic measures to help maintain bone mass, and they may benefit from formal bone density measurement to more precisely quantify risk. Other factors contributing to bone loss include cigarette smoking, ethanol abuse, insufficient dietary calcium, and lack of physical exercise.

Diseases or conditions associated with low bone density include Cushing syndrome, glucocorticoid therapy, thyrotoxicosis, excessive thyroid hormone replacement, primary hyperparathyroidism, hypogonadism, intestinal malabsorption, chronic obstructive pulmonary disease, chronic renal or hepatic failure, multiple myeloma and other malignancies, hypopituitarism (growth hormone deficiency), rheumatoid arthritis and other connective tissue diseases, and organ transplantation.

Diagnosis

Although risk-factor analysis assists in determining which patients are at greatest risk for osteoporosis and fracture, the measurement of bone density remains an essential tool to assess risk. Several modalities for measuring bone density are currently in use, including DXA, quantitative CT (QCT), and ultrasound. QCT is not yet widely used clinically. Ultrasound is used for screening purposes, but selected patients must be followed with central DXA measurements. DXA has the highest accuracy

and precision of any densitometric method and is currently the diagnostic tool preferred by most authorities.[30,31] It is also the method most widely employed in large clinical trials of osteoporosis treatment regimens and is both widely available and safe. DXA should therefore be used for the initial screening and follow-up.

In a typical DXA report, the bone density measurements (expressed in g/cm^2) are converted to T scores and Z scores. The T score is the number of SDs the patient's BMD falls above or below the mean value for young, healthy persons at peak bone density. The Z score represents the number of SDs the patient's BMD falls above or below the average value for persons of the patient's age and sex. The T score is the best indicator of fracture risk. Bone density reference databases are currently available only for whites and African Americans; this limits the value of the results obtained for other ethnic groups. The most common sites measured by DXA are the proximal femur and lumbar spine, although the distal nondominant radius can also be assessed. Pitfalls in the interpretation of DXA scans include incorrect patient positioning and improper selection of the region of interest for analysis. Degenerative disease or scoliosis in the lumbar spine can make the bones appear denser, leading to falsely reassuring results. Each SD below peak bone mass represents a loss of 10% to 12% of bone mineral content and corresponds to an approximate twofold to 2.5-fold increase in fracture risk at that site. It should be noted, however, that factors other than bone density play important roles in the risk of fracture. Recent attention has been directed to so-called bone quality, which refers to the microarchitecture and fracture resistance of the bone, and which may not correspond to BMD as measured by DXA.[32] In elderly persons, in particular, additional factors that increase the risk of fractures include low visual acuity, impaired neuromuscular function, decreased mobility, cognitive decline, sedative drug use, and residence in a nursing home.[33] In a review of the risk of fracture in almost 8,000 women enrolled in a longitudinal study of osteoporosis, the clinical factors found to be most important for risk of fracture included a history of fracture after 50 years of age, maternal history of hip fracture, weight less than 125 lb, current cigarette smoking, and the inability to raise oneself from the seated position without use of the arms. By combining these factors with the T score at the hip, these researchers were able to create a fracture risk index that predicted the patient's likelihood of hip fracture over the subsequent 5 years with greater accuracy than seen with the bone density result alone.[34]

In 1998, the National Osteoporosis Foundation recommended that DXA be used as a screening modality in women with established osteoporotic fractures (to establish a baseline for follow-up measurements) and in women without established osteoporotic fractures who are 65 years of age or older or who are younger than 65 years but have one or more accepted risk factors for fragility fracture. These risk factors include low body weight (< 128 lb); current smoking; and personal history of, or a first-degree family relative with, a low-trauma fracture.[29] Indications for bone density measurement in any patient include fracture from mild or moderate trauma, evidence of osteopenia on plain radiography, pending organ transplant, and ongoing or anticipated long-term corticosteroid therapy. Bone density measurements are also useful in the evaluation of patients with conditions that might adversely affect bone mass (e.g., hyperparathyroidism) and for monitoring patients who are receiving therapy for osteoporosis**.** When follow-up bone density studies are performed, it is important that they be done in a reproducible fashion, so that an accurate comparison can be made. It is best to use the same densitometer at the same facility from one year to the next. Identical patient positioning for each scan will also help eliminate error.

Once the diagnosis of osteoporosis or osteopenia is made, the clinician may wish to undertake a selective evaluation to exclude causes of secondary osteoporosis (other than estrogen deficiency). In a premenopausal woman or a man with decreased bone density, such investigations are imperative. A comprehensive history and physical examination will reveal many of the causes of secondary bone loss. The evaluation should explore symptoms of chronic illness, hyperthyroidism, hyperparathyroidism, intestinal disease, and glucocorticoid use.[35] Lifelong calcium and vitamin D intake should be reviewed. In women, the menstrual history should also be discussed, because even relatively short periods of amenorrhea (reflecting estrogen deficiency) in the past may have a detrimental effect on bone mass.[36] Lifestyle factors such as physical activity level, eating disorders, cigarette smoking, and alcohol abuse should also be addressed. In men, osteoporosis is more often associated with a secondary cause, the more common ones being alcoholism, steroid use, and hypogonadism.[37] However, in about half of men with osteoporosis, the disorder is idiopathic.

An extensive biochemical assessment of the patient, other than that indicated by the clinical evaluation, is not necessary. It is reasonable, however, to perform routine blood chemistry studies, including measurement of levels of serum calcium and phosphorus, serum creatinine, and alkaline phosphatase along with a complete blood count. Immunofixation electrophoresis can also be performed to rule out early myeloma if there is any suspicion of malignancy. Subclinical hyperthyroidism can be ruled out with a thyroid-stimulating hormone determination. Measurement of PTH and vitamin D levels is often helpful, because asymptomatic disease is common. Measurement of 24-hour urinary calcium excretion will evaluate for calcium malabsorption or excessive renal losses of calcium.

Treatment

Modifiable risk factors Lifestyle modification is the first step in the prevention or treatment of osteoporosis. Smoking cessation and moderation of alcohol consumption are important first steps. Exercise is an important aspect of osteoporosis management. Weight-bearing physical activity attenuates bone loss; exercise also helps maintain the proximal muscle strength and balance necessary to avoid falls.[38] A physical therapy evaluation is appropriate for patients considered at high risk for falls. Physical therapists can conduct home safety evaluations to identify and address conditions that might promote falls (e.g., trailing electric cords, throw rugs). Physical therapy can also improve strength and gait stability, thus decreasing fall risk. For frail elderly patients, it is prudent to review medication lists and try to eliminate medications that may cause dizziness or sedation and thus predispose patients to falls. Hip protectors have been shown in some, but not all, studies to prevent hip fracture if a patient falls.[39]

Nutritional therapy Any patient being treated for bone loss must consume adequate amounts of both calcium and vitamin D. The recommended daily dietary intake of elemental calcium is 1,000 to 1,500 mg, depending on age and menopausal status [*see Table 5*],[40] and recommended vitamin D intake ranges from

Table 5 Dietary Reference Intakes for Calcium*[76]

Population	*Age (yr)*	*DRI (mg)*
Children	1–3	500
	4–8	800
Males and females	9–18	1,300
	19–50	1,000
	> 50	1,200
Pregnant/lactating women	≤ 18	1,300
	≥ 19	1,000

*Recommended Daily Allowances (RDA) are being replaced with dietary reference intakes (DRI).

400 to 800 IU a day. Patients taking medications that increase vitamin D metabolism (e.g., phenytoin) may need higher vitamin D doses. Substantial and prolonged deficiencies in calcium intake may lead to secondary hyperparathyroidism with reduction of bone mass, as bone is resorbed to release calcium for systemic requirements. Several investigators have demonstrated that calcium and vitamin D supplementation has a beneficial effect on postmenopausal bone loss, although the effects are not as dramatic as those seen with antiresorptive or anabolic therapies.[41] In addition, vitamin D supplementation in the elderly appears to be associated with as much as a 22% decreased risk of falls.[42] Skeletal muscle has vitamin D receptors, and it is thought that vitamin D sufficiency is necessary for optimal muscle strength.

Preferably, calcium and vitamin D should be from dietary sources.[40] Unless milk products are a major component of the diet, however, achieving adequate intake may be difficult; therefore, commercially available supplements should be used. In patients who are elderly, in patients who are taking proton pump inhibitors or H_2-blockers, or in patients who have pernicious anemia, calcium citrate may be better absorbed than calcium carbonate. In all major clinical trials of osteoporosis therapies, participants were also provided basal calcium and vitamin D supplements. Thus, the efficacy of currently available pharmacologic agents for osteoporosis generally has been demonstrated only in persons with adequate calcium and vitamin D intake.

Antiresorptive therapy Osteoporosis is most often treated with antiresorptive agents. FDA-approved agents for the treatment of established osteoporosis include the bisphosphonates (e.g., alendronate, risedronate), selective estrogen receptor modulators (SERMs) (e.g., raloxifene), calcitonin,[28] and estrogen.[43-46] All of these agents reduce vertebral and nonvertebral fracture rates (on the order of 30% to 60%) over 2 to 3 years,[28,37,40,43,44,47-53] but only estrogen[54] and the bisphosphonates have been shown to reduce hip fracture risk.[47-49] All of these agents tend to be more effective for increasing bone density and lowering fracture risk at the spine than at the hip. Estrogen is less widely used for prevention of postmenopausal bone loss since the publication of the Women's Health Initiative (WHI) results. The WHI studies showed an increased risk of cardiovascular disease, breast cancer, stroke, and pulmonary embolism in patients treated with estrogen in combination with progestin,[55] as well as an increase in stroke risk for women treated with estrogen alone.[56]

Antiresorptive therapy should be considered for postmenopausal women for the prevention of osteoporosis, particularly in those with established fracture and those who are at high risk for fracture. For the prevention of osteoporosis, the antiresorptives currently approved by the FDA are alendronate, risedronate, raloxifene, and estrogen. These agents increase BMD at both the hip and the spine during the first 2 to 3 years of use, with subsequent stabilization.

Bisphosphonates Given their demonstrated safety record and their ability to prevent hip fractures, the bisphosphonates should be considered for initial prevention and treatment of osteoporosis. Bisphosphonates bind to skeletal hydroxyapatite and decrease osteoclast activity, thus slowing bone resorption while new bone formation continues. Over a period of 2 to 3 years, they produce a 6% increase in bone density and a 30% to 50% reduction in fracture risk at both vertebral and nonvertebral sites, with greater effectiveness at the former.[48-51] Alendronate is dosed at 70 mg once weekly for osteoporosis treatment and at 35 mg once weekly for osteoporosis prevention.[57] Risedronate is given at 35 mg once weekly for prevention or treatment of osteoporosis.[58] Risks of bisphosphonate therapy include esophagitis; these agents are contraindicated in patients with active esophagitis, achalasia, or esophageal stricture, and they should be used with caution in anyone with a history of esophagitis or gastroesophageal reflux disease. Caution should be taken in prescribing these agents for women of childbearing age: they persist in bone matrix and can be measured in the blood for years after discontinuance, so there is a risk of passage to the fetus even in patients no longer taking them.

Because they are poorly absorbed, bisphosphonates should be taken on an empty stomach immediately upon awakening in the morning. After taking the agent, the patient should remain upright and should not consume food for at least 1 hour. How long bisphosphonate therapy should be provided is an area of active interest in osteoporosis research. Alendronate use for up to 10 years provides a sustained benefit and is well tolerated.[59] The bone-preserving effects of alendronate may persist for up to 2 years after the drug is discontinued, presumably because it remains in bone matrix. There has been concern that prolonged therapy with bisphosphonates might lead to adynamic bone, a condition associated with low bone turnover, microfractures, and chronic pain. It may be appropriate to consider a 1- to 2-year drug holiday after 5 to 10 years of bisphosphonate therapy to avoid these theoretical risks, although no guidelines currently exist for duration of bisphosphonate therapy for osteoporosis.

Raloxifene Raloxifene, a SERM, can be used for osteoporosis prevention or treatment.[60] Raloxifene acts as an estrogen agonist in bone, but it acts as an estrogen antagonist in breast and uterus. Thus, its use is not associated with endometrial hyperplasia, and concurrent treatment with progestins is not required. Raloxifene also does not increase the risk of breast cancer. In fact, it is under active investigation for its potential role in preventing breast cancer in high-risk patients.[61] Raloxifene increases bone density by only about 1% over 12 to 24 months, but data on vertebral fracture are comparable to those of estrogen replacement therapy (ERT) or bisphosphonate therapy. Raloxifene has not been shown to reduce the incidence of hip fracture. It is generally well tolerated but may exacerbate menopausal hot flashes. Patients should be advised that raloxifene carries a threefold increased risk of thromboembolic disease, which is similar to that seen with estrogen. Preliminary reports suggest no detrimental effect on cardiovascular risk.[62] Raloxifene is a good choice for patients who have bone loss primarily in the spine, for

women with relatively low risk of hip fracture, and for patients who are unable to tolerate oral bisphosphonates. Raloxifene is not approved for use in premenopausal women or men.

Calcitonin Calcitonin has much less potent effects on BMD and fracture than do the bisphosphonates, raloxifene, or estrogen.[63] This hormone, which is normally produced by the parafollicular cells (C cells) of the thyroid, typically circulates in low concentration in humans. The precise role of calcitonin in the body is not fully understood, but it appears to be a weak regulator of serum calcium concentrations and bone turnover. Commercially available products include calcitonin injections and nasal spray. Both are approved for the treatment of established osteoporosis but not for its prevention. In most of the calcitonin trials, the average increase in bone density was only 1% to 2% over 2 years. Calcitonin has been primarily shown to prevent vertebral fractures and has not been shown to prevent nonvertebral or hip fractures.[52] Calcitonin is generally safe; occasional flushing, headaches, anosmia, or nasal irritation is observed with the nasal spray. There is a concern about tachyphylaxis, or decreased effectiveness over time, with calcitonin use. Because of the availability of other safe and more potent drugs for osteoporosis, calcitonin is rarely used except when other options are lacking.

Estrogen Until recently, ERT was widely recommended as first-line therapy for both the prevention and treatment of osteoporosis, although it is approved by the FDA for prevention only.[43] Advocates argued that estrogen directly corrected the chief pathophysiologic defect of the menopause: estrogen deficiency. However, use of ERT to maintain bone health has fallen out of favor because of data indicating that it may actually increase the risk of cardiovascular disease, as well as the risk of breast cancer and ovarian cancer. The multicenter WHI was created to study the effects of hormone replacement therapy in healthy postmenopausal women. Women receiving estrogen in combination with progestin had a lower incidence of fracture, but this arm of the study was stopped prematurely because of a 26% increase in the risk of breast cancer and a lack of overall benefit in this treatment group. The WHI also found that, compared with women taking a placebo, women taking the combination of estrogen and progestin had a 29% increase in myocardial infarction, a 41% increase in stroke, and a doubling of thromboembolic events. For hysterectomized women taking estrogen without progestin, the risk of stroke was increased compared with the group receiving placebo. As a result of the WHI findings, estrogen should probably no longer be considered the optimal first-line preventive or therapeutic agent for bone loss in postmenopausal women.[55] On the basis of these data, the use of estrogen for osteoporosis prevention or treatment should be limited to women who require its beneficial effects for menopausal symptoms. For other women, there are equally effective and probably safer alternatives. When used, ERT should be accompanied by a comprehensive screening program consisting of regular lipid profiles, breast examinations, mammography, and gynecologic assessments.[64]

Anabolic therapy with recombinant human PTH (1-34) Currently, PTH (1-34)—teriparatide—is the only available anabolic agent for osteoporosis in the United States, although other anabolic agents have been developed [*see* Future Therapies, *below*]. Teriparatide was approved by the FDA in late 2002 for use in osteoporosis. Although chronic elevation in PTH results in bone loss, brief increases in PTH have anabolic effects on bone. A daily injection of recombinant human PTH (hPTH) provides a brief rise in PTH, resulting in increased BMD. To date, teriparatide is the anabolic agent with the most potent effects on BMD. Its effects are particularly dramatic in the spine: in one study comparing teriparatide and alendronate treatment, at the end of 14 months, alendronate-treated patients had a 5.6% increase in lumbar spine BMD, whereas teriparatide-treated patients had a 12.2% increase.[65] It should be noted, however, that teriparatide has not been demonstrated to prevent hip fracture, and it does not have FDA approval for that purpose.

Teriparatide is administered nightly in a standard subcutaneous dose by a pen delivery system. Side effects include flushing, hypercalcemia, and hypercalciuria. Patients must be monitored with measurement of serum calcium and 24-hour urine calcium levels, and calcium intake must be adjusted as needed to keep urine and serum calcium in a normal range. Teriparatide comes with a black-box warning from the FDA concerning an association with risk of sarcomas, based on its effects in rats. For this reason, it is administered for no longer than 2 years, and its use is contraindicated in patients with active malignancy. Unfortunately, the high cost of teriparatide has limited its use, because much of its target population is on Medicare and does not have prescription drug coverage.

Selection of patients for this costly and potent drug should be done with care. Osteoporosis experts have developed a consensus opinion, published in the spring of 2004, to help clinicians identify appropriate patients for teriparatide therapy. Indications for its use were as follows: (1) history of vertebral fracture, T score –3.0 or below, or age greater than 69 years; (2) fracture or unexplained bone loss in patients on antiresorptive therapy; and (3) intolerance of oral bisphosphonate therapy. Contraindications listed include hypercalcemia, Paget disease, history of irradiation to the skeleton, sarcoma, or malignancy involving bone.[66]

Combining teriparatide and bisphosphonates Simultaneous administration of teriparatide and oral bisphosphonates impairs the anabolic effects of teriparatide.[67] When these agents are given sequentially, however, the increase in BMD seen with initial teriparatide therapy is followed by additional gain during subsequent bisphosphonate treatment.[68] This increase in BMD in the setting of bisphosphonate use is thought to reflect mineralization of bone matrix laid down during the teriparatide treatment. Interestingly, when teriparatide is administered to patients who have previously been treated with bisphosphonate, their response to teriparatide is blunted.[69] This finding is of concern, because many patients currently being considered for teriparatide therapy have already been treated with bisphosphonates.

National Osteoporosis Foundation guidelines The most comprehensive set of guidelines for the management of osteoporosis comes from the National Osteoporosis Foundation (NOF).[70] These guidelines, which were updated in 2004, recommend that any postmenopausal women with a prior vertebral or hip fracture should receive pharmacologic therapy to reduce fracture risk. Therapy should also be initiated in women with a hip T score lower than –1.5 and one or more of the following risk factors for osteoporotic fracture: (1) a family history of osteoporosis in a first-degree relative, (2) a personal history of any fracture as an adult, (3) low body weight (< 127 lb), (4) current smoking,

or (5) use of oral corticosteroid therapy for more than 3 months. Women with no risk factors for osteoporotic fracture (other than age, gender, and menopausal status) should be treated if the hip T score is below –2.0. In the NOF guidelines, the choice of antiosteoporotic therapy follows current FDA indications, without specific recommendations of one agent over another [*see Table 6 for other sources of information*].

Follow-up For purposes of monitoring, a follow-up bone density study is indicated no sooner than 1 to 2 years after the initial determination, depending on the results and whether any therapy is initiated. Subsequent measurements may be made at similar or longer intervals, depending on the patient's progress and any further therapeutic alterations. For more precise comparison, follow-up studies should be performed using the same DXA unit, if possible. It should be borne in mind that with many of these therapies, the expected increase in BMD seen on follow-up DXA studies will be minimal in comparison with the improvement in fracture risk. However, patients who continue to lose bone despite ongoing antiresorptive therapy should be evaluated for previously unrecognized causes of secondary osteoporosis. Biochemical bone turnover markers (e.g., N-telopeptide, pyridinoline cross-links) may be helpful to document patient response to antiresorptive therapy, but they show significant variability within individuals, and therefore large changes are necessary for proper interpretation. In addition, their concentrations may be influenced by timing of collection, diet, and other factors. Accordingly, widespread consensus is lacking on their precise role in osteoporosis management.

Future therapies Recombinant hPTH (1-84) is currently in phase III trials and appears to have effects similar to those of hPTH (1-34) (see above). Additional agents in the SERM class include lasofoxifene (currently being evaluated for FDA approval) and bazedoxifene (in phase III trials). Strontium ranelate is an anabolic agent that appears to act on the CaSR to induce osteoblast differentiation. It enhances both bone resorption and formation, with an emphasis on formation, resulting in significantly decreased risk of vertebral fracture.[71] It was approved for use in Europe in late 2004. Preclinical studies of the anabolic effects of vitamin D on bone are under way[72] and may lead to the development of vitamin D analogues for osteoporosis therapy.

OSTEOMALACIA

Osteomalacia is a condition in which the bone matrix is normal in quantity but is weakened by insufficient mineral content. Osteomalacia in the growing skeleton is termed rickets. Causes of osteomalacia include nutritional deficiencies of calcium, phosphate, or vitamin D; intestinal disease affecting the absorption of these substances; abnormalities in vitamin D metabolism, such as occurs in liver disease, renal failure, or through the use of antiepileptic drugs; vitamin D resistance; renal phosphate leak; and oncogenic osteomalacia (a humoral syndrome of increased urinary phosphate loss associated with rare tumors of mesenchymal origin).[73] In adults, severe osteomalacia presents as fatigue, proximal muscle weakness, and diffuse or focal skeletal pain. Mild osteomalacia is common and often asymptomatic.[74] Decreased or low-normal concentrations of both calcium and phosphorus are noted on biochemical testing, and the alkaline phosphatase concentration is elevated. Depending on the cause, decreased levels of either 25-$(OH)D_3$ or calcitriol may be seen. Plain films may demonstrate osteopenia and pseudofractures. When necessary, the diagnosis can be confirmed with bone biopsy processed and analyzed by an experienced bone pathologist. The treatment of osteomalacia depends on the pathogenesis of the condition. For the majority of cases in which the problem is dietary insufficiency or malabsorption of vitamin D, administration of high doses of cholecalciferol and calcium will rapidly correct deficits and heal the bone. Underlying conditions such as celiac disease (which may be asymptomatic) should be identified and treated. Other conditions, such as tumor-induced osteomalacia, represent special cases and require a different approach (e.g., phosphate supplementation).

PAGET DISEASE OF BONE

Paget disease is a relatively common condition in which abnormal osteoclast function leads to accelerated and disordered bone remodeling, producing highly disorganized bone microarchitecture in affected areas. This sometimes leads to deformity of affected bones, increased vascularity, nerve impingement syndromes, and a propensity to fracture. Paget disease is commonly seen in the elderly and may be familial. The precise etiology is not yet known, although a viral origin is suspected. Many persons with Paget disease are asymptomatic. The sole manifestation may be increased serum alkaline phosphatase activity, detected incidentally on blood testing. If the disease is severe or extensive, pain syndromes may result. Very often, the discomfort originates not from bone itself but from arthritic changes in adjacent joints caused by altered biomechanics. The skull may be enlarged, or there may be significant bowing of the long bones of the legs. Bony overgrowth may lead to local impingement on spinal nerve roots, with pain or neurologic deficits; overgrowth in the inner ear can lead to sensorineural hearing loss. Rare complications include high-output chronic heart failure (from multiple vascular shunts in bone) and transformation to osteosarcoma.

Diagnosis

The diagnosis of Paget disease is typically made after finding isolated elevation of the serum alkaline phosphatase level without evidence of liver disease. (Fractionation of alkaline phosphatase isoenzymes can confirm bone as the source). A nuclear bone scan is performed next to identify involved areas. The results of the bone scan will identify which bones should be evaluated by plain x-ray to exclude signs of metastatic disease and confirm pagetic findings.

Treatment

Treatment of Paget disease is indicated for patients with bone pain; it is also indicated, regardless of symptoms, if there is involvement of a weight-bearing bone or a joint. Antiresorptive

agents, such as high-dose oral or injectable bisphosphonates (see above) or injectable calcitonin, can be used to treat this disorder.[75] Treatment of any vitamin D deficiency is essential before starting intravenous bisphosphonate therapy to avoid hypocalcemia. Disease activity and response to therapy are assessed with serial measurement of alkaline phosphatase or other bone turnover markers. The goal of treatment is normalization of alkaline phosphatase. Re-treatment is indicated if the alkaline phosphatase level begins to rise above normal. Patients with skull involvement should have periodic audiometry to exclude hearing loss.

VII GENETICS FOR THE CLINICIAN

Robb Moses, m.d.
Jone E. Sampson, m.d.

The human genome consists of approximately three billion pairs of nucleotides (bases) that encode about 40,000 genes in a string array consisting of a DNA polymer duplex. The information in the protein-coding genes is converted to functional elements through the copying of base sequences to RNA. RNA may itself be active—heterogeneous ribonucleotide proteins can interact with newly synthesized RNA to regulate structural changes or conformation—or it may be copied to protein. Whereas DNA is a relatively stable molecule, RNA is much less so, and RNA molecules are replaced by other RNA molecules rapidly in the cell. Models of how the genome is packaged within the nucleus, copied, and read by the cell have evolved at the molecular level. Science has also come to recognize how the genome is partitioned during cell division and during the formation of germ cells. At all levels, the information content is protected by mechanisms safeguarding the stability of the genome. Information is transferred out of the genome along two paths: information is transferred within the cell for defined functions specific to cell type (horizontal information transfer) and is transferred from one generation of cells to another through cell division, either for cell multiplication or for reproduction (vertical transfer).

The advances in the past century, from the verification of Mendel's observations[1] to having in hand the essentially complete sequence of the human genome, occurred in bursts in understanding or in technology. During the first 50 years of the 20th century, the principle of inheritance by means of packets of genetic information that were stable and that persisted independently of other units of inheritance from generation to generation was verified in animals and plants, with the fruit fly *Drosophila melanogaster* being a notable organism of study. In the 1940s, DNA was unequivocally shown to be the chemical basis of the gene.[2] Within another dozen years, the structure of DNA at the chemical level was proposed by Watson and Crick.[3] The model had immediate implications for the copying of genes and the mode of transfer of information. During the next 2 decades, the fundamental rules and mechanisms of these processes were determined; these advances relied heavily on the study of bacteria and their viruses, the phages. In the 1970s, three different technological advances catapulted genetics to the point at which the human DNA sequence was determined by century's end. These disparate techniques were as follows: the development of the ability to determine DNA sequence information in a relatively simple and reproducible manner; the ability to move and duplicate isolated segments of DNA; and the evolution of computers with adequate power for storing and comparing large amounts of sequence information. Refinements in these basic advances, coupled with automation, led to the sequencing of the human genome during the last 15 years before the turn of the millennium.

With progress in technology, genetics has become applicable to clinical practice. The physician needs to be responsive to patterns of inheritance suggestive of genetic disease in a family member; the physician should also be aware of diagnostic capabilities for inherited diseases and be able to interpret the results of genetic testing for the patient or refer the patient for counseling. Given the pace of advances and the complexity of techniques, it is important that clinicians have knowledge of resources for patient referral and other relevant information. These resources include the Internet and other resources for technical and medical information and patient referral.

Diagnostic capabilities continue to improve, but therapies based on genetic technologies still lag. Prenatal diagnosis and neonatal screening are already powerful tools for the prevention of disease. However, researchers in genetic medicine are striving to address and develop treatments. New diagnostic powers based on microarray analysis, the hope of gene therapy, and the tailoring of drug therapies to maximize responsiveness and sensitivity for individuals seem feasible.

This subsection addresses basic knowledge of the human genome for the physician, gives reference points for the nongenetic physician, and focuses on the pathophysiology of genetic disease.

Genome Structure and Function

DNA STRUCTURE

Understanding the structure of the DNA duplex led at once to recognition that the polymer strand, composed only of four bases, could encode information in a linear format. DNA is composed of two polymer strands with a sugar-phosphate backbone, with the bases attached to each deoxyribose moiety [*see Figure 1*]. The two strands of DNA are stabilized by the bonding of hydrogen between the bases—the purine adenine (A) pairs with the pyrimidine thymine (T), and the purine guanine (G) pairs with the pyrimidine cytosine (C). The discovery of this was pivotal in modeling the structure of DNA. Alternative forms of pairing can be projected, but the pairings based on the most common structures of the bases and the strongest hydrogen bonds are predominant. The sugar-phosphate backbones of the strands have a chemical polarity, and the strands are antiparallel with respect to the polarity of the bonds between deoxyribose components. The information can be duplicated using each separate strand as a template. The linear code of the four-base alphabet allows enormous potential for information content—each cell contains about 1 m of DNA packaged within it.

DNA REPLICATION

The replication of DNA is a critical step in information storage. Although the structure is suggestive of a model for the replication of DNA, the definition of the apparatus took decades [*see Figure 2*]. Because the information is contained in the sequence of the bases, any change of a base could result in a subsequent change (mutation); mutations may be silent, in which case they do not lead to a change in protein function, or mutations may result in the inactivation of the product of the gene. Cells possess mechanisms to protect against changes in the DNA sequence, although natural variety—an advantage in selection—requires a low rate of change.

The replication machinery is centered on a DNA polymerase. DNA polymerase is an unusual enzyme in that it catalyzes a reaction directed by the base sequence of the strand be-

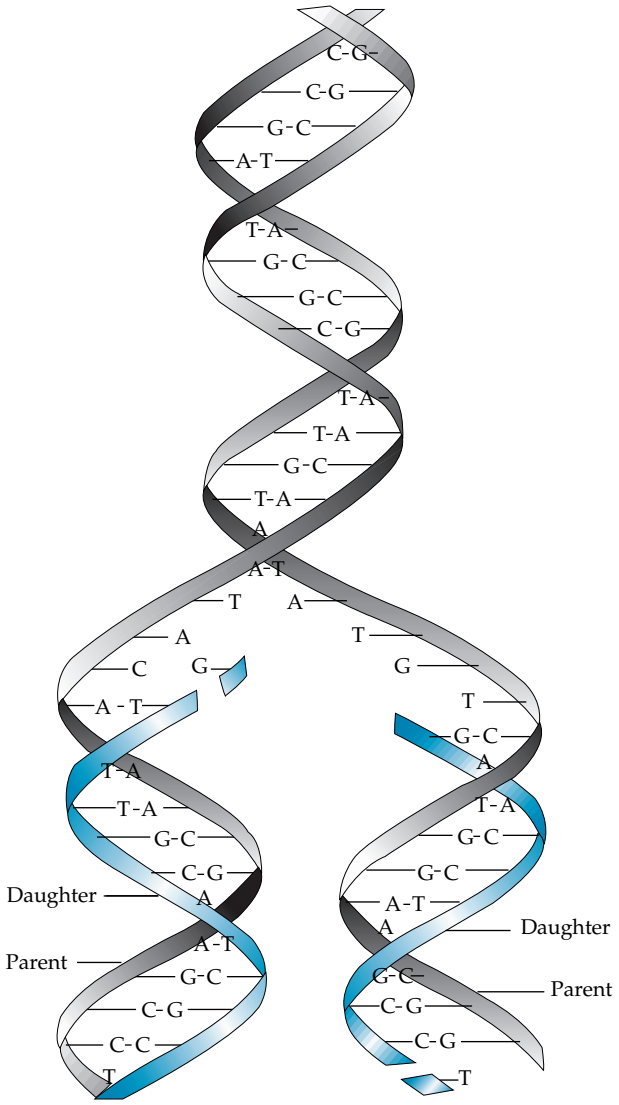

Figure 1 **In replication, the two strands of the parent DNA molecule (gray) separate as the base pairs detach. The daughter strands (blue) form when guanine (G) pairs with cytosine (C) and when adenine (A) pairs with thymine (T). The orientation of the two strands is antiparallel, so the strands grow in opposite directions.**

ing copied; that is, the base inserted into the new strand is directed by the base opposite. The enzyme uses all four bases with equal affinity, and the reaction is determined by the template. DNA polymerases are part of an assembly of proteins termed the replisome. The synthesis of new DNA is faithful; only about one base in 100,000 is a misincorporation. The replisome is actively proofreading the product, an exonuclease, which can remove a mispaired base from the growing end of the DNA strand (all DNA is made only in the 5′ to 3′ direction, based on the convention for the sugar-phosphate backbone). This proofreading by the replisome removes 99% of misincorporations. A last line of defense for integrity of information during replication is the system of mismatch repair. A complex of proteins tracks DNA synthesis, recognizes mismatches in the DNA that occur as a result of misincorporation, and corrects those mismatches. About 99% of mismatches are removed; the overall mistake rate in replication is about one in one billion to 10 billion.

Information is copied from the long-lived DNA molecule to the less stable messenger RNA (mRNA) molecule, which serves to translate the information into proteins. mRNA represents only 1% or so of the RNA in the cell; other categories of RNA synthesize proteins or act as catalytic units in the processing of genetic information. For protein synthesis, the mRNA must be read and the information transferred in a three-base code (codon). This allows for more triplet codons than the 20 amino acids used to build proteins would require. Several of the codons are delegated to terminating protein synthesis, and there is redundancy in the codons for the amino acids.[4]

mRNA is initially transcribed as a long, exact copy of the DNA strand, but posttranslational processing results in retention of the essential information needed for translation to protein. The genome contains introns, which interrupt the coding sequences, the exons. The intron material does not contain information for translation, so it must be removed for translation. This occurs during the RNA processing step, which is regulated by conserved sequences that identify the end and start of the exons [*see Figure 3*], allowing the coding portions to be spliced together. Because the signals that lead to removal are not stringent, it is possible for exons to be occasionally skipped and for splice variants and splice mutations to occur. This gives a great degree of flexibility for the final gene product and allows tissue-specific products.

The primary RNA transcript has other notable features. The 5′ end is capped with a protective methylated base; the 3′ end contains a region rich in pyrimidines and ends in a stretch of A residues, the poly-A region. After processing, the mRNA is transported to the cytoplasm, where translation on the ribosome protein synthesizing machine occurs.

After a protein is made, it may be modified through the attachment of sugars, acetyl groups, phosphates, or other modifying groups. Specific sequences direct the export or subcellular localization of the protein.

CHROMOSOME STRUCTURE AND IDENTIFICATION

The DNA double helix is packaged into the chromosome, a structure recognizable by light microscopy. The packaging is very efficient; the DNA is in the form of supercoils—like a rubber band that is tightly wound until it compacts upon itself. It is then folded into the chromatin assembly by the binding of basic histone proteins. The resulting structure resembles beads on a string, with the DNA wound tightly around a core of histone proteins—two H2A, two H2B, two H3, and two H4 residues—to form the nucleosome. Nucleosomes are spaced approximately 80 bases apart. The DNA structure is further condensed by the addition of other proteins. The DNA in chromatin also may be modified by the addition of methyl groups to certain positions, and the histones may be modified by phosphorylation, acetylation, or the addition of ubiquitin. These modifications to the chromatin are related to the regulation of gene expression.

There are 23 chromosome packages of genes in a cell; two of these chromosomes, X and Y, are the sex chromosomes. In females, there are two X chromosomes; in males, an X and a Y chromosome. The remaining 22 pairs of chromosomes are the autosomes. In the process of cell division, or mitosis, the chromosomes condense and are duplicated, with a complete, new set going to each daughter cell [*see Figure 4*]. In producing germ cells for reproduction, the number of chromosomes is halved to a haploid number of autosomes through the process of meiosis,

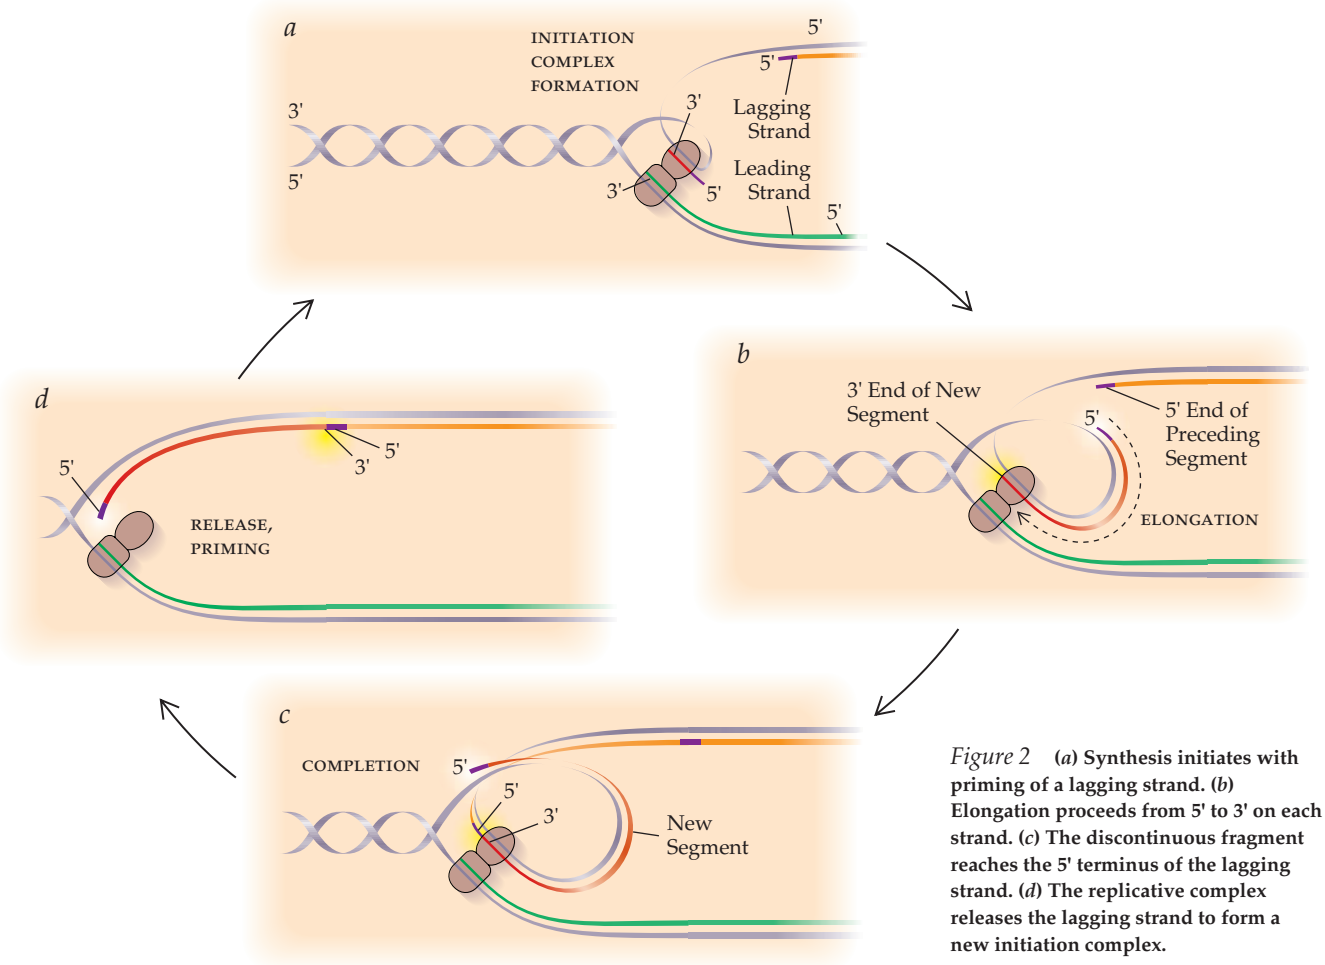

Figure 2 **(*a*) Synthesis initiates with priming of a lagging strand. (*b*) Elongation proceeds from 5' to 3' on each strand. (*c*) The discontinuous fragment reaches the 5' terminus of the lagging strand. (*d*) The replicative complex releases the lagging strand to form a new initiation complex.**

with either an X or a Y chromosome in spermatozoa and an X chromosome in oocytes. Telomeres are special DNA sequences at the ends of chromosomes that maintain integrity at chromosome termini and require telomerase enzyme activity for maintenance of normal length. The chromosomes contain a region of repeated sequence DNA, which is the centromere. This is the portion that anchors the replicated duplexes (chromatids) together at the time of cell division. The centromere is not centrally located; this results in a long arm, termed the q arm, and a short arm, termed the p arm, for petite. There is a standard system of nomenclature for describing the number of chromosomes and recognizable alterations or rearrangements of the chromosomes. For example, the normal male karyotype is listed as 46,XY and the normal female as 46,XX.

Chromosome identification and characterization was much improved by the development of staining or banding techniques. This process involves partial denaturation of the DNA and proteins, followed by staining. The resulting preparations allow identification of up to 800 bands, which may then be evaluated for structural changes. These techniques have led to the recognition of many rearrangements, leading to localization of genes.

Additional staining techniques based on binding to complementary short stretches of DNA tagged with fluorescent probes have been developed. Further development has led to chromogenic stains, which allow the identification of individual chromosomes and of certain regions of the chromosome—for example, the centromere or telomere.

Mutations in Clinical Conditions

Mutations are changes in the sequence of nucleotides within DNA, which may result in an abnormal or deleterious function of the gene product. There are different types of mutations leading to genetic disease. These mutations range in size from single base changes that alter the gene product to the addition or deletion of whole chromosomes. Intermediate structural rearrangements may involve segments that are large enough to be able to be detected microscopically, or they may involve segments that are so small as to require detection by molecular labeling methods. Genetic diseases resulting from single gene mutations are inherited in classic Mendelian fashion, although there is always the possibility of new mutations occurring in individuals with unaffected parents. Several disorders were originally thought to be genetic in nature, but the pedigrees of affected individuals were not consistent with known patterns of Mendelian inheritance. Understanding the mechanisms by which mutations occur in these disorders led to an understanding of other factors that influence disease; such factors include the effect of imprinting on phenotype expression, the role of trinucleotide expansion in genetic diseases, and the role of mitochondrial DNA (mtDNA) mutations in disorders of energy metabolism.

The following discussions describe the roles of the different mechanisms of mutation in genetic conditions seen more commonly in the general population.

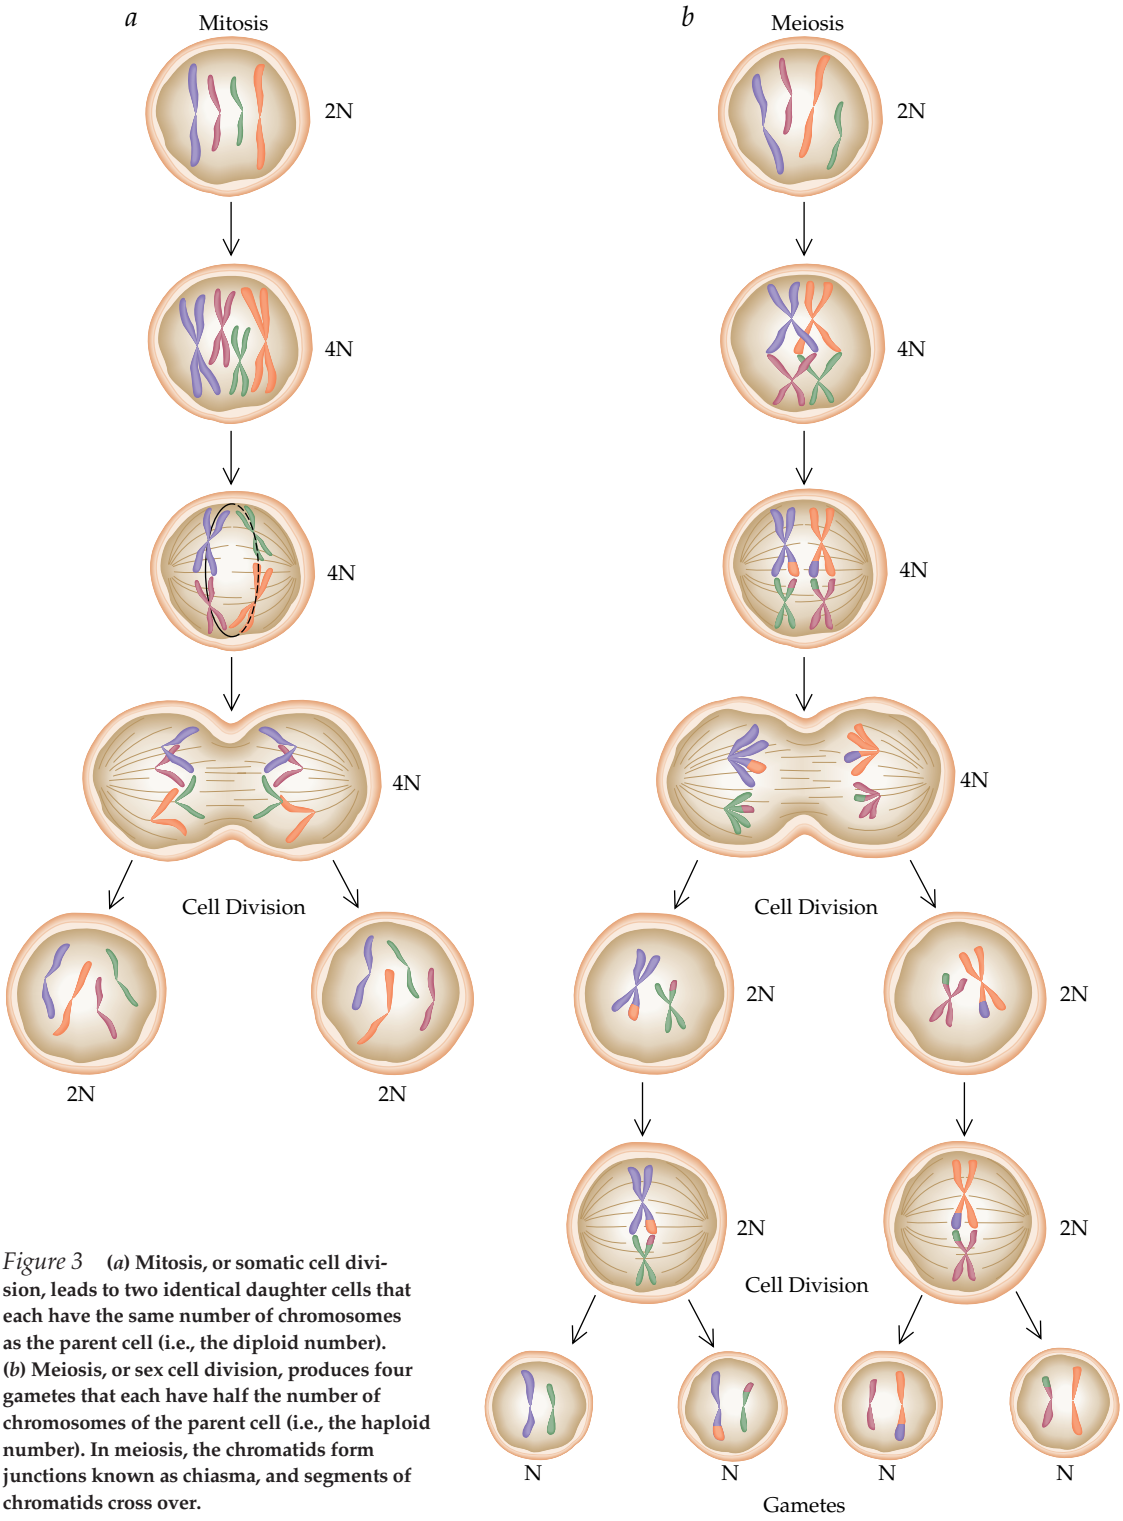

Figure 3 **(*a*) Mitosis, or somatic cell division, leads to two identical daughter cells that each have the same number of chromosomes as the parent cell (i.e., the diploid number). (*b*) Meiosis, or sex cell division, produces four gametes that each have half the number of chromosomes of the parent cell (i.e., the haploid number). In meiosis, the chromatids form junctions known as chiasma, and segments of chromatids cross over.**

DISORDERS CAUSED BY AN ABNORMAL NUMBER OF CHROMOSOMES

Our ability to associate clinical disease with detectable changes in genetic material was established in patients who were identified as having an abnormal number of chromosomes, including trisomy 21 and the sex chromosomes. Before the development of techniques for identifying and separating individual chromosomes from cell preparations, these patients were described clinically on the basis of a shared constellation of congenital anomalies and dysmorphic features (i.e., a syndrome). Individuals with Down syndrome have characteristic facial features; they experience hypotonia in infancy, delayed development, and cognitive impairment, as well as a pattern of congenital malformations. With the ability to karyotype individuals, rarer abnormalities of whole chromosomes were detected in dysmorphic stillborn infants or in live-born infants who subsequently died early in infancy (for example, from trisomy 18 or 13 syndrome) and were detected in analyses of

first-trimester abortuses, which in general have a 50% rate of chromosome abnormalities.

The gain or loss of an entire chromosome is generally the result of nondisjunction or the missegregation of chromosomes at the time of cell division (i.e., in meiosis or mitosis). This results in one daughter cell having two copies of a particular chromosome and in the other daughter cell having no copy. Fertilization of a germ cell with two copies of a single chromosome results in a zygote trisomic for that chromosome. Three autosomal trisomy syndromes have been described in live-born infants: the syndromes associated with trisomies 13, 18, and 21. Occasionally, trisomies of other autosomes occur, but there is usually a normal cell line present as well (mosaicism). In most cases, this is the result of a postzygotic segregation error in mitosis that occurs early in embryogenesis. Extra chromosomal material is better tolerated than missing material; there are no viable autosomal monosomy syndromes. The lack of one of the sex chromosomes is deleterious; the lack of a single X chomosome is lethal. Having a single X chromosome without a Y chromosome (Turner syndrome, which is associated with karyotype 45,X) results in a high proportion of fetal wastage. Triploidy and tetraploidy result in abnormal embryogenesis, and a haploid conceptus has never been reported.[5]

The development of techniques for chromosome banding allowed the identification of individual chromosomes by banding pattern rather than merely by size. This enabled the detection of the addition, loss, or rearrangement of large groups of genes by means of changes in chromosome appearance; thus, translocations, inversions, duplications, isochromosomes, and ring or marker chromosomes were described. These changes may or may not have an effect on phenotype, depending on whether there is a net conservation of genetic material, but they can have profound effects on reproductive fitness, affecting the process of chromosome segregation in meiosis. In approxi-

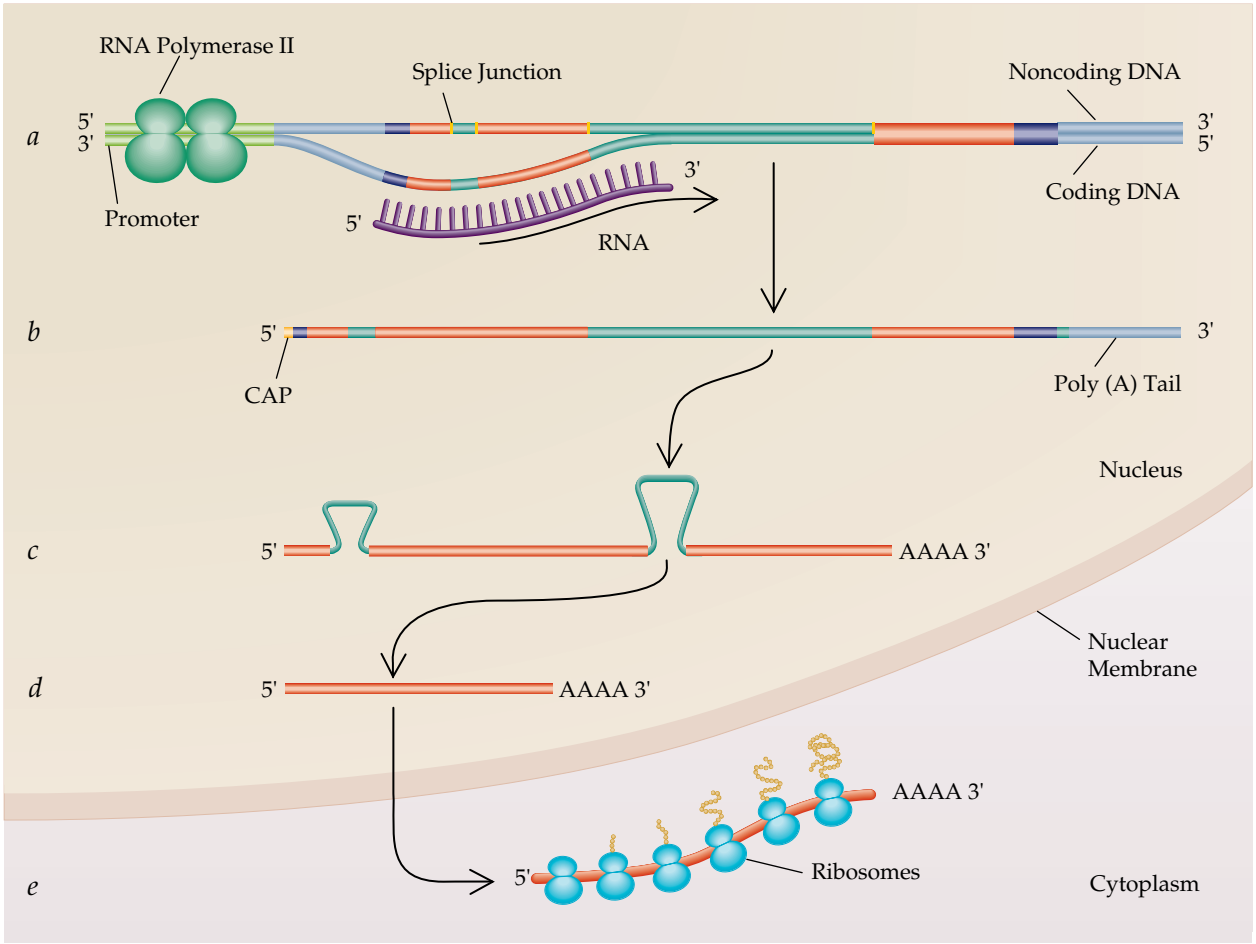

Figure 4 **(*a*) The β-globin gene contains three exons (orange) separated by two introns (green). The boundaries between exons and introns are known as splice junctions and contain specific nucleotide sequences that are required for proper joining of the exons. The synthesis of messenger RNA (mRNA) from the β-globin gene proceeds in a 5′ to 3′ direction. The enzyme RNA polymerase II (dark green) binds to a promoter region (light green) located 200 to 300 base pairs in the 5′ direction or located upstream of the point at which mRNA synthesis begins. (*b*) mRNA begins with a 7-methylguanosine residue, referred to as the CAP site, and includes a 5′ untranslated region (light purple), a coding region of exons and introns, and a 3′ untranslated region (light purple). Nearly all mRNAs that encode proteins terminate at their 3′ ends with a string of approximately 200 adenine residues [known as the poly (A) tail], which are added 18 to 20 base pairs downstream from an AAUAAA signal in the 3′ untranslated region. (*c*) After mRNA is synthesized but before it leaves the nucleus, the introns are excised and the exons are spliced together to form mature mRNA (*d*). (*e*) Once the mature mRNA reaches the cytoplasm, it attaches to ribosomes and is translated into protein.**

mately 5% of couples with a history of three or more first-trimester losses, one of the partners will be found to have a chromosome abnormality; thus, karyotype analysis is indicated in such persons.[6]

DISORDERS OF PARTIAL CHROMOSOME DELETION

22q11 deletion syndrome is a microdeletion syndrome that is common (occurring in one in 4,000 persons) and unique, in that most cases are de novo, not inherited from an affected individual. Persons with 22q11 deletion syndrome have variable clinical features, including (1) congenital heart disease (occurring in 74% of patients), particularly conotruncal malformations, such as tetralogy of Fallot, interrupted aortic arch, and truncus arteriosus; (2) palatal abnormalities (69%), notably velopharyngeal incompetence, submucosal cleft, and cleft palate; (3) characteristic facial features, including auricular abnormalities, hypoplastic alae nasi with a bulbous nasal tip, prominent nasal root, malar flatness, and hooded eyelids (> 50%); and (4) learning disabilities (70% to 90%).

Before the identification of the 22q11 microdeletion, patients were diagnosed on the basis of clinical features. The condition went under several names, including velocardiofacial syndrome, DiGeorge syndrome, Shprintzen syndrome, CATCH-22 (*c*ardiac defects, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, *h*ypocalcemia), Cayler syndrome, and conotruncal anomaly face syndrome. Velocardiofacial syndrome was originally described as the combination of velopharyngeal incompetence, congenital heart disease, characteristic facial features, and developmental delay. DiGeorge syndrome, which includes the previously mentioned features as well as parathyroid deficiency and immune dysfunction from thymic aplasia or hypoplasia, was thought to be a developmental field defect of the third and fourth pharyngeal pouches.

In 1992, the first report of a microdeletion of chromosome 22 at the 11.2q band was reported; this was subsequently confirmed in other cases. In approximately 15% of cases, a visible deletion can be seen. Deletion 22q11 is diagnosed in individuals with submicroscopic deletions by use of fluorescence in situ hybridization (FISH) using DNA probes from the DiGeorge chromosome region [*see Figure 3*]. Fewer than 5% of patients with clinical features of deletion 22q11 have normal results on cytogenetic studies and negative results on FISH testing.[7]

The typical deletion encompasses three million base pairs, with smaller deletions of several hundred thousand base pairs reported. However, there is no correlation between the size of the deletion and the expression of the syndrome. It is still unknown whether the syndrome is a contiguous gene syndrome or whether the majority of the phenotype is the result of a single gene deletion that is variably expressed in affected individuals. The broadness of the phenotype and the unification of the various above-mentioned syndromes under the umbrella of deletion 22q11 have created some confusion. All cases of velocardiofacial syndrome, DiGeorge syndrome, Cayler syndrome, and conotruncal anomaly face syndrome that are associated with a deletion at 22q11 represent the same disorder.

The high occurrence of de novo deletions of 22q11 suggests some instability in this region. Because the overwhelming majority of patients have the same deletion in the 3 Mb (megabase) region, this area has been sequenced and carefully examined. This region contains four copies of duplicated sequence or low copy repeats, located nearer to the end points of the region. Each low copy repeat contains one or more duplicated modules, which contain duplicated markers. The presence of these low copy repeats at this typically deleted region suggests that sometimes these areas misalign; during cell division and homologous recombination, this leads to duplication of the region on one chromatid and deletion on the other. The presence of these low copy repeats, therefore, gives us some insight into the mechanisms responsible for the recurrence of this common de novo deletion involving chromosome 22.[8] Repetitive sequences contribute to the inherent instability of some chromosome regions.

DISORDERS OF SINGLE GENE MUTATIONS

Anemia, which is a common clinical problem, is an excellent example of a condition that has many causes, both genetic and environmental. As monogenic disorders, the hemoglobinopathies are varied and complex. Approximately 7% of the world's population are carriers of different inherited disorders of hemoglobin, including structural hemoglobin variants and the thalassemias, which are disorders that result from defective synthesis of the globin chains. Hemoglobin is a tetramer of two pairs of dissimilar globin chains, commonly α-globin and β-globin chains in hemoglobin A (HbA) or α-globin and δ-globin chains in HbA_2. Healthy adults can have a residual amount of HbF (fetal hemoglobin, composed of two α-globin and two γ-globin chains), which is produced during fetal life and then replaced by adult hemoglobin in the first year of life. Since the discovery of a single point mutation that leads to the amino acid substitution of valine for glutamine, resulting in sickle cell anemia, over 700 structural hemoglobin variants have been identified, the most common of which are sickle hemoglobin HbS, HbC, and HbE. The thalassemias are generally classified on the basis of the particular globin chain or chains that are inefficiently synthesized.[9]

β-Thalassemia results from defective β-globin synthesis, which leads to an excess of α-globin chains. Over 200 mutations in β-globin genes have been identified in patients with β-thalassemia. The majority of these are point mutations—the loss of one or two bases that results in the disruption of gene function at the transcriptional, translational, or posttranslational level and in the decreased synthesis of the β-globin chain. Clinically, one would expect the severity of the condition to correlate with the amount of β-globin chain produced, with homozygotes or compound heterozygotes being profoundly anemic and requiring lifelong blood transfusions and heterozygotes having a milder or silent condition. Sibship studies have demonstrated phenotypic diversity in family members with the same genotype. This diversity may be a reflection of the inheritance of mutations in other loci involved in globin synthesis, because mutations for thalassemias and structural hemoglobinopathies occur together at a higher frequency in many populations. Combinations of structural hemoglobinopathies may positively alter the phenotype of thalassemia and reduce the concurrence of α- and β-thalassemia mutations in an individual; the occurrence of this process can vary from individual to individual in families. In addition, there are several mutations in the β-globin gene cluster and in the promoter region of the γ-globin genes that result in the persistence of fetal hemoglobin; such persistence produces a milder phenotype overlaying either a structural hemoglobinopathy or a β-thalassemia. Finally, mutations or polymorphisms in genes involved in bilirubin, iron, and bone metabolism may play a role in the clinical course of the disease in affected individuals.[10]

IMPRINTING DEFECTS

Gregor Mendel reported that the outcomes of reciprocal crosses were independent of the parental origin of a trait. In the late 1980s, however, researchers discovered that the two parental genomes are not equivalent in mammals. In the mouse zygote, the two pronuclei are distinct from one another and can be individually removed from the cell, and a zygote containing two female pronuclei or two male pronuclei can be created (a phenomenon known as uniparental disomy). Early embryonic development in such zygotes is abnormal. Purely female-derived embryos have poorly developed extraembryonic tissues, and purely male-derived embryos demonstrate abnormal embryo development. This phenomenon occurs sporadically in human conception, when a sperm fertilizes an egg without a pronucleus. This causes a doubling of the sperm chromosomes. The resulting diploid conceptus is a hydatidiform mole, which is a mass of extraembryonic membranes without an embryo. In contrast, ovarian dermoid cysts are derived from the spontaneous division of an oocyte; this results in the duplication of the maternal genome.

This phenomenon whereby progeny phenotypes differ according to whether the genetic material is maternal or paternal in origin is called genomic imprinting. This represents an extreme situation wherein the genetic material is derived entirely from one parent. In studying this phenomenon, investigators focused on the chromosomal regions responsible for the genomic imprinting effects observed in mouse embryos. Certain regions of distinct chromosomes were found to produce markedly different phenotypes, depending on whether the two copies were inherited from one parent, resulting in duplication or deficiency of one parental complement. An imprinted allele is one whose expression is changed or silenced as it passes through a particular sex. An allele is paternally imprinted if it is not expressed when it is inherited from the father. It is maternally imprinted if it is not expressed when it is inherited through the mother. Imprinted regions have been identified in both mouse and human chromosomes; alterations in normal imprinting patterns are associated with disorders of growth and development, cell proliferation, and behavior.

It is thought that during gamete formation in mammals, some genes are altered by the methylation of certain cytosine groups in DNA. This process tends to prevent access by transcription machinery to that region of the chromosome for transcription, thus resulting in the "silencing" of that gene or genes. Whatever the process, the imprinting procedure would have to be erased during embryogenesis so that an individual could reimprint its genes according to its own sex during gametogenesis. Demethylation in embryonic cells occurs in the early cleavage divisions. Shortly after implantation, the embryonic somatic cells are methylated again, whereas the germ cells in the developing embryo are methylated later, as they develop in the gonads. An imprinting center on chromosome 15 may play a role in this process.[11]

Prader-Willi syndrome (PWS) and Angelman syndrome (AS) are two clinically distinct genetic diseases associated with deletions of the same region of chromosome 15. These syndromes are characterized by deficiencies in growth and sexual development, behavioral abnormalities, and mental retardation. Major diagnostic criteria for PWS include hypotonia; hyperphagia with resulting obesity; hypogonadism; and developmental delay. Patients with AS may have ataxia; sleep disorders; seizures; and hyperactivity with severe mental retardation. They may exhibit characteristic outbursts of inappropriate laughter.

Approximately 70% of patients with PWS and AS have a de novo 3 to 4 Mb deletion in the q11–q13 region of chromosome 15. Because this region is imprinted, the phenotypes that result from this deletion differ, depending on the allele upon which the deletion occurred. When the deletion occurs on the paternal chromosome, it results in PWS; when it occurs in the maternal copy, it results in AS. This suggests that the normal *PWS* gene is expressed from the paternal chromosome and that the normal *AS* gene is expressed from the maternal chromosome. Most of the remaining cases of PWS are the result of maternal uniparental disomy; paternal uniparental disomy accounts for only 4% of AS cases.[12] In uniparental disomy, an individual inherits both copies of a chromosome from either the mother or the father through a nondisjunction error in meiosis. Again, lack of paternal 15q11–15q13 results in PWS; lack of maternal 15q11–15q13 results in AS. Imprinting defects have been implicated in some individuals with these syndromes.

Defects in a region termed the imprinting center, located within 15q11–15q13, can change the DNA methylation and transcription activity of certain genes that reside in the region. Thus, if there is a mutation in the imprinting center, the process of activation or inactivation of the imprinted region may not occur. Because the different mechanisms are associated with different risks of recurrence, it is recommended that the diagnostic workup begin with a search for a deletion by use of chromosome analysis and FISH; if the results are normal, DNA methylation should be performed. Although the risk of recurrence of a deletion is low, a mutation of the imprinting center is associated with a recurrence risk of 50%.

TRINUCLEOTIDE REPEAT DISORDERS

Several inherited disorders are known to have a worsening phenotype in each subsequent generation of family members affected by the disease.

Fragile X Syndrome, Huntington Disease, and Friedreich Ataxia

In the early 1990s, molecular geneticists discovered a new type of mutation, first in fragile X syndrome and then in a series of inherited neurologic disorders, including myotonic dystrophy, Huntington disease, and Friedreich ataxia. The mutation involves a repeat expansion of a DNA triplet, a trinucleotide repeat in an exon, or an intron of the gene. In patients with these conditions, the normal number of repeats (in an unaffected individual) is expanded. The number of nucleotide repeats can increase in successive generations, causing disease symptoms to appear at an earlier age. The molecular basis of repeat instability is not well understood, but increased severity of the phenotype and earlier age of onset in successive generations (a phenomenon termed anticipation) are generally associated with larger repeat length. The parental origin of the disease allele can also influence expression; for most of these disorders, there is greater risk of repeat expansion with paternal transmission, although in fragile X syndrome and congenital myotonic dystrophy (see below), the maternally transmitted alleles are more prone to expansion, thereby causing more severe phenotypes. Most of the trinucleotide repeat disorders are inherited in an autosomal dominant or X-linked fashion, with the exception of Friedreich ataxia, which is an autosomal recessive disorder [*see Table 1*].[13]

Table 1 Trinucleotide Repeat Disorders

Disease	*Gene Locus/Protein*	*Repeat*	*Location*
Fragile X syndrome	Xq27.3/FMR-1 protein	CGG	Noncoding
Fragile XE syndrome	Xq28/FMR-2 protein	GCC	Noncoding
Friedreich ataxia	9q13–9q21.1/frataxin	GAA	Noncoding
Myotonic dystrophy 1	19q13/myotonic dystrophy protein kinase	CTG	Noncoding
Myotonic dystrophy 2	3q21	CCTG	Noncoding
Spinobulbar muscular atrophy	Xq13–Xq21/androgen receptor	CAG	Coding
Huntington disease	4p16.3/huntington	CAG	Coding
Dentatorubral-pallidoluysian atrophy	12p13.31/atrophin-1	CAG	Coding
SCA type 1	6p23/ataxin-1	CAG	Coding
SCA type 2	12q24/ataxin-2	CAG	Coding
SCA type 3 (Machado-Joseph disease)	14q32.1/ataxin-3	CAG	Coding
SCA type 6	19p13/α-1A (voltage-dependent calcium channel subunit)	CAG	Coding
SCA type 7	3p12–3p13/ataxin-7	CAG	Coding
SCA type 8	13q12/none identified	CTG	?
SCA type 12	5q31–5q33	CAG	Noncoding

SCA—spinocerebellar ataxia

Myotonic Dystrophy

Myotonic dystrophy is a trinucleotide repeat disorder resulting in multisystem involvement of skeletal and smooth muscle, as well as involvement of the eye, heart, endocrine system, and central nervous system. The disorder represents a continuum of clinical findings; it has been classified for diagnostic purposes into three somewhat overlapping phenotypes: mild, classic, and congenital. Mild myotonic dystrophy is characterized by the development of cataracts in early adulthood and mild myotonia (difficulty relaxing the muscles after contraction). The symptoms may be so subtle that diagnosis is made retrospectively, after the birth of an affected offspring. Classic myotonic dystrophy is characterized by muscle weakness and wasting, myotonia, cataract formation, and cardiac conduction abnormalities that occur in adulthood. The life span of these patients may be somewhat shorter than normal.

Congenital myotonic dystrophy is a disease of the neonate characterized by generalized hypotonia, respiratory insufficiency requiring ventilatory support, and mental retardation if the infant survives to childhood. Individuals have characteristic facial features, which include drooping eyelids, facial weakness resulting in an open-mouthed appearance, and wasting of the muscles in the jaw and neck. The overall incidence of myotonic dystrophy is estimated to be one in 20,000 persons.

The diagnosis of myotonic dystrophy is confirmed by detection of an expansion of the CTG trinucleotide repeat that affects the noncoding regions of two adjacent genes (*DMPK* and *SIX5*) on chromosome 19q13. Normal individuals have a repeat of 37 trinucleotides or fewer. The trinucleotide repeat is located at the 3′ end of the gene (the transcription occurs in the 5′ to 3′ direction), but it is in a part of the gene that is transcribed but not translated into the final protein product. Unaffected individuals have a polymorphic repeat length of 5 to 37 CTG repeats; this repeat length is stable when passed from generation to generation. Stability is disrupted, however, when the number of repeats exceeds 37. When the number exceeds 37, this repeat expansion not only disrupts the function of the gene but also engenders further instability and larger expansions. This tendency accounts for the phenomenon of anticipation seen in families with this disorder, in which a mildly affected adult can give birth to a child with the congenital form of the disease. In rare cases, the region will contract, with the CTG repeat being smaller in an offspring. In affected individuals, further expansion can occur during somatic cell division, resulting in mosaicism from tissue to tissue.[14]

The gene product of *DMPK* is a protein kinase. It is expressed in the different organs involved in the disease: skeletal muscle, the heart, the brain, and the testes. The function of the protein is unknown, and it is unclear how the expansion in the untranslated region leads to the phenotype. There is evidence, however, that the mutant *DMPK* transcripts accumulate abnormally in the nuclei and bind to RNA-binding proteins, thus disrupting RNA splicing and metabolism. A second form of myotonic dystrophy has recently been described. This form involves a chromosome 3 trinucleotide repeat, which also results in the accumulation of RNA in cells.[15]

This disorder presents a unique genetic counseling problem. Individuals who are mildly affected have a 50% chance of passing on the expanded allele to their offspring. However, because of the instability of the expanded region, it is impossible to predict the severity of the condition in an affected child. There is a risk of having a child with the severe form of the disease—congenital myotonic dystrophy—only if the mutation is transmitted through the mother. Approximately 20% of the offspring of an affected mother who inherit the mutation manifest the severe form, depending on the size of the expansion in the mother. Although prenatal testing for the expansion is available, often the diagnosis of mild myotonic dystrophy in the mother is established only after the birth of an infant with the congenital form of the disease.

Mitochondrial Inheritance

In general, the inheritance (autosomal dominant, recessive, or X-linked) of a condition can be determined by pedigree analysis of large families. Mechanisms such as imprinting and

anticipation affect the expression of mutations, but transmission still abides by classic Mendelian patterns of inheritance. Recently, mutations in mtDNA have been associated with a number of disorders with a unique inheritance pattern, termed maternal transmission. In maternal transmission, a condition affects individuals in each generation, suggesting dominant inheritance. Males and females may be affected, but men never transmit the disorder to their offspring. Women pass the trait on to all of their children, although there is great variability in expression.

Mitochondria are the cellular organelles responsible for the generation of energy in the form of adenosine triphosphate (ATP) through aerobic metabolism. Some mtDNA molecules are encoded in the nuclear genome and are transported out to the mitochondria, but a minority are encoded and synthesized in the mitochondria. mtDNA is a circular, double-stranded structure without introns; it resembles a prokaryotic genome. It contains 16,569 base pairs that encode at least 13 proteins required for oxidative phosphorylation. In addition, it contains the transfer RNA (tRNA) and ribosomal RNA (rRNA) involved in the translation of these proteins in the organelle.

The manner in which mitochondria are passed from one generation to the next accounts for the phenomena of maternal transmission. At the time of fertilization, the sperm sheds its cytoplasm, and only the nuclear DNA enters the egg. Therefore, all mitochondria in the zygote are contributed by the egg cell. However, there are hundreds of copies of mtDNA in each cell. During cell division, each mtDNA replicates, but unlike nuclear DNA, the newly synthesized mitochondria segregate passively to the daughter cells. A mitochondrial mutation arises randomly, and chance segregation leads to an accumulation of mutant mitochondria in a cell. The phenotypic expression of a mutation in mtDNA depends on the relative proportion of normal functioning product above a certain threshold value for manifesting the phenotype. This unpredictability in phenotype from individual to individual is the result of this random segregation of mitochondria; such random segregation of mitochondria is termed heteroplasmy. Additionally, different types of mtDNA mutations are inherited differently; deletions occur only sporadically and are not transmitted from affected females to their offspring. Examples of disorders associated with such deletions are chronic progressive external ophthalmoplegia, Kearns-Sayre syndrome, and Pearson syndrome. Point mutations result in mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes (MELAS), myoclonic epilepsy with ragged-red fibers (MERRF), and neuropathy, ataxia, and retinitis pigmentosa (NARP).[16]

The number of mitochondria per cell is dependent on the energy production in the cell. The brain, retina, and muscle cells have a relatively higher demand for energy than other cell types. Thus, mutations in mtDNA tend to result in disorders with muscle and neurologic dysfunction, such as myopathies, cardiomyopathy, ophthalmoplegia, encephalopathies, and encephalomyopathies. Defects in oxidative phosphorylation should be considered in the differential diagnosis of any patient with unexplained multisystem involvement, including a progressive myopathy or neurologic problem. Although routine laboratory testing in such patients may reveal hypoglycemia, abnormal liver function, or elevated blood lactate levels, muscle biopsy is often necessary to make a diagnosis. The abnormal pathologic appearance of the cellular mitochondria is apparent on electron microscopy and through the use of special staining. Some examples of conditions resulting from mutations in mtDNA are listed [*see Table 2*]. Defects in oxidative phosphorylation may also result from mutations in nuclear DNA that code for mitochondrial proteins. Diagnosis of these disorders is difficult, and subsequent counseling issues can be complex.

Cancer Genetics

Thus far, we have focused on genetic diseases with specific phenotypes associated with the presence of germline mutations that lead to expression of one or more abnormally functioning proteins. This type of mutation is presumably present in all the cells of an individual from birth, although there can be a degree of mosaicism, depending on the stage of development at which the mutation occurs. Investigation into the control of cell growth has given new insight into genetic changes that occur in both germ cells and somatic cells and that can lead to malignancy. Mutations in three types of genes that regulate cell growth are involved in the development of cancer: tumor suppressor genes, proto-oncogenes, and DNA repair genes. Somatic mutations in these genes may result in unchecked proliferation or clonal expansion of a single cell with subsequent loss of cellular organization; somatic mutations may also confer the ability to metastasize. This process generally requires a number of mutations, because there is an elaborate backup system in place to prevent faulty cell proliferation. Although sporadic mutations arise in individual somatic cells and ultimately play a role in cancer development, the study of familial or inherited cancer syndromes has contributed to our understanding of the genetic changes responsible for the development of some of the more common cancers.

It is perhaps easiest to understand how a germline mutation in a tumor suppressor gene could lead to a predisposition to

Table 2 Disorders Resulting from Mitochondrial Mutations

Disease	*Phenotype*
Chronic progressive external ophthalmoplegia	Progressive weakness of extraocular muscles; ptosis
Kearns-Sayre syndrome	Progressive external ophthalmoplegia before age 20; pigmentary retinopathy and CSF protein > 1g/L; cerebellar ataxia or heart block
Leber hereditary optic neuropathy	Rapid bilateral optic nerve death resulting in loss of central vision in early adulthood
Mitochondrial encephalopathy with lactic acidosis and strokelike episodes	Strokelike episodes before age 40, seizures, dementia, ragged-red fibers, lactic acidosis
Myoclonic epilepsy with ragged-red fibers	Myoclonus, epilepsy, ataxia, myopathy, sensorineural deafness
Pearson syndrome	Sideroblastic anemia, pancytopenia, pancreatic insufficiency, lactic acidosis
Leigh disease	Neuropathy, ataxia, retinitis pigmentosa, developmental delay, lactic acidemia
Deafness	Progressive sensorineural deafness often induced by aminoglycoside antibiotics

cancer. Such is the case in families with an inherited mutation in *BRCA1* and *BRCA2*. Such individuals have only one functional copy of the gene; a subsequent somatic mutation in the normal copy in a single cell gives rise to a population of cells that have no *BRCA1* or *BRCA2* gene and have therefore lost the tumor suppressor activity that limits cell proliferation. In individuals with a germline mutation in *BRCA1,* the chance of developing breast cancer over one's lifetime is estimated to be 80%; the chance of developing ovarian cancer is 15%. The cancer usually develops at an earlier age than is seen in the general population, and there can be multiple primary sites. Nevertheless, most breast cancer disease is sporadic, and the disease is common enough that family history may be misleading, particularly in a large family. There are algorithms for assessing a patient's risk of developing breast cancer, as well as the risk of carrying a germline mutation. Such risk-assessment algorithms are based on personal health history and family history of breast cancer, ovarian cancer, or both. With regard to family history, important factors include the age of onset in affected individuals and whether there was more than one primary site. Verification of the family member's medical records is imperative.[17]

Proto-oncogenes are recessively acting genes that regulate the cell cycle. Mutant dominant genes, called oncogenes, are usually gain-of-function mutations; the altered products of such mutations cause uncontrolled cell proliferation. Oncogenes were discovered by transformation experiments in tissue culture. In these experiments, normal cells were made into malignant cells by the insertion of a mutant piece of DNA (the oncogene). A number of proto-oncogenes have been located in the human genome, and mutations in them have been implicated in the development of leukemias, lymphomas, breast and ovarian carcinomas, and cancer of the colon, thyroid, lung, and pancreas. Many oncogenes are caused by chromosomal changes that result from breakage and translocations occurring as cell proliferation becomes more disorganized. The so-called Philadelphia chromosome seen in chronic myelogenous leukemia is a translocation between chromosomes 9 and 22. The breakpoint in chromosome 9 occurs in the cellular proto-oncogene *ABL,* which normally codes for a tyrosine kinase that binds to DNA. The breakpoint in chromosome 22 is in a gene called *BCR,* or breakage cluster region, which codes for a serine kinase. The fused *BCR-ABL* gene in the Philadelphia chromosome makes a novel protein, which leads to unregulated proliferation of hematopoietic stem cells and chronic myeloid leukemia.[18]

Although most cases of colorectal cancer are sporadic, there are two more common forms of autosomal, dominantly inherited colorectal cancer, familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer, which together account for about 10% of cases of colorectal cancer. FAP is caused by a germline mutation in a tumor suppressor gene, the *APC* gene. Loss of function of the second *APC* allele leads to adenoma formation and progression to cancer through the accumulation of other somatic mutations.

Supporting the concept that accumulated genetic changes underlie the development of neoplasia, the defect in hereditary nonpolyposis colorectal cancer (HNPCC) was found to be in a group of genes that function in DNA mismatch repair. In the course of normal cell division, DNA replication is subject to error, although, as discussed earlier, the fidelity of DNA polymerase is quite good. The mismatch repair genes, of which at least six are known (*MSH2, MSH6, MLH1, MLH3, PMS1,* and *PMS2*) function in DNA replication errors resulting from misincorporation. The mismatch repair proteins function as a complex to recognize the deformation in the double helix and to then recruit enzymes to correct the error. Without these proteins, errors are propagated in successive generations of cells. Individuals with a germline mutation in the mismatch repair system, again, may undergo loss of function in the second mismatch repair allele, resulting in the characteristic microsatellite instability (MSI). Microsatellites are repeating DNA sequences of unknown function that are found throughout the genome. These repetitive sequences are more prone to errors in replication. Loss of mismatch repair mechanisms permits expansion of these repeats, as may be demonstrated in tumor specimens. The presence of MSI indicates an increased likelihood of HNPCC, although MSI is seen in 15% of sporadic colorectal cancers. Families with HNPCC have an increased incidence of other types of cancers, including endometrial, ovarian, upper GI, renal, pelvis, and brain cancers.[19]

Human Genome Project

The Human Genome Project was undertaken to determine the sequence of the entire human genome. It is a massive effort that will have major effects on medical research and practice. With the advent of recombinant DNA technology and the development of DNA sequencing, the question arose in the 1980s as to whether the genome might be sequenced. By 1990, the National Institutes of Health had founded a National Institute of Human Genome Research. The projected date of completion of the sequencing of the human genome was 2005; advances in technology, chiefly in terms of sequencing, were incorporated into the time estimate. As it turned out, the genome was for the most part completed by 2000; some 3% to 5% of the genome remained uncertain because of high redundancy.[20,21] However, the remaining sequences are not thought to contain many meaningful coding sequences.

The earlier-than-expected completion was in part the result of a strong organization and cooperation among the centers. Investigators around the world who had linked constructs of DNA sent them to genome centers for sequence determination. The government-sponsored project required that such sequences be made public within a day, thus aiding dissemination of information. A second factor in timely completion was that technology improved even faster than anticipated. A third factor was the cooperative interaction of private industry, which participated under the original NIH rules. A fourth factor contributing to early completion was the competition of private industry using a modified approach to sequence determination. By 1998, 3% of the sequence was actually known. Three years later, more than 95% of the sequence had been determined.

Hybridization, or complementary pairing, of single strands of DNA to each other, allows identification of overlapping DNA fragments by labeling the short fragment and hybridizing to a library. The genome of a person contains regions that vary in a manner specific to that individual. By definition, a variation present in 1% of the population is termed a polymorphism. For the Human Genome Project, the most useful of these turned out to be blocks of CA sequence, which vary in the number of times the dinucleotide is repeated.[22] The repeats serve as signposts in the genome of an individual. As the genome project progressed, these, along with

other markers, served to build a map of signposts along the genome.

Amplification of DNA sequences for cloning and for utilization of the markers depended on the polymerase chain reaction technique.[23] If the sequence of a region of DNA is known, then a large amount of the sequence can be cloned and mapped by the use of excess primers, which hybridize to the specific sequence. Usually, the primers are about 20 nucleotides long; this length is sufficient to give adequate specificity in binding. The amplification depends on the repeated denaturing and renaturing of the DNA, so that the excess primers create a site for DNA synthesis in each cycle. With a thermoresistant DNA polymerase, the progress can be automated [*see Figure 5*].

Another major technical advance facilitating positional cloning and the genome project was the cloning of large blocks of human genome sequence. Stable vectors containing up to 1 Mb of genome sequence were developed using yeast artificial chromosomes.[24] However, these tend to recombine the DNA frequently; bacterial artificial chromosomes (BACs) proved to be more useful for the genome project because they are more stable. As libraries of BACs were made, the assignment of markers to each BAC allowed the development of a map for signposts and the establishment of contiguous sequences (contigs) as subunits of the overall genome. These were frequently verified by cytogenetics with the use of FISH.

As the Human Genome Project developed many markers along the genome, a second technique became feasible—

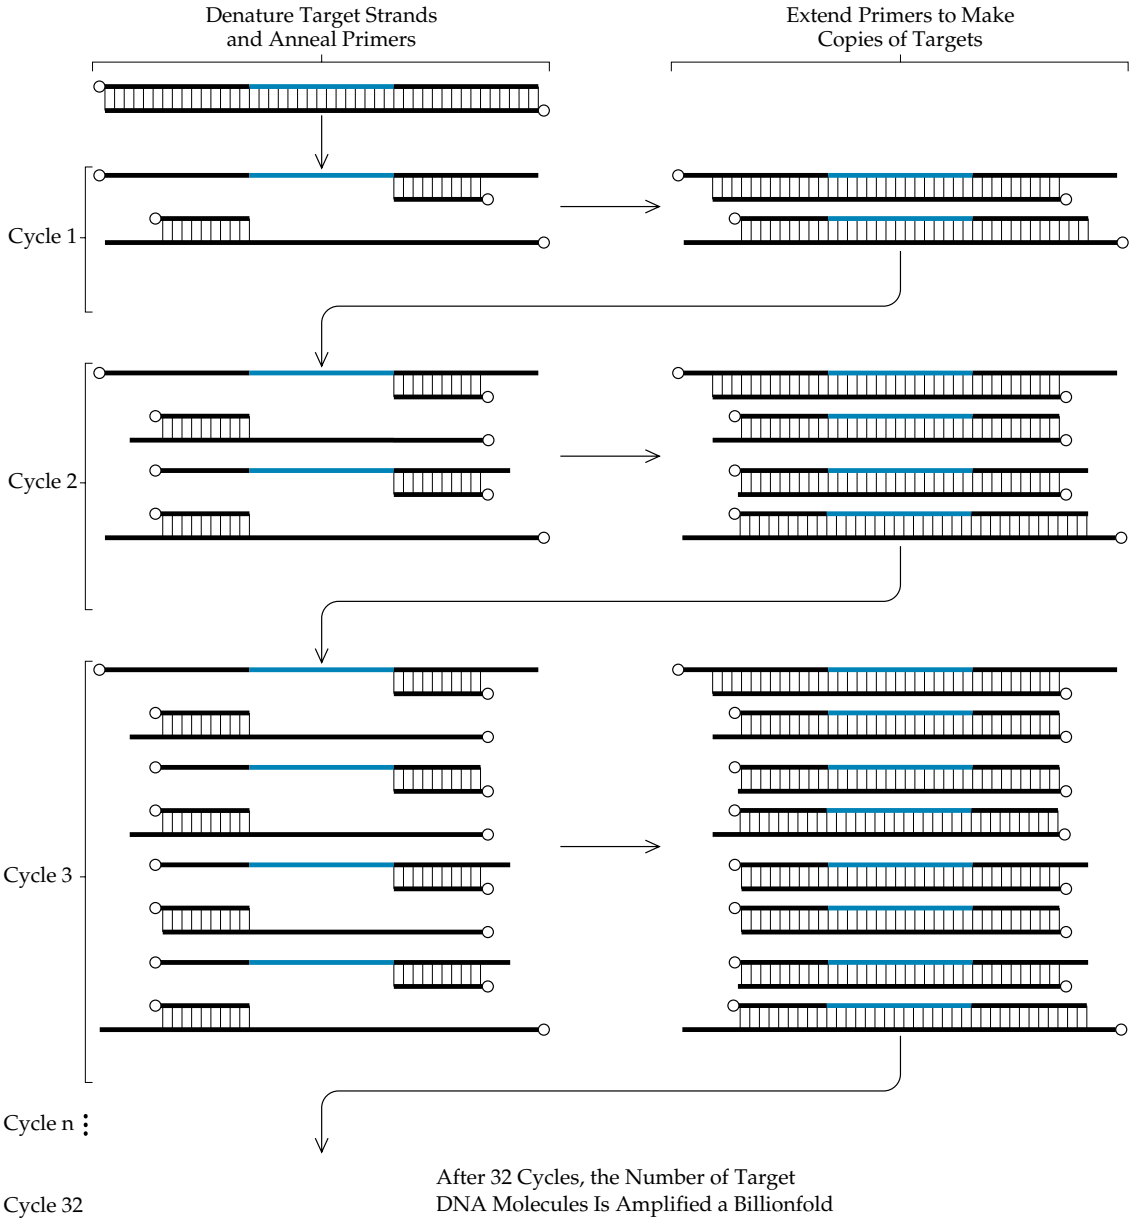

Figure 5 **The polymerase chain reaction. The strands in each targeted DNA duplex are separated by heating and then cooled to allow single-stranded oligonucleotide primers that are complementary to the end sequences of the opposite strands to bind to those sequences. DNA polymerase extends the primers (i.e., adds nucleotides), using the target DNA strands as templates. In this way, duplicates of the original DNA strands are produced in each cycle, and the quantity of the target DNA duplex increases exponentially.**

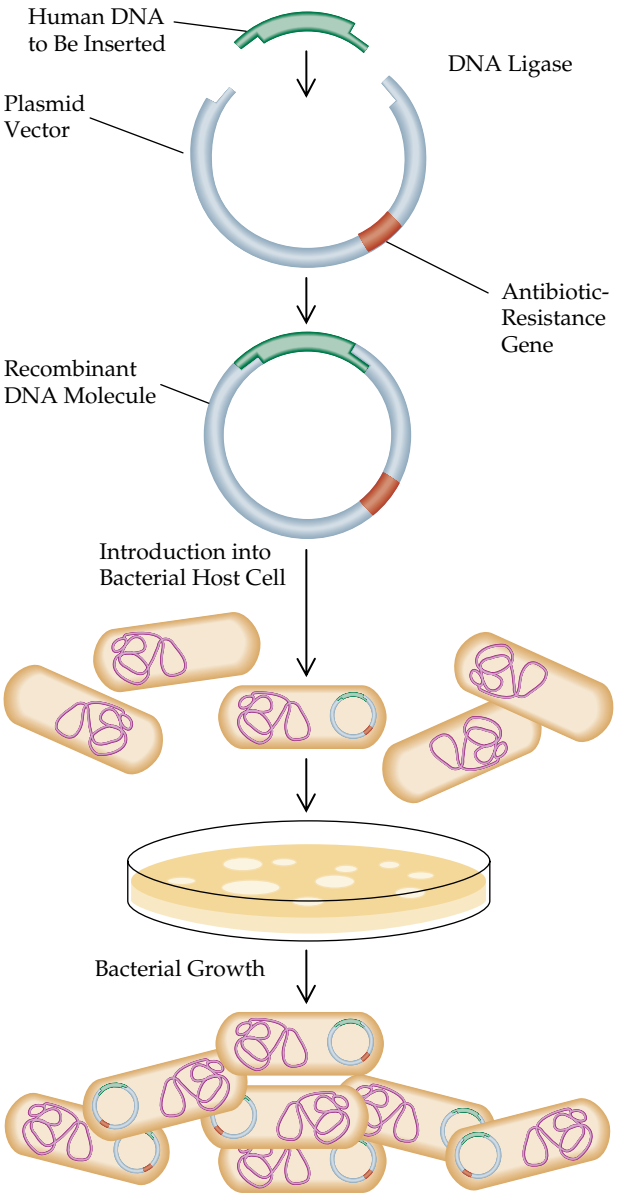

Figure 6 **Restriction fragments of human DNA generated by digestion of chromosomal DNA with a restriction endonuclease (e. g., *Eco*RI) can be inserted into a cloning vector, such as an *Escherichia coli* plasmid. The plasmid contains a single recognition site for *Eco*RI and a bacterial gene that confers antibiotic resistance. After EcoRI cuts the plasmid, the fragments of human DNA and the linear plasmid can be covalently joined by the action of the enzyme DNA ligase. The plasmid can replicate within a bacterial host to produce many copies of the DNA fragment, and the bacteria themselves reproduce. The bacteria are grown on plates containing antibiotics to select for those cells that contain copies of the plasmid with the human DNA insert. The human DNA (e.g., a gene) can then be recovered when the harvested plasmid DNA is digested with *Eco*RI.**

shotgun sequencing. In that approach, the genome was sequenced repetitively in small fragments; with appropriate computer algorithms, it was then possible to reconstruct the sequence. This method was aided by the existence of the knowledge of the markers that had already been obtained. Regions of redundancy present problems for the combined methodologies.

UNRESOLVED QUESTIONS

Currently, the human genome appears to contain approximately 38,000 genes. In terms of complexity of function, it is thought that protein modification may be the basis for varied activities of gene products. Only about 1% of the genome codes directly for information. About 24% is intronic sequence; the remaining 75% is intergenic. The genes are not distributed at an average frequency but are clustered in gene-rich regions, and there is significant variability among the chromosomes as to gene content per unit length. The human genome contains many retroviruses, or transposable elements, most of which do not appear to be active; however, many can function as mobile genetic elements in the genome. The results emphasize the presence of introns and lead to the question of whether there is additional information encoded in them, other than by the triplet code. For example, do these introns contain topologic or conformational information that is important in gene regulation?

Another remaining difficulty is that we do not understand the rules of genomic "punctuation." With genes embedded in small exons occupying less than 1% of the genome, recognition of the coding regions is difficult. Identification of genes is based on the assumption that genes are expressed and usually converted to mRNA. Because mRNA has a poly-A 3′ tail, it is possible to capture portions of messages. These snippets are termed expressed sequence tags; they were used to identify the signposts for genes in the genome project. The portion of DNA coding for the desired sequence was expanded by cloning the DNA into plasmid vectors and then growing these vectors in bacteria [*see Figure 6*]. Cloning depends on restriction enzymes that cut double-stranded DNA at specific sites; recognition is usually based on a sequence of 4 to 8 bases, and the cleavage may produce overhang or blunt termini in the DNA. If the same enzyme is used to cut the plasmid vector, the DNA piece may be joined to the plasmid by ligase enzyme, and the plasmid will thus be able to replicate with the complementary

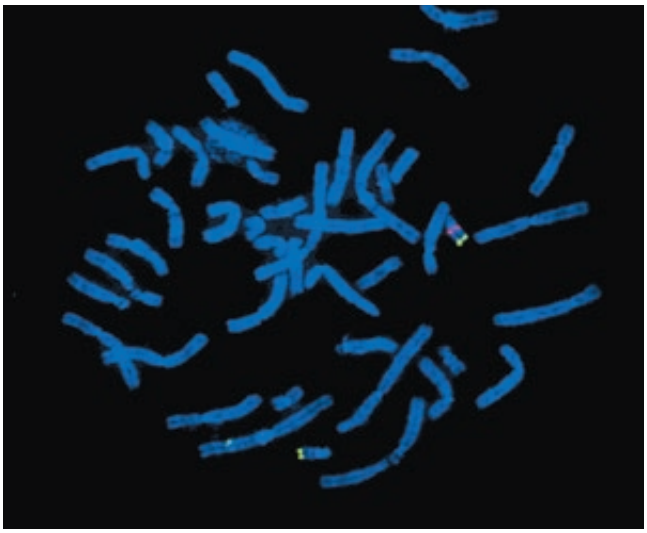

Figure 7 **Fluorescence in situ hybridization (FISH) was performed using the TUPLE1 probe (red) for the VCFS/DGS region at 22q11.2 along with an identifier probe (green) (Vysis, Inc., Downers Grove, Illinois). One homologue has both probe signals (red and green); however, the other homologue has only the identifier signal (green), which indicates that this homologue is deleted.**

Selected Internet Resources for Genetic Information

PubMed

http://www.ncbi.nlm.nih.gov/PubMed

A convenient entry point to search for publications or to search the genome database for sequence information. Published by the National Library of Medicine.

The Online Mendelian Inheritance of Man (OMIM)

http://www.ncbi.nlm.nih.gov/Omim

Provides a compilation of heritable diseases and a summary of the clinical and molecular information relating to them. It is organized under the direction of the National Center for Biotechnology Information.

GeneClinics

http://www.geneclinics.org

Provides information for clinicians regarding molecular testing laboratories. This resource is helpful in patient evaluation and in locating laboratory testing sites for families with known diagnoses or risk of genetic diseases.

American Society of Human Genetics

http://gopher.faseb.org/genetics/ashg/ashgmenu.htm

Provides access to electronic publications and links to other sources of information.

DNA (cDNA) insert [*see Figure 7*]. Plasmids were engineered that would exist in the bacterial host cell in groups of several hundred copies each; in this way, the DNA insert was amplified, and such amplifed inserts were relatively easy to rescue for study.

Our knowledge of human genetics and its application to clinical medicine is constantly evolving. We have progressed from inferring inheritance modes by pedigree analysis and from inferring risk to future offspring by probability calculations to molecular testing based on the identification of mutations in a gene or genes involved in a specific disorder. The human genome has been sequenced, but it still must be deciphered as to the genetic bases of the remaining single-gene disorders, the genetic component of multifactorial inheritance conditions, and the function of noncoding DNA. Aided by improvements and advances in molecular technology, scientists will have this task in the 21st century.

FUTURE APPLICATIONS OF GENETICS TO MEDICINE

Scanning the Genome for Risk of Disease

Technology holds the promise of detailed analysis of the genomes of individuals with attention to particular areas. By combining computer-chip design with DNA hybridization techniques, arrays of DNA sequences containing many thousands of specified sequence variations can be made.[13] This will allow searching for disease-specific mutations or associated polymorphisms in a person. However, because it appears that most common diseases have a genetic component but are made manifest on the basis of other factors (multifactorial disease), so-called array analysis offers a new tool. The human genome contains single base variations—single nucleotide polymorphisms (SNPs) that occur at a rate of about one per 1,000 bases; there are close to three million SNPs in the human genome. Of these, perhaps 1% are in exons and can be used to identify disease risk by linkage. As associations with multifactorial disease are made, scanning for markers linked to risk—even though, at the molecular level, the basis of the risk remains unknown—will allow determination of the apparent risk of multifactorial disease in an individual patient. It is expected that array analysis will prove useful in assessing the risk of diabetes, heart disease, cancers, and other common diseases.

Identifying Drug Responsiveness

A second avenue of use for the complex analysis of individual genomes may come with regard to drug prescription. Associations of drug responsiveness and genome markers will develop. It seems likely that genome variations affect a patient's response to drug therapy and that such variations may thus have a role in drug selection and dosage schedules. Medical practice may thus come to utilize an array analysis for a given drug.

Privacy Issues in Genetics

The testing capabilities and the ability to store and compare sequence data raise ethical concerns. To a large degree, these questions are not new in medicine, but the extent of the knowledge and the possible predictive nature of the information make the issue one of new focus and attention. Collection, storage, and dissemination of an individual's genetic information have become topics for discussion at the state and national level. Already a number of states have revised statutes regarding privacy. The question of privacy in a time of electronic records is in itself a difficult one for health care providers. Access to records is a thorny issue. Added to this are concerns over the availability of health care insurance and life insurance for individuals with a family history of genetic disease. With patient profiles that include a large number of disease-causing sequence alterations now a reality, the problem has only become larger.

Online Resources for Genetic Information

Several Web-based sites for information regarding the genome or genetic diseases are available [*see Sidebar* Selected Internet Resources for Genetic Information].

The authors have no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

VIII GENETIC DIAGNOSIS AND COUNSELING

Roberta A. Pagon, m.d.

Genetic testing is an increasingly useful, cost-effective, sensitive, noninvasive tool that allows clinicians to identify disease in symptomatic persons, predict the probability of disease in asymptomatic at-risk persons, detect carriers of heritable disorders, and diagnose genetic disease in fetuses.

Although genetic tests involve the analysis of DNA, RNA, chromosomes, proteins, and certain metabolites, the most widely used of these tests over the past decade have been DNA-based tests for the diagnosis of heritable disorders and for genetic counseling. The effectiveness of genetic tests depends on the technical skill with which they are performed, the clinical skill with which they are interpreted, and the patient's interest in the results. As with all other medical testing, genetic testing is context specific. Before recommending a test, the clinician must be able to answer the question, "Why am I testing this patient at this time?"

Genetic testing differs from traditional medical testing in two ways: genetic test results always have implications for disease risk for the individual patient and, frequently, for his or her family; and genetic testing may be used for the sole purpose of personal decision making rather than medical care.

The focus of this chapter is on germline (inherited) mutations that are present at conception and have phenotypic (clinical) effects, implications for reproduction, or both. Germline mutations contrast with somatic (acquired) mutations, which are the basis of certain acquired disorders, such as many cancers. Somatic mutations, with the exception of so-called germline mosaicism in which the mutations affect the gonads, are not heritable and are not discussed here.

Molecular Genetic Testing

Direct and indirect testing are the two broad categories of DNA-based testing. Direct testing is synonymous with mutation detection—the positive identification of disease-causing genetic alterations that establish a person's genetic status independent of knowledge of family history or prior risk status. The most commonly used methods for direct testing include the following:

1. Targeted mutation analysis, which screens for the presence of a specific mutation, a specific type of mutation, or a specific set of mutations.
2. Mutation scanning (mutation screening), which screens a segment of DNA by one of a variety of methods to identify a variant gene region or regions, which are further analyzed by sequence analysis or mutation analysis to identify the sequence alteration.
3. Sequence analysis (sequencing), which determines the nucleotide sequence for a segment of DNA. The nucleotide sequence may involve either an entire gene or a portion of a gene. Sequence analysis is considered the gold-standard genetic test by many; however, interpretation of the significance of a sequence alteration may not be straightforward, and failure to detect a sequence alteration may not indicate the absence of a disease-causing mutation [*see Table 1*].
4. Other direct testing methods, including Southern blotting, protein truncation testing, and methylation testing, have more specific applications.

The methodology selected depends on such parameters as the size of the gene, possible mutation types, and the presence of recurrent (common) mutations. The mutation-detection rate in a given disorder is likely to vary by methodology. Thus, the clinician needs to be aware of the test method used by a given laboratory and its relevance to the questions being addressed in the testing of a given patient. For example, in testing for familial adenomatous polyposis (FAP), three test types are used in varying combinations by different laboratories, each with a different mutation-detection rate [*see Table 2*].

Once a disease-causing mutation is identified in one affected family member, others at risk in the family need only be tested by targeted mutation analysis for that exact mutation. Conversely, testing at-risk family members when the disease-causing mutation has not been identified in an affected family member is problematic: detection of a disease-causing mutation is informative, but failure to detect a mutation is not informative, because one cannot distinguish between true absence of a disease-causing mutation and failure to detect the disease-causing mutation by the laboratory method employed.

Indirect testing relies on linkage analysis, in which DNA sequences serve as markers to track a gene mutation within a family. However, linkage analysis is now rarely used in patient care, having been replaced by gene sequencing and mutation scanning, which provide improved mutation detection.

In the evaluation of patients and their families, genetic-testing information can be used in a medical-testing paradigm, a genetic-counseling paradigm, or both [*see Table 3*].

Table 1 Interpretation of Sequence-Alteration Results*

Types of Sequence Alterations That May Be Detected
Pathogenic sequence alteration reported in the literature
Sequence alteration predicted to be pathogenic but not reported in the literature
Unknown sequence alteration of unpredictable clinical significance
Sequence alteration predicted to be benign but not reported in the literature
Benign sequence alteration reported in the literature
Possible Significance if a Sequence Alteration Is Not Detected
Patient does not have a mutation in the tested gene (e.g., a sequence alteration exists in another gene at another locus)
Patient has a sequence alteration that cannot be detected by sequence analysis (e.g., a large deletion)
Patient has a sequence alteration in a region of the gene (e.g., an intron or regulatory region) not covered by the laboratory's test

*Adapted from Reference 42. For more details, see http://www.acmg.net.

Table 2 Molecular Genetic Testing: Familial Adenomatous Polyposis

Test Type	*Mutation Detection Rate*
Full gene sequencing	Up to 90%
Mutation screening and protein truncation testing	~80%–90%
Protein truncation testing	~80%

Medical Paradigm of Genetic Testing

In the medical paradigm of genetic testing, genetic tests provide patients and their physicians with information that directly influences medical care. Issues of sensitivity, specificity, cost, and the risk of recurrence (i.e., the probability that a disease will recur in a family) are relevant. Sensitivity refers to the frequency with which a test yields a positive result when the person being tested is affected and has a disease-causing mutation in the gene in question. Specificity refers to the frequency with which a test yields a negative result when the person being tested is unaffected and does not have the gene mutation. Positive predictive value refers to the likelihood that a person with a disease-causing mutation will develop the condition. Diagnostic testing establishes or confirms a diagnosis in a symptomatic person.

DIAGNOSTIC TESTING IN SYMPTOMATIC PERSONS

A DNA-based diagnostic test relies on knowledge of the disease-causing genetic alterations and on the ability to detect them in readily obtainable tissue samples, usually blood.

High Sensitivity, Specificity, and Positive Predictive Value

Trinucleotide repeat diseases, caused by the presence of an abnormally large number of tandem trinucleotide repeats within a gene, are examples of diseases for which DNA-based testing is highly sensitive [*see Table 4*].[1,2] Targeted mutation analysis and, when necessary, Southern blotting measure the repeat size (i.e., number of trinucleotide repeats present). The cost of these methods is low because of the straightforward laboratory methodologies used in testing.

Because the molecular genetic basis of trinucleotide repeat diseases is known, the disease spectrum for a number of these disorders has been redefined. Thus, establishing the diagnosis requires molecular testing; the sensitivity and specificity of molecular testing for these diseases approaches 100%.

In spinocerebellar ataxia type 3 (Machado-Joseph disease), four overlapping but age-related phenotypes are recognized. The spectrum of clinical involvement ranges from spasticity or a predominance of extrapyramidal findings (i.e., rigidity, dystonia, or involuntary movements) with cerebellar findings (i.e., ataxia or ophthalmoplegia) in young patients to a predominance of parkinsonism and neuropathy in patients older than 40 years. The different clinical phenotypes all derive from mutations of the same gene.[3]

Another example of a spectrum of clinical phenotypes resulting from trinucleotide repeat mutations in the same gene is Friedreich ataxia (FDRA). In a study that examined the predictive value of the molecular test for FDRA in 187 patients with autosomal recessive childhood-onset ataxia, only 60% had findings that were considered typical of FDRA by strict diagnostic criteria.[4] All of the patients with typical findings and 46% of the patients with atypical presentations had GAA expansions in the *FDRA* gene, which encodes the protein frataxin; such findings were consistent with the diagnosis of FDRA. To accommodate the molecular diagnostic criteria, the phenotypic spectrum of FDRA was broadened to include older age at onset and preservation of deep tendon reflexes.

A rough correlation exists between the number of trinucleotide repeats and the severity and age at onset of disease in all of these disorders; however, the positive predictive value of the number of repeats for these findings is less than 100%. This value is not relevant when the test that measures repeat number is used for the diagnosis of symptomatic persons, but it becomes relevant when the test is used for predictive testing in asymptomatic at-risk relatives and for recurrence-risk counseling of the offspring of an affected person. Recurrence-risk counseling for trinucleotide repeat disorders depends not only on the usual mendelian genetics but also on the empirical risk of further gene expansion (i.e., the increase in length of the trinucleotide repeat) during meiosis. For unknown reasons, expansion can be influ-

*It is not common for parents to request prenatal testing for conditions that typically manifest in adulthood. Differences in perspective may exist among medical professionals and within families regarding the use of prenatal testing when the testing is being considered for the purpose of pregnancy termination or for early diagnosis. Most centers would consider decisions about prenatal testing to be the choice of the parents; however, careful discussion of these issues is appropriate.

†Molecular testing may be necessary to establish the diagnosis in individuals with the mild variant form of familial adenomatous polyposis.

Table 4 Trinucleotide Repeat Diseases[1,2]

Disease Name	*Type of Repeat*	*Mode of Inheritance*	*Normal Allele Size**	*Intermediate Allele Size*†*	*Abnormal Allele Size*‡*	*Stabilization by Repeat Interruption*	*Parental Effect*	*Somatic Mosaicism*
X-linked spinal and bulbar muscular atrophy	CAG	XLR	≤ 34		≥ 38	No	pat > mat	No

*Allele size is described by the number of CAG trinucleotide repeats.
†A person with an allele in this range of CAG repeats is not at risk of developing symptoms of the disorder but may be at risk of having a child with an allele in the abnormal range.
‡Alleles of abnormal size fall into two categories: (1) reduced-penetrance alleles comprising 36–40 CAG repeats and (2) full-penetrance alleles, comprising 41 CAG repeats or more. Reduced-penetrance alleles may or may not lead to symptoms of HD within normal life expectancy.[20] Full-penetrance alleles are associated with the development of HD.
AD—autosomal dominant AR—autosomal recessive mat—maternal ND—no data pat—paternal XLR—X-linked recessive

enced by the sex of the transmitting parent; for example, further expansion is probable when a mother transmits the expanded allele in fragile X syndrome and myotonic dystrophy type 1 and when the father transmits the abnormal allele in Huntington disease, Kennedy disease, dentatorubral-pallidoluysian atrophy (DRPLA), or spinocerebellar ataxia types 1 and 3.[1] The risk of further expansion may depend on the total length of the trinucleotide repeat region and the presence of different stabilizing sequences within or adjacent to the gene.

High Sensitivity and Low Positive Predictive Value

Factor V Leiden targeted mutation analysis is the most commonly ordered genetic test. The specific mutation in coagulation factor V, named factor V Leiden, is a glutamine substituted for an arginine at codon 506.[5] By definition, the test that detects this mutation is 100% sensitive. Factor V Leiden causes resistance to activated protein C, a natural anticoagulant that allows extravascular blood to clot while maintaining intravascular fluidity.[5] Epidemiologic data support a predisposition to primary and recurrent venous thrombosis in factor V Leiden heterozygotes. It is estimated that 5% of whites are heterozygous for factor V Leiden and that approximately 20% of all persons with venous thromboembolism are heterozygous for factor V Leiden.[6] Heterozygotes with the mutation have a 2.4-fold greater risk of recurrent thromboembolism than patients without the mutation. Factor V Leiden is present in more than half of families with a so-called thrombophilic tendency; that is, several family members have deep vein thromboses that often are multiple, are of early onset, or occur in the absence of clear risk factors. It is presumed that in these families, other risk factors—some genetic and some environmental—are present.

Factors that increase the risk for venous thrombosis include the presence of two factor V Leiden alleles; the presence of other inherited and acquired thrombophilic disorders, including protein C deficiency, protein S deficiency, antithrombin deficiency, the prothrombin gene mutation, and hyperhomocysteinemia[7]; age; surgery; the use of oral contraceptives[8]; hormone replacement therapy[9]; and pregnancy.[10]

Increased Sensitivity by Use of Tests in Combination

Molecular genetic testing of leukocyte DNA in the diagnosis of Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) is an example of diagnostic molecular genetic testing in which sensitivity has increased because of new test methodologies. Allelic heterogeneity reduces the ability of one test method to detect all disease-causing mutations. Allelic heterogeneity (sometimes called mutational heterogeneity) refers to the situation in which more than one disease-causing mutation (allele) at one locus causes a given phenotype. About 65% of males with DMD have a deletion in the *DMD* gene, which encodes the protein dystrophin. Deletions are detected by a combination of multiplex polymerase chain reaction, Southern blotting, and fluorescence in situ hybridization testing. In DMD, deletions result in a frameshift and an absence of production of the protein dystrophin. The detection of an out-of-frame mutation is sufficient to establish the diagnosis of DMD. When no

deletion is detected, mutation scanning and sequence analysis can be used to detect an additional 30% of DMD-causing mutations.[11,12] Thus, muscle biopsy using immunohistochemical and immunoelectron microscopic techniques to visualize the protein dystrophin in the subsarcolemmal area, which was the diagnostic test previously used when no deletion was detected, is now necessary to establish the diagnosis of DMD in a small percentage of patients. In muscle-biopsy testing, the absence of dystrophin is diagnostic of DMD.

BMD is allelic to DMD; that is, the two disorders are caused by different mutations at the same gene (*DMD*). BMD is rarer than DMD, and BMD has a later onset and a milder course than DMD. Skeletal muscle function and lifespan are better for persons with BMD than for those with DMD; however, life-threatening dilated cardiomyopathy is common in patients with BMD. Deletions of the *DMD* gene occur in about 85% of males with BMD, but these deletions are in-frame mutations that lead to the production of a truncated dystrophin protein. Sequence analysis and, if necessary, muscle biopsy can be diagnostic in patients suspected of having BMD who have no discernible *DMD* deletion. In such cases, dystrophin is detectable in the subsarcolemma but is reduced in quantity.

The use of *DMD* molecular genetic testing exemplifies the positive predictive value of molecular genetic testing through genotype-phenotype correlation of frameshift (DMD phenotype) and in-frame (BMD phenotype) mutations.

The cost of molecular genetic testing on leukocytes varies by method; however, in general, genetic testing is less expensive than an open muscle biopsy, which requires a surgeon, an anesthesiologist, a pathologist, and related staff. Furthermore, use of molecular genetic testing to clarify the genetic status of female relatives of patients with DMD and BMD necessitates that the specific disease-causing mutation be identified through use of molecular genetic testing in at least one affected male relative.

PREDICTIVE TESTING IN ASYMPTOMATIC AT-RISK PERSONS

Predictive testing refers to testing of at-risk asymptomatic relatives for a disease-causing gene alteration known to be present in the family to clarify the relatives' genetic status. Predictive testing is considered presymptomatic when it is certain that all persons who have the altered gene will become symptomatic; it is considered predispositional when penetrance of the gene is reduced (i.e., fewer than 100% of persons with the altered gene will be affected).

For predictive testing to be useful, specificity and positive predictive value must be high. Cost-effectiveness of predictive testing is realized by reducing morbidity and mortality in patients at high risk through (1) early detection and treatment of those with a disease-causing mutation and (2) removal of persons who do not have the mutation from screening protocols, which can be expensive and invasive.[13] The disorders in this category are primarily autosomal dominant cancers [*see Table 5*].[14] The distinctions between presymptomatic testing and predispositional testing may not be meaningful when the test is for a mutation associated with a high risk of a disorder for which the general population is at relatively low risk (e.g., hereditary nonpolyposis colon cancer [HNPCC]). Molecular genetic testing may not be required to establish the diagnosis in the proband when the disorder is diagnosed by clinical findings. However, testing of an affected family member is required to identify the family-specific mutation for the purpose of testing asymptomatic at-risk relatives. The interest of at-risk relatives in pursuing testing for certain disorders is largely unknown. Hadley and colleagues determined that 51% of first-degree relatives at risk for HNPCC chose to undergo predispositional testing after education and genetic counseling to clarify the risk to their children. The potential effect on health insurance was the single most common reason to decline testing.[15]

Table 5 Autosomal Dominant Cancer Syndromes for Which Molecular Genetic Testing Is Available

Von Hippel–Lindau disease	Multiple endocrine neoplasia type 2
Familial adenomatosis polyposis	Multiple endocrine neoplasia type 1
Hereditary nonpolyposis colorectal cancer	Breast cancer
Retinoblastoma	Melanoma

Presymptomatic Testing

FAP is an autosomal dominant disorder in which penetrance of the disease-causing gene mutations is 100%. Persons with an *APC* gene mutation develop adenomas in the colorectum starting at around 16 years of age; in these individuals, the number of adenomas increases to hundreds or thousands, and colorectal cancer develops at a mean age of 39 years. The mean age at death is 42 years in those who go untreated. Early diagnosis via presymptomatic testing reduces morbidity and increases life expectancy through improved surveillance and timely prophylactic colectomy.[16] Testing of the *APC* gene has been shown to be cost-effective when used to identify individuals with the disease-causing *APC* mutation among at-risk relatives of persons with FAP.[17] For years, the mainstay of FAP testing was protein truncation testing (PTT). However, the mutation-detection rate with PTT was only about 80%; the introduction of other test methods—namely, gene sequencing—has increased the mutation-detection rate to 98%.

Predispositional Testing

Retinoblastoma is an example of a disorder in which penetrance of disease-causing gene mutations is less than 100%. It is caused by mutations in the *RB1* gene and can be inherited in an autosomal dominant manner. On average, penetrance of *RB1* gene mutations is 90% (i.e., 90% of persons with a germline disease-causing gene mutation will develop retinoblastoma). Cost-effectiveness and improved outcome through the use of predispositional gene testing have been demonstrated.[18]

Improved outcome is defined as the preservation of vision in at-risk persons through early detection and treatment of ocular tumors, as well as the reduction of morbidity through early detection of nonocular secondary tumors. Early detection of retinoblastoma, while the tumor is small, allows less aggressive treatments that ablate tumors but preserve vision. Before the availability of molecular genetic testing, recurrence-risk counseling for the parents of a child with retinoblastoma or for an adult with retinoblastoma was empirical; counseling was offered on the basis of a positive or negative family history and the presence of a single tumor or multiple tumors. The surveillance protocol is required whether a child has a 6% risk of retinoblastoma (parent or sibling with unilateral, sporadic retinoblastoma), a 40% risk (parent with bilateral retinoblastoma), or a 90% risk (person known to have a germline *RB1* mutation).

Sequencing of the *RB1* gene detects mutations in over 80% of patients with bilateral or hereditary retinoblastoma.[19] Although it is both labor intensive and expensive, gene sequencing is required to establish the molecular diagnosis in a proband. Because of extensive allelic heterogeneity, gene sequencing is the gold standard for detection of *RB1* gene mutations. Thus, an adult proband who has had retinoblastoma can undergo *RB1* sequence analysis in hopes of identifying the disease-causing mutation so that molecular genetic testing can be used in the management of his or her at-risk offspring. When a germline *RB1* mutation is identified in the proband, the offspring can be tested prenatally or at birth to determine the genetic status and whether there is a need for frequent ophthalmologic examinations. When no mutation is identified in the adult, the risk of recurrence is determined empirically, and all offspring must be evaluated regularly by an ophthalmologist. Cost-effectiveness results from not subjecting at-risk children to unnecessary and expensive screening protocols after they test negative for an *RB1* germline mutation known to be in their family.[13]

Counseling-Only Paradigm of Genetic Testing

In the counseling-only paradigm of genetic testing, genetic tests provide persons with information pertaining to disease risk for the purpose of personal decision making, which may include reproductive planning. Issues of test sensitivity, specificity, positive predictive value, and recurrence risk are as relevant in the genetic-counseling paradigm as they are in the medical model, but cost-effectiveness cannot be assessed when testing is used only for personal decision making.

PREDICTIVE TESTING

Predictive testing used for presymptomatic and predispositional diagnosis of persons at risk for disorders for which no medical interventions exist falls into the genetic-counseling paradigm.

Presymptomatic Diagnosis

Huntington disease is an example of a disorder for which no medical intervention exists. Huntington disease is caused by a CAG trinucleotide repeat expansion in the *HD* gene. When the CAG expansion is greater than 41 repeats, the penetrance is 100%—that is, all persons with an allele that size will eventually develop Huntington disease. Clarification of genetic status in persons at risk for Huntington disease allows those who have inherited the altered gene and those who have not inherited the altered gene to make informed personal and social decisions. Such decisions may include matters of lifestyle, employment, personal finance, and family planning.

Offering genetic testing to persons at risk for an untreatable, debilitating, fatal disorder requires careful forethought. The molecular diagnosis must always be confirmed in a symptomatic relative before testing can be offered to asymptomatic family members who are at risk. Because no medical intervention can be offered, anticipating and addressing the patient's psychoemotional needs are paramount. In a position paper, the National Society of Genetic Counselors emphasized that pretest education and genetic counseling are necessary and that posttest follow-up care must be in place at the time of genetic testing.[20] Informing the patient of normal results requires as much preparation and counseling as the relaying of abnormal results. The pretest counseling with the patient must address the positive predictive value of the test, particularly as relating to age at onset and severity of the disease. Greater repeat length is usually associated with earlier onset and more severe disease, but repeat length is not always a predictor of disease onset or severity. Furthermore, patients with an intermediate (or moderately abnormal) number of trinucleotide repeats (i.e., 36 to 40 CAG repeats) may have an indeterminate genetic risk.[21] Trinucleotide repeat sizes in this range are considered to have reduced penetrance because they can cause disease symptoms but do not always do so within a normal life expectancy.[2] Thus, the patient who is prepared to hear a negative or a positive result may be in the same uncertain position after testing as before.

Confidentiality of test results and possible discrimination in employment and health insurance coverage[22] may be issues for an asymptomatic person who has undergone genetic testing. Predictive genetic testing of asymptomatic at-risk individuals younger than 18 years is strongly discouraged in the genetic-counseling paradigm because of concerns that children will be inappropriately labeled at a time when they cannot be expected to use this information for personal planning or reproductive decision making.[23] Diagnostic testing of symptomatic at-risk children is always appropriate.

Predispositional Testing

Predispositional testing for a disorder may not be appropriate when the disorder is highly prevalent in the general population and when the efficacy of measures to reduce risk in persons with disease-predisposing mutations is unknown. Predispositional testing for breast cancer through molecular genetic testing of the genes *BRCA1* and *BRCA2* can be considered in this category, because the efficacy of measures to reduce cancer risk for individuals with *BRCA1* or *BRCA2* cancer-predisposing mutations is unknown.[24] Furthermore, the high prevalence of breast cancer in the general population means that the rigorous screening for early breast cancer identification recommended for all women cannot be relaxed even when an at-risk woman does not have the *BRCA1* or *BRCA2* cancer-predisposing mutation identified in a relative.

The dilemma posed by the indeterminate role of *BRCA1* and *BRCA2* molecular genetic testing in reducing morbidity from breast cancer may turn out to be a recurring issue in genetic testing for common diseases. Breast cancer, like such other common disorders as coronary artery disease, diabetes mellitus, and Alzheimer disease, is regarded as a complex disorder. Complex disorders have multiple etiologies, including heritable single genes, multiple genes with an additive effect that interact with often undefined environmental influences, and acquired environmental or genetic changes. With regard to the overall incidence and morbidity of common diseases, the contribution of single heritable genes is relatively small. For example, breast cancer affects one in nine women, yet only 5% to 10% of cases of breast cancer are attributed to mutations in single genes, including *BRCA1* and *BRCA2*. For a woman whose relatives have a known *BRCA1* mutation but who has tested negative for the mutation known to be in the family, the chance of breast cancer developing is still one in nine. She therefore has the same need for close surveillance as women in the general population. Furthermore, detection of a *BRCA1* or *BRCA2* mutation may not alter the surveillance protocol for breast cancer that is recommended for all women, but it may increase the utilization of mammography, breast self-examination, and oophorectomy.[25] The options for breast cancer prevention (e.g., bilateral mastectomy), however, might be considered in a different light for

women with a *BRCA1* or *BRCA2* mutation. Such a prevention strategy should be undertaken with caution because the positive predictive value of a *BRCA1* or *BRCA2* mutation for the development of breast cancer may not be fully understood and may be biased upward as a result of higher risks and different disease spectra in the high-risk families studied initially.

Serious issues surround testing for *BRCA1* and *BRCA2* mutations, including appropriate pretest counseling for at-risk women[26]; appropriate interpretation of positive and negative test results [*see Table 1*]; the high probability of missense mutations, which are considered indeterminate test results; recommendations for surveillance; and consideration of prophylactic mastectomy [*see 12:VII Breast Cancer*].

CARRIER TESTING

Carrier testing is used primarily to identify carriers of autosomal recessive gene mutations and X-linked gene mutations. There are no health-related issues for carriers of an autosomal recessive gene mutation, because all are expected to be asymptomatic. Health-related issues are a concern for a subset of female carriers of an X-linked gene mutation.

Autosomal Recessive Disorder

In cases of autosomal recessive disorders, testing may be used for diagnosis in a symptomatic person, for evaluation of at-risk asymptomatic persons, and for detection of carriers and affected fetuses. Although the gene causing an autosomal recessive disorder may be well characterized, allelic heterogeneity may reduce the sensitivity of molecular genetic testing below levels acceptable for diagnostic use, because it may not be technically feasible to identify all possible disease-causing mutations. In other cases, carrier detection and prenatal testing may be possible only through molecular genetic testing, which may provide information for reproductive decision making that would not otherwise be accessible [*see Table 6*].

Cystic fibrosis (CF) is an example of such an autosomal recessive disorder. Although discovery of disease-causing mutations in the *CFTR* gene has led to new tests for CF and redefinition of the disease spectrum, the traditional diagnostic criteria for classic CF are still valid.[27] The diagnosis of CF is established when the amount of sweat chloride is greater than 60 mEq/L in the presence of one or more characteristic clinical findings (e.g., typical gastrointestinal or sinopulmonary disease or obstructive azoospermia) or when the family history is positive for the disease. In questionable cases, *CFTR* molecular genetic testing can be helpful in establishing the diagnosis; however, genotyping alone rarely establishes the diagnosis of CF. Some individuals may have classic CF without a detectable *CFTR* disease-causing mutation because of allelic heterogeneity. Allelic heterogeneity in CF is extensive, with over 1,000 known disease-causing mutations. The American College of Medical Genetics (ACMG) has recommended a panel of 25 mutations for routine testing in clinical laboratories.[28] With the use of this panel, mutation detection rates vary by ethnicity; in white Europeans, 2% of patients with CF have no detectable abnormal alleles and 26% have only one detectable abnormal allele.

When two disease-causing alleles are identified in the proband, both parents can be tested to determine which parent carries which allele. Then, relatives of the mother can be tested for the presence of her disease-causing allele, and relatives of the father can be tested for the presence of his disease-causing allele. Any relative who is found to be a carrier of a disease-causing allele has the option of having his or her spouse tested with the clinically available panel of 25 common disease-causing alleles. Couples in which both partners are carriers of disease-causing alleles have a 25% chance of having a child who inherits two *CFTR* disease-causing mutations; however, the clinical manifestations and severity of the disease cannot necessarily be predicted by the specific mutations present. When the spouse has no identifiable disease-causing mutations, carrier risk can be calculated using Bayesian analysis.[29]

Table 6 Autosomal Recessive Disorders for Which Genetic Molecular Testing Permits Carrier Detection*

Cystic fibrosis	Congenital disorders of glycosylation
Phenylketonuria	β-Thalassemia
21-Hydroxylase deficiency	Canavan disease
Tay-Sachs disease	α-Thalassemia

* Partial list of disorders.

The use of DNA-based testing is sensitive in high-risk families. Its use in preconceptual counseling for carrier detection is more complicated because of its low sensitivity; however, such testing was endorsed by the American College of Obstetrics and Gynecology (ACOG), the ACMG, and the National Human Genome Research Institute in 2001.

X-Linked Disorders

In X-linked disorders, molecular genetic testing may be used to diagnose symptomatic males and the occasional symptomatic female and to detect carrier females and affected male fetuses. As in autosomal recessive disorders, molecular genetic testing is often the only option for carrier detection and prenatal testing. Certain factors make the testing for carriers of X-linked disorders more complicated; these include the high frequency of new gene mutations in males who are the only affected family member, as well as the possibility of germline mosaicism in the mother of a male who is the only affected family member. New gene mutations are borne by only a single egg or a single sperm. Germline mosaicism is the presence in some germline cells (eggs or sperm) of a mutation that is not found in other germline cells or somatic cells. Germline mosaicism for an X-linked disorder is surmised to be present in the mother of two or more affected males when there is no evidence of their disease-causing mutation present in her leukocytes.

DMD is an example of an X-linked disorder in which these issues must be considered in genetic counseling. Carrier detection in DMD can be problematic because a significant number of cases of DMD in males are simplex cases (i.e., single occurrences in a family). The following three equally probable possibilities exist for males with DMD who have a negative family history:

1. The affected boy has a new (de novo) gene mutation. In this case, his mother does not carry a disease-causing allele, and her female relatives are not at risk to be carriers of the altered allele.
2. The mother carries a de novo mutation, which places her daughters but not her sisters at risk for being carriers of the altered allele.
3. The maternal grandmother carries a de novo mutation, which places all her daughters at risk for being carriers of the altered allele.

Thus, in families in which DMD occurs in one male only, recurrence-risk counseling depends on establishing which, if any, of the women are carriers of a disease-causing mutation. The following testing and recurrence-risk counseling paradigm is used:

- DNA testing is performed on the male proband with DMD to identify the causative *DMD* gene mutation. When a *DMD* gene mutation is identified, a blood sample from the proband's mother is tested for the same mutation.
- If she has the same mutation as her son, she is counseled regarding the 50% risk of other sons being affected and the 50% risk of daughters being carriers; it is appropriate to test the proband's maternal grandmother for the same disease-causing mutation.
- If the proband's mother tests negative for his mutation, two possibilities exist: the son has a new gene mutation or the mother has germline mosaicism, which occurs in about 20% of women in this situation.
- If the son has a new gene mutation, the mother is not at increased risk for having other affected sons, and other women in the family are not at increased risk for being carriers.
- If the mother has germline mosaicism, she is at risk for having carrier daughters and additional affected sons. Her sisters, however, are not at increased risk for being carriers.

PRENATAL TESTING

Prenatal testing is used to evaluate a fetus at high risk for a genetic disorder on the basis of family history or to evaluate a fetus at no known increased risk but who is suspected of having a genetic disorder because of suggestive findings during the pregnancy.

Positive Family History

Testing of fetuses using molecular genetic testing can be offered to couples at risk for having a child with an autosomal dominant, autosomal recessive, or X-linked disorder for which the specific gene mutation (or mutations) has been identified in the family. Genetic counseling must be offered to provide the family an opportunity to review their reproductive options. Molecular genetic testing can be performed on tissues obtained by chorionic villus sampling at 9 to 11 weeks' gestation or from amniocentesis at 16 to 18 weeks' gestation to provide timely information should pregnancy termination be considered.

Findings Suggestive of a Genetic Disorder

Prenatal molecular genetic testing can be a part of the diagnostic evaluation of a fetus not known to be at increased risk for a genetic disorder that is being evaluated further because of abnormalities detected during routine monitoring of the pregnancy. When such findings are detected early in the pregnancy, DNA-based diagnosis may be undertaken if pregnancy termination is being considered. When findings are not apparent until the third trimester, diagnosis may be initiated for the purpose of perinatal management. For example, ultrasound findings of intestinal obstruction with hyperechoic meconium would warrant *CFTR* molecular genetic testing because of the association of *CFTR* with cystic fibrosis. Such testing can be performed on DNA extracted from amniocytes obtained from amniocentesis after 16 weeks' gestation, when timing is not an issue, or from white cells obtained by percutaneous umbilical blood sampling (PUBS) when results are needed urgently.

Genetic Consultation

Genetic consultation is as essential to the care of the patient with a genetic disorder as the testing itself; it is required for persons considering either the medical paradigm or the counseling-only paradigm of genetic testing. A positive genetic test result always raises the consideration of referral for genetic counseling.[30-33] Genetic counseling is the process of helping patients understand the nature and cause of the inherited disorder, of outlining the advantages and disadvantages of genetic testing to allow them to make informed medical and personal decisions, and of offering necessary psychosocial support and referral.[30,31,34] Genetic evaluation is the process of information gathering regarding a patient or family with a known or suspected genetic disorder. Genetic evaluation and genetic counseling are integral to genetic testing.

Genetic evaluation involves the gathering of information before a clinic visit and during the initial portion of the visit, which usually lasts 1 hour. The following information is obtained from the patient or family: the reason for referral; a family history, including the history of first- and second-degree relatives of the consultand; additional directed family history based on the known or suspected diagnosis and information provided by the patient or other family members; medical records of affected relatives; prenatal and perinatal history; past medical history; and information on growth, development, education, and employment. In addition, family functioning is assessed, potential ethical issues are identified, and a physical examination is performed on the patient and other family members as needed.

Once the gathering of information is complete, genetic counseling is provided. Discussion with the patient or family includes a summary of information obtained; the possible diagnosis and the degree of certainty of that diagnosis, determined on the basis of available information; recommended tests and evaluations necessary to establish the diagnosis or for management of the patient; the sensitivity and positive predictive value of such tests; the natural history of the disorder, including prognosis; inheritance pattern, including penetrance and variable expressivity (i.e., the variation in the type and severity of a genetic disorder between affected individuals, even within the same family); and recurrence risk for affected persons and for at-risk persons, including reproductive options and options for prenatal diagnosis. Medical management and referrals to appropriate medical specialists are discussed. Psychosocial issues discussed include anticipatory guidance of the patient and family, the availability of community support services, and the availability of regional or national disease-specific or umbrella organizations, many of which can be identified through the Genetic Alliance (www.geneticalliance.org). Genetic-counseling issues for the extended family are addressed. Geographically dispersed family members are referred to local genetic services that can be identified through the GeneTests Clinic Directory, which is available on the GeneTests Web site; the Clinic Directory can be searched by location within the United States, disease specialty, and services offered. Clinic visits and genetic-counseling sessions are documented with detailed summaries suitable for distribution to the family and health care providers. Summary letters are often sent to the family. Short-term follow-up is planned for conveying outstanding test results or other information; long-term follow-up at 2- to 5-year intervals is planned for routine management and updating of genetic-counseling issues.

Difficulties Encountered in DNA-Based Testing for Inherited Disorders

LACK OF AWARENESS OF TEST AVAILABILITY

For many inherited disorders, molecular genetic testing is not available, because the causative gene (or genes) is not known. In other instances, the gene is known but test sensitivity is less than that of clinical evaluation, and testing is done only in a research context. For rarer disorders, the gene may be known and clinical testing may be theoretically possible, but clinical laboratories do not offer the test because the cost of low-volume, highly complex testing is prohibitive. For other inherited diseases, the causative gene or genes are known, research testing is currently available, and clinical testing is expected to be available in the near future.[35,36] The rapid transition of testing from research laboratory to clinical practice makes it difficult even for those who are familiar with genetic testing to keep abreast of new developments. For those not familiar with genetic testing and its applications to patient care, the task is even more daunting.[37]

GeneTests is a genetic-testing information resource, funded by the National Institutes of Health (NIH) and maintained at the University of Washington in Seattle, that is designed to facilitate awareness of test availability and use.[38] The Web site (http://www.genetests.org) includes a laboratory directory that serves to help health care providers identify clinical and research laboratories offering testing of heritable disorders. As of July 2005, the Laboratory Directory contained listings of about 1,100 diseases for which clinical (~ 800) and research-only (~ 300) testing was available from approximately 575 laboratories. Clinical laboratories are defined as those that examine human specimens and report results for the purpose of diagnosis, prevention, or treatment in the care of individual patients; such laboratories must be licensed according to the Clinical Laboratory Improvement Amendments (http:\\www.cms.hhs.gov/clia). The Laboratory Directory can be searched by disease name, gene symbol, protein name, clinical features, the laboratory director's name, and the laboratory's geographic location.

COMPLEXITY OF TESTING METHODOLOGIES AND INTERPRETATION OF TEST RESULTS

Physicians may not be familiar with the use and limitations of molecular genetic tests in patient care. For example, Giardiello and colleagues determined that almost 20% of clinicians ordering *APC* molecular genetic testing for FAP used the wrong testing strategy.[31] These investigators also determined that 34% of clinicians ordering *APC* molecular genetic testing were unable to identify and interpret false negative results. Several genetic concepts that are intrinsic to the correct use of testing may be confusing. These concepts include (1) locus heterogeneity, in which the identical phenotype can be caused by a single mutation in one of two or more genes (e.g., mutation in either the *TSC1* or *TSC2* gene can cause tuberous sclerosis complex), which means that negative testing of the gene at only one locus does not rule out the disease; (2) allelic heterogeneity, in which multiple disease-causing mutations at a locus reduce the sensitivity of molecular testing below an acceptable level for use in diagnosis but not for recurrence-risk counseling; and (3) redefinition of phenotypes on the basis of molecular genetic findings (e.g., trinucleotide repeat diseases, CF, and the dystrophinopathies, including DMD, BMD, and X-linked dilated cardiomyopathy).

In a survey of genetic counselors in the United States, McGovern and colleagues determined that genetic counselors contacted laboratory-testing personnel for 58% of tests ordered regarding details of test ordering or interpretation of test results.[39] Only 72% felt that laboratory reports contain enough information to explain results to patients. There are concerns that nongeneticist health care providers face even greater challenges in using genetic-testing laboratories.

The *GeneReviews* portion of the GeneTests Web site contains current information on the use of genetic testing in diagnosis, management, and genetic counseling for specific inherited disorders. Entries on over 300 diseases (as of July 2005) provide expert-authored, peer-reviewed information for health care professionals. A context-sensitive illustrated glossary familiarizes nongeneticists with genetic counseling and genetic testing terms.

CONFUSION BETWEEN TESTING PARADIGMS

The intertwining of genetic testing for medical management and testing for personal decision making may lead to confusion about medical necessity, privacy, and discrimination. Just as the application of testing to patient care is context specific, consideration of these social issues is also context specific.

UNDERUTILIZATION OF GENETIC SERVICES

Giardiello and colleagues determined that only 18% of patients undergoing predictive testing for FAP, an autosomal dominant disorder that has 100% penetrance and that is associated with a 100% risk of cancer by 40 years of age, received genetic counseling.[31] A survey of 600 primary care physicians in Oregon revealed that 20% of internists did not know of any genetic services available to them for consultation.[40] Furthermore, most felt they did not need to refer patients for genetic consultation, preferring to offer risk-assessment and recurrence-risk counseling themselves, even though they were unfamiliar with the specific disorders and genetic-counseling concepts.[40] The need for primary care physicians to understand and use genetic services has been emphasized.[33,37,41,42] Possible explanations of underutilization of genetic services are the so-called therapeutic gap between diagnosis and prediction of diseases and the ability to treat or prevent them[43]; real or perceived restrictive reimbursement policies of health care payers; and concern about ethical and social issues that would seem to create "genetic exceptionalism" (the justification, provided by genetic testing, for special consideration regarding issues of informed consent and privacy),[44] which would move genetic testing beyond the purview of traditional medical care.[45] The change in the use of some genetic tests from a diagnostic role to a screening role (e.g., testing for factor V Leiden) may shift the emphasis of testing away from the evaluation of at-risk family members and genetic counseling to a broader role related to population-based health care.

IX HYPOGLYCEMIA

F. John Service, m.d., ph.d.

Definition

Hypoglycemia is a clinical syndrome of diverse etiologies characterized by episodes of low blood glucose. These episodes are typically marked by autonomic manifestations such as trembling, sweating, nausea, and, in more severe episodes, central nervous system manifestations (neuroglycopenia) such as dizziness, confusion, and headache.

Classification

Hypoglycemic disorders have long been categorized as fasting or postprandial (reactive). This classification lacks practical value. Insulinoma, which is the archetypal cause of fasting hypoglycemia, may produce symptoms postprandially and, indeed, in some cases solely postprandially. Patients with factitious hypoglycemia evince symptoms irrespective of meals.

A more useful approach for the practitioner is a classification based on the patient's clinical characteristics. Persons who appear otherwise healthy have hypoglycemic disorders different from those of persons who are ill.

hypoglycemia in apparently healthy patients

In apparently healthy persons, single episodes of hypoglycemia may result from accidental drug ingestion (e.g., ethanol in children). In addition to ethanol, salicylates and quinine can lower blood glucose levels; the combined effects of ethanol and quinine are responsible for so-called gin-and-tonic hypoglycemia. The healthy-appearing adult patient with a history of repeated episodes of neuroglycopenia usually has a disorder involving excessive insulin production, such as insulinoma; rarely, the hypoglycemia is factitious, caused by surreptitious or inadvertent use of a hypoglycemic agent (e.g., insulin or a sulfonylurea) [*see* Conditions That Cause Hypoglycemia, *below*].

Hypoglycemia may occur in patients who have coexistent disease but whose disease is being controlled with medical treatment. Typically, the hypoglycemia in these cases is a side effect of the medication being used to treat the coexistent disease, or it results from the mistaken dispensing of a sulfonylurea instead of the prescribed drug.

hypoglycemia in ill patients

Illness can lead to hypoglycemia through a variety of mechanisms, only some of which involve insulin and not all of which are known. Many illnesses (e.g., renal failure and sepsis) are known to pose the risk of low blood glucose levels [*see Table 1*]; hypoglycemia in a patient with one of these illnesses requires little if any investigation of its cause. However, not all patients with a disease that has a proclivity to generate hypoglycemia actually experience low blood glucose levels. Why only some ill patients experience hypoglycemia is unknown.

Hospitalized patients are at increased risk for hypoglycemia, often from iatrogenic factors. In any inpatient with hypoglycemia, medication should be considered a potential cause.

Low blood glucose levels may be found on laboratory testing of ill patients who have no symptoms of hypoglycemia. In patients with leukemia or severe hemolysis, the hypoglycemia may be an artifact resulting from consumption of glucose in the blood collection tube by large numbers of leukocytes or by nucleated red blood cells, respectively.[1,2] Patients with glycogen storage disease may be asymptomatic because they have adapted to lifelong hypoglycemia from their disease.[3]

Diagnosis

Although the diagnosis of hypoglycemia requires the measurement of blood glucose, such measurement often is not feasible when symptoms arise during activities of ordinary life. Under these circumstances, the physician must take a detailed history to determine whether to proceed with further evaluation. The history should include a full description of the patient's symptoms and the circumstances under which they occur.

A medication history is also an important aspect of the evaluation in a patient with clinical manifestations of hypoglycemia, especially if the onset coincides with the filling of a new prescription. Because of the potential for drug error, all medications taken by the patient should be identified by a medical professional, such as a physician or pharmacist.

clinical manifestations

The symptoms of hypoglycemia have been classified into two major groups: autonomic and neuroglycopenic. In a study of experimentally induced hypoglycemia in diabetic and nondiabetic persons, a principal-components analysis assigned sweating, trembling, feelings of warmth, anxiety, and nausea to the autonomic group and dizziness, confusion, tiredness, difficulty in speaking, headache, and inability to concentrate to the neuroglycopenic group. Hunger, blurred vision, drowsiness, and weakness could not be confidently assigned to either group.[4] In a retrospective analysis of 60 patients with insulinomas, 85% had various combinations of diplopia, blurred vision, sweating, palpitations, and weakness; 80% had confusion or abnormal behavior; 53% had amnesia or went into coma during the episode; and 12% had generalized seizures.[5]

The symptoms of hypoglycemia differ between persons but are nevertheless consistent from episode to episode in any one person.[6,7] There is no consistent chronologic order to the evolution of symptoms; autonomic symptoms do not always precede neuroglycopenic ones. In many patients, neuroglycopenic symptoms are the only ones observed.[7] Patients who have autonomic symptoms only are unlikely to have a hypoglycemic disorder. An additional factor that influences the generation of symptoms in hypoglycemia is their blunting by earlier hypoglycemic episodes.

physical examination

In patients who appear healthy, with or without coexistent compensated disease, the physical examination is normal or reveals only minor abnormalities that are unlikely to be germane to the underlying hypoglycemic disorder. In patients suspected of having factitious hypoglycemia from injection of insulin, a search for needle-puncture sites is fruitless. In ill patients with a primary disorder that can cause hypoglycemia, the results of physical examination will reflect that disease. For the patient observed while hypoglycemic, findings may include diaphoresis,

Table 1 Causes of Hypoglycemia

Drugs	Disopyramide Ethanol Haloperidol Quinine Salicylates
Drugs in specific illnesses	Pentamidine in *Pneumocystis* pneumonia Propoxyphene in renal failure Quinine in malaria Trimethoprim-sulfamethoxazole in renal failure Topical salicylates in renal failure
Endogenous hyperinsulinism	Insulinoma Islet hyperplasia/nesidioblastosis Persistent hyperinsulinemic hypoglycemia of infancy Noninsulinoma pancreatogenous hypoglycemia syndrome Insulin autoimmune hypoglycemia

widened pulse pressure, and neurologic abnormalities ranging from slowed mentation or withdrawal from spontaneous communication to more overt confusion, erratic behavior, coma, seizure, and hypothermia.

LABORATORY TESTS

Serum Glucose

Studies of acute insulin-induced hypoglycemia in healthy persons have shown that the threshold for the development of symptoms is a serum glucose concentration of approximately 60 mg/dl; the threshold for impairment of brain function is approximately 50 mg/dl.[8,9] These measurements were taken from arterialized venous blood (i.e., blood drawn from a vein in a heated hand [the application of heat shunts arterial blood into the venous system]); comparable levels in venous blood would probably be about 3 mg/dl lower. The rate of decrease in the serum glucose level does not influence the occurrence of the symptoms and signs of hypoglycemia.

Because symptoms of hypoglycemia are nonspecific, it is necessary to verify their origin. This is accomplished by applying a set of criteria first proposed by Whipple in 1938. The Whipple triad comprises spontaneous symptoms consistent with hypoglycemia, a low serum glucose concentration at the time the symptoms occur, and relief of the symptoms through normalization of the glucose level.[10]

A normal serum glucose concentration, reliably obtained during the occurrence of spontaneous symptoms, eliminates the possibility of a hypoglycemic disorder. Capillary glucose measurements that patients take themselves with a blood glucose meter during the occurrence of spontaneous symptoms are often unreliable, because nondiabetic patients usually are not experienced in this technique and because the measurements are obtained under adverse circumstances. Patients with a confirmed low serum glucose level (< 50 mg/dl) or a history of neuroglycopenic symptoms should undergo further testing. This is best accomplished with a prolonged fast.

The Prolonged (72-Hour) Fast

The prolonged (72-hour) fast is the classic diagnostic test for hypoglycemia. It should be conducted in a standardized manner [*see Table 2*]. The fast may be undertaken to demonstrate the Whipple triad and thereby establish that hypoglycemia is the basis for the patient's symptoms. If the Whipple triad has already been documented, the fast may be conducted for the purpose of determining the mechanism of the hypoglycemia, through measurement of beta cell polypeptide and plasma sulfonylurea levels. In the latter case, the fast can be terminated when the serum glucose level drops to 55 mg/dl or less (or, better yet, ≤ 50 mg/dl), which is the concentration at which beta cell polypeptides should be suppressed. Not all patients will need the full 72 hours to accomplish the purpose for the fast. In a study of 170 patients with surgically proven insulinomas, termination of the fast occurred within 12 hours in 33% of patients, within 24 hours in 65%, within 36 hours in 84%, within 48 hours in 93%, and within 72 hours in 99%.[11] Truncation of the fast at 48 hours, if hypoglycemia has not occurred by then, risks misdiagnosis.

Starting the fast overnight has allowed 40% of patients (including those with insulinoma and other causes of hypoglycemia) to conclude their fast in the outpatient endocrine-testing unit. Patients whose fast is not completed by the end of the business day are admitted to the hospital to complete the fast.

The decision whether to end the fast may not be easy to make when the Whipple triad is the goal. Because of delays in the availability of glucose measurements, the bedside glucose meter may have to serve as a guide. Some patients have slightly depressed glycemic levels without symptoms or signs of hypoglycemia. In other patients, fasting evokes the symptoms they experience in ordinary life but their serum glucose levels are not in the hypoglycemic range. In such instances, symptoms cannot be attributed to hypoglycemia. To complicate matters, young, lean, healthy women—and, to a lesser degree, some men—may have serum glucose concentrations in the range of 40 mg/dl or even lower during prolonged fasting.[12] Careful examination and

testing for subtle signs or symptoms of hypoglycemia should therefore be conducted repeatedly when the patient's serum glucose level is near or in the hypoglycemic range. To end the fast solely on the basis of a low serum glucose level, in the absence of symptoms or signs of hypoglycemia, may jeopardize accurate diagnosis. On the other hand, failing to appreciate the manifestations of neuroglycopenia and, hence, concluding that the results of the fast are negative is an equally egregious error. It is essential to monitor patients closely during the fast and to be vigilant for subtle signs of neuroglycopenia.

Beta Cell Polypeptides and Their Surrogates

Concentrations of beta cell polypeptides (insulin, C-peptide, and proinsulin) are interpreted in the context of the concomitant serum glucose concentration. The normal overnight fasting ranges for these polypeptides do not apply when the serum glucose level is low. When immunochemiluminometric assays (ICMA) are used, the criteria for endogenous hyperinsulinemia are as follows: serum insulin, 3 µU/ml or greater; C-peptide, 200 pmol/L or greater; and proinsulin, 5 pmol/L or greater [*see Figure 1*].[13]

Insulin concentrations rarely exceed 100 µU/ml in patients with insulinomas. Values above this level suggest recent insulin administration or the presence of insulin antibodies.

Ratios of glucose to insulin, and vice versa, have no diagnostic utility [*see Figure 1*]. The molar ratio of insulin to C-peptide is the same for patients with insulinomas and healthy persons (approximately 0.2). The molar ratio of proinsulin to insulin appears to be higher in persons with insulinoma, but it provides poor diagnostic utility.

Because insulin has an antiketogenic effect, serum levels of the ketone body β-hydroxybutyrate can be used as a surrogate for measurement of insulin. The serum β-hydroxybutyrate level is low—2.7 mmol/L or less—in patients with insulin-mediated hypoglycemia; normal persons and those with non–insulin-mediated hypoglycemia have higher levels [*see Figure 1*].[13]

At the end of the fast, the patient is given an intravenous dose of 1 mg of glucagon, and the subsequent glucose response is measured. Because insulin is glycogenic and antiglycogenolytic, the glucagon injection results in an increase in the serum glucose level of 25 mg/dl or greater in patients with insulin-mediated hypoglycemia, whereas normal persons or those with non–insulin-mediated hypoglycemia have lesser increases [*see Figure 1*].[13] An exuberant serum insulin response to intravenous glucagon has been considered an indication of insulinomas, but unfortunately, no normative data have been generated for this test. Measurement of beta cell polypeptides and insulin surrogates (β-hydroxybutyrate and glucose response to intravenous glucagon) has diagnostic utility only when the serum glucose level is 60 mg/dl or lower at the end of the fast.

Table 2 Protocol for Prolonged Supervised Fast

1. Date the onset of the fast as of the last ingestion of calories. Discontinue all nonessential medications.
2. Allow the patient to drink calorie-free and caffeine-free beverages.
3. Ensure that the patient is active during waking hours.
4. Measure plasma glucose, insulin, C-peptide, and, if an assay is available, proinsulin in the same specimen. Repeat measurements every 6 hr until the plasma glucose drops below 60 mg/dl; then repeat the measurements every 1–2 hr.
5. When the plasma glucose is less than 45 mg/dl and the patient has symptoms or signs of hypoglycemia, measure plasma glucose, insulin, C-peptide, proinsulin, β-hydroxybutyrate, and sulfonylurea in the same specimen; then inject 1 mg of glucagon I.V. and measure plasma glucose after 10, 20, and 30 min.
6. Feed the patient.

Sulfonylureas and Meglitinides

Persons with hypoglycemia from inappropriate use of sulfonylureas or meglitinides (e.g., repaglinide) have concentrations of beta cell polypeptides that are identical to those observed in persons with insulinoma. Consequently, plasma assays for these drugs is an essential aspect of the evaluation. I use a highly sensitive and accurate liquid chromatographic tandem mass spectroscopy method to identify these drugs. A positive assay suggests either covert or inadvertent usage.

Insulin Antibodies

An assay for insulin antibodies should be done in every patient with clear evidence of hypoglycemia. The detection of insulin antibodies in a nondiabetic patient was once considered to be firm evidence of insulin factitious hypoglycemia, especially when animal insulin was the only commercially available type. Currently, most patients with factitious hypoglycemia have no detectable insulin antibodies, possibly because of the use of human insulin, which is less antigenic than beef or pork insulin. Rather, the presence of insulin antibodies, especially in high titers, is diagnostic of insulin autoimmune hypoglycemia (IAH) (see below).[13] Very low titers of insulin antibodies may sometimes be detected in persons without hypoglycemia[14] and, in rare instances, in patients with insulinomas.

Glycated Hemoglobin

Measurement of glycated hemoglobin is not a standard aspect of the clinical evaluation of hypoglycemia. Concentrations of glycated hemoglobin are statistically significantly lower in patients with insulinomas than in normal persons, but there is too much overlap between the two groups for this test to provide a diagnostic criterion.[6]

Oral Glucose Tolerance Test

The oral glucose tolerance test should not be used for the evaluation of hypoglycemia, because it is fraught with risk of misdiagnosis. At least 10% of healthy persons have serum glucose nadirs below 50 mg/dl, and the results of the test do not correlate with serum glucose responses to a mixed meal (i.e., a meal containing a balance of proteins, carbohydrates, and fat).

Mixed-Meal Test

For persons with a history of neuroglycopenic symptoms within 5 hours after food ingestion, a mixed-meal test may be conducted. The test is considered to be positive if the patient experiences neuroglycopenic symptoms when a concomitant serum glucose level measures 50 mg/dl or less. A positive mixed-meal test does not provide a diagnosis, only biochemical confirmation of the history.

C-Peptide Suppression Test

C-peptide is formed during the conversion of proinsulin to insulin by the pancreatic beta cells. In the C-peptide suppression

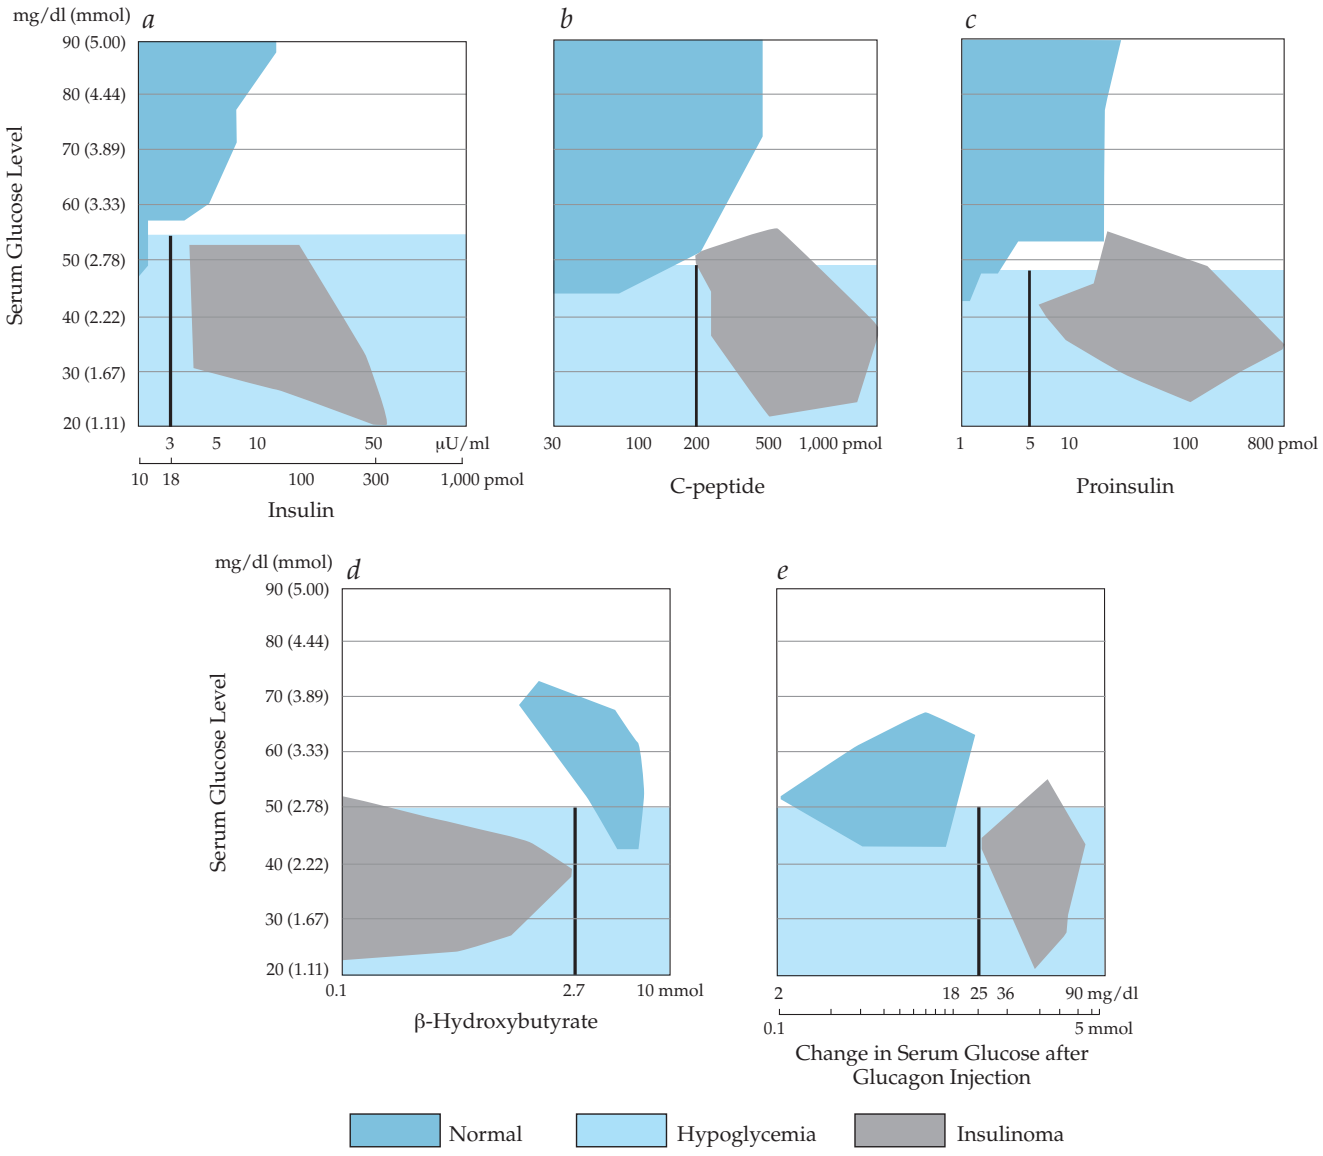

Figure 1 **During the 72-hour fast, levels of serum glucose are compared with serum levels of insulin (*a*), C-peptide (*b*), proinsulin (*c*), and β-hydroxybutyrate (*d*). At the end of the fast, 1 mg of glucagon is injected intravenously, and its effect on glucose levels is measured (*e*). Normal patients may have glucose levels that drop into the hypoglycemic range, so careful documentation of hypoglycemic symptoms is necessary.**

test, the patient fasts overnight and then receives an hour-long intravenous infusion of insulin, during which levels of serum glucose and C-peptide are measured. In normal patients, hypoglycemia from the exogenous insulin results in suppression of C-peptide production; patients with insulinomas have higher levels of C-peptide. When the likelihood of a hypoglycemic disorder is not high, a normal result on the C-peptide suppression test may preclude the need for a 72-hour fast. Interpretation of the C-peptide suppression test requires normative data appropriately adjusted for the patient's body mass index and age.[7]

Intravenous Tolbutamide Test

In the past, serum glucose response to an intravenous injection of tolbutamide was used in the diagnosis of insulinoma. This test is potentially dangerous and is less accurate than other tests for insulinoma and, therefore, has been rarely used in recent years.

Conditions That Cause Hypoglycemia

The causes of hypoglycemia in healthy-appearing adults encompass the following conditions: insulinoma, factitious hypoglycemia from insulin or sulfonylurea, noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS), and insulin autoimmune hypoglycemia.

INSULINOMA

Epidemiology

Between 1927 and 1986, 224 hypoglycemic patients underwent their first pancreatic exploration at the Mayo Clinic and were found to have insulinoma. Because of the relatively large number of cases of insulinoma treated at the Mayo Clinic, in comparison with other medical centers, and the comprehensive epidemiologic database that the Mayo Clinic maintains for Olm-

sted County, Minnesota, it was possible to determine the population-based incidence of insulinoma, the risk of recurrence, and the survival in patients with insulinoma.[15]

The median age of the Mayo Clinic insulinoma patients was 47 years, with a range of 8 to 82 years; 59% were female. The incidence in Olmsted County was 4 cases per 1 million person-years. Of the 224 patients, 7.6% had multiple endocrine neoplasia type I (MEN I) and 5.8% had malignant insulinoma. The risk of recurrence was greater in patients with MEN I (21%) than in those without this condition (7%). Over a 45-year period, overall survival of the total cohort was similar to the expected survival (78% versus 81%).

Insulinomas have been found in pregnant patients and in patients with type 2 (non–insulin-dependent) diabetes mellitus. One case of insulinoma in type 1 (insulin-dependent) diabetes mellitus has been reported.[16]

Diagnosis

Laboratory tests Insulinoma is characterized by hypoglycemia caused by elevated levels of endogenous insulin. Confirmation of the diagnosis requires exclusion of hypoglycemia from exogenous sources.

Localization Once a biochemical diagnosis of insulinoma has been made, the next step is localization. Success with the various modalities reflects local skill and experience. Great success has been seen with transabdominal ultrasonography and triple-phase spiral computed tomography. Magnetic resonance imaging and scintigraphy with indium-111 (In-111)–pentetreotide (OctreoScan) can also be used. I reserve endoscopic ultrasonography for complex cases. Percutaneous transhepatic portal venous sampling has been abandoned even by its former proponents.

In patients whose tumor is not found by ultrasonography or CT, the selective arterial calcium stimulation test provides a means to both regionalize and confirm endogenous hyperinsulinemia. This test involves serial injections of calcium into the splenic, gastroduodenal, and superior mesenteric arteries. Subsequent doubling of serum insulin concentrations in the right hepatic vein indicates hyperfunctioning beta cells in the part of the pancreas served by that artery.

There is general agreement that the best localization of insulinomas is achieved with intraoperative ultrasonography and careful mobilization and palpation of the pancreas by a surgeon experienced with insulinoma surgery. This approach has seen a 98% success rate in the identification of insulinoma. After this test, these patients go straight to surgery.

Management

The treatment of choice for insulinomas is surgical removal. Depending on the lesion, the surgery required may range from enucleation of the insulinoma to subtotal pancreatectomy. It is advisable for the surgery to be performed at an institution with expertise in the management of insulinoma.

Medical therapy is less effective than tumor resection, but the former can be used in patients who are not candidates for surgery, who refuse surgery, or whose surgery is unsuccessful. The most effective medication for controlling symptomatic hypoglycemia in these patients is diazoxide, which lowers insulin secretion. Diazoxide is given in divided doses of up to 1,200 mg daily. Side effects include edema, which may require high doses of loop diuretics, and hirsutism. Other medications for insulinomas include verapamil, phenytoin, and octreotide.

FACTITIOUS HYPOGLYCEMIA

The term factitious (or factitial) has been used in medical parlance to imply covert patient activity. The consideration of such a possibility often changes the patient-physician relationship, leading the physician to feel deceived and the patient to feel mistrusted. However, the pejorative connotation with which factitious illness has been encumbered requires softening because some patients with factitious disease suffer through no fault of their own.

Epidemiology

Factitious hypoglycemia is more common in women and occurs most often in the third or fourth decade of life. Many of these patients work in health-related occupations.

Factitious hypoglycemia in patients with diabetes is probably more common than the incidence noted in published series.[17] Confirmation of the diagnosis in these cases can be very difficult. When deprived of access to hypoglycemic agents, diabetic patients with factitious hypoglycemia become hyperglycemic.

Etiology

Factitious hypoglycemia results from the use of insulin or the use of sulfonylureas or meglitinides that stimulate insulin secretion. The most common form of factitious hypoglycemia is the covert self-administration of a hypoglycemic drug or insulin by a patient without diabetes or the inappropriate manipulation of hypoglycemic drugs or insulin by a patient with diabetes. Less often, a parent may administer a hypoglycemic agent to a child; this is a form of child abuse.[18] In all reported cases, the alleged perpetrator was the patient's mother, who had ready access to insulin. Insulin has also been used to attempt suicide or homicide.[19]

There are increasing numbers of patients who, by taking a prescribed medication in good faith, incur hypoglycemia because a sulfonylurea was mistakenly dispensed.[20] In most instances, confusion in dispensing the drug arose because of similarity in spelling between the intended medication and the sulfonylurea. In some cases, however, the dispensing error was a result of negligence. On occasion, cases have arisen in which a nondiabetic person mistakenly takes hypoglycemic medication belonging to another member of the household.

Diagnosis

The possibility of factitious hypoglycemia should be considered in every patient undergoing evaluation for a hypoglycemic disorder, especially when the hypoglycemia has a chaotic occurrence—that is, when it has no relation at all to meals or fasting. All medications should be identified; the assistance of a pharmacist is desirable. The practice of searching personal effects and labeling insulin with a traceable substance that can be detected in blood or urine is probably unacceptable in the current climate of patients' rights.

The diagnosis of factitious hypoglycemia can usually be established by measuring serum insulin, sulfonylurea, and C-peptide when the patient is hypoglycemic. If a spontaneous episode of hypoglycemia is not observed, the patient should undergo a 72-hour fast. The results of the fast may be negative, however, should the patient not take the offending agent.

In a patient whose hypoglycemia results from covert use of a hypoglycemic agent, the agent will be present in the blood. A sensitive method such as liquid chromatography linked to mass

spectroscopy should be used for the detection of sulfonylureas and meglitinides.

In insulin-related factitious hypoglycemia, the serum insulin level is high and the C-peptide level is suppressed, usually being close to the lower limit of detection. This observation applies both to nondiabetic patients and to those with type 2 diabetes. Patients with type 1 diabetes are characteristically severely insulin deficient and have low or undetectable serum concentrations of C-peptide. Although the C-peptide values in these patients cannot be further suppressed, confirmation that the values are low during a hypoglycemic episode eliminates any consideration of endogenous hyperinsulinism.

Management

Treatment of factitious hypoglycemia is simple: the patient stops taking the offending medication. The difficulty involved when medication is taken in error is identification of the drug. In the case of deliberate covert use, psychiatric referral is indicated.

NONINSULINOMA PANCREATOGENOUS HYPOGLYCEMIA SYNDROME

There have been cases of adults who do not have insulinomas but have hypoglycemia resulting from postprandial hypersecretion of insulin by pancreatic beta cells. Because of the unique clinical, diagnostic, radiologic, surgical, and histologic features of this disorder, it warrants designation as a new syndrome. We have termed it noninsulinoma pancreatogenous hypoglycemia syndrome, or NIPHS.[21]

Epidemiology

Like insulinoma, NIPHS affects patients across a broad age range—16 to 78 years, in one series—and causes severe neuroglycopenia, with loss of consciousness and, in some cases, generalized seizures. Unlike insulinoma, NIPHS occurs predominantly in males (70%).

Pathophysiology and Pathogenesis

Histologic analysis of pancreatic tissue from patients with NIPHS shows cells budding off ducts, which is best seen by chromogranin A and insulin immunohistochemical staining. Islet cell hypertrophy is also evident. No gross or microscopic tumor has been identified on hematoxylin-eosin–stained sections in any NIPHS patients.

Whether islet hypertrophy, nesidioblastosis, or both are pathogenic in these patients is open to question, as is the case with persistent hyperinsulinemic hypoglycemia of infancy (PHHI). However, a role for some form of diffuse islet cell dysfunction appears well established in these cases. Whatever the pathologic process may be, it is nonfocal, yet it does not necessarily involve the entire pancreas uniformly.

The histologic findings in NIPHS are similar to those in PHHI. Although familial forms of PHHI may be associated with mutations in the *Kir6.2* and *SUR1* genes, analysis of these genes in NIPHS patients has not shown such mutations.[22] However, these patients may have common mutations at another, as yet unspecified, locus.

Diagnosis

Clinical manifestations Symptoms of NIPHS occur primarily in the postprandial state 2 to 4 hours after eating. Although insulinoma patients may experience symptoms postprandially, they also have symptoms during food deprivation. It is extremely rare for insulinoma patients to have symptoms solely in the postprandial state.

Laboratory tests Patients with NIPHS have low serum glucose levels and elevated serum insulin levels in the postprandial period. Because of the short half-life of insulin, the criteria for hyperinsulinemia used in the fasting state appear to apply in the postprandial state, as long as the low glucose level occurs more than 30 minutes from the peak postprandial insulin level. Supervised 72-hour fasts have shown normal results in patients with NIPHS, whereas a negative 72-hour fast in a patient with insulinoma is a rare occurrence.

The selective arterial calcium stimulation test has shown positive results for patients with NIPHS.[23,24] All radiologic localizing studies in patients with NIPHS (transabdominal ultrasonography, triple-phase CT, celiac axis angiography, and intraoperative ultrasonography) have been negative for insulinoma.

Management

Gradient-guided partial pancreatectomy has been effective in relieving symptoms in patients with NIPHS. The pancreas is resected to the left of the superior mesenteric vein when results of the selective arterial calcium stimulation test are positive only for the splenic artery, and the pancreas is resected to the right of the superior mesenteric vein when the test is positive for an additional artery. Fortunately, gradient-guided debulking of the pancreas can ameliorate the symptoms of NIPHS even in patients whose disease would appear to have involved the whole pancreas. In rats, the mechanism for this effect may be related to decreased insulin secretion, attributed to reduced glucose transporter GLUT2, in remnant pancreas after partial pancreatectomy.[25] Unfortunately, recurrence of hypoglycemia after a few symptom-free years has developed in a few of the NIPHS patients.

INSULIN AUTOIMMUNE HYPOGLYCEMIA

Epidemiology

IAH is an extraordinarily rare disorder that is observed primarily, although not exclusively, in persons of Japanese and Korean ethnicity. The disorder may occur at any age. IAH tends to be be self-limited in Asians, but it may be persistent in whites. There is no gender predilection. Many patients have an ongoing autoimmune disorder or a history of treatment with a sulfhydryl-containing drug such as antithyroid medication. No patients have had a history of exposure to insulin.[14]

Pathogenesis

IAH is characterized by the presence of autoantibodies to insulin or the insulin receptor. There is speculation that meal ingestion in these patients may result in the unbinding of insulin from these antibodies. However, measurements of total insulin and free insulin have shown no postprandial alteration in their relative concentrations. The mechanism for the generation of insulin antibodies is unknown but may involve enhanced immunogenicity resulting from an effect of the disulfide bond in drugs with a sulfhydryl component.

Diagnosis

Clinical manifestations Patients with IAH typically experience postprandial hypoglycemia resulting in neuroglycopenia. The symptomatic severity of IAS appears to vary greatly. Whites may become more seriously debilitated than Asians.

Laboratory tests Serum insulin levels are markedly elevated in IAH, because the insulin antibodies interfere with this assay. Values can be as high as 1,000 μU/ml. Oddly, C-peptide levels are usually not suppressed. Insulin antibody titers are very high, higher than those seen in insulin-treated diabetic patients. The antibodies may bind only to human insulin or to both human insulin and beef and pork insulin. The antibodies may be polyclonal or monoclonal, and they usually have characteristics similar to those that occur in patients with type 1 diabetes mellitus. It should be noted that very low titers of insulin antibodies may also be observed in healthy persons without hypoglycemia and occasionally in persons with insulinoma.

Management

Supportive treatment, such as frequent small meals, may be effective in IAH, especially for mild cases. For more severely affected patients, a variety of approaches have been tried, including glucocorticoids, immunosuppressants, plasmapheresis, octreotide, and diazoxide. Unfortunately, all these treatments usually fail. Use of partial pancreatectomy and splenectomy has led to amelioration but not complete resolution of symptoms.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this subsection.

X OBESITY

Jonathan Q. Purnell, m.d.

Obesity and its associated disorders are leading causes of morbidity and premature mortality around the world. Obese persons are also vulnerable to low self-esteem and depression because of the psychological and social stigmata that can be associated with obesity. Despite societal prejudicial perceptions that obesity develops because of deficient self-control, research has provided insight into the physiology behind unwanted weight gain. Indeed, during the past decade, the field of body-weight regulation (the study of the homeostatic mechanisms controlling body weight and fat content and the pathophysiology leading to unwanted weight gain or weight loss) has undergone an explosion in research, particularly in the area of neuroendocrine control of appetite and energy expenditure. As with other leading diseases in developed countries, such as hypertension and diabetes, obesity is recognized as a chronic condition resulting from an interaction between environmental influences and an individual's genetic predisposition to weight gain.

The initial evaluation of overweight and obese patients begins with the exclusion of secondary causes of weight gain and the identification of comorbid disorders such as hypertension, diabetes, heart disease, and sleep apnea. Once screening is completed, the approach to the treatment of overweight and obesity is similar to that of other chronic diseases: begin with lifestyle improvements, and then consider medical and surgical options. Although the weight loss that accompanies current therapeutic options is modest on average, the future promises better diagnostic and treatment options for obesity that are based on research into the mechanisms of weight regulation and their role in unwanted weight gain and maintenance of the obese state.

Definition of Obesity

Obesity is an abnormal accumulation of body fat in proportion to body size. Overweight persons have a body-fat proportion that is intermediate between normal and obese. Ideally, an obesity classification system would be based on a practical measurement of body fat that could be performed in the office, would accurately predict disease risk, and would apply to patients from diverse ethnic backgrounds. The most direct measures of body fat, such as underwater weighing or dual-energy x-ray absorptiometry (DXA) scanning, are impractical for use in a clinical setting. Indirect estimates of body fat are clinically more practical.

Classification of Obesity

BODY MASS INDEX

Body mass index (BMI), which is calculated by dividing the body weight in kilograms by height in meters squared, is a classification system that attempts to allow comparison of weights independent of stature across populations. Except in persons who have increased lean weight as a result of intense exercise (e.g., bodybuilders), BMI does correlate with percentage of body fat, but this relationship is independently influenced by sex, age, and race.[1] In the United States, data from the second National Health and Nutrition Examination Survey (NHANES II) were used to define obesity in adults as a BMI of 27.3 kg/m^2 or more for women and a BMI of 27.8 kg/m^2 or more for men.[2] These definitions were based on the gender-specific 85th-percentile values of BMI for persons 20 to 29 years of age. In 1998, however, the National Institutes of Health (NIH) Expert Panel on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults adopted the World Health Organization (WHO) classification for overweight and obesity.[3] The WHO classification, which predominantly applies to people of European ancestry, assigns an increasing risk for comorbid conditions—including hypertension, type 2 diabetes mellitus, and cardiovascular disease—to persons with higher BMIs [*see Table 1*] relative to persons of normal weight (i.e., those with a BMI between 18.5 kg/m^2 and 25 kg/m^2). Asian populations, however, are known to be at increased risk for diabetes and hypertension at lower BMI ranges than those for non-Asian groups.[4] Consequently, the WHO has suggested lower cutoff points for consideration of therapeutic intervention in Asians: a BMI of 18.5 to 23 kg/m^2 represents acceptable risk, 23 to 27.5 kg/m^2 represents increased risk, and 27.5 kg/m^2 or higher represents high risk.[5]

FAT DISTRIBUTION

In addition to an increase in total body fat, a proportionally greater amount of fat in the abdomen or trunk compared with fat in the lower extremities or hips has been associated with increased risk for diabetes, hypertension, and heart disease in both men and women.[6] Abdominal obesity is commonly reported as a waist-to-hip ratio, but it is most easily quantified by a single circumferential measurement obtained at the level of the superior iliac crest.[3] Current guidelines categorize men at increased relative risk for coronary artery disease, diabetes, and hypertension if they have a waist circumference greater than 40 inches (102 cm); women are at increased risk if their waist circumference exceeds 35 inches (88 cm) [*see Table 1*]. Thus, an overweight person with abnormal fat patterning may be at high risk for these diseases even if that person is not obese by BMI criteria. In those of Asian descent, abdominal (central) obesity is recognized to be a better predictor of comorbidity than BMI.[7] Therefore, the WHO has recommended lower waist circumference cutoffs to assign increased risk for comorbidities in this population: 36 inches (90 cm) or more in men and 32 inches (80 cm) or more in women.[4]

Table 1 Classification of Weight and Risk for Comorbid Conditions[2]

Classification	*Body Mass Index (kg/m^2)*	*Risk for Diabetes, Hypertension, and Cardiovascular Disease*	
		*Normal Waist Circumference**	*Increased Waist Circumference**
Underweight	< 18.5	Average	Average
Normal	18.5–24.9	Average	Average
Overweight	25–29.9	↑	↑↑
Obese	30–34.9	↑↑	↑↑↑
	35–39.9	↑↑↑	↑↑↑
	≥ 40	↑↑↑↑	↑↑↑↑

*Normal waist circumference is ≤ 102 cm (40 in) in men, ≤ 88 cm (35 in) in women.

Epidemiology

In the United States, the prevalence of overweight has been increasing over the past several decades [*see Figure 1*]. In the most recently published United States data (1999 to 2002), 65% of adults are overweight (BMI 25 to 30 kg/m^2), 30% of the total population are obese (BMI 30 to 40 kg/m^2), and 5% have a BMI of 40 kg/m^2 or higher.[8,9] The prevalence of obesity has also risen in some minority populations, with the highest rates found in some Native American groups, Hispanics, and African Americans; the lowest rates have been found in populations of Asian ancestry [*see Figure 2*].[9-12] Prevalence rates for obesity in the United States are also highest in populations with less education and lower income levels.[12] Internationally, obesity rates are generally lower than those in the United States.[13] However, even in societies that traditionally had the lowest prevalence of overweight and obesity, the rates of weight gain are beginning to meet or exceed those of Western societies.[14]

The age at which obesity is most prevalent has also increased. Until NHANES III (1988 through 1994), obesity in the United States peaked between the ages of 40 and 59 years, then declined in the older-age groups.[9] According to the most recent NHANES data (1999 to 2002), the prevalence of obesity now remains high past the age of 60 years, reaching 30.5% in men and 34.7% in women.[9] In studies that have measured body composition in unselected populations, fat mass also peaks just past middle age in men and women, but percent body fat continues to increase past this age, particularly in men, because of a proportionally greater loss in lean mass.[15-17] The menopausal period has also been associated with an increase in percent body fat and propensity for central fat distribution, even though total body weight changes very little during this time.[18] A propensity for greater abdominal adiposity has also been demonstrated in men,[19] in older individuals,[20] and in persons with impaired glucose tolerance or type 2 diabetes.[21]

Etiology and Genetics

Studies of populations, families, adoptions, and twins have established a strong genetic role in determining body weight. Estimates of the genetic contribution to the variance of relative body weight and adiposity range from a low of approximately 20% to a high of 90%.[22] The largest study to date to address the contribution of nature versus nurture to body weight, which used a dataset that included over 25,000 twin pairs and 50,000 biologic and adoptive family members, found that genetic factors accounted for 67% of the variance in adiposity in men and women.[22] Rarely, childhood-onset obesity will manifest itself as a result of a single-gene obesity syndrome, such as Prader-Willi syndrome or Bartlett-Biedel syndrome, or from a mutation in one of the genes encoding proteins involved with body-weight regulation, such as the pro-opiomelanocortin (*POMC*) gene, which makes α-melanocortin–stimulating hormone (α-MSH); the melanocortin receptor (MC4); leptin; the leptin receptor; and prohormone convertase enzymes.[23]

Although the genetics explaining the tendency toward overweight and obesity in the majority of the population remains to be elucidated, over 600 genetic markers have been described in association with obesity-related variables in humans (e.g., BMI, skin-fold thickness, waist-to-hip ratio, fat mass, and percent fat mass).[23] With time, discoveries of specific gene products, the role that these proteins play in the pathophysiology of weight regulation, and their interaction with the environment in the expression of unwanted weight gain should lead to more specific pharmacologic treatments for overweight and obese patients who fail to respond adequately to lifestyle measures alone.

Epidemiologic studies have identified several environmental factors that contribute to the continued weight gain documented over the past several decades in westernized countries. The foremost among these factors are an increasingly sedentary lifestyle (e.g., increased car use, community and work environments that discourage activity, and more time spent watching television) and the availability of energy-dense (high-fat, concentrated-sugar), low-fiber foods.[24-28] In children, the increased consumption of sugar-added beverages and reduction of dairy intake have also been associated with greater weight gain in prospective studies.[29,30] Similar environmental predictors of weight gain have been described in societies adopting Western lifestyles in the transition to First World economies.[14,31] Additional societal trends that are thought to have contributed to the increasing weight gain in the United States include smoking cessation (cigarette smoking is known to reduce body weight)[25,32] and eating a greater proportion of food away from home, particularly at fast-food restaurants, where food is typically very calorically dense.[28,33]

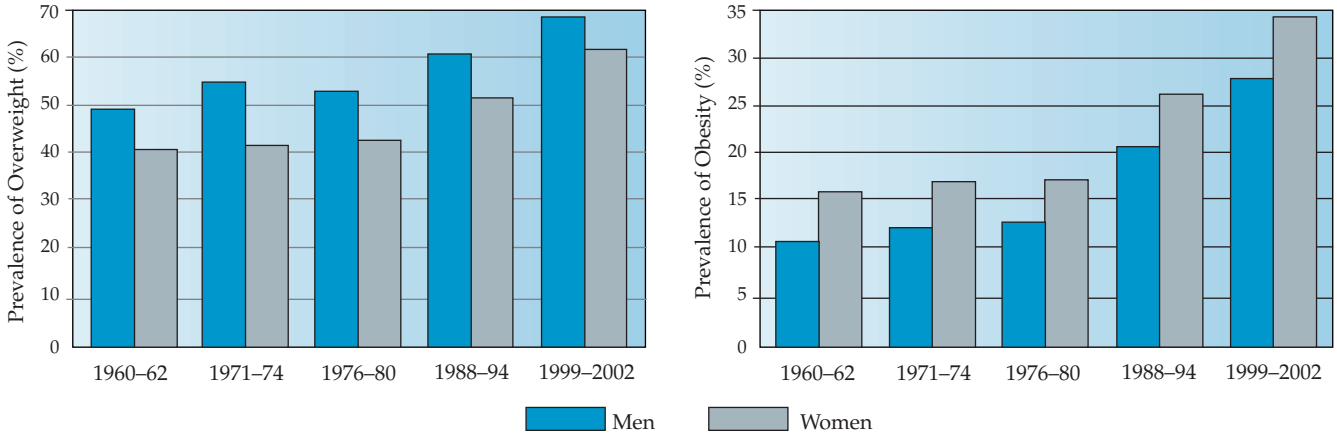

Figure 1 **Time trends of age-adjusted prevalence of overweight (BMI ≥ 25 kg/m^2) and obesity (BMI ≥ 30 kg/m^2) in United States men and women who are 20 years of age and older.[8]**

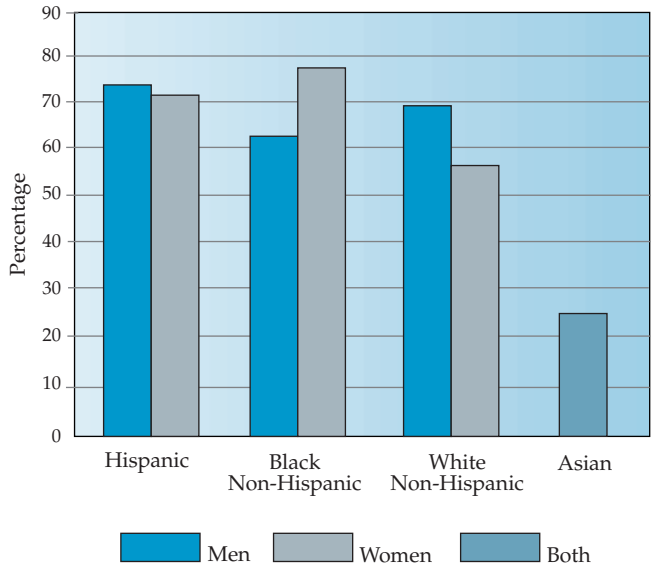

Figure 2 **Age-adjusted percentage of United States adults who were overweight (BMI ≥ 25 kg/m^2), by sex and race/ethnicity, 1999–2002.[8] Data for Asians include both men and women in 2003.[11]**

Pathophysiology and Pathogenesis

Arguably the most significant recent advances in the science of obesity have been in the area of neuroendocrine control of energy homeostasis, including the understanding of the mechanisms that lead to unwanted weight gain and the counterregulatory systems that restore weight lost after caloric restriction. At its most basic level, body weight is the end result of a balance between energy taken in and energy expended. Weight gain ensues when more energy is consumed than expended. Weight loss occurs through restriction of energy intake, increased energy output, or both. However, this simple model fails to incorporate what are now known to be complex homeostatic systems that counteract voluntary energy perturbations, whether they be forced overfeeding or caloric restriction.

A homeostatic model of weight regulation is conceptually identical to other tightly regulated systems in the body. For example, blood glucose levels reflect input from meals and hepatic stores balanced against clearance through uptake by peripheral tissues and excretion by the kidneys. Glucose levels are kept within a normal range by complex, integrated responses from insulin, glucagon, and other so-called counterregulatory hormones such as catecholamines, cortisol, and growth hormone, which regulate production and clearance. Elevated blood glucose levels and diabetes result when the secretion of primary regulators (i.e., insulin and glucagon) is impaired, when resistance to insulin signaling develops, or both.

Like glucose, body weight is regulated at multiple levels to maintain a normal range or set point through an interaction between systems that control meal-to-meal intake (satiety) and those that control relative fat mass (adiposity) [*see Figure 3*].[34] Although short-term (meal-to-meal) signals such as cholecystokinin have been studied for decades, a long-term afferent signal from the fat tissue, leptin, was not discovered until 1994.[35] Leptin is a hormone that is secreted by fat cells in direct proportion to total fat mass, is transported across the blood-brain barrier, and has receptors in hypothalamic nuclei that control appetite and energy expenditure.[34] When leptin levels decline with weight loss from caloric restriction or when they increase with overfeeding, altered signaling in central hypothalamic centers become integrated with other input signals (e.g., insulin and ghrelin) to set in motion systems that restore body weight to baseline. Therefore, most obese patients fail to sustain long-term weight loss with calorie restriction alone because of activation of these counterregulatory systems and their promotion of a positive energy balance. In this feedback-loop model of weight regulation, primary obesity results when leptin signaling to central centers is reduced (leptin resistance),[34] resulting in uncompensated weight gain that eventually reestablishes energy homeostasis at a higher body-weight set point and blood level of leptin, analogous to insulin levels rising in compensation for acquired insulin resistance.

Although this model oversimplifies the complex nature of body-weight regulation, it nonetheless provides a starting point for clinicians in their education of patients about the pathophysiology of obesity and in the rationale for medical management. To achieve sustained weight reduction in overweight and obese patients, interventions must prevent activation of counterregulatory systems that act to restore lost weight by increasing appetite or reducing energy expenditure. Future medical therapies will be based on an understanding of the body's weight regulatory system and will have greater promise for success in maintaining weight loss.

With aging, dysregulation of a number of hypothalamic-pituitary systems may contribute to increased fat mass and sarcopenia. For example, growth hormone secretion diminishes with age.[36] Prospective trials in older adults that involved replacing growth hormone and targeting levels of insulinlike growth factor–1 (IGF-1) to the midnormal to upper-normal range have demonstrated improved body composition (less fat, more lean tissue) and, in some studies, reduced central fat.[36-38] In addition, the decline in testosterone levels in men, the drop in estrogen levels in women at menopause, and increased levels of cortisol in both sexes may also contribute to reduced muscle mass, central fat distribution, or both.[18,39-41]

Diagnosis

The history, physical examination, and laboratory evaluation of overweight and obese patients are directed toward three goals: first, to identify secondary causes of obesity [*see* Differential Diagnosis, *below*]; second, to identify comorbid conditions [*see Figure 4*]; and third, to establish the patient's dietary and activity habits.

HISTORY

A number of the symptoms associated with diseases that can cause or contribute to unwanted weight gain, such as hypothyroidism or Cushing disease, occur frequently in overweight patients. These include fatigue, aches, cold intolerance, constipation, poor exercise tolerance, central obesity, loss of libido, and depression. Deciding when to screen a patient for secondary causes of obesity, therefore, can be a challenge for the practitioner. Establishing a pattern of weight gain may be helpful. A patient with a lifelong history of being heavy and a stable adult weight is unlikely to have a secondary cause of obesity. A sudden or rapid weight gain over a few months or years, however, especially when accompanied by onset of comorbid conditions, may correspond to the prescription of medications that contribute to excess weight gain (especially steroids and newer an-

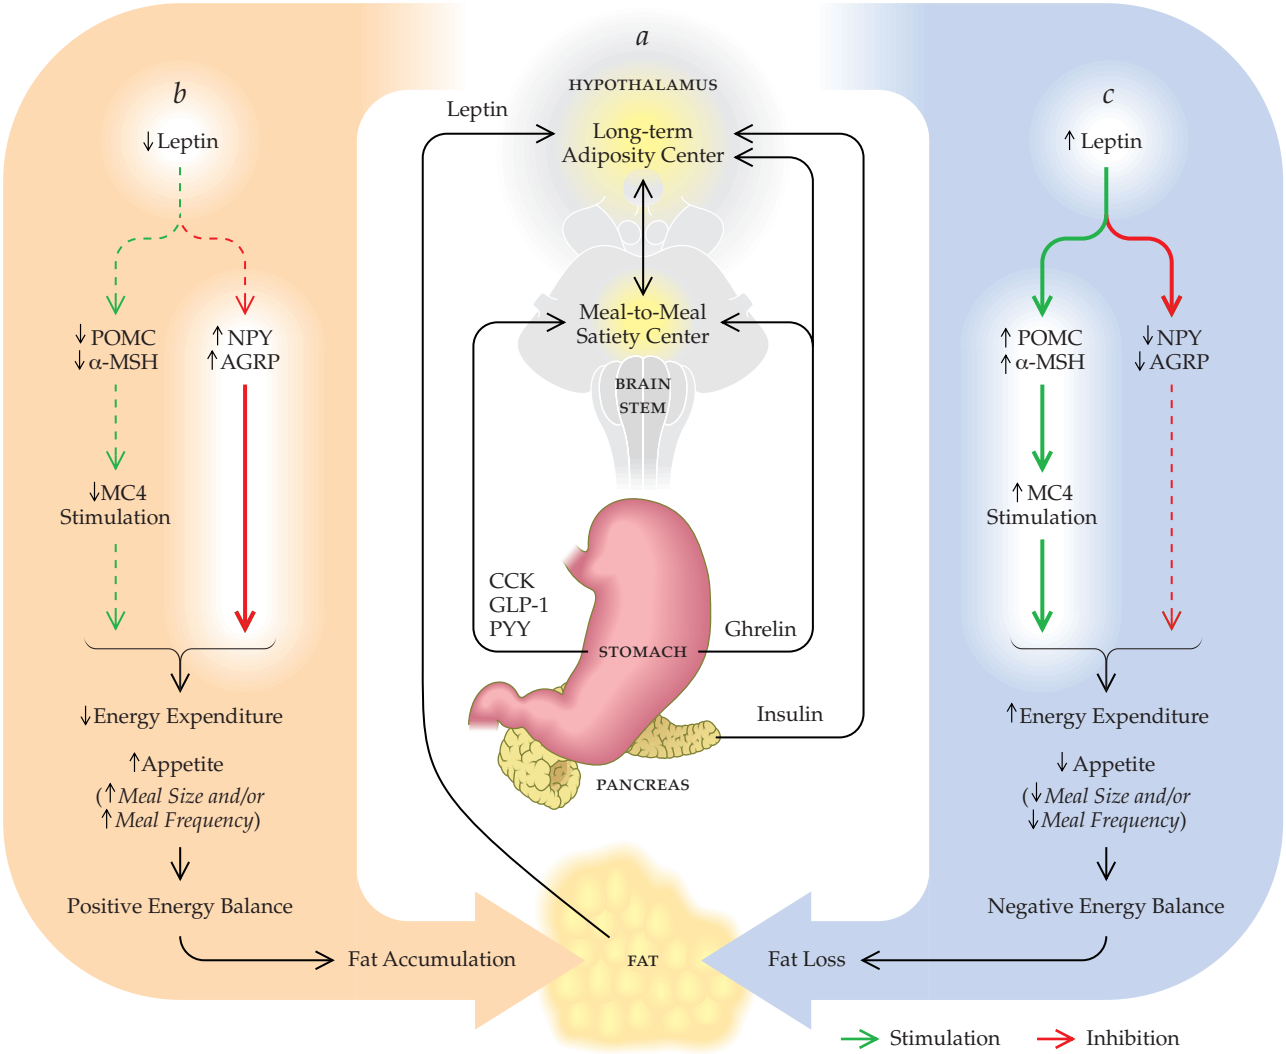

Figure 3 **(*a*) A feedback model for body-weight regulation in humans based on data from animal models.[34] Hypothalamic centers that control long-term energy homeostasis sense fat stores through circulating levels of leptin and insulin. Satiety signals (short-term or meal-to-meal regulators) from the gut are relayed through the brain stem to the hypothalamus, where they are integrated with signals reflecting fat stores. These integrated signals then affect appetite and energy expenditure so as to maintain body weight within a set point range. (*b*) Leptin controls appetite and energy expenditure in the hypothalamus by alternatively stimulating production of pro-opiomelanocortin (POMC) and α-melanocortin (α-MSH) and inhibiting production of neuropeptide-Y (NPY) and agouti-related protein (AGRP). α-MSH binds to the melanocortin-4 receptor (MC4), which inhibits appetite and increases energy expenditure. NPY and AGRP stimulate appetite while decreasing energy expenditure. Reduced leptin secretion, such as that which occurs after voluntary caloric restriction,[59,146] leads to enhanced NPY/AGRP signaling, diminished MC4 signaling, and positive energy balance once caloric restriction ceases.[147,148] On the other hand, overfeeding leads to increased fat mass and leptin secretion,[149] reduced NPY/AGRP signaling, increased MC4 signaling, and negative energy balance[148,150] until body weight is restored to baseline. (CCK—cholecystokinin; GLP-1—glucagonlike peptide–1; PYY—peptide YY)**

tipsychotics) or indicate onset of an illness that requires further evaluation.

The history should include questions about diseases for which overweight and obese patients are at higher risk, including hypertension, impaired glucose tolerance or diabetes, hyperlipidemia, heart disease, pulmonary disease, and sleep apnea. These conditions may cause minimal or no symptoms and therefore may be present for months or years before a diagnosis is made. Sleep apnea in particular is a common cause of fatigue and poor concentration or work performance in obese patients; these symptoms are often mistakenly ascribed to an abnormally functioning thyroid gland (despite normal results on thyroid function tests) or a so-called altered metabolism. This diagnosis may be missed unless the clinician specifically asks about characteristic symptoms: restless sleep at night, snoring or observed apnea, fatigue or headache upon awakening and during the daytime, and spontaneous daytime sleep when inactive or while driving. In severely obese patients, increasing peripheral edema, orthopnea, and worsening exercise tolerance may be symptoms of congestive heart failure or pulmonary hypertension and right-sided heart failure from severe sleep apnea. New-onset headaches may indicate normal-pressure hydrocephalus. Gastroesophageal reflux disease usually results in heartburn or an acid taste in the throat. During a period of weight gain, women may develop ir-

regular periods or symptoms of androgen excess. Although commonly diagnosed as polycystic ovary syndrome (PCOS), these findings differ from classic PCOS in that they occur after menarche and are not usually associated with polycystic ovaries.

Finally, inquiring about past and present dietary and activity habits is important for subsequent discussions of medical and surgical management. Most overweight and obese patients will have made numerous attempts to lose weight, through diets, exercise regimens, or commercial weight-loss programs. Because of unrealistic expectations and the inevitable weight regain that occurs, patients are often discouraged or leery of new advice. These failures can also compound feelings of guilt or inadequacy, fueling cycles of worsening self-image and depression. A broad survey of the types of foods people eat can often be accomplished in an office visit; in particular, asking about intake of calorically dense foods, including sodas, and frequency of meals outside the home may identify habits that can be improved. More detailed dietary analysis requires a visit with a nutritionist. Physical impediments such as arthritis, back pain, and asthma should be identified and treated so as to optimize daily activity and adherence to exercise recommendations.

PHYSICAL EXAMINATION AND LABORATORY TESTS

Height and weight measurements in the office are used to classify patients as overweight or obese according to BMI criteria [*see Table 1*]; however, these criteria may not apply to patients who have gained weight as the result of increased muscle mass from intensive exercise. Evaluation of abdominal obesity requires the use of a tape measure. A waist circumference (obtained at the level of the superior iliac crest) greater than 40 inches (102 cm) in a man or greater than 35 inches (88 cm) in a woman is considered abnormal.

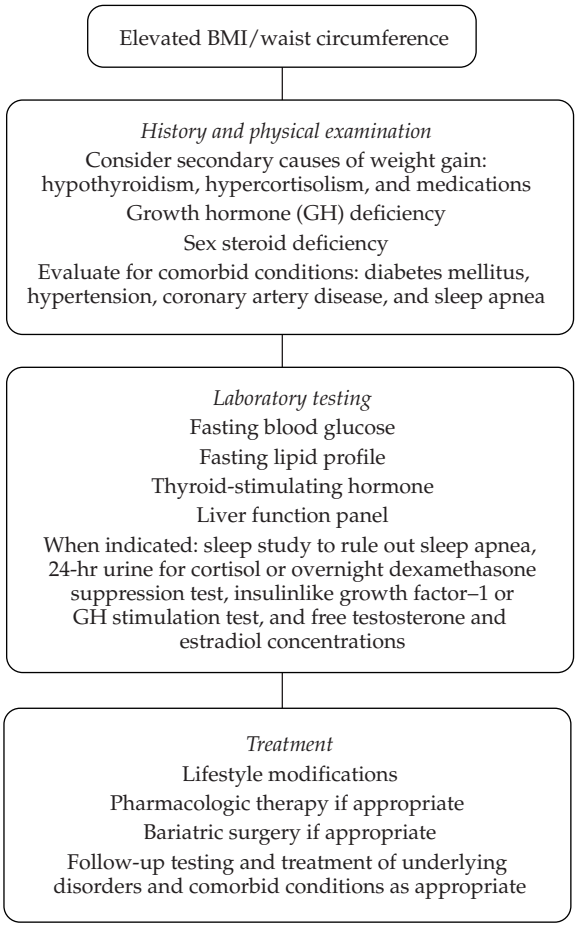

Figure 4 **Evaluation, laboratory testing, and treatment of overweight and obese patients.**

Specific physical findings that might indicate secondary causes of obesity include pretibial edema and delayed tendon reflexes (hypothyroidism), purple striae, supraclavicular fat pad enlargement, and muscle weakness (Cushing syndrome). Other aspects of the clinical evaluation focus on comorbid conditions. Documentation of hypertension requires properly obtained blood pressure measurements (i.e., using the correctly sized cuff for larger persons). Insulin resistance and type 2 diabetes may manifest themselves as acanthosis nigricans—patches of feathery-pigmented skin (hyperkeratotic and hyperpigmented) on the extensor surfaces of the hands and elbows, in the axilla, or on the neck [*see 2:I Cutaneous Manifestations of Systemic Diseases*]. Hepatomegaly can indicate hepatosteatosis, especially in centrally obese subjects.

With or without acanthosis nigricans, impaired glucose tolerance may be diagnosed by a fasting plasma glucose level between 100 and 125 mg/dl or a 2-hour glucose level between 140 and 200 mg/dl during an oral glucose tolerance test. Type 2 diabetes is diagnosed by two fasting blood glucose measurements of 126 mg/dl or greater, a 2-hour glucose level of 200 mg/dl or more during an oral glucose tolerance test, or a random glucose level of 200 mg/dl or greater and symptoms of diabetes.

Screening for macrovascular risk involves obtaining an electrocardiogram when appropriate and carefully examining the patient for xanthomata, which can indicate the presence of elevated blood levels of chylomicrons (eruptive xanthoma), type III hyperlipidemia (palmar xanthoma or tuberoeruptive xanthoma), or familial hypercholesterolemia (tendon xanthoma). Each of these physical manifestations of hyperlipidemia, although rare in a primary care practice, indicates a severe or potentially life-threatening condition that requires urgent diagnosis and treatment. A fasting lipid profile should be obtained to complete the cardiovascular risk assessment, and if necessary, treatment should be instituted according to guidelines from the National Cholesterol Education Program Expert Panel.[42] This panel also incorporated several nonlipid risk factors for cardiovascular disease into its recommendations for clinical care by defining criteria for a condition that has become known as the metabolic syndrome (also called syndrome X, the deadly quartet, and the insulin-resistance syndrome). The metabolic syndrome includes the most common abnormalities of lipid and glucose metabolism that accompany abdominal obesity [*see Table 2*]. Identifying these abnormalities in a patient allows the practitioner to better assign that patient's risk for diabetes and coronary artery disease.[43] Similar criteria are now recognized by the Centers for Disease Control and Prevention (CDC) as the dysmetabolic syndrome X and have been assigned a diagnosis code (277.7) in the International Classification of Diseases, 9th Revision (ICD-9). Screening laboratory tests for hepatosteotosis include a liver panel. In addition, all overweight patients should have documentation of normal thyroid function with a thyroid-stimulating hormone level.

Although obesity is associated with abnormal levels of a number of hormones and cytokines, including leptin, ghrelin, interleukins, and tumor necrosis factor, measurement of these variables should be limited to research protocols and are not currently recommended for general clinical practice.

Table 2 Criteria for Metabolic Syndrome[42,151]

Any Three of the Following:

Increased waist circumference
- Men: > 102 cm (40 in)
- Women: > 88 cm (35 in)

Fasting plasma glucose ≥ 100 mg/dl

Elevated blood pressure
- Systolic ≥ 130 mm Hg
- Diastolic ≥ 85 mm Hg

Serum triglyceride level ≥ 150 mg/dl

Decreased high-density lipoprotein (HDL) cholesterol level
- Men < 40 mg/dl
- Women < 50 mg/dl

Differential Diagnosis

It is important for clinicians to be alert for secondary medical causes of obesity but also to be aware that, in most cases, treatment of these coexisting diseases rarely leads to complete reversal of the obese state. As an example, hypothyroidism is relatively common in the general population and may be present in an obese patient, but the weight loss that might be expected with thyroid hormone replacement is limited and variable.

Hypercortisolemia of Cushing syndrome is a rare cause of unwanted weight gain, but clinicians should have a low threshold for screening for this disease when patients experience large amounts of weight gain in a short period, especially when the weight gain is accompanied by hypertension, diabetes, or muscle weakness. Deficiencies of growth hormone or gonadal steroids are also associated with modest increases in body adiposity. Growth hormone deficiency can lead to reduced muscle mass and increased fat mass, which is improved with hormone replacement therapy.[44] Similar changes in body composition have been described in hypogonadal men[45] and in postmenopausal women.[18] Unfortunately, obesity is often accompanied by low levels of IGF-1 and, in men, low testosterone levels because of low sex-hormone–binding globulin levels. To distinguish obesity-associated low testosterone from a true deficiency state, free testosterone levels can be measured. In addition, weight loss will increase both IGF-1 and total testosterone levels in obese patients but not in patients with true deficiencies.

A number of medications can lead to unwanted weight gain and obesity; if possible, such patients should be switched to alternative agents [*see Table 3*]. Drug-related weight gain occurs most commonly during long-term glucocorticoid treatment of inflammatory conditions (e.g., asthma and inflammatory arthritis), with immunosuppression after transplantation, and with cancer chemotherapy. When possible, reducing or discontinuing a glucocorticoid in favor of an alternative medication can reverse this weight gain. Patients with type 1 or type 2 diabetes often gain weight after starting therapy; this weight gain is proportional to the degree of improved glycemic control and results from a reduction in glucosuria and improvement in metabolic efficiency.[46] Long-term studies have shown that intensive insulin treatment of type 1 diabetes can result in excessive weight gain and obesity in up to 25% of patients; in type 2 diabetes, intensive glycemic control with insulin, a sulfonylurea, or one of the thiazolidinediones may also result in greater weight gain than that predicted by improved glycemic control alone.[47] Therapy with metformin plus nighttime long-acting insulin may reduce or prevent this extra weight gain,[48] and newer diabetes medications, such as pramlintide and exenatide, can improve glycemic control in both type 1 and type 2 diabetes with a modest weight loss.[47] Neuropsychotropic drugs, particularly newer antipsychotic and antiseizure medications, have been associated with weight gain (sometimes massive), obesity, and diabetes.[49,50]

Table 3 Medications Commonly Associated with Weight Gain and Obesity, with Possible Alternative Agents[47,49,152]

Medication Class	*Agents*	*Alternatives*
Steroids	Glucocorticoids	Asthma: inhalers Cancer chemotherapy: non–glucocorticoid-based regimens Rheumatoid arthritis: methotrexate and remitting agents
Antidiabetic drugs	Insulin Sulfonylureas Thiazolidinediones	Metformin, acarbose, pramlintide, exenatide
Antiepileptic drugs	Gabapentin Valproic acid	Lamotrigine Topiramate Zonisamide
Antipsychotic agents	Clozapine Olanzapine Quetiapine Risperidone Sertindole	Aripiprazole Haloperidol Ziprasidone
Antidepressants	Tricyclic antidepressants Monoamine oxidase inhibitors Mirtazapine	Bupropion Nefazodone Selective serotonin reuptake inhibitors Venlafaxine

Treatment

As a first step in the management of obesity, appropriate follow-up testing and treatment should be provided for any secondary causes of obesity and comorbid conditions identified during screening. Then, the approach to the treatment of obesity is similar to that of other chronic conditions, such as hypertension, hypercholesterolemia, and diabetes. Intervention starts with lifestyle measures for 3 to 6 months. For obesity, these lifestyle interventions include improved diet and increased activity. For patients whose weight does not change with lifestyle intervention alone or whose weight loss is insufficient to lower their long-term health risk, consideration is then given to pharmacologic or surgical management. An NIH expert panel has suggested that patients whose BMI is 30 or more or who have a BMI of 27 or more plus obesity-related risk factors (i.e., diabetes, hypertension, or hyperlipidemia) could be considered for pharmacologic therapy.[3] Patients with a BMI of 40 or more or a BMI of 35 or more plus obesity-related risk factors could be considered for surgical therapy.

The weight-loss goal for the treatment of obesity is sustained weight loss of 5% or more of initial body weight. Although this goal does not result in attainment of a normal body weight (BMI of 19 to 25) in the majority of patients, it still represents a weight loss that can be achieved with available intervention modalities and that has been associated with lower morbidity, including reductions in risk for diabetes and heart disease.[51,52]

For some patients who are experiencing a period of weight gain, weight stability may be their primary goal. This is especially common in patients who have just completed a low-calorie weight-loss program and are struggling to remain below their initial weight.

NONMEDICAL (LIFESTYLE) THERAPY

Diet Modification

Caloric restriction Hypocaloric diets have been a mainstay recommendation by the medical community for obese patients. These diets range from a moderate reduction in daily intake (200 to 500 fewer calories a day) to more stringent, very low calorie diets (600 to 800 total calories a day), which require careful follow-up by a nutritionist and a physician to avoid life-threatening electrolyte disorders and symptomatic cholelithiasis. Although it is possible to achieve short-term weight loss with these strategies, long-term weight loss is poor even when behavior-modification weight-maintenance programs are continued. Analyses of published data on long-term weight-loss maintenance showed that approximately 50% of the initial lost body weight is regained within the first 1 to 2 years, and 95% or more is regained by 5 years after the completion of the calorie-restriction phase.[53,54] This restoration of lost body weight after a period of calorie-restriction–induced weight loss can be explained by the reduction of fat-dependent feedback signals to the brain, such as leptin, which then activate counterregulatory systems to restore body weight to baseline [*see* Pathophysiology and Pathogenesis, *above*].

The long-term failure to maintain weight loss after caloric restriction also indicates that the central set point for body weight is not reset at a lower body weight with the passage of time. Another important implication of these data is that obesity treatments lacking mechanisms that interfere with this counterregulatory system will likely fail to allow long-term weight-loss maintenance. Some existing therapies do result in limited weight loss without activation of appetite (see below) and can be combined with caloric restriction for improved long-term weight-loss maintenance; these include a low-fat diet,[55,56] exercise,[56] and pharmacologic treatments.[57,58]

Dietary-fat restriction An increase in dietary-fat intake leads to obesity in animal studies and has been associated with a higher prevalence of overweight and obesity in many human-population studies.[25] Prospectively randomizing overweight and obese persons to ad libitum feeding (eating until one feels full, then stopping) of a fat-restricted diet results in a spontaneous reduction in caloric intake and subsequent modest weight loss, compared with results in persons on a diet that contains a higher amount of fat typical of Western societies.[59] This calorie reduction occurs despite a concomitant fall in leptin levels, in contrast to the increase in appetite that follows a fall in leptin levels with weight loss from caloric restriction.[59-61] By implication, an increase in dietary fat results in a state of central leptin resistance, requiring a higher level of body fat and leptin levels to attain a new body-weight equilibrium,[62] whereas dietary-fat restriction leads to partial improvement in leptin signaling, resulting in spontaneous reduction in appetite and body weight.

The average amount of weight loss attributable to a low-fat diet in these studies, however, is only on the order of 3 to 4 kg (6.6 to 8.8 lb).[59] In addition, the weight-loss responses of persons to a low-fat diet can vary tremendously, with some individuals losing 13 kg (28.7 lb) or more and others losing no weight or even gaining weight.[63] This variable response to a lifestyle intervention, such as a change in a specific diet component, is common in chronic diseases whose expression results from an interaction between a genetic predisposition and environmental influence. In patients with hypertension, for example, blood pressure reductions in response to restriction of dietary salt are also heterogeneous.

An apparent paradox has been reported in that the average percent fat content of the American diet is dropping, yet the weight of the American population keeps increasing. Although it is true that the average percentage of total calories from fat in the American diet has declined over the past several decades (from 36% to 34%, according to the most recent NHANES data),[64] this did not occur because Americans have been eating less fat (daily dietary fat intake was 81.9 g in 1972 and increased to 85.5 g in 1990) but, rather, because total calories increased, leading to a lower fat percentage.[65] In contrast, studies that documented weight loss with a lower fat intake did so by lowering the absolute amount of fat in the diet. It is worth noting that the levels of fat restriction leading to weight loss in these studies were not severe. Severe fat restriction (< 20% of total calories) may not be sustainable for many patients because of limited food options and palatability.

Dietary-carbohydrate changes Increasing dietary-carbohydrate intake while lowering total fat intake results in modest spontaneous reduction in caloric intake and weight loss in overweight and obese persons. In the studies that documented this effect, the additional carbohydrates were derived from fruits, vegetables, and grain products, and the resulting increase in dietary fiber also may have played a role in greater satiety and weight loss. In society (especially in young people), however, dietary carbohydrates have increasingly been consumed in the form of processed foods sweetened with sucrose or fructose. These simple carbohydrates (especially fructose) may potential-

ly have deleterious effects on insulin resistance, lipid levels, and body weight when consumed in large amounts.[29,66]

Paradoxically, severe carbohydrate restriction (< 30 g/day) may also lead to modest spontaneous weight loss without initial activation of appetite. Such severe carbohydrate restriction initially mobilizes glycogen stores in the liver and induces ketogenesis, and the resulting diuresis accounts for some of this weight loss.[67] At one time, the ability to draw meaningful conclusions about the longer-term safety and efficacy of low-carbohydrate diets was impeded by the paucity of controlled studies and the variability of carbohydrate restriction from study to study (from < 20 to ≥ 200 g/day).[68] Although methodological issues remain, randomized, controlled studies have now shown that during the first 6 months of diet treatment, persons placed on a low-carbohydrate diet lose weight more rapidly than those placed on a low-calorie, low-fat diet.[69-71] Subsequently, however, individuals on the low-carbohydrate diet either stop losing weight or regain weight, and by 1 year, weight loss is the same with the two diets.[70-72] The average 1-year weight loss ranged from 2.5 to 5.1 kg in these studies, and both diets had a high dropout rate, of approximately 30% to 40%.[70-72] Contrary to popular beliefs about the potential adverse effects of consuming diets high in fat or carbohydrates, lipid levels and glucose metabolism improved with both diets in proportion to weight loss.[69-73]

Dietary-protein changes Increasing dietary-protein intake has also been associated with weight loss. In one of the few prospective, randomized studies of an ad libitum high-protein diet (fat restricted), obese patients experienced significantly greater weight loss than obese control subjects who followed a regular diet or a low-fat, high-carbohydrate diet over a period of 6 months.[74] After 12 months, however, total weight loss on the high-protein diet was attenuated and no longer differed from that seen with the high-carbohydrate diet.[74]

Most nutrition societies recommend limiting protein intake to approximately 10% to 15 % of daily calories because of concerns regarding long-term health consequences of high intake of protein (especially animal protein). These concerns include the possible association of increased protein intake with intestinal cancers, bone disease, and renal disease. To date, prospective studies have shown that increasing dietary protein increases the glomerular filtration rate,[75] which may be harmful to patients with existing renal disease or diabetes, but the long-term effect of increased glomerular filtration rate in otherwise healthy persons is not known.

Dietary fiber Increased dietary fiber has been shown to improve body weight and cardiovascular risk factors .[76,77] Typical high-fiber foods include fruits, vegetables, oat and wheat bran, and legumes, which are also low in fat. Even after controlling for low-fat content, however, diets higher in fiber result in reduced intake and a weight loss of approximately 2 kg.[76] Although it is possible to increase fiber through the use of supplements such as psyllium or methylcellulose, the current intake of fiber in the United States of about 15 g/day could be increased to 25 to 30 g/day by avoiding calorically dense, refined-sugar foods and increasing consumption of fruits, vegetables, and whole-grain products.

Summary of dietary recommendations Overall, an initial recommendation to lower dietary-fat intake and increase dietary-fiber intake for weight loss is reasonable and supported by the scientific literature. Long-term studies of greater than 1 year have not been conducted to show that this weight loss is sustained. Nevertheless, animal models of obesity, population studies, and prospective studies of 1 year or less of low-fat, high-fiber diets versus high-fat diets have documented that a high-fat diet is detrimental to body weight and that restriction of dietary fat to 25% to 30% of calories and an increase of 10 to 15 g of fiber a day result in a significant, albeit limited, weight loss for the average patient.

It is important that clinicians discourage unrealistic expectations about weight loss from a low-fat, high-fiber diet so that patients do not become disillusioned with this therapy. Also, patients should be informed that low-fat, high-fiber diets have been shown to reduce numerous health risks, especially when instituted as part of an overall lifestyle change that includes exercise.[50,78] For this dietary advice to be effective, however, it is often necessary to refer patients to a nutritionist for evaluation and follow-up.

A low-fat diet can be achieved by substituting either carbohydrate or protein for fat; this allows tailoring of the diet to the individual patient. Some patients may respond better to a high-carbohydrate diet in terms of food preferences and weight loss, whereas others might have better responses to a high-protein diet, although all these diet variations have shown only moderate weight loss.[72] A low-carbohydrate diet cannot currently be recommended for clinical practice, because it has not been shown to be superior to other diets[70,72]; the long-term health outcomes of sustained ketosis are uncertain; and increased intake of saturated fat and *trans*-fatty acids may negate the benefit of weight loss by increasing serum cholesterol and triglyceride levels in some patients.[72,73] Many questions concerning the effects of a higher protein intake (up to 30% of total calories) on patients' renal function remain unanswered. For this reason, high-protein diets should be avoided in patients with existing renal disease and diabetes.

Exercise

Increasing energy expenditure through exercise has been another mainstay of obesity therapy. Without counterregulation (alteration in appetite or non–exercise-based energy expenditure), an increase in activity should lead to continued and sustained weight loss. Prospective intervention studies have shown, however, that the average amount of weight loss attributable to exercise alone (no caloric restriction in addition to the exercise) is small, ranging from 1 to 4 kg (2.2 to 8.8 lb).[79,80] Further weight loss presumably is limited by alterations in nonexercise energy expenditure that compensate for the increase in exercise-induced energy expenditure; increased appetite can be discounted as the source of counterregulation, because most studies show little change in energy intake.[81]

Current recommendations are to participate in 3 to 5 hours of moderate to vigorous activity per week. For many patients, especially those with limited mobility, simply increasing activity may be an initial goal. As with alterations in the macronutrient content of the diet, exercise leads to variable degrees of weight loss, ranging from little or none to a substantial amount. Even with moderate weight loss, which is typical, patients should be encouraged to continue with increased activity because of the numerous health benefits attributable to being fit.[82,83]

Combined Diet and Exercise

A number of studies have prospectively examined the effect of combined diet and exercise interventions on health outcomes.

Sustained weight loss with caloric restriction can be improved with a low-fat diet[84,85] or regular exercise.[79,86] In a national survey seeking to determine the characteristics of persons who have been able to sustain a weight loss of at least 13.6 kg (30 lb) for 1 year, responders reported that on average, they followed a diet consisting of approximately 24% fat[87] and expended an average of 2,827 kcal/wk in exercise (roughly the equivalent of walking 28 miles/wk).[88] This level of activity is nearly three times more than the 1,000 kcal/wk recommended by the American College of Sports Medicine for the minimum weekly exercise for the purposes of reducing body weight.[88] Prospective studies of dietary-fat restriction and exercise have also demonstrated reduced progression, or even reversal, of heart disease in patients with known cardiovascular disease[78] and up to a 58% reduction in the incidence of type 2 diabetes in overweight patients with impaired glucose tolerance.[50]

Because of the overall health benefits, the initial treatment of overweight and obese patients should include increased activity in addition to dietary-fat restriction and increased dietary fiber. If caloric restriction is recommended, the likelihood of long-term weight-loss maintenance may be improved by the addition of these interventions. Dietary and activity advice should be implemented using individualized, sustainable behavioral and lifestyle changes. Again, it is important for both clinicians and patients not to have unreasonable expectations for weight loss from diet and exercise. For some patients, the best that may be achieved through lifestyle improvements is prevention of further weight gain. Patients who fail to meet unreasonable goals may become frustrated and return to a less healthy lifestyle. Even when little or no weight loss ensues, these lifestyle changes offer many health benefits, including improved lipid levels, increased insulin sensitivity, and reduced risk for progression of cardiovascular disease and for onset of type 2 diabetes.[89] After institution of lifestyle measures, if a patient's body weight remains above the guideline cutoff points, medical and surgical treatment options remain.[90]

Prevention

Once patients have become overweight or obese, lifestyle interventions play an important role in reducing comorbidities, but they typically have modest effects on body weight (see above). These patients will then require lifelong medical or surgical management to achieve more meaningful weight loss (see below). This failure of the body-weight set point to remain at a lower level in the average patient greatly increases the importance of prevention of unwanted weight gain. Prevention requires targeted improvements in food choices for pregnant mothers and children and, more importantly, a reversal of the societal trend toward reduced activity levels.

The hurdles for implementing these simple recommendations are, however, considerable. Increasing intake of healthy foods includes not only overcoming personal and cultural preferences for higher-fat foods but also consideration of the economic costs of food at home and at schools (calorically dense foods are often cheaper than fruits and vegetables) and the impact of family and work demands on ability to eat at home or purchase prepared foods.[91] Increasing activity does not necessarily require going to a gym on a regular basis. Rather, it includes maintaining physical activity in routine daily events, such as physical education in schools, designing work spaces and buildings to promote walking and stair use, planning urban environments to promote more pedestrian activity (e.g., safer streets, more sidewalks, increased density of commercial and residential properties), and overcoming a cultural reliance on automobiles for routine travel.[92] Even with immediate institution of lifestyle improvements, though, it is likely that reversing the current decades-long trend in weight gain will take several generations.

PHARMACOLOGIC THERAPY

The Food and Drug Administration has approved several prescription medications for the treatment of obesity [*see Table 4*].[90] These medications fall into two categories: centrally acting drugs, which suppress appetite, and peripherally acting drugs, which reduce fat absorption. For example, phentermine and sibutramine act centrally, reducing appetite by promoting the release of norepinephrine from presynaptic terminals (phentermine) and inhibiting the uptake of both norepinephrine and serotonin (sibutramine) in central nuclei. Orlistat acts peripherally, inhibiting the action of lipases in the brush border of the intestine and thereby reducing lipid absorption.

Clinicians who treat obese patients with medical therapy should keep in mind four important principles. First, most studies have included an initial treatment phase in which patients are placed on a hypocaloric diet (usually, daily caloric intake is reduced by 500 to 1,000 kcal) at the time of randomization or just before drug treatment. Second, the weight loss with obesity agents varies considerably: some patients lose a dramatic amount of weight; others lose only a little weight; and still others lose some weight only to regain it despite continuation of the medication. In any case, average weight loss with currently approved medications does not usually exceed 10% of the baseline weight. Third, weight loss is greatest during the first 3 to 6 months, followed by a plateau at a new lower weight even with continuation of the therapy. Intermittent therapy (i.e., 3 months on therapy followed by 3 months off, 3 months on, etc.) does not increase weight loss[93,94] and has been associated with increased side effects (e.g., dry mouth).[93] Finally, every drug-treatment study that has included posttreatment follow-up has shown rapid weight regain toward baseline after discontinuance of the medication. The plateauing of weight after initial weight loss and the regaining of weight after medication discontinuance have been interpreted to indicate that the medication became ineffective with time or failed because weight loss was neither sufficient nor sustained after cessation of the treatment. However, pharmacologic therapy for obesity is no different from therapy for other common chronic diseases. For instance, patients with hypertension often have a variable response to a first-line agent. In some cases, blood pressure lowering may be insufficient and may require the addition of a second medication, and hypertension returns when the medication is discontinued. Once a person begins receiving medical therapy for obesity, continued efficacy is evidenced by sustained weight-loss maintenance. Treatment should therefore be continued indefinitely unless the weight is regained or significant side effects develop.

Agents Approved for Short-Term Use

Benzphetamine, phendimetrazine, diethylpropion, mazindol, and phentermine are approved by the FDA for the short-term treatment of obesity (weeks). All but phentermine are rarely, if ever, used in clinical practice today. Benzphetamine and phendimetrazine are both Drug Enforcement Administration (DEA) schedule III drugs, with higher abuse potential than the others. Diethylpropion and mazindol have indications and side effects identical to those of phentermine (all are DEA schedule IV), but

Table 4 Pharmacologic Agents Approved by the Food and Drug Administration for the Treatment of Obesity

Duration of Treatment	*Drug (Trade Name)*	*Dose*	*Average Weight Loss*	*Comments*
Short term	Phentermine	30 mg resin; 15 or 37.5 mg tablets	8.7 kg	—
Long term*	Orlistat (Xenical)	250 mg with each meal (two or three times a day)	7–13 kg	Patients must already be on a low-fat diet (< 30% of total calories from fat); supplemental multivitamins are needed to prevent reduction in fat-soluble vitamins
	Sibutramine (Meridia)	5 mg 10 mg 15 mg	3.7 kg 5.7 kg 7.0 kg	On average, blood pressure and pulse rise slightly with treatment; contraindicated in patients with untreated hypertension and coronary artery disease

*Data are for treatment duration of 6 mo to 1 yr when combined with a low-calorie diet.

they are less well studied and have not had the same acceptance in clinical practice as phentermine; consequently, diethylpropion and mazindol are not extensively discussed in this chapter.

Phentermine Phentermine inhibits appetite and causes an average weight loss of 8.7 kg (19.2 lb) (net weight loss of 5.1 kg [11.2 lb] when compared with placebo).[95] The agent is available as a 30 mg resin and in 15 mg and 37.5 mg tablets. Doses in excess of 37.5 mg are not recommended because of unacceptable side effects.

Little information is available about subsequent improvement in health outcomes with phentermine treatment alone, because studies of this drug have historically been short term, and the drug was frequently used in combination with fenfluramine. A group of postmenopausal women treated with phentermine and a low-calorie diet experienced a 14% weight loss, along with reduction in low-density lipoprotein (LDL) cholesterol and triglyceride levels and an increase in high-density lipoprotein (HDL) cholesterol levels over 9 months.[96] In patients with diabetes, despite a net loss of 3.8 kg (8.4 lb) compared with placebo over 6 months, use of phentermine produced no improvement in glycemic control or glycosuria and no significant reduction in hypoglycemic drug use.[97]

As a result of central nervous system activation by phentermine, patients may experience anxiousness, insomnia, palpitations, and dry mouth. In case reports, phentermine treatment has been associated with vasospasm, psychosis, and ischemic events,[98-100] although in a larger cohort study, phentermine was not associated with stroke.[101]

Agents Approved for Long-Term Use

Sibutramine The FDA approved sibutramine for the medical treatment of obesity in 1997. The recommended duration for therapy was 1 year, but treatment may be continued beyond that time if no significant side effects occur and sustained weight loss is documented.

The average weight loss on the highest currently approved dose, 15 mg, is 7.0 kg (15.4 lb) (net weight loss of 5.7 kg [12.6 lb] when compared with placebo).[102] In a 2-year study of sibutramine therapy, a weight loss of 10.2 kg (22.5 lb) (net weight loss of 5.5 kg [12.1 lb] when compared with placebo) persisted for up to 18 months, at which time a slight upward trend became evident.[57] With placebo, in contrast, patients began to regain weight immediately after completion of the hypocaloric phase, which was at 6 months. After 2 years, significantly greater proportions of patients taking sibutramine, compared with control subjects, had maintained 5% and 10% weight loss. These results may have limited applicability, however, because only persons who completed the initial 6-month weight-loss phase and lost at least 5% of their initial body weight by caloric restriction were subsequently randomized to placebo or continued sibutramine therapy. This represents a 23% dropout rate before randomization to drug therapy. In addition, approximately 30% of the patients treated with sibutramine and 50% of the patients given placebo withdrew from the study. A higher pretreatment body weight[103] and weight loss of at least 1.8 kg (4 lb) during the first month of therapy[102] have been shown to predict continued weight-loss response with longer treatment.

Sibutramine treatment is also associated with improvements in lipid levels, including lower triglyceride levels and higher HDL levels.[57,94,104] Sibutramine has been safely used in patients with type 2 diabetes, with improvements in lipid levels being similar to those reported in nondiabetic patients.[105] Glycemic control also improves in diabetic patients on sibutramine therapy, with the greatest reductions in hemoglobin A_{1c} occurring in those patients who lose more than 10% of their initial body weight.[105] Common side effects of sibutramine treatment include dry mouth, constipation, insomnia, palpitations, and headache. Sibutramine consistently raises average blood pressures slightly and pulse rate more so, even with weight loss.[57,102] In populations not selected for hypertension, studies have documented increases in average diastolic pressure of 0 to 3.4 mm Hg, increases in systolic blood pressure of 0 to 2.7 mm Hg, and increases of average pulse rate of 4.1 to 6 beats/min.[57,94,102] Similar results with sibutramine have been shown for hypertensive patients receiving a variety of antihypertensive medications.[106,107] Therefore, sibutramine treatment can be used if blood pressure is controlled, but blood pressure and pulse rate should be monitored routinely.[108] However, because of the potential for added cardiovascular demand, sibutramine should not be used in patients with a diagnosis of cardiovascular disease, heart failure, arrhythmia, or stroke. To date, sibutramine has not been associated with either valvular disease or pulmonary hypertension.

Orlistat Orlistat inhibits lipases in the gastrointestinal lumen, thereby antagonizing triglyceride hydrolysis and reducing fat absorption by roughly 30%. Because orlistat is not absorbed to any significant extent, its primary mechanism of action is thought to

be through providing what is in effect a low-fat diet, thereby promoting lower caloric intake and weight loss [*see* Dietary-Fat Restriction, *above*], as well as improved weight-loss maintenance, when combined with a low-calorie diet.[109] As with sibutramine, orlistat treatment should be continued as long as the patient maintains weight loss and avoids significant side effects.

To minimize side effects related to fat malabsorption, candidates for orlistat treatment are first placed on a diet containing only 30% of calories from fat. When combined with a calorie-restricted diet, orlistat treatment (120 mg with each meal) results in an average weight loss of 7.2 to 13 kg (16 to 28.7 lb) (net weight loss of 1.3 to 5.6 kg [2.9 to 12.3 lb] when compared with placebo). After 1 year, patients taking orlistat maintain greater weight loss than those taking placebo [*see Table 4*].[58,110,111] During continued follow-up for another year, regaining of weight is seen but remains less than that in patients given placebo.[57,110,111]

Patients who lose weight with orlistat also experience a significant reduction in levels of total and LDL cholesterol (approximately 4% to 8%, which is significantly lower than reductions in patients given placebo).[110,111] Levels of triglycerides and HDL cholesterol are either reduced or left unchanged; these results are not different from those in the placebo group. Blood pressure and insulin levels also decrease with weight loss in patients on orlistat therapy.[58,110,111] Similar improvements in lipid levels, along with improvements in glycemic control, have been documented in obese persons with type 2 diabetes who lose weight with orlistat.[112]

Gastrointestinal side effects may occur in up to 80% of patients when they begin therapy with orlistat (such side effects are also seen in 50% to 60% of patients given placebo), but this incidence diminishes with time. Symptoms include abdominal discomfort, flatus, fecal urgency, oily spotting, and fecal incontinence. When administered to patients who adhere to a low-fat diet, orlistat is generally well tolerated. The fat malabsorption that accompanies orlistat treatment can also lead to reductions in fat-soluble vitamins, but in prospective studies, the average levels for vitamins A, D, E, and β-carotene remained in the normal range.[58,110,113] In one study, only 2.4% of orlistat-treated patients had documented below-normal levels of β-carotene; only 3.1%, below-normal levels of vitamin D; and only 1.6%, below-normal levels of vitamin E.[110] Nevertheless, orlistat should not be given to patients with existing malabsorptive states, and it is recommended that patients take a daily multivitamin supplement during therapy.

Non–FDA-Approved Medical Therapy for Obesity

Observational data from studies of patients with depression suggested that treatment with selective serotonin reuptake inhibitors (SSRIs) may result in weight loss, but this effect is slight and short-lived. Moreover, in prospective studies, SSRI treatment is sometimes associated with mild weight gain.[49] Bupropion is currently approved as an antidepressant and for smoking cessation. The mechanism of action of bupropion is not precisely known, but it includes weak inhibition of norepinephrine and dopamine reuptake. Combining bupropion (300 to 400 mg/day) with moderate daily caloric restriction has been shown to result in greater weight loss than placebo (net weight loss of 3 to 4 kg [6.6 to 8.8 lb], on average) after 6 months in obese patients with no symptoms or mild symptoms of depression.[114-116] Bupropion is contraindicated in patients with seizures, anorexia nervosa, and bulimia.

Deficiencies of growth hormone and sex steroids have been associated with higher body-fat content and greater central obesity. Replacing growth hormone reduces fat mass, increases lean mass, and reduces central obesity. Similar improvements in body composition have been reported with testosterone replacement in hypogonadal men. Although obese persons have documented abnormalities in the hypothalamic-pituitary-gonadal and somatotropic axes, treatment of overweight or centrally obese persons with growth hormone, sex steroids, or both has not been shown to produce clear improvements in body composition, fat distribution, or comorbid conditions.

Surgical Therapy

With improved safety from technical advances and demonstrated efficacy, bariatric (obesity) operations clearly have a role in the current management of severely obese patients.[90] The mechanisms whereby these operations result in sustained weight loss are poorly understood, but they likely include alterations in the gut-derived hormonal and neural inputs to the central nervous system.[117] In general, these procedures can be classified into one of three types: restriction of food passage, malabsorption of nutrients, or a combination of the two [*see Table 5*]. As an example of a purely restrictive procedure, vertical-banded gastroplasty involves the formation of a small stoma for the passage of food. The rationale behind this procedure is to increase a sense of fullness and reduce food intake. Procedures resulting in malabsorption typically involve bypassing sections of small or large intestine. Early procedures in which large sections, or even the entire length, of the small intestine were bypassed often resulted in severe malabsorption and sometimes hepatic failure and death. Subsequent modifications have led to bypass of shorter sections and lower morbidity. Patients must understand that bypass surgery is anatomically irreversible in most cases and has a potentially high postoperative complication rate.

Several large-scale studies have demonstrated the efficacy of various bariatric procedures in severely obese patients. One study of gastric bypass reported sustained loss of approximately 50% of baseline body weight (at 5- to 10-year follow-up).[118] In the ongoing Swedish Obesity Subjects (SOS) Intervention Study of 1,157 severely obese persons (average BMI of 42 kg/m^2), weight loss in the first postoperative year ranged from 21% after gastric banding to 38% after gastric bypass.[119] Some weight regain was found on 10-year follow-up, but the gastric banding patients remained 13% below and the gastric bypass patients 25% below their initial body weight.[119]

A more recent technique known as laparoscopic gastric banding, in which a restrictive band is placed around the upper stomach, has also shown efficacy in sustained weight loss in studies up to 4 years. The weight loss with laparoscopic gastric banding is generally felt to be similar to that with vertical-banded gastroplasty but not as great as that with gastric bypass.[120]

An important benefit of bariatric surgery is that the large weight losses bring improvements in the comorbid conditions that accompany obesity,[121,122] including lowering of lipid levels and blood pressure and reduced rates of diabetes, progression to diabetes, and sleep apnea.[119,122] Moreover, cohort and population-based studies have demonstrated that weight loss after bariatric surgery is associated with both reduced mortality and reduced use of health care resources.[123]

Complication rates for bariatric surgery will vary by surgeon, site, and technique. The most common operative-related complications, occurring in up to 30% of patients, are wound infections, atelectasis or pneumonia, and hernia.[118,124-127] Serious but rare complications include anastomotic stenosis or leakage, throm-

Table 5 Most Commonly Used Bariatric Procedures[118,153,154]

Type of Surgery	*Procedure*	*Average Weight Loss*	*Medical Complications*	*Management*
Restrictive	Vertical-banded gastroplasty	~17% (5 yr)	Nausea, vomiting Gastric distention	Reversal of procedure if complications unacceptable
	Laparoscopic adjustable gastric banding	17%–21% (3 yr)	Nausea, vomiting Slippage Erosion and leakage	Adjustment of band to minimize nausea; reversal of procedure if necessary
Malabsorptive	Biliopancreatic diversion	~27% (5 yr)	Diarrhea, fatty stools Protein-calorie malnutrition Anemia (low iron) Deficiency of vitamin D (and other fat-soluble vitamins) Hypocalcemia Hyperparathyroidism Metabolic bone disease Vitamin B_{12} deficiency, Wernicke encephalopathy (rare)	Monitoring of levels and replacement of nutritional deficiencies; patients often require high oral or parenteral doses
Combination	Gastric bypass	~27% (5 yr)	Dumping syndrome Reductions in levels of iron, vitamin B_{12}, folate, calcium, vitamin D Nesidioblastosis (rare)	Small, frequent meals; monitoring of nutrient levels and oral supplementation with iron tablets (325 mg), vitamin B_{12} (500 μg), folate (1 mg), calcium (500–1,000 mg), and vitamin D

boembolism, and bowel obstruction. Perioperative death rates have ranged from 0.2% to 1.3%.[118,125-127] The laparoscopic techniques offer greater safety than open procedures without sacrificing efficacy.[128,129] Nesidioblastosis has been described in a small series of obese patients after gastric bypass operations.[130] These patients experienced serious or life-threatening postprandial hypoglycemic episodes. A number of questions remain, however, regarding the frequency of this finding, the validity of the link between the gastric bypass and beta cell hypertrophy, and how to best do a workup of patients who may have this condition. Nevertheless, clinicians should include nesidioblastosis in the differential diagnosis of gastric bypass patients who complain of symptoms that have heretofore been ascribed to the so-called dumping syndrome (i.e., rapid transit of food into the small intestine associated with rapid increases in blood volume to the gut and insulin secretion): weakness, dizziness, palpitations, and near-syncope.

Because of the potential for rapid weight loss after bariatric surgery, follow-up by a nutritionist and physician is important to ensure that patients preserve lean mass and maintain hydration and to monitor for symptomatic cholelithiasis. Lifelong alteration of dietary habits may be required to ensure the continued success of the surgery, and dietary supplements may be needed to prevent nutritional deficiencies [*see Table 5*].

Surgical therapy for obesity results in significant, sustained weight loss in a majority of patients with severe obesity.[121,122] With regard to total weight loss and improved disease outcomes, the gastric bypass procedure has the greatest support from published studies,[121,122] whereas the gastric banding procedure has the lowest published rates of morbidity (11%) and mortality (0.05%).[120] With the considerable improvements in comorbidity and quality of life that result from this weight loss, bariatric surgery is not only efficacious but also cost-effective in the management of severe obesity.[122,123,131]

Complications of Obesity

Persons who are overweight or obese and have central adiposity are at increased risk for hyperlipidemia, hypertension, and cardiovascular disease mortality.[6,132-135] In addition, obesity and central adiposity are both strong risk factors for the development of type 2 diabetes.[11,136] Other diseases with a higher incidence in obese persons include gallstones, high uric acid levels and gout, hepatic steatosis, osteoarthritis, obesity hypoventilation, atrial fibrillation, nephrolithiasis, and certain cancers.[137,138] Sleep apnea is likely underdiagnosed in overweight and obese patients[139] and should be strongly considered in patients with complaints of fatigue, daytime somnolence, snoring, restless sleep, and morning headaches. People who are overweight and obese also carry a significant psychosocial burden. Obesity is accompanied by lower self-esteem in children[140] and prospectively predicts depression in adults.[141] Young adults who were overweight as adolescents are less likely to marry, will complete less schooling, and have lower incomes than nonoverweight peers.[142] The economic costs of the treatment of obesity and its comorbidities are high: estimates from 1995 United States data put the costs at $99.2 billion, and of this, $52 billion, or 5.7% of the United States national health expenditure, went to pay direct medical costs.[143]

Prognosis

Mortality increases when men and women become overweight or obese, in large part because of comorbid conditions (see above). This impact of obesity on mortality is greatest in younger age groups and diminishes with age[144,145] and may be significantly influenced by the patient's fitness status. Prospective observational studies suggest that mortality and risk associated with coronary artery disease are highest in the least fit and lowest in the most fit, independent of body weight.[82,83] Evidence of lower mortality after specific lifestyle, medical, or surgical in-

terventions for obesity is currently lacking. Instead, decreased severity of a number of diseases and cardiovascular risk factors associated with increased mortality have been demonstrated after even modest weight loss.[89] Insulin resistance, hyperlipidemia, hypertension, sleep apnea, diabetes, and cardiovascular disease have all been shown to improve with weight loss that follows intensive lifestyle interventions (e.g., low-fat, high-fiber diet and exercise) and medical therapy.[51,52,58,78,89,104,105] With the greater weight loss that accompanies bariatric surgery, resolution of diseases such as diabetes and sleep apnea[119,123] and increased survival[124] have been reported. Optimal therapy for obesity, however, remains elusive. Simple caloric restriction alone results in short-term weight loss (months to years), but without additional interventions such as a low-fat diet, exercise, pharmacologic therapy, or a combination of these, 95% or more of the weight initially lost will be regained within 5 years.[54] Lifestyle interventions alone, including a low-fat, high fiber diet and increased activity, have only small effects on body weight but result in significant improvements in obesity-related morbidity.[51] Current pharmacologic therapy is effective in achieving weight loss of up to 10% of initial body weight for at least up to 2 years.[57,110] Bariatric surgery has been shown to increase weight loss to up to 50% of initial weight for at least 10 years,[118,119] but it carries the risks of surgery and, with most operations, irreversible anatomic modification. Nonetheless, for patients with severe obesity who are at high risk for morbidity and mortality, bariatric surgery can offer hope for improved survival while more effective medical therapies are being developed.

The author has served as a consultant for Amylin Pharmaceuticals, Inc.

The drug bupropion, which is discussed in this chapter, has not been approved by the FDA for use in obesity.

I ESOPHAGEAL DISORDERS

Stuart Jon Spechler, m.d.

Approach to the Patient with Dysphagia

The esophagus is susceptible to three types of diseases that cause dysphagia [*see Table 1*]: (1) mucosal (intrinsic) diseases that narrow the lumen of the esophagus through inflammation, fibrosis, or neoplasia; (2) mediastinal (extrinsic) diseases that encase and obstruct the esophagus by direct invasion or through lymph node enlargement; and (3) diseases affecting the esophageal muscle or its innervation (esophageal motility disorders) that disrupt peristalsis, interfere with sphincter relaxation, or both. The American Gastroenterological Association has endorsed algorithms summarizing the approach to the patient with dysphagia [*see Figures 1 through 4*].[1]

clinical evaluation

History

On the basis of a careful history alone, the astute clinician can determine the cause of dysphagia in approximately 80% of patients.[2] Eight questions form the key elements of the history.

Is the dysphagia for solid foods, liquids, or both? Mucosal and mediastinal diseases that involve the esophagus cause dysphagia by narrowing the lumen. Such mechanical narrowing usually does not impede the passage of liquids, and consequently, such a disease causes dysphagia for solid foods only. Diseases that disrupt peristalsis, however, may cause dysphagia for both solids and liquids. Of the esophageal motility disorders, achalasia is the one most likely to cause dysphagia for liquids. In achalasia, chronic contraction of the lower esophageal sphincter (LES) causes complete mechanical obstruction of the esophagus that persists until either the sphincter relaxes or the hydrostatic pressure of the retained material exceeds the pressure generated by the sphincter muscle. Even in the absence of peristalsis, gravity often can empty the esophagus of liquid effectively, provided that the LES is relaxed. Therefore, patients who have disordered peristalsis with an LES that is profoundly hypotensive often experience no dysphagia or experience dysphagia only for solid foods.

Where does the patient perceive that ingested material sticks? Patients with esophageal strictures often perceive that swallowed material sticks at a point that is either above or at the level of the stricture.[3] It is uncommon for patients to perceive that swallowed material is stuck below the obstructing lesion. Thus, the history that a swallowed bolus sticks above the suprasternal notch is of little value in localizing the obstruction, because this sensation could be caused by a lesion located anywhere from the pharynx to the gastroesophageal junction. If the patient localizes the obstruction to a point below the suprasternal notch, however, then it is highly likely that the dysphagia is caused by an esophageal disorder.

Are there symptoms of oropharyngeal dysfunction? Oropharyngeal dysfunction often results from diseases that affect the striated muscles of the oropharynx or their innervation. Examples include muscular dystrophies, dermatomyositis, myasthenia gravis, and cerebrovascular accidents.[4] Patients with these neuromuscular diseases may experience difficulty in initiating a swallow, and swallowing may be accompanied by nasopharyngeal regurgitation, pulmonary aspiration, and a sensation that residual material remains in the pharynx. If any of these symptoms are prominent, evaluation for oropharyngeal dysfunction (e.g., with videofluoroscopy) is appropriate.

Is the dysphagia intermittent or progressive? Patients who have a lower esophageal mucosal (Schatzki) ring (see below) typically complain of discrete episodes of dysphagia for solid foods that are intermittent and nonprogressive. The episodes often occur during meals in restaurants (hence the term steakhouse syndrome) or at social functions. Dysphagia episodes may be separated by a period of weeks, months, or years, and the patient typically experiences no swallowing difficulty between episodes. In contrast, esophageal strictures usually cause dysphagia that is progressive in frequency and severity. With benign strictures, the progression is typically slow and insidious (over a period of months to years), and weight loss is minimal. Malignant esophageal strictures usually cause dysphagia that progresses rapidly (over a period of weeks to months), and weight loss may be profound.

Is there a history of chronic heartburn? Heartburn is the cardinal symptom of gastroesophageal reflux disease (GERD). Thus, a history of chronic heartburn supports the possibility that dysphagia may result from a peptic esophageal stricture. However, up to 25% of patients with peptic strictures have no antecedent history of heartburn. Furthermore, the majority of patients with dysphagia from adenocarcinoma in Barrett esophagus have a history of long-standing heartburn. Also, around 30% of patients with achalasia complain of heartburn. Therefore, conclusions regarding the etiology of dysphagia should not be based primarily on the presence or absence of heartburn.

Has the patient taken medications likely to cause pill esophagitis? A number of medications taken in pill form are

Table 1 Diseases of the Esophagus That Cause Dysphagia

potentially caustic to the esophagus and can cause ulceration with stricture formation if they have prolonged contact with the esophageal mucosa. Although a large number of medications have been reported to cause pill esophagitis, most cases have been caused by antibiotics (e.g., doxycycline), potassium chloride preparations, nonsteroidal anti-inflammatory drugs (NSAIDs), and quinidine.

Is there a history of collagen vascular disease? Collagen vascular diseases such as scleroderma, rheumatoid arthritis, and systemic lupus erythematosus can cause disordered esophageal motility that is often associated with Raynaud phenomenon.[5] In scleroderma and related collagen vascular disorders, fibrosis and vascular obliteration in gut smooth muscle cause poor esophageal contractility and weakness of the lower esophageal sphincter that predisposes to severe GERD. Also, patients with collagen vascular disease often are treated with medications, such as NSAIDs, that can cause pill esophagitis. Consequently, dysphagia associated with collagen vascular disease may be the result of disordered esophageal motility, severe GERD, pill esophagitis, or some combination thereof.

Is the patient immunosuppressed? Infectious esophagitis occurs most often in patients whose immune system has been compromised by infection with HIV, by advanced malignancy, or by organ transplantation with the administration of potent immunosuppressive drugs. Odynophagia is usually the predominant symptom in infectious esophagitis, but most patients with this disease also experience dysphagia.[6] In rare cases, esophageal stricture can be a late complication of infectious esophagitis.

Physical Examination

The physical examination of the patient with dysphagia is important primarily for assessing the patient's nutritional status and ability to tolerate the invasive procedures that may be considered to treat the esophageal disorder. Only infrequently does the physical examination provide specific clues to the etiology of dysphagia. For patients with dysphagia caused by collagen vascular disease, physical examination may reveal characteristic features such as joint abnormalities, calcinosis, telangiectasias, sclerodactyly, proximal muscle weakness, and rashes. A palpable left supraclavicular (Virchow) lymph node suggests dysphagia from a malignancy in the abdomen (e.g., adenocarcinoma of the esophagogastric junction). Also, the physical examination may reveal evidence of a neuromuscular disorder that can interfere with swallowing (e.g., Parkinson disease).

DIAGNOSTIC TESTS

Testing in patients with dysphagia generally starts with barium swallow or endoscopy. If initial testing discloses an esophageal motility disorder, manometry may then be done. Videofluoroscopy, in which a motion recording is made while the patient swallows barium suspensions and barium-coated materials, is an excellent technique for assessing oropharyngeal function but generally is not needed for evaluating esophageal disorders.

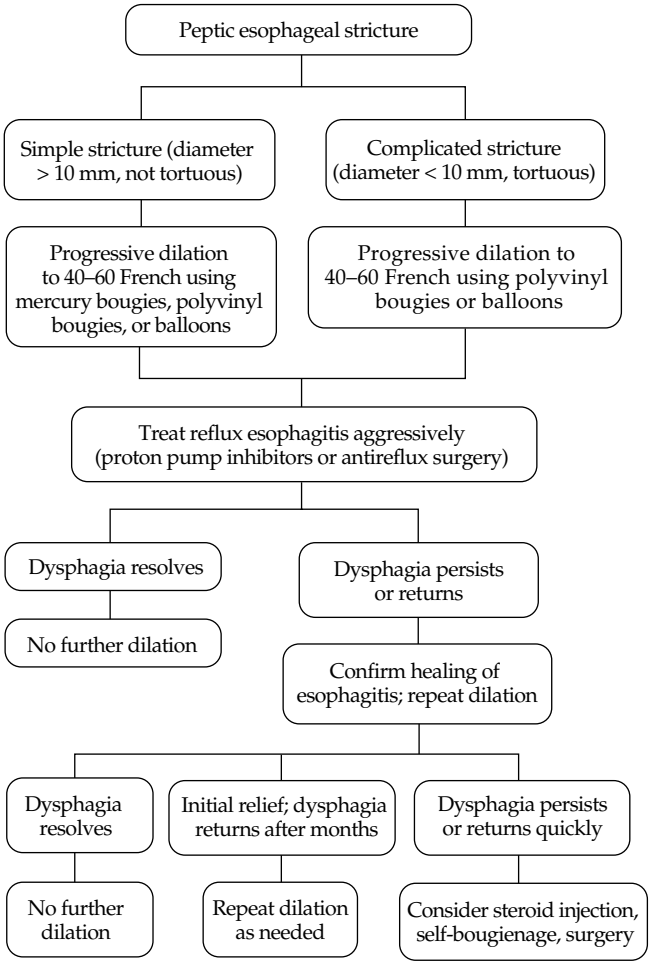

Figure 2 **Management of peptic esophageal stricture.**

There is an unresolved debate about whether to start the evaluation of dysphagia with a barium swallow or with esophageal endoscopy. Proponents of the latter approach argue that endoscopy is almost always required to evaluate dysphagia, for both diagnostic and therapeutic purposes, and that a barium swallow usually does not provide sufficient additional information to justify its expense and inconvenience. On the other side of the argument are those who contend that a barium swallow can provide valuable anatomic information about the esophagus that may help direct therapy and prevent procedural complications. In the absence of studies validating the cost-effectiveness of either approach, this debate continues.

Barium Swallow

A barium contrast examination can be more sensitive than endoscopy for detecting subtle narrowings of the esophagus (e.g., rings, peptic strictures greater than 10 mm in diameter) and for identifying esophageal dysmotility.[7] A barium swallow may be especially helpful in suggesting the diagnoses of achalasia and diffuse esophageal spasm, conditions that may be difficult to identify endoscopically. The early radiographic demonstration of achalasia may spare the patient repeat endoscopy, a situation that can occur because the endoscopist either did not recognize the disorder on the initial evaluation or was not prepared to perform endoscopic therapy at that time. A barium swallow can identify lesions that may pose potential hazards or confuse the endoscopist, such as a large Zenker diverticulum or an epiphrenic diverticulum. For patients with an esophageal stricture, a barium swallow can provide information on the extent and severity of the lesion that may help in choosing the type of dilator to be used for treatment. Finally, an initial barium swallow provides an objective baseline record of the esophagus that can be useful in assessing the response to therapy or progression of disease.

Endoscopy

For virtually all patients with dysphagia of esophageal origin, endoscopy is recommended to establish or confirm a diagnosis, seek evidence of esophagitis and malignancy, and implement therapy when appropriate. The endoscopist can obtain biopsy and brush cytology specimens of esophageal lesions that may establish the diagnosis of neoplasms or specific infections. Endoscopy also is more sensitive than radiology for identifying subtle mucosal lesions of the esophagus (e.g., mild esophagitis).

Esophageal Manometry

Esophageal manometry is the gold standard test for esophageal motility disorders. Esophageal manometry has been shown to be especially useful for establishing the diagnoses of achalasia and diffuse esophageal spasm and for detecting esophageal motor abnormalities associated with collagen vascular diseases.[8]

For patients with dysphagia, the history and the results of the barium swallow or endoscopy can be used to decide whether esophageal manometry is indicated. An esophageal motility study usually is not needed for patients with mechanical causes of dysphagia, such as peptic strictures or rings, unless their dysphagia persists despite appropriate treatment. For patients thought to have dysphagia caused by motility abnormalities associated with collagen vascular diseases, manometry need not be performed routinely if dysphagia responds to treatment of any associated reflux esophagitis and esophageal stenoses. If the dysphagia persists despite such treatment, manometry can establish the nature of the motility problem.

Dysphagia from Benign Esophageal Strictures and Rings

BENIGN ESOPHAGEAL STRICTURES

Strictures develop from severe esophageal inflammation, usually associated with ulceration, that stimulates fibrous tissue production and collagen deposition. Approximately two thirds of all cases of benign esophageal stricture in the United States are caused by reflux esophagitis (so-called peptic strictures).[9] The remainder are the result of caustic ingestions (e.g., lye), pill esophagitis, infectious esophagitis, and radiation esophagitis.

Treatment

Benign esophageal strictures usually are treated with dilation [*see Figure 2*]. Three major types of esophageal dilating devices are used commonly: (1) mercury-filled bougies that are passed blindly through the mouth (e.g., tapered-tipped Maloney dilators, blunt-tipped Hurst dilators); (2) polyvinyl bougies that can be passed over a fine guide wire that is positioned in the stricture, under either fluoroscopic or endoscopic guidance (e.g., Savary dilators), and (3) balloon dilators that are passed either over a guide wire or through the endoscope (so-called through-the-scope [TTS] balloons). Usually, the physician passes a series of dilators of increasing diameter to stretch

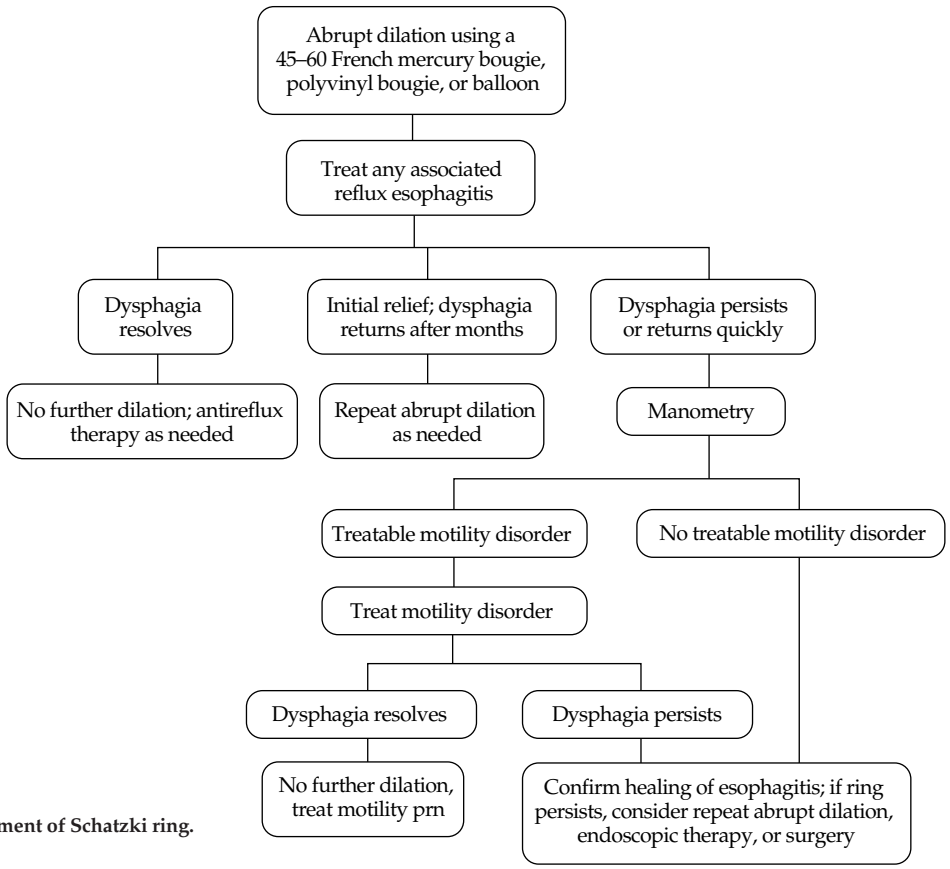

Figure 3 **Management of Schatzki ring.**

the stricture gradually. No study has established the superiority of one type of dilator over another. Serious complications such as perforation and bleeding occur in approximately 0.5% of all esophageal dilation procedures.[2]

For patients with peptic strictures caused by GERD, aggressive treatment with proton pump inhibitors both improves dysphagia and decreases the need for subsequent esophageal dilations.[10] Surgical therapy can be used for esophageal strictures that do not respond to dilation and antisecretory therapy. There are two major surgical approaches: (1) antireflux surgery with intraoperative stricture dilation for patients with peptic strictures or (2) resection of the stenotic esophagus with esophageal reconstruction (e.g., by interposing a loop of bowel between the remaining esophagus and the stomach).

lower esophageal (schatzki) rings

The lower esophageal mucosal (Schatzki) ring is a thin, diaphragmlike, circumferential fold of mucosa that protrudes into the lumen of the distal esophagus, thereby posing a physical barrier to the passage of solid material.[11] Mucosal rings usually are located at the squamocolumnar junction and have squamous epithelium lining their upper surface and columnar epithelium lining the lower aspect. With careful radiologic technique aimed at distending the distal esophagus, a lower esophageal ring can be found in approximately 15% of all patients who have barium swallows. Only a minority of these rings cause dysphagia, however.

The pathogenesis of lower esophageal mucosal rings is disputed. It is not clear whether they are congenital or acquired structures. Lower esophageal mucosal rings often are associated with hiatal hernias and GERD, and some authorities have suggested that the rings are in fact thin peptic strictures. Data on the role of GERD in the pathogenesis of Schatzki rings are inconclusive and contradictory, however.

Treatment

Dilation therapy is recommended for patients who have dysphagia from Schatzki rings [*see Figure 3*]. Traditionally, this involves the passage of a single large bougie or balloon (45 to 60 French) aimed at fracturing (rather than merely stretching) the mucosal fold. This approach differs from that for peptic strictures, which are treated by gradual stretching for fear of rupturing the fibrotic esophagus with a single, abrupt dilation. Most patients experience immediate relief of dysphagia after dilation, but recurrence is common and many patients require repeated dilations.

Esophageal Motility Abnormalities

Spechler and Castell have recently proposed a classification system for esophageal motility disorders. This system categorizes such disorders according to four major patterns of esophageal manometric abnormalities: inadequate LES relaxation, uncoordinated contraction, hypercontraction, and hypocontraction [*see Table 2*].[12] Most esophageal motility abnormalities fall predominantly into one of these four major categories, although there can be considerable overlap.

Processes that affect the inhibitory innervation of the LES (e.g., achalasia) can interfere with LES relaxation and thereby delay esophageal clearance. In the body of the esophagus, abnormal motility is characterized by uncoordinated contraction, hypercontraction, and hypocontraction. Uncoordinated esopha-

Table 2 Classification of Esophageal Motility Abnormalities[12]

Inadequate relaxation of lower esophageal sphincter (LES)
Classic achalasia
Atypical disorders of LES relaxation

Diffuse esophageal spasm
Hypercontraction
Nutcracker esophagus
Isolated hypertensive LES
Hypocontraction
Ineffective esophageal motility

geal contractions (i.e., contractions that are not peristaltic and directed toward the stomach) can delay esophageal clearance. Such uncoordinated contractions are the hallmark of diffuse esophageal spasm. Hypercontraction abnormalities are those that are characterized by contractions that are of high amplitude, long duration, or both. The putative disorders of hypercontraction (e.g., nutcracker esophagus, isolated hypertensive LES) are perhaps the most controversial of the abnormal esophageal motility patterns because it is not clear whether esophageal hypercontraction has any pathophysiologic significance. In contrast, hypocontraction abnormalities that result from weak (low-amplitude) muscle contractions can cause ineffective esophageal motility that delays esophageal clearance, and LES hypotension can result in GERD.

ACHALASIA

Primary achalasia is the best characterized of all the esophageal motility disorders.[13] In achalasia, there is degeneration of neurons in the wall of the esophagus, especially the nitric oxide–producing inhibitory neurons that effect the relaxation of esophageal smooth muscle necessary for opening of the LES and for coordinated esophageal contraction. Degenerative changes also may be found in brain stem ganglion cells and their efferent fibers, but the disordered motility appears to result primarily from the degeneration of intramural neurons. The loss of inhibitory innervation in the LES causes basal sphincter pressures to rise and interferes with sphincter relaxation. In the body of the esophagus, the loss of intramural neurons results in aperistalsis.

Primary achalasia has an annual incidence of approximately one case per 100,000 population. The disorder affects men and women equally and usually is diagnosed in patients who are between 25 and 60 years of age.

Secondary achalasia, or pseudoachalasia, which can be

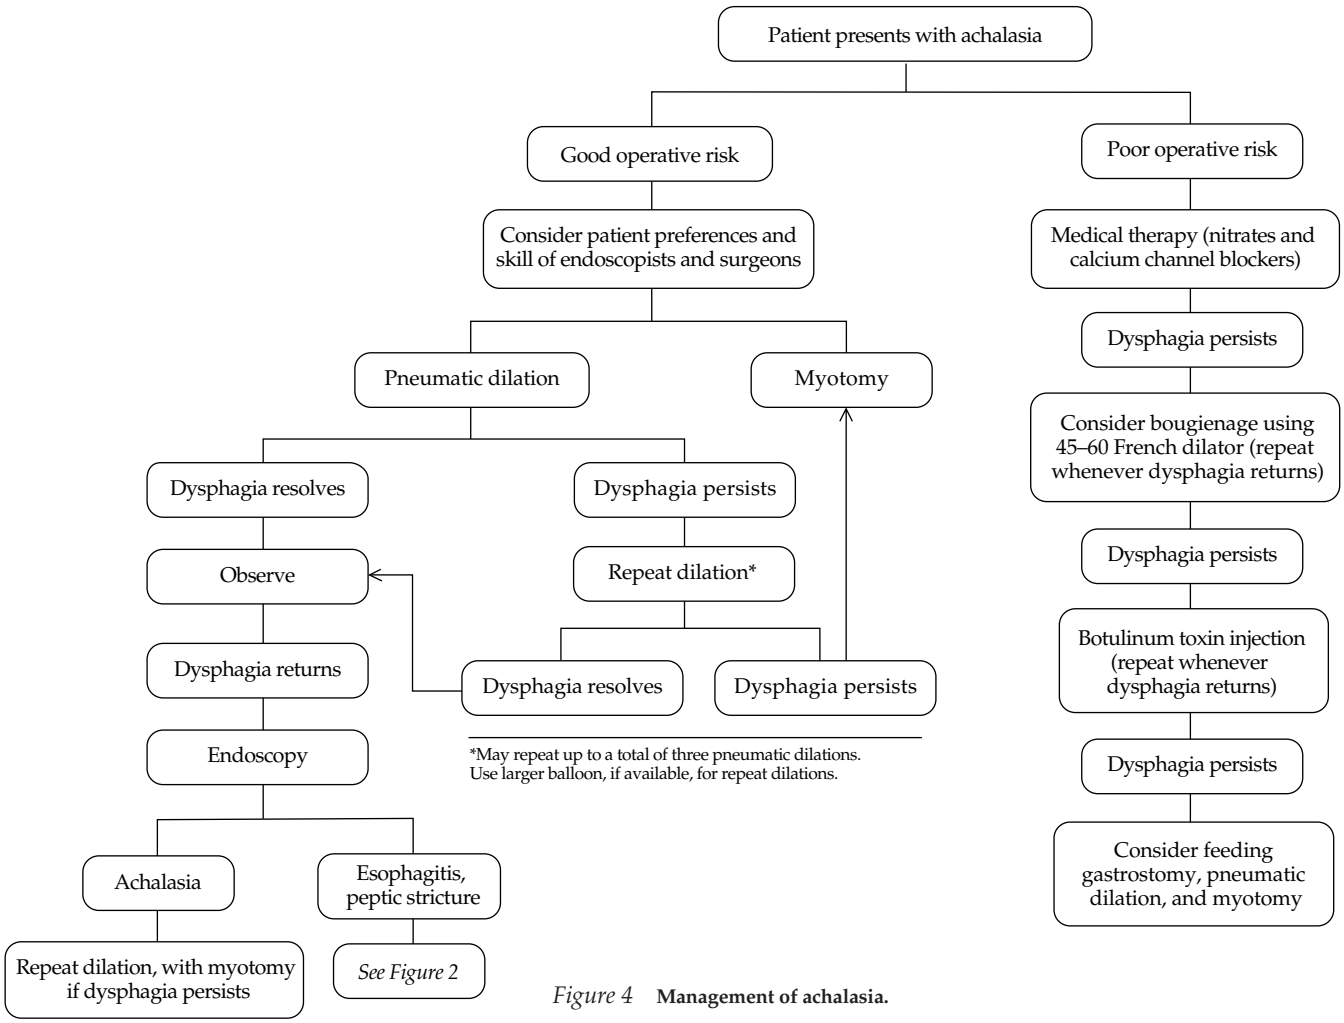

Figure 4 **Management of achalasia.**

caused by certain diseases, exhibits esophageal motor abnormalities identical to those of primary achalasia. In Chagas disease, for example, esophageal infection with *Trypanosoma cruzi* can destroy intramural ganglion cells and cause aperistalsis with incomplete LES relaxation. Malignancies can cause pseudoachalasia by invading the esophageal neural plexuses directly or, very rarely, by releasing uncharacterized humoral factors that disrupt esophageal function as part of a paraneoplastic syndrome.

Diagnosis

Clinical features Dysphagia for both solid foods and liquids is the primary symptom of achalasia. Moderate weight loss, regurgitation, and chest pain also are common clinical features. For reasons that are not clear, approximately one third of patients complain of heartburn, and achalasia occasionally can be confused with GERD. The symptoms of achalasia can be insidious in onset and gradual in progression, and patients frequently experience symptoms for years before seeking medical attention.

Diagnostic studies Achalasia can be confirmed with radiographic, manometric, and endoscopic evaluation. Occasionally, the diagnosis is suggested on a plain radiograph of the chest that shows widening of the mediastinum from the dilated esophagus and reveals absence of the normal gastric air bubble, because LES contraction prevents swallowed air from entering the stomach. Barium swallow, which has a diagnostic accuracy for achalasia of 95%, typically shows a dilated esophagus that terminates in a beaklike narrowing caused by persistent contraction of the LES [*see Figure 5*].

Esophageal manometry is the gold standard for the diagnosis of achalasia. The requisite manometric features are (1) incomplete relaxation of the LES (defined as a mean swallow-induced fall in resting LES pressure to a nadir value more than 8 mm above gastric pressure) and (2) aperistalsis characterized either by simultaneous esophageal contractions with amplitudes less than 40 mm Hg or by no apparent esophageal contractions. Other common manometric features of classic achalasia include LES hypertension (resting pressure greater than 45 mm Hg) and resting pressure in the esophageal body that exceeds resting pressure in the stomach.

Diagnostic endoscopy is recommended for patients with achalasia, primarily to exclude malignancy at the esophagogastric junction. In primary achalasia, the endoscopist sees a dilated esophagus that often contains residual food. The LES does not open spontaneously, but in contrast to cases of obstruction caused by neoplasms or fibrotic strictures, the contracted LES of achalasia usually can be traversed easily with gentle pressure on the endoscope.

Treatment

Treatments for achalasia are aimed at decreasing the resting pressure in the LES to the point that the LES no longer impedes the passage of swallowed material [*see Figure 4*]. There is no therapy that can halt or reverse the degeneration of enteric neurons, and no treatment reliably restores peristaltic function in the body of the esophagus.

Pharmacotherapy Nitrates and calcium channel blockers relax the smooth muscle of the LES, and these agents have been used to treat achalasia, with limited success. The drugs usually are taken sublingually 10 to 30 minutes before meals. Unfortunately, pharmacotherapy for achalasia is inconvenient, often ineffective, and frequently associated with side effects (e.g., headache and hypotension) and tachyphylaxis. Consequently, pharmacotherapy is used primarily for patients who are unwilling or unable to tolerate invasive therapies.

Figure 5 **Barium swallow in a patient with achalasia shows dilatation of the esophagus with a beaklike narrowing at the esophagogastric junction.**

Pneumatic dilation therapy In pneumatic dilation therapy for achalasia, a large deflated balloon is passed through the mouth to the LES, where the balloon is inflated rapidly to tear the sphincter muscle and thereby weaken the LES.[14] Most studies describe good short-term relief of dysphagia in 60% to 85% of patients who are treated with a single session of pneumatic dilation. Esophageal perforation is the most common serious complication of the procedure, occurring in 2% to 6% of cases in most large series. Approximately 50% of patients who are treated with pneumatic dilation will require further therapy within 5 years, and subsequent pneumatic dilations are progressively less likely to result in a sustained remission.

Surgical therapy Achalasia also can be treated by surgical myotomy, in which the surgeon weakens the LES by cutting its muscle fibers. The procedure now can be performed laparoscopically, and good to excellent relief of symptoms has been described in 70% to 90% of patients. There are few serious complications, although reflux esophagitis develops postoperatively in approximately 10% of patients. Some surgeons recommend that an antireflux (fundoplication) procedure be performed at the time of myotomy to prevent this complication. The few long-term studies available suggest that surgical myotomy results in sustained remission rates of approximately 85% at 10 years and 65% at 20 years. In a prospective, randomized comparison of myotomy with pneumatic dilation, excellent results were found after median follow-up of approximately 5 years in 40 of 42 (95%) patients in the surgical group, compared with 24 of 37 (65%) patients who had pneumatic dilation.[15] Currently, the decision between pneumatic dilation and myotomy as initial therapy for achalasia should take into consideration the patient's preferences and the experience of available personnel.

Botulinum toxin therapy Endoscopic injection of botulinum toxin into the LES poisons the excitatory (acetylcholine-releasing) neurons that contribute to LES smooth muscle tone, thereby decreasing LES pressure and relieving achalasia.[16] The procedure is safe, and most patients treated with botulinum toxin injection experience immediate symptomatic improvement. Unfortunately, this effect usually is short lived. With repeated injections, approximately two thirds of patients with achalasia can be maintained in remission for 6 months. Of those patients in remission at 6 months, however, only about two thirds are still in remission at 1 year, despite repeated injections. Botulinum toxin injection is used primarily to treat patients with serious comorbidities, for whom pneumatic dilation and surgical myotomy pose inordinate risks.

DIFFUSE ESOPHAGEAL SPASM

Diffuse esophageal spasm is a rare condition of unknown etiology characterized by uncoordinated (spastic) motor activity in the smooth muscle portion of the esophagus. The esophageal spasms are manifested clinically by episodes of dysphagia and chest pain and on radiography and manometry by tertiary (nonperistaltic) contractions of the esophagus. The requisite manometric features of diffuse esophageal spasm are (1) simultaneous contractions associated with more than 10% of wet swallows and (2) a mean simultaneous contraction amplitude greater than 30 mm Hg.[12] A common manometric pattern is intermittent normal peristalsis alternating with periods of spontaneous, repetitive, and multiple-peaked contractions.

Diffuse esophageal spasm is treated with agents that relax esophageal smooth muscle, such as nitrates and calcium channel blockers, although few reports document the efficacy of this therapy. Psychotropic agents such as tricyclic antidepressants may help relieve the pain of diffuse esophageal spasm. Surgical treatment by long myotomy of the esophagus has been reported, but the efficacy of this operation is poorly documented.

NUTCRACKER ESOPHAGUS

In nutcracker esophagus, manometry reveals peristaltic waves in the distal esophagus that have mean amplitudes more than 2 standard deviations above normal values.[17] Although high-amplitude peristalsis is the most common motility abnormality observed in patients with noncardiac chest pain,[18] the clinical and physiologic importance of this manometric finding is disputed. It is not clear whether the hypercontraction of esophageal muscle is a cause of chest pain or is merely an epiphenomenon that is associated with the chest pain syndrome. The clinical response to smooth muscle–relaxing agents (nitrates and calcium channel blockers) is often disappointing. Treatment with psychotropic agents such as tricyclic antidepressants can be effective in controlling the chest pain.

ISOLATED HYPERTENSIVE LES

In patients with isolated hypertensive LES, esophageal motility is normal and the LES relaxes appropriately, but the mean resting LES pressure is abnormally high (i.e., > 45 mm Hg). Although this condition has been reported in patients with noncardiac chest pain, it is unlikely that the isolated hypertensive LES has any clinical consequences.

SCLERODERMA

In 80% of patients with scleroderma (progressive systemic sclerosis), fibrosis and ischemia damage the esophageal muscles and nerves. This damage causes manometric abnormalities, including weak contractions in the body of the esophagus and hypotension of the LES.[19] The LES hypotension can result in GERD. When the amplitude of peristaltic contractions falls below 30 mm Hg, esophageal clearance is compromised.

In addition to weak peristalsis, patients with scleroderma often exhibit abnormalities in the progression of peristalsis, including (1) failed peristalsis, in which the peristaltic wave progresses through the pharynx and proximal esophagus but fails to traverse the entire length of the distal esophagus; (2) simultaneous esophageal contractions; and (3) absent esophageal contractions.

The manometric features of scleroderma are not specific for the disorder. Identical manometric abnormalities can be found in patients with the CREST variant (limited scleroderma [calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasias]) and other collagen vascular disorders (e.g., mixed connective tissue disease, rheumatoid arthritis, and systemic lupus erythematosus) and certain nonrheumatic diseases (e.g., diabetes mellitus and amyloidosis). Furthermore, otherwise healthy patients who have GERD often exhibit scleroderma-like motility disturbances, yet such patients infrequently develop rheumatic diseases. For these reasons, some authorities discourage use of the term scleroderma esophagus and recommend use of the term ineffective esophageal motility to describe the constellation of manometric abnormalities typical of scleroderma.[20]

There is currently no effective treatment for ineffective esophageal motility. Proton pump inhibitors can treat and prevent complications from associated GERD. Prokinetic agents such as metoclopramide are often used but are rarely effective, especially when the disease is advanced.

Gastroesophageal Reflux Disease

In GERD, the reflux of gastric juice into the esophagus or oropharynx causes symptoms, tissue injury, or both. Approximately 20% of adults in the United States experience GERD symptoms such as heartburn and acid regurgitation at least once a week.[21] Severe GERD can result in ulceration of the esophagus,

which can lead to fibrosis and esophageal stricture formation. In some cases, the ulcerated squamous epithelium of the distal esophagus is replaced by a metaplastic, intestinal-type mucosa (a condition called Barrett esophagus) that predisposes to cancer. Consequently, GERD is a strong risk factor for esophageal adenocarcinoma,[22] a tumor whose frequency has increased profoundly in western countries over the past 2 decades.

PATHOPHYSIOLOGY

The development of GERD is a multifactorial process involving dysfunction of the antireflux mechanisms that normally prevent gastric juice from entering the esophagus and of the clearance mechanisms that normally rid the esophagus of refluxed material.[23]

Antireflux Mechanisms

The normal barrier to gastroesophageal reflux comprises three major components: (1) the LES, (2) the crural diaphragm, and (3) anatomic features of the gastroesophageal junction.

Lower esophageal sphincter The LES normally prevents reflux by maintaining a resting pressure that is 10 to 30 mm Hg higher than ambient pressure in the stomach.[24] In the 1980s, Dodds showed that episodic collapse of LES pressure, a phenomenon called transient LES relaxation (TLESR), is the major mechanism for gastroesophageal reflux both in normal individuals and in patients with GERD.[25] Unlike the brief (2- to 8-second) LES relaxations that normally accompany primary (swallow-induced) peristalsis, TLESRs are not preceded by swallowing and last from 10 to 45 seconds.[26] When LES pressure becomes identical to gastric pressure during a TLESR, the sphincter can no longer function as a barrier to acid reflux.

TLESRs occur two to six times per hour in normal persons, especially after meals, and 40% to 50% of these TLESRs are accompanied by brief episodes of acid reflux. In patients with GERD, TLESRs occur three to eight times per hour, and 60% to 70% of these are associated with acid reflux. In severe GERD, approximately 70% of reflux episodes are the result of TLESRs; the remaining reflux episodes are from feeble basal LES pressure, swallow-induced LES relaxation, and sudden elevations in abdominal pressure.[24]

Gaseous distention of the stomach normally triggers a TLESR that allows the gas to escape into the esophagus (the belch reflex).[26] The nucleus tractus solitarius in the medulla mediates the belch reflex by integrating sensory information from the stomach and by controlling the neural circuits that induce the TLESR. Activation of medullary neurons with γ-aminobutyric acid B ($GABA_B$) receptors inhibits TLESRs, as does cholinergic blockade with atropine. The sphincter relaxation of the TLESR is effected by the activation of cholecystokinin-A receptors in LES muscle.

Crural diaphragm The right crus of the diaphragm normally encircles the distal esophagus. During inspiration, contraction of the diaphragmatic crura pinches the distal esophagus to prevent reflux. Crural contraction also helps minimize reflux during the sudden increases in abdominal pressure that accompany events such as coughing, sneezing, and straining. Thus, the crural muscle functions as an external esophageal sphincter that buttresses the LES.[27] TLESRs often are accompanied by relaxation of the crura, and studies in dogs have shown that gastroesophageal reflux does not occur during a TLESR unless the episode is attended by neural inhibition of the crural diaphragm.

Anatomic features of the gastroesophageal junction The acute angle formed by the junction of the esophagus and the stomach (the angle of His) can function as a one-way flap valve that stops reflux. Also, a portion of the distal esophagus normally is located within the abdomen, where the high ambient pressure pushes the esophageal walls together to prevent reflux.[27]

Disruption of the Antireflux Barrier by Hiatal Hernia

Most patients with severe GERD have a hiatal hernia in which the proximal portion of the stomach herniates into the chest through the diaphragmatic hiatus formed by the right crus of the diaphragm. With a large hiatal hernia, the LES muscle is completely dissociated from the crural diaphragm. In this situation, contraction of the crural diaphragm does not pinch the esophagus; rather, it creates an intrathoracic pouch of stomach whose contents may reflux readily into the esophagus.[28,29] With no buttressing of the internal sphincter by the crural diaphragm, sudden elevations in abdominal pressure caused by inspiration, coughing, and straining can far exceed LES pressure, resulting in reflux. Reduction of the angle of His and loss of the intra-abdominal portion of the esophagus also may compromise the antireflux barrier. Furthermore, patients with large hiatal hernias have an abnormally high frequency of TLESRs induced by gastric distention.[30]

Disruption of Esophageal Clearance

To injure the esophagus, caustic refluxed material must remain in contact with the mucosa for a sufficient period. The duration of this contact is determined by the efficacy of the esophageal clearance mechanisms, which include gravity, peristalsis, salivation, and bicarbonate secretion by the submucosal glands of the esophagus. When gastric juice refluxes into the esophagus, most of the material is cleared by the combined effects of gravity and peristalsis.[31] The small quantity of residual acidic material is neutralized by alkaline saliva and, to a lesser extent, by bicarbonate secreted by the submucosal glands.

Peristaltic abnormalities that can interfere with esophageal emptying (e.g., failed peristalsis, hypotensive peristalsis) have been found in 25% to 48% of patients with reflux esophagitis.[32] Patients with large hiatal hernias frequently have impaired esophageal clearance because of the retrograde flow of material from the hernia back into the esophagus. Cigarette smoking also has been shown to increase esophageal acid exposure both by increasing the frequency of acid reflux events and by decreasing salivary flow.[33]

Normal persons regularly experience brief episodes of acid reflux that do not cause esophageal injury. Most patients with reflux esophagitis have prolonged esophageal acid exposure that overwhelms the normal epithelial defenses. In some patients with reflux esophagitis, however, 24-hour pH monitoring studies demonstrate a normal daily duration of acid reflux. It is conceivable that these patients have uncharacterized defects that render the esophageal epithelium vulnerable to normal acid reflux.

ETIOLOGY

NSAIDs

There is evidence to suggest that aspirin and other NSAIDs may contribute to GERD.[34,35] Some NSAID preparations are caustic to the esophageal mucosa, and esophagitis can result if the tablet lingers in the esophagus (pill esophagitis). Patients

with esophageal strictures may be especially susceptible to NSAID-induced esophageal injury.

Helicobacter pylori

Some studies suggest that gastric infection with *H. pylori* protects the esophagus from GERD and its complications.[36] In general endoscopy units, *H. pylori* infection has been found significantly less often in patients with reflux esophagitis than in control patients without GERD.[37] Reflux esophagitis has developed in some patients with duodenal ulcers after their *H. pylori* infections were eradicated with antibiotics.[38] There is a negative association between esophageal adenocarcinoma and *H. pylori* infections, particularly for infections with *cagA*-positive strains that may be especially likely to cause severe pangastritis.[39,40] Graham and others have proposed that *H. pylori* infections that cause pangastritis also cause a decrease in gastric acid production that may protect against GERD.[41] This issue remains highly controversial, however, and the role of *H. pylori* infection in GERD is not yet clear.

DIAGNOSIS

Clinical Features

Heartburn, the cardinal symptom of GERD, is an uncomfortable, burning sensation that is located behind the sternum. The sensation often originates in the epigastrium and radiates up the chest. Patients who describe heartburn often wave an open hand vertically over the sternum, whereas patients with angina pectoris typically hold a clenched fist stationary over the chest while describing their pain. Heartburn may be associated with the ingestion of foods that predispose to reflux by decreasing pressure in the LES, such as chocolate, onions, and fat. Spicy foods, citrus products, and tomato products may cause the sensation of heartburn by irritating the inflamed esophageal mucosa directly. Some patients experience heartburn when they bend over or exercise, presumably because these activities induce acid reflux by increasing intra-abdominal pressure. Characteristically, heartburn caused by gastroesophageal reflux is relieved immediately by antacids and can be eliminated by the administration of potent acid-suppressing agents.

When refluxed gastric juice reaches the oropharynx, patients may complain of regurgitation of sour (acid) or bitter-tasting (bilious) material. Dysphagia may result from a peptic stricture or from reflux esophagitis alone. With ulcerative esophagitis, patients may complain of odynophagia. Some patients experience water brash, in which the mouth suddenly fills with saliva as a result of reflex salivation stimulated by acid in the esophagus.

In addition to these typical symptoms, GERD can have a variety of so-called atypical manifestations.[42-45] Esophageal irritation by acid reflux may result in chest pain that can mimic ischemic heart disease. If gastric juice reaches the oropharynx, it can cause globus, sore throat, and burning tongue, and the acid can erode dental enamel. Laryngitis and pulmonary problems such as chronic cough and asthma can result from aspiration of material into the airway. Asthma may also be a consequence of acid in the esophagus that triggers reflex bronchoconstriction.

Diagnostic Studies

Patients who have a typical history of heartburn that disappears with antisecretory therapy can be assumed to have GERD, and diagnostic tests are not necessary merely to confirm the diagnosis. Moreover, by definition, patients with GERD can have symptoms without objective evidence of esophageal damage, so normal test results often cannot exclude GERD as a cause of symptoms. However, diagnostic tests may be needed to evaluate atypical symptoms or to look for complications of GERD. For such patients, several options are available, such as radiography, endoscopy, biopsy, acid perfusion test, and pH monitoring.

Radiography Radiography has a limited role in the evaluation of GERD. A barium swallow can show signs of reflux esophagitis (e.g., thickening of the esophageal folds, erosions, and ulcerations) that support the diagnosis of GERD. A barium swallow can also identify peptic strictures. Radiography is considerably less sensitive than endoscopy for demonstrating esophagitis, however; and endoscopic examination has the added advantage of permitting biopsy of specimens from any abnormal areas.

Endoscopy An endoscopic examination is the most sensitive test for establishing the diagnosis of reflux esophagitis and Barrett esophagus. However, the clinician should appreciate that a normal endoscopic examination does not eliminate GERD as a cause of symptoms. Gastroesophageal reflux can cause disabling symptoms without causing visible esophageal damage.[46] Endoscopy shows reflux esophagitis in only 50% to 70% of patients who complain of frequent heartburn, and heartburn severity is not a reliable index for the severity of esophagitis.[47] Furthermore, the esophagus typically appears normal on endoscopy in patients who have only extraesophageal symptoms of GERD, such as chronic cough and laryngitis.

The Practice Parameters Committee of the American College of Gastroenterology recommends that endoscopy be reserved for patients with uncomplicated GERD in whom empirical therapy is unsuccessful. Endoscopic evaluation without an empirical trial of therapy is appropriate in patients who have symptoms suggesting complicated disease, including fever, anorexia, weight loss, dysphagia, odynophagia, and bleeding.[48] In patients with long-standing GERD symptoms, particularly those 50 years of age and older, endoscopy is indicated to look for Barrett esophagus.[49] It is important to appreciate that these guidelines are merely committee recommendations whose efficacy has not been established by clinical studies.

Biopsy Biopsy specimens of the squamous epithelium in the distal esophagus of patients with GERD frequently show the histologic abnormalities of reflux esophagitis, including lengthening of the papillae, hyperplasia of cells in the basal zone, and infiltration of the epithelium with eosinophils and polymorphonuclear cells. The importance of these histologic changes of GERD is disputed, however; and routine biopsy of the squamous epithelium to seek evidence of reflux esophagitis generally is not recommended for clinical purposes.

Acid perfusion test The acid perfusion (Bernstein) test has been used in patients who have atypical chest pain. The esophagus is perfused with 0.1N hydrochloric acid; reproduction of the chest pain implicates GERD as the etiology. This test has limited sensitivity and specificity, however, and has largely been replaced by ambulatory esophageal pH monitoring.

pH monitoring Ambulatory monitoring of esophageal

pH is used to document the pattern, frequency, and duration of acid reflux and to seek a correlation between reflux episodes and symptoms. In most ambulatory systems, an episode of acid reflux is defined as a drop in esophageal pH below 4. Esophageal pH monitoring records a number of different variables, such as the total number of reflux episodes, the number of episodes that last longer than 5 minutes, and the duration of the longest episode. The most useful variable appears to be the percentage of the monitoring period in which esophageal pH remains below 4 (in normal individuals, this is less than 4.5% of the 24-hour test). Ambulatory esophageal pH monitoring usually is not needed for patients with typical signs and symptoms of GERD. For patients with atypical or unresponsive symptoms, however, the test can be very useful in documenting an association between symptoms and acid reflux, as well as the efficacy of antisecretory therapy in reducing acid reflux.

TREATMENT

The efficacy of antireflux therapy is inversely related to the severity of the underlying reflux esophagitis.[50] A treatment that is highly effective for mild esophagitis may be virtually useless for patients with severe disease. Ulcerative esophagitis does not respond reliably to medical therapy with agents other than proton pump inhibitors (PPIs), the most effective antisecretory medications. For patients with mild or moderate esophagitis, some authorities advocate a step-up approach to therapy that begins with antireflux lifestyle modifications and progresses eventually to the most potent medications (i.e., PPIs) only when the disease does not respond to lesser treatments.[51] Others advocate a step-down approach that begins with the most effective therapy (PPIs).[52] The optimal approach remains disputed. However, for patients who are known to have severe, ulcerative reflux esophagitis, it is appropriate to begin therapy immediately with PPIs rather than proceeding stepwise through trials of agents unlikely to effect healing.

Lifestyle Modifications

A number of lifestyle modifications have been proposed to decrease esophageal acid exposure [*see Table 3*]. Few published data support the efficacy of these lifestyle modifications in controlling GERD, however, and it is unclear how many patients for whom such modifications are prescribed actually comply with them.

Antacids and Alginic Acid

Antacids and alginic acid can provide temporary relief of episodic heartburn. Despite the wide use of these over-the-counter products, surprisingly few data are available on their utility for healing reflux esophagitis or for the long-term management of GERD symptoms.

H_2 Receptor Blocking Agents

H_2 receptor antagonists are safe medications that relieve GERD symptoms and heal esophagitis within 12 weeks in approximately one half to two thirds of all patients.[50,53] The H_2 blockers are most useful for patients with GERD of mild to moderate severity, in whom the highest rates of healing can be anticipated. However, healing rates with these agents are poor in patients who have severe reflux esophagitis. High doses of H_2 receptor blockers (up to eight times the conventional dose) have been used effectively to treat esophagitis in severe cases of GERD, but this approach generally is not recommended. Few data document the long-term efficacy of H_2 receptor blockers used in any dosage, and many patients develop tolerance to the antisecretory effects of these agents. For patients with severe GERD, most authorities prescribe PPIs rather than high-dose H_2 receptor blocker therapy.

Table 3 Lifestyle Modifications for Gastroesophageal Reflux Disease

- Elevate the head of the bed on 4- to 6-in blocks
- Weight loss for obese patients
- Avoid recumbency for several hours after meals
- Avoid bedtime snacks
- Avoid fatty foods, chocolate, peppermint, onions, and garlic
- Avoid cigarettes and alcohol
- Avoid drugs that decrease lower esophageal sphincter pressure and delay gastric emptying, such as calcium channel blocking agents
- Avoid nonsteroidal anti-inflammatory drugs

Prokinetic Agents

In theory, prokinetic agents may decrease gastroesophageal reflux by increasing LES pressure and by enhancing esophageal and gastric clearance. Currently, metoclopramide is the only prokinetic agent available in the United States for the treatment of GERD. Metoclopramide is a dopamine antagonist, and its use is limited by side effects such as agitation, restlessness, somnolence, and extrapyramidal symptoms, which occur in up to 30% of patients. Cisapride, a serotonin-4 (5-HT_4) receptor agonist, demonstrated efficacy in mild GERD, but this agent was withdrawn when it was found to cause lethal cardiac arrhythmias in patients with a number of predisposing conditions.

Sucralfate

Sucralfate, a complex metal salt of sulfated sucrose, is an exceptionally safe medication that has some demonstrated efficacy in the treatment of mild reflux esophagitis. Few published data are available on the use of sucralfate in GERD, however, and the drug has never achieved popularity as an antireflux therapy.

Proton Pump Inhibitors

The PPIs are substituted benzimidazoles that decrease gastric acid secretion through inhibition of H^+,K^+-ATPase, the proton pump of the parietal cell. These agents are clearly the most effective inhibitors of gastric acid secretion available. Five PPIs are used widely for the treatment of GERD: omeprazole, esomeprazole (the S-optical isomer of omeprazole), lansoprazole, pantoprazole, and rabeprazole. All of these preparations are similar in efficacy and side-effect profiles, although when used in conventional dosages, esomeprazole may effect marginally higher rates of healing of reflux esophagitis than lansoprazole.[54] Patients with mild to moderately severe reflux esophagitis who are treated with PPIs in conventional dosages achieve healing rates of 80% to 100% within 8 to 12 weeks.[50,55] Very severe reflux esophagitis may persist despite conventional-dose PPI therapy in up to 40% of cases, however.[56] In most of these resistant cases, the esophagitis usually can be healed by increasing the dose of the PPI.[57] Recent studies also have shown

that aggressive acid suppression with PPIs improves dysphagia and decreases the need for esophageal dilation in patients who have peptic esophageal strictures.[10]

Most patients with severe GERD who respond to PPIs require maintenance therapy, because GERD recurs shortly after stopping the drug.[58] For most patients, the dose of PPI necessary to maintain remission is at least the dose required to heal the acute esophagitis. In some patients with severe GERD, furthermore, PPI maintenance-dose requirements may increase with time. One long-term study of patients with severe GERD who were given a maintenance dose of 20 mg of omeprazole daily found that relapses occurred at the rate of 1 per 9.4 treatment-years and that patients often required increasing doses of omeprazole (up to 120 mg/day) to maintain GERD in remission.[57]

The profound acid suppression that can be achieved with PPIs has raised theoretical concerns regarding their long-term safety.[53] Nevertheless, there are no reports of tumors or nutritional deficiencies clearly attributable to the use of PPIs after more than a decade of extensive clinical experience with these agents.

Antireflux Surgery

Antireflux operations share four fundamental features: (1) reduction of the hiatal hernia, (2) restoration of an intra-abdominal segment of esophagus, (3) approximation of the diaphragmatic crura, and (4) fundoplication, in which the surgeon wraps a portion of the gastric fundus around the distal esophagus. The operations differ primarily in the approach (e.g., transthoracic versus transabdominal) and in the extent of fundoplication.

The precise mechanisms whereby these operations prevent reflux are not clear, but a number of potential ones have been proposed.[59] The fundoplication may prevent the distention of the gastric fundus that ordinarily triggers TLESRs. Restoration of the distal esophagus to the positive pressure environment of the abdomen may prevent reflux, and the anatomic rearrangement of the gastroesophageal junction may create an antireflux flap-valve effect. Also, reduction of the hiatal hernia and approximation of the diaphragmatic crura may restore the normal antireflux function of the crural diaphragm.

Antireflux surgery can be performed laparoscopically.[60] The laparoscopic approach has become popular not because it is safer or produces a better functional result than the open procedure, but because it supposedly offers the advantages of less postoperative discomfort, shorter hospital stay, and better cosmetic outcome. Two recent randomized trials of laparoscopic versus open Nissen fundoplication found no significant differences in the functional results of the two procedures (i.e., relief of GERD symptoms and reduction in esophageal acid exposure).[61,62] However, one of the studies was terminated prematurely because an interim analysis showed an excess of adverse outcomes (primarily dysphagia) in the group treated laparoscopically.[62] At least one study has shown that the primary factor involved in overall patient satisfaction with antireflux surgery is the relief of GERD symptoms. These observations suggest that the primary decision for the clinician to make is whether the patient should have an antireflux operation, not how the operation should be performed.

Uncontrolled retrospective studies of antireflux surgery generally have described excellent results, with success rates exceeding 80%.[60] Few randomized trials have done direct comparisons of medical and surgical antireflux therapies, however. In the late 1980s (before the release of PPIs for clinical use in the United States), the Department of Veterans Affairs conducted a large cooperative study that prospectively compared the efficacy of medical therapy with that of surgical therapy in 247 patients with complicated GERD.[63] Patients were prescribed antireflux lifestyle modifications and randomly assigned to receive one of three types of treatment: (1) continuous medical therapy (antacid tablets and ranitidine taken on a daily basis regardless of symptoms, with metoclopramide and sucralfate added if necessary to control symptoms); (2) symptomatic medical therapy (the same drugs as in the continuous-medical-therapy group but used only when necessary for control of symptoms); or (3) surgical therapy (open Nissen fundoplication). All three groups showed significant improvements in the symptoms and endoscopic signs of GERD for up to 2 years. However, surgical therapy was significantly better than both medical therapies during that period, and surgical patients had higher overall satisfaction.

In the 1990s, a Scandinavian group conducted a randomized trial of omeprazole versus open antireflux surgery in 310 patients with erosive esophagitis.[64] In patients who received a fixed dose of 20 mg of omeprazole a day, antireflux surgery was superior in maintaining GERD in remission for the 3-year duration of the study. In clinical practice, however, the dose of a PPI is typically titrated to control symptoms. In this study, when the physician was permitted to titrate the PPI dose, there was no statistically significant difference between the medical group and the surgical group in maintaining remission for 3 years.

Relatively few reports have described the long-term outcome of antireflux surgery. Some uncontrolled studies have found success rates that exceed 90% at 10 to 20 years after open fundoplication,[65] whereas others have described breakdown of the operation and the return of reflux esophagitis in more than 50% of cases.[66] A follow-up study was conducted on the patients who participated in the VA cooperative study (see above).[67] During the follow-up period of 10 to 13 years, surgical patients were significantly less likely to have taken antireflux medications regularly, and when antireflux medications were discontinued, the GERD symptoms in these patients were significantly less severe than those in the medical group. However, 62% of the surgical patients took antireflux medications on a regular basis, and there were no significant differences between the groups in the rates of neoplastic and peptic complications of GERD, overall physical and mental well-being scores, and overall satisfaction with antireflux therapy. There were 79 deaths, involving 33 (40%) of the 82 surgical patients and 46 (28%) of the 165 medical patients ($P = 0.047$). For reasons that are not clear, the excess deaths in the surgical group were from heart disease. This and other studies suggest that antireflux surgery does not effect a permanent cure for GERD in the majority of patients and that surgery is no better than medication for preventing the peptic and neoplastic complications of GERD.

Endoscopic Antireflux Procedures

Two endoscopic therapies for GERD have been approved by the Food and Drug Administration. One system uses an endoscopic sewing-machine device to plicate the gastroesophageal junction; the other system delivers radiofrequency (microwave) energy to create thermal lesions in the LES muscle, which may narrow the lumen and destroy nerves that mediate TLESRs. A number of other endoscopic antireflux procedures are under in-

vestigation. Small studies describe promising results,[68,69] but the safety and efficacy of these procedures are not yet known, and their role in the treatment of GERD is not clear.

Barrett Esophagus

Barrett esophagus is a sequela of chronic GERD in which the stratified squamous epithelium that normally lines the distal esophagus is replaced by an abnormal columnar epithelium.[70] The abnormal columnar epithelium typical of Barrett esophagus is an incomplete form of intestinal metaplasia called specialized intestinal metaplasia. This metaplastic epithelium predisposes to esophageal adenocarcinoma, which develops in patients with Barrett esophagus at the rate of approximately 0.5% a year.

DIAGNOSIS

Endoscopy

The diagnosis of Barrett esophagus is established when the endoscopist sees columnar epithelium lining the distal esophagus. Columnar epithelium has a characteristic dull, reddish appearance that is readily distinguished from squamous epithelium, which is normally glossy and pale [*see Figure 6*]. The diagnosis is confirmed by esophageal biopsy specimens showing specialized intestinal metaplasia.

Barrett esophagus can be further categorized according to the extent of esophageal involvement. In traditional, or long-segment, Barrett esophagus (LSBE), specialized intestinal metaplasia extends for 3 cm or more into the distal esophagus. LSBE is usually found in patients who have severe GERD. Less than 3 cm of metaplasia constitutes short-segment Barrett esophagus (SSBE), a condition often associated with only mild GERD. It is not clear whether these two types of Barrett esophagus have the same pathogenesis and natural history, nor is it clear whether SSBE progresses to LSBE. Currently, however, SSBE and LSBE are managed similarly.

Regular endoscopic surveillance for esophageal cancer has been recommended in patients with Barrett esophagus. Retrospective studies have documented that cancers discovered during surveillance endoscopies tend to be less advanced than those detected during endoscopies performed because of cancer symptoms (e.g., dysphagia and weight loss). There is no direct proof that surveillance reduces cancer mortality in Barrett esophagus, however.

Biopsy

Esophageal biopsy specimens are taken during surveillance endoscopy primarily to identify dysplasia, a histologic diagnosis suggesting that one or more clones of epithelial cells have acquired genetic alterations rendering them neoplastic and predisposed to malignancy. Unfortunately, dysplasia is an imperfect predictor of malignancy in Barrett esophagus. The histologic abnormalities of low-grade dysplasia are not specific for neoplasia, and interobserver agreement for the diagnosis of low-grade dysplasia in Barrett esophagus may be less than 50%. For high-grade dysplasia, in contrast, interobserver agreement is approximately 85%. Dysplasia has no distinctive gross features, so endoscopists must rely on random biopsy sampling techniques to find it. Consequently, biopsy sampling error is a major problem. Of patients with Barrett esophagus whose biopsy specimens show high-grade dysplasia, approximately one third already have an invasive cancer that was missed because of sampling error. Extensive biopsy sampling can reduce, but not eliminate, this problem. Finally, the natural history of dysplasia is not well defined.

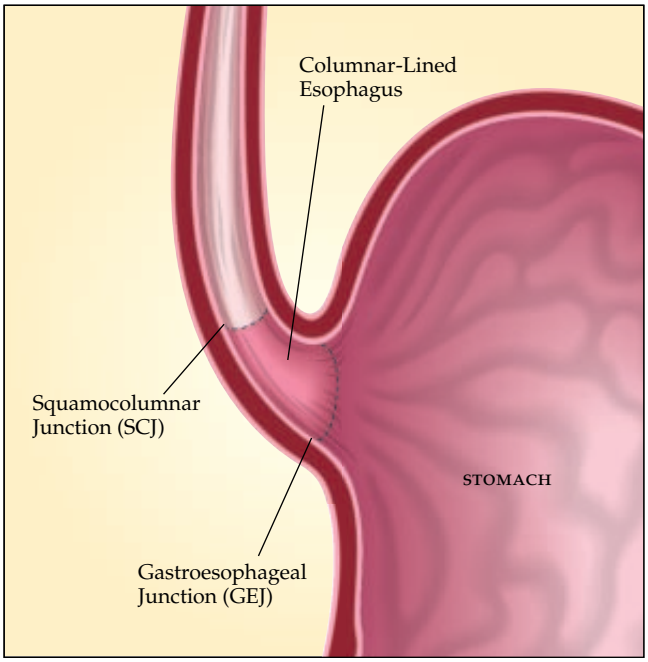

Figure 6 **In Barrett esophagus, columnar epithelium extends proximal to the gastroesophageal junction (the imaginary line at which the esophagus ends and the stomach begins, which corresponds to the most proximal extent of the gastric folds).**

Researchers have been searching for better alternatives to random biopsy sampling for dysplasia in Barrett esophagus. Other markers for malignant potential (e.g., flow cytometry and abnormalities in p53 expression) have been studied, as have endoscopic techniques to target dysplastic areas for biopsy. Despite some promising preliminary data, none of these tests and techniques has yet been shown to provide sufficient clinical information to justify its routine application in practice.

TREATMENT

Fit patients with verified high-grade dysplasia in Barrett esophagus have three management options: esophagectomy, endoscopic ablative therapy, and intensive surveillance (withholding invasive therapy until biopsy specimens show adenocarcinoma). Esophagectomy, the only therapy that clearly can prevent the progression from dysplasia to invasive cancer, is associated with operative mortality of 3% to 12% and with a 30% to 50% rate of serious operative complications. Endoscopic ablative therapies (e.g., laser photoablation and photodynamic therapy) use thermal or photochemical energy to destroy the metaplastic esophageal epithelium.[71] No study has shown that endoscopic ablation decreases the long-term risk for cancer development, so at present these therapies should be considered experimental. Although intensive surveillance for high-grade dysplasia (e.g., endoscopy every 3 months) has been endorsed as a management option by the American College of Gastroenterology, few published data directly support the safety and efficacy of the practice. The esophagus has an extensive lymphatic system and no confining serosa, features that can facilitate the spread of malignant cells and contribute to the

dismal prognosis for patients with esophageal cancer. The concern about surveillance for high-grade dysplasia is that by the time biopsy specimens reveal adenocarcinoma, the tumor already may be incurable because of systemic metastases.

Management Recommendations

A management algorithm for patients with Barrett esophagus has been developed [*see Figure 7*].[70] This strategy assumes that patients have had an initial endoscopic examination in which four-quadrant biopsy specimens are taken at intervals of 2 cm or less throughout the columnar-lined esophagus. If biopsy sampling during the initial endoscopic procedure is not adequate or if there is any question regarding the degree of dysplasia, endoscopy should be repeated to resolve these issues. If inflammation interferes with the histologic assessment of dysplasia, the patient should be treated with intensive antireflux therapy (e.g., a PPI administered at least twice daily) for 8 to 12 weeks before repeating the endoscopy. Data regarding the safety of intensive endoscopic surveillance for patients with high-grade dysplasia are limited, and available studies have involved primarily older patients. The clinician should be especially cautious in applying the results of these studies to the management of high-grade dysplasia in younger patients. Intensive endoscopic surveillance may be a valid alternative to immediate esophagectomy for older patients with high-grade dysplasia who can comply with the program. For patients who are too old, infirm, or unwilling to assume the risks of esophagectomy, endoscopic ablative therapy may be a reasonable alternative if the procedure is performed as part of a study protocol. Finally, the clinician should bear in mind that these recommendations have not been validated by studies demonstrating that this strategy prolongs survival or enhances quality of life.

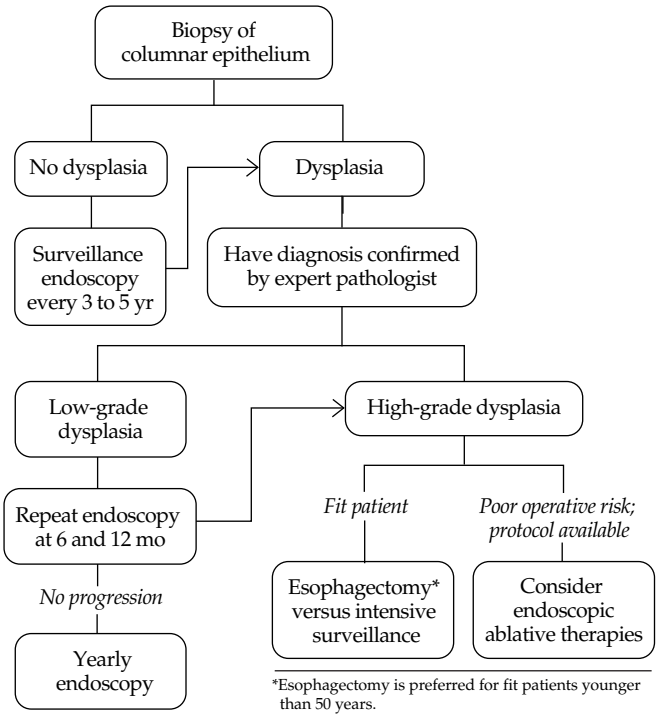

Figure 7 **Management of patients with Barrett esophagus.[73]**

Infectious Esophagitis

Most esophageal infections are caused by *Candida*, herpes simplex virus (HSV), or cytomegalovirus (CMV), alone or in combination.[6] These organisms rarely infect the esophagus of normal persons, but they often cause esophagitis in patients whose immune system has been compromised by AIDS, advanced malignancy, or the immunosuppressive drugs used to prevent rejection of organ transplants. Immune dysfunction that can accompany diabetes mellitus, alcoholism, and advanced age also may predispose to esophageal infection, especially by *Candida*. Antibiotic therapy that alters the normal microbial flora of the oropharynx and esophagus and corticosteroid therapy that suppresses immune function also can result in candidal esophagitis, as can abnormalities that delay the clearance of *Candida* from the esophagus, such as progressive systemic sclerosis (scleroderma), achalasia, and esophageal strictures.

The clinical manifestations of esophageal infections are similar, regardless of the pathogen. Dysphagia and odynophagia are the presenting symptoms in 60% to 95% of patients with infectious esophagitis, and weight loss is reported by 35%.[6] CMV esophagitis often is only one component of a generalized CMV infection, and 20% to 40% of patients with CMV esophagitis have systemic symptoms [*see* Cytomegalovirus Esophagitis, *below*]. In contrast, *Candida* and HSV esophagitis usually are not associated with infection in other organs, and systemic symptoms are uncommon. However, oral lesions (e.g., thrush and focal ulcerations) are found frequently in patients who have *Candida* and HSV esophagitis, but they are not found in patients with CMV esophagitis.

A surprising number of esophageal infections are asymptomatic. In published series, approximately one quarter of all cases of candidal esophagitis were discovered incidentally during radiographic or endoscopic examinations performed for the evaluation of extraesophageal symptoms.

CANDIDAL ESOPHAGITIS

Candida, a yeast that is part of normal oropharyngeal flora, is the most frequent cause of esophageal infections in immunocompromised patients. Most cases of candidal esophagitis are caused by *C. albicans*, although other candidal species, such as *C. tropicalis* and *C. glabrata*, occasionally infect the esophagus. Approximately 85% of patients with candidal esophagitis have oral thrush, and the combination of oral thrush and esophageal symptoms has a high positive predictive value for candidal esophagitis.

Typically, endoscopic evaluation of patients with candidal esophagitis reveals raised, white plaques that resemble cottage cheese clinging to the esophageal mucosa. On barium swallow, coating of the raised plaques and their interstices with barium gives the esophageal mucosa a characteristic irregular, shaggy appearance. Confirmation of the diagnosis requires the demonstration of budding yeast cells, hyphae, or pseudohyphae in brush cytology or biopsy specimens of the esophagus.

Several antifungal agents are available for the treatment of *Candida* infections. The decision regarding which agent to choose is influenced principally by the severity of the infection and the severity of the patient's immunocompromise. A patient who has a mild esophageal infection and minimal immunocompromise (e.g., a young patient who develops mild candidal esophagitis during a limited course of steroid therapy for asthma) often can be treated effectively with a topical anti-

fungal agent such as clotrimazole. In contrast, a patient with moderately severe candidal esophagitis and substantial immunocompromise (e.g., a patient with troublesome odynophagia and AIDS) usually requires the oral administration of a systemic antifungal agent such as fluconazole. Patients who have severe infection and profound immunocompromise (e.g., disseminated candidiasis or candidal esophagitis in the setting of severe granulocytopenia) generally require treatment with intravenous amphotericin B [*see 7:XXXVIII Mycotic Infections in the Compromised Host*].

herpes simplex virus esophagitis

Primary HSV infections of the oropharynx are common in the general population, and they result when oral mucous membranes or breaks in the facial skin are exposed to secretions from a person with an active HSV infection. The virus enters the nerves that supply the infected epithelium, where it remains in latent form after healing of the primary infection. The latent virus in the neurons can be reactivated and spread to epithelial cells through the nerve fibers. In immunocompetent persons, HSV reactivation commonly causes cold sores of the lips (herpes labialis). When reactivation of latent virus occurs in the setting of immunodeficiency, however, HSV can spread to involve the squamous epithelium of the oropharynx and esophagus.

The endoscopic findings in persons with HSV esophagitis vary with the duration of infection.[72] The earliest lesions are small (1 to 3 mm), rounded vesicles that usually involve the middle to distal esophagus. Sloughing of the vesicles results in small, sharply demarcated ulcers that have raised margins and a yellowish base. In severe cases, the small ulcers coalesce to form large ulcers that can be covered with dense exudates resembling candidal plaques.

Histologic diagnosis is best accomplished by examining biopsy and brush cytology specimens from the squamous epithelium at the edges of ulcerated areas. Specimens obtained from the ulcer base often contain only nonspecific granulation tissue and exudates. Typical histologic changes in HSV infection include multinucleated giant cells and intranuclear Cowdry type A inclusion bodies.

In immunocompetent patients, HSV esophagitis usually is a short-lived illness that may require no therapy other than supportive care and expectant management. HSV esophagitis often does not resolve spontaneously in immunocompromised patients, however, so such patients should receive systemic antiviral therapy. Acyclovir currently is the drug of choice for HSV infections of the esophagus.

cytomegalovirus esophagitis

CMV is a ubiquitous herpesvirus that usually is transmitted from person to person by exposure to infected secretions. The virus can also be transmitted through transfused blood that carries infected leukocytes or through transplanted infected organs. CMV can infect virtually any tissue in the body, and after recovery from the primary infection, evidence of latent CMV infection can be found in most organs. With the development of immunodeficiency, the latent virus can reactivate and cause esophagitis.[73] Immunocompromised patients can also develop CMV esophagitis during primary CMV infections. CMV esophagitis is extremely uncommon in immunocompetent persons.

Patients who have CMV esophagitis often have widespread CMV infection, with systemic symptoms such as fever, weight loss, nausea, vomiting, and diarrhea. CMV tends to cause discrete, shallow esophageal ulcerations that are very elongated (up to 15 cm in length) and surrounded by normal-appearing esophageal mucosa. Tissue sampling for histologic examination and culture is necessary to distinguish these giant CMV ulcerations from the giant idiopathic esophageal ulcerations that can be associated with HIV infection.

Histologic examination of cells infected with CMV reveals distinctive abnormalities that include cellular enlargement and inclusion bodies in both the nucleus and the cytoplasm. Although the virus is found most often in fibroblasts and endothelial cells, biopsy specimens from granulation tissue in the base of the esophageal ulcer have a higher yield on histology and culture than specimens from squamous epithelial cells at the edges of the ulcer. Unfortunately, no single test for CMV infection is highly sensitive. In a study of 14 bone marrow transplant recipients who developed CMV disease, for example, conventional and centrifugation cultures of endoscopic biopsy specimens identified the organism in only 57% of patients, and conventional histologic examination of the specimens revealed characteristic findings in only 30%.[74] For patients with negative test results, therefore, repeated diagnostic testing may be necessary if the suspicion of CMV infection is high. However, evidence of CMV infection is not proof of the presence of CMV disease. The mere identification of CMV in an inflamed esophagus does not establish that CMV is the cause of the inflammation.

CMV disease can respond to treatment with ganciclovir. Maintenance therapy with ganciclovir may be indicated for patients who have recurrences of CMV disease or who have a high risk of recurrence (e.g., patients with advanced AIDS). Prophylactic antiviral therapy is commonly recommended for recipients of solid-organ and bone marrow transplants.

esophageal disease in hiv infection

Within 2 to 3 weeks after primary exposure to HIV, some patients develop a self-limited, infectious mononucleosis–like illness with malaise, fever, myalgias, pharyngitis, and rash. This acute HIV seroconversion syndrome can be complicated by the development of esophageal ulcerations that cause odynophagia.[75] Endoscopically, the ulcers are typically multiple, round, 3 to 15 mm in diameter, well demarcated, and surrounded by normal-appearing esophageal mucosa. Usually, the ulcers heal and the symptoms of the acute HIV seroconversion syndrome resolve spontaneously within 2 weeks. Patients then may remain asymptomatic for years until the development of AIDS.

Symptoms of esophageal disease occur in 30% to 40% of AIDS patients.[76] Although the symptoms are usually from infections with *Candida*, HSV, or CMV, these patients can also have large esophageal ulcerations in which no pathogenic microorganism can be identified by culture or by histologic and immunohistochemical tests. Radiographically and endoscopically, HIV-associated idiopathic ulcerations of the esophagus closely resemble the large esophageal ulcerations caused by CMV. HIV-associated idiopathic esophageal ulcerations can be found in approximately 10% of patients with AIDS who complain of esophageal symptoms and in up to 40% of such patients who have discrete esophageal ulcerations on endoscopic examination.

HIV-associated idiopathic ulcerations generally do not respond to therapy with antimicrobial agents. Rather, patients with these lesions usually experience symptomatic relief and ulcer healing during treatment with systemic corticosteroids. Al-

though corticosteroid therapy entails substantial risk for patients who already are profoundly immunosuppressed, the treatment is surprisingly well tolerated in most cases. The injection of methylprednisolone through the endoscope directly into idiopathic ulcerations also has resulted in relief of esophageal symptoms in some cases, but experience with this treatment is limited. Finally, thalidomide, which has immunomodulatory effects, has been used successfully to treat idiopathic ulcerations.

Candida is by far the most common cause of esophageal infection in AIDS, and candidal esophagitis is found in more than 50% of AIDS patients who have esophageal symptoms. Although CMV and HSV esophagitis also occur commonly in AIDS patients, these viruses often are not the sole pathogens that can be identified in the inflamed esophagus. CMV usually is discovered in biopsy specimens from an esophagus that is also infected by *Candida*, and most patients with coexistent CMV and candidal esophagitis respond well to antifungal therapy alone. Consequently, authorities have recommended that patients with AIDS who have esophageal symptoms should be treated empirically with antifungal therapy, usually fluconazole; endoscopy is reserved for patients who fail to respond to empirical treatment.

Esophageal Cancer

EPIDEMIOLOGY

The two major histologic types of esophageal cancer, squamous cell carcinoma and adenocarcinoma, differ profoundly in their epidemiologic features.[77] Squamous cell carcinoma of the esophagus has a strong predilection for blacks and Asians, whereas esophageal adenocarcinoma is predominantly a disease of whites. In the United States, the incidence of squamous cell carcinoma of the esophagus is six times greater in African Americans than in whites, whereas esophageal adenocarcinoma is at least four times more frequent in whites than in African Americans. Worldwide, more than 90% of all esophageal cancers are squamous cell carcinomas; this tumor ranks among the world's 10 most frequent malignancies. Exceptionally high incidence rates of squamous cell carcinoma are found in the Transkei region of South Africa, in southern Brazil, in parts of northern France and Italy, and throughout an esophageal cancer belt that extends from the shores of the Caspian Sea of Iran across northern China. In the Henan province of China, the incidence of esophageal squamous cell carcinoma exceeds 100 per 100,000. In the United States, in contrast, the incidence of this tumor in the general population is less than 4 per 100,000. In most countries, cancer of the esophagus affects men two to four times more often than women.

RISK FACTORS

GERD and Barrett esophagus are the major risk factors for adenocarcinoma of the esophagus.[70] For squamous cell carcinoma, cigarette smoking and alcoholism are the major risk factors.[78] The combination of cigarette smoking and alcoholism appears to have a synergistic (rather than merely additive) effect in esophageal carcinogenesis, but the mechanism of this synergy is not known. Generalized malnutrition and a variety of specific nutritional deficiencies, including deficiencies in vitamin A, vitamin C, magnesium, selenium, and zinc, have been associated with squamous cell carcinoma. In contrast, obesity is a risk factor for adenocarcinoma. Carcinogens such as *N*-nitroso compounds can be formed from the nitrates and amines in pickled vegetables and cured meats, and ingestion of these foods has been linked to esophageal cancer. Regional practices such as opium smoking and the long-term ingestion of very hot foods and beverages may contribute to the pathogenesis of squamous cell cancers. Also, some high-incidence areas for squamous cell carcinoma have soils that are deficient in certain elements, such as molybdenum and zinc.

Local differences in endemic microflora have been proposed as underlying reasons for some of the regional variations in the incidence of esophageal squamous cell carcinoma. For example, the food and water in some high-incidence areas are contaminated with fungi and bacteria that promote the formation of *N*-nitroso compounds from dietary nitrates. The human papillomavirus (HPV) can infect squamous epithelial cells, and HPV infection has been implicated in the development of squamous cell carcinoma of the esophagus. In high-incidence regions for esophageal cancer, such as China and South Africa, researchers have found HPV DNA in more than 20% of squamous cell carcinomas. In low-incidence areas, such as the United States, however, esophageal tumors generally do not show evidence of HPV infection.

A number of medical conditions predispose to the development of esophageal squamous cell carcinoma. Patients with tylosis, a rare heritable disorder characterized by hyperkeratosis of the palms and soles, are at very high risk for development of the esophageal tumor. These patients have mutations in the tylosis esophageal cancer gene, a putative tumor suppressor gene located on the long arm of chromosome 17. Achalasia, lye stricture of the esophagus, and Plummer-Vinson, or Paterson-Kelly, syndrome also are risk factors for squamous cell cancers, perhaps because these conditions are associated with stasis of esophageal contents that leads to chronic inflammation of the mucosa. Squamous cell cancer of the esophagus is strongly associated with malignancies of the head, neck, and lungs, probably because these tumors share the strong risk factor of cigarette smoking. Finally, celiac sprue has been associated with esophageal cancer, for reasons that are not clear.

DIAGNOSIS

Clinical Features

Most patients with cancer of the esophagus present with dysphagia and weight loss. The dysphagia usually involves solid foods only and progresses rapidly in severity (over a period of weeks to months). Approximately 60% of patients who have esophageal adenocarcinoma have a long-standing history of GERD symptoms. Proximal esophageal tumors can invade the recurrent laryngeal nerve, causing vocal cord paralysis with hoarseness. The development of coughing associated with swallowing may indicate that the tumor has invaded the airway and caused an esophagobronchial fistula. Ulcerated tumors can cause odynophagia, and tumor necrosis occasionally causes esophageal hemorrhage. Local tumor invasion can cause chest pain, and metastatic disease can cause bone pain. Symptoms of esophageal cancer generally develop only when the tumor has grown to the extent that it has narrowed the lumen of the esophagus substantially, has invaded local structures, or has metastasized. Therefore, the presence of symptoms usually indicates advanced disease and a poor prognosis.

Figure 8 **Barium swallow showing an extensive cancer of the esophagus.**

Diagnostic Studies

Barium swallow and endoscopy Both barium swallow and endoscopy are useful for the evaluation of patients with esophageal cancer. Radiographic features that suggest malignancy include irregular borders and sharp angles [*see Figure 8*]. Endoscopically, esophageal cancers typically appear as nodular lesions that protrude into the lumen of the esophagus [*see Figure 9*]. In Asian countries where there is a high incidence of esophageal cancer, endoscopists often recognize early esophageal cancers that cause either slight elevations or shallow depressions in the mucosal surface. Staining of the esophagus with vital dyes such as toluidine blue or Lugol iodine (chromoendoscopy) can be useful for finding such early lesions during endoscopic evaluation. These superficial esophageal cancers are diagnosed infrequently in western countries.

Imaging studies Computed tomography of the chest and abdomen generally is recommended to assess the extent of disease within the chest and to look for metastases. However, the sensitivity and specificity of CT for determining the depth of esophageal tumor penetration (the T level) and the presence of regional lymph node metastases (the N status) are poor. Endoscopic ultrasonography (EUS) is superior to CT in this regard, accurately predicting the T level and N status in 70% to 80% of patients.

Invasive modalities In addition to EUS, invasive diagnostic modalities sometimes used for the staging of esophageal cancer include bronchoscopy, laparoscopy, thoracotomy, and thoracoscopy. There is little consensus regarding the need for these procedures in the routine evaluation of patients with esophageal cancer, and usage of the procedures varies widely among different institutions.

MANAGEMENT

Cancer of the esophagus usually is disseminated at the time of diagnosis, and because there is no treatment that reliably eradicates metastatic disease, cure is not possible in most cases. Furthermore, patients are often elderly, and many have severe comorbidities (e.g., malnutrition or pulmonary, cardiac, or liver disease) that further limit their treatment options. Initial treatment usually involves a choice between surgery, radiation therapy, chemotherapy, and some combination of these three modalities.[79,80] Squamous cell cancer and adenocarcinoma are treated similarly, with similarly poor survival rates. Despite recent advances in therapeutic options, overall cure rates for cancer of the esophagus remain below 10%.

Surgical therapy Esophagectomy, with or without lymphadenectomy, can provide immediate palliation of symptoms and, arguably, the best potential for cure of esophageal cancer. Mortality for esophagectomy ranges from 3% to more than 12%, and serious complications of the operation (e.g., pneumonia, atelectasis, arrhythmias, myocardial infarction, heart failure, wound infections, and anastomotic leaks) can be expected in 30% to 50% of patients. Cure rates vary widely among institutions. Prognostic factors include tumor stage and the number of positive lymph nodes. Surgery generally is not recommended for patients who have metastatic disease.

Radiation therapy The acute mortality of radiation therapy is low, and radiation can cover a wider treatment area than is practical with surgery (to eradicate local and regional disease). However, radiation therapy usually takes 2 to 8 weeks to complete; palliation can be delayed for weeks; there can be substantial radiation damage to surrounding normal tissues; and the overall cure rate is low. Trials of radiation therapy as the

Figure 9 **Endoscopic photograph of an esophageal adenocarcinoma.**

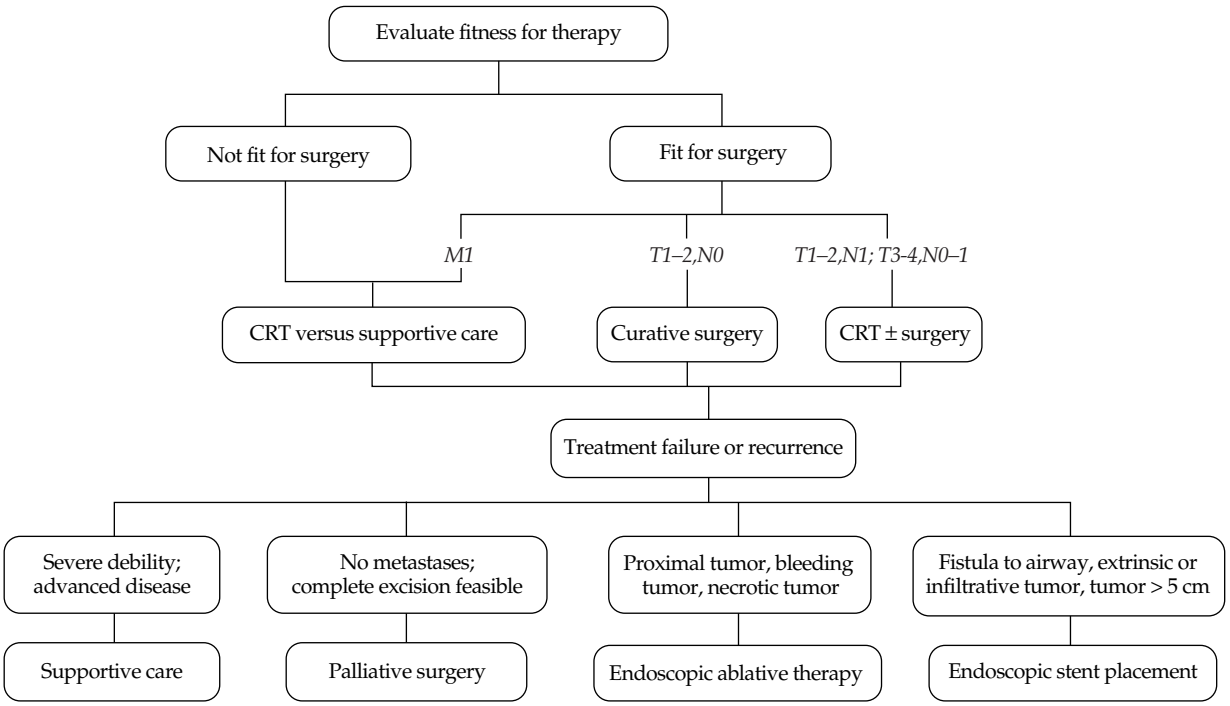

Figure 10 **Management of patients with cancer of the esophagus. (CRT—chemoradiotherapy)**

sole treatment modality for esophageal cancer have involved primarily patients with advanced squamous cell carcinomas that were deemed unresectable. Results appear to be comparable to surgery, but there are no randomized trials directly comparing radiation therapy alone with surgery alone.

Chemotherapy Chemotherapy has the potential to reach the disseminated disease that usually is present in symptomatic patients. Unfortunately, chemotherapy is associated with substantial morbidity and considerable mortality; it is often ineffective; and the tumor response, if any, is often brief. Studies of chemotherapy as the sole treatment modality have included primarily patients with unresectable tumors. Modern studies have used cisplatin-based regimens, and response rates appear to be better with combination regimens than with single agents. Chemotherapy alone does not appear to improve survival, however.

A number of studies have explored the role of radiation therapy or chemotherapy used either before (neoadjuvant) or after (adjuvant) definitive surgery for squamous cell carcinoma of the esophagus. Unfortunately, most randomized, controlled trials have shown no convincing benefit for neoadjuvant or adjuvant treatment with either radiation therapy or chemotherapy for patients with potentially resectable tumors. One recent trial showed a modest survival benefit for patients who received preoperative chemotherapy in a relatively low dose, however.[80]

Combination therapy Much recent interest has focused on the role of combining chemotherapy with radiation therapy (chemoradiotherapy) for esophageal cancer.[81] In some studies of patients treated with chemoradiotherapy followed by esophagectomy, complete histologic response (defined as no histologic evidence of tumor in the resected specimen) has been observed in almost 30% of cases. Complete histologic response is not tantamount to cure, however, and even complete responders frequently succumb to recurrent disease. Furthermore, chemoradiotherapy is associated with serious toxicity. Some randomized trials of chemoradiotherapy for patients with potentially resectable tumors have shown significant improvements in survival, whereas others have not. Consequently, the role of chemoradiotherapy remains unclear. Preliminary studies suggest that patients who have locally advanced tumors might benefit from preoperative chemoradiotherapy.

Palliative therapy Purely palliative therapies include esophageal dilatation and the placement of intraluminal stents. There also are palliative techniques designed to ablate the portion of the neoplasm that obstructs the esophageal lumen. These ablative therapies include endoscopic laser irradiation, the application of tumor probes that burn the neoplasm directly, the injection of caustic chemicals directly into the tumor body, and photodynamic therapy that uses photochemical energy to destroy the tumor.

Given that the optimal treatment for cancer of the esophagus is not clear, patients should be treated according to well-designed, established research protocols whenever possible. If the initial use of research protocols is not feasible, management should be individualized [*see Figure 10*]. After staging of the tumor that includes at least EUS and a CT scan of the chest and abdomen, the next step is to decide whether the patient is fit enough to undergo surgery. If surgery is not a viable option because of advanced age or comorbidity, primary therapy might include chemoradiation or supportive care alone. In general, surgery is not indicated for patients with metastatic disease. For tumors that do not invade beyond the muscularis propria and do not involve local lymph nodes, surgery appears to offer the best hope for cure. For lesions that are more advanced (i.e., with lymph node involvement or invasion to the esophageal adventitia and beyond), the choices for primary therapy include chemoradiation with or without surgery.

If these primary treatments fail or if the tumor recurs, there are a number of palliative treatment options. For patients who are severely debilitated and have advanced disease, the most humane option may be supportive care only, with careful attention to pain control. If there are no apparent metastases and complete excision of the tumor is possible, surgery can be considered for palliation. The other options are ablative therapies or stents. Stents may not provide good palliation for patients with proximal tumors, bleeding tumors, and necrotic tumors; ablative therapy may be preferable in these circumstances. Alternatively, ablative therapy has little to offer for a patient with an esophagobronchial fistula or for a patient with a tumor that is extrinsic or infiltrative. Also, ablative therapy may be difficult and time-consuming for patients with very long tumors. Stenting may be preferable in these circumstances.

II PEPTIC ULCER DISEASES

MARK FELDMAN, M.D.

Definition

Peptic ulcers are holes in the inner lining of the gastrointestinal (GI) tract that are attributed to exposure of the mucosa to gastric acid and pepsin. Peptic ulcers extend through the mucosa and the muscularis mucosae, a thin layer of smooth muscle separating the mucosa from the deeper submucosa, muscularis propria, and serosa. Most peptic ulcers are round or oval, but some are linear, triangular, or irregular in shape. Ulcers have depth when viewed through an endoscope. Typically, only a single ulcer is present. An erosion is a focal loss of superficial epithelial cells and glands, without extension through the muscularis mucosae. On endoscopy, erosions appear as breaks in the mucosal lining without depth. At the other extreme, a peptic ulcer may burr itself entirely through the wall of the GI tract, thus connecting the GI lumen with the peritoneal cavity (perforated ulcer), a solid organ such as the pancreas (penetrating ulcer), or another hollow organ such as the intestine or bile duct (fistulizing ulcer).

Epidemiology

In the United States, peptic ulcer disease affects 10% of men and 4% of women at some time in their lives. The incidence is influenced by age (older persons are more susceptible than younger persons) and gender (males are more susceptible than females). Because ulcer disease is often recurrent, its prevalence exceeds its incidence. Eradication of *Helicobacter pylori* from the stomach markedly reduces recurrence of ulcer disease. With the widespread use of treatment regimens for *H. pylori*, the prevalence of peptic ulcer is decreasing in the United States. Reinfection with *H. pylori* remains an uncommon event in the United States (approximately one reinfection per 100 patients a year).

Pathogenesis and Etiologic Factors

The normal stomach and duodenum are able to resist autodigestion by acid-pepsin. However, high rates of acid-pepsin secretion or impaired mucosal resistance factors, such as prostaglandin deficiency, can predispose to duodenal ulcer formation (typically in the most proximal part of the duodenum, the bulb) or to gastric ulcer formation (typically in the most distal part of the stomach, the antrum).

On rare occasions, peptic ulcers occur in the second, third, or fourth portion of the duodenum (postbulbar ulcer) or even in the proximal jejunum. Ordinarily, alkaline secretions from the duodenum, biliary tract, and pancreas neutralize gastric acid in the duodenum, but high rates of gastric acid secretion (e.g., in Zollinger-Ellison syndrome) can overwhelm these endogenous alkaline secretions and lead to postbulbar or jejunal ulcerations.

In patients with pathologic amounts of gastroesophageal reflux of acid-pepsin and in many patients with gastric acid hypersecretion, erosions and ulcers may develop in the lower esophagus [*see 4:I Esophageal Disorders*]. Peptic ulcers may also occur where acid and pepsin are secreted heterotopically, such as in a congenital ileal (Meckel) diverticulum.

Regardless of location and etiology, chronic peptic ulcers are similar pathologically. In addition to the focal loss of mucosal epithelial cells, these ulcers have four characteristic layers at their base: fibrinoid necrosis, exudate, granulation tissue, and a fibrous scar, the deepest layer. A layer of granulation tissue and fibrosis may be absent in acute ulcers that occur in settings of serious trauma or severe surgical or medical illnesses [*see* Acute Stress Ulcers, *below*].

Why a peptic ulcer is such a focal lesion is unclear. Although peptic ulcers require the presence of acid-pepsin, acid-pepsin alone is only rarely sufficient to produce an ulcer—such as in Zollinger-Ellison syndrome, in which marked gastric hypersecretion is present. In the majority of patients, there must be another predisposing factor, such as *H. pylori* infection of the stomach,[1,2] use of nonsteroidal anti-inflammatory drugs (NSAIDs), or stress [*see Figure 1*].

H. PYLORI ULCERS

The prevalence of *H. pylori* infection of the stomach is much higher in duodenal ulcer patients and, to a somewhat lesser extent, in gastric ulcer patients than in age-matched control subjects [*see Figure 2*].[3] In addition, cure of *H. pylori* infection with antimicrobial therapy markedly reduces recurrences of duodenal and gastric ulcers.[4,5] The correlation of *H. pylori* infection with peptic ulcers is not consistent, however. Duodenal ulcers develop in some infected persons and gastric ulcers in others, but most infected persons experience no ulcers at all. Patients with duodenal ulcers tend more often to be infected with *cagA*-positive strains than do *H. pylori*–infected patients without ulcer,[6] but how this is mediated is not clear.

The etiologic mechanism linking *H. pylori* infection with ulcer development is not yet absolutely established, for the following reasons: (1) voluntary ingestion of *H. pylori* led to gastric *H. pylori* infection and to gastritis but not to ulcers; (2) duodenal or gastric ulcers develop in only 10% to 20% of individuals with *H. pylori* gastritis, implying that only certain persons with additional genetic, anatomic, physiologic, or environmental risk factors are predisposed to ulcers or that only certain *H. pylori* strains are ulcerogenic; (3) *H. pylori* induces diffuse inflammation in the stomach, yet the strongest link between *H. pylori* and peptic ulcer is with focal duodenal bulbar ulcer; and (4) gastric *H. pylori* infection is as common in women as in men, yet duodenal ulcer is two to three times less common in women. Currently, *H. pylori* can be considered the most important risk factor for duodenal and gastric ulcers, but it is clear that the mere presence of *H. pylori* in the stomach is not sufficient to cause peptic ulcers [*see Figure 1a*].

NSAID ULCERS

The ulcerogenicity of NSAIDs has been established experimentally by exposing animals, human volunteers, and patients to these drugs. Experimental studies have been corroborated by numerous case-control studies and autopsy studies. Unlike *H. pylori*–related peptic ulcers, which more often occur in the duodenal bulb, NSAID ulcers typically occur in the stomach. A gastric or duodenal ulcer associated with NSAID use is classified as a peptic ulcer, and it usually heals with potent acid antisecretory therapy, even if NSAID use is continued. NSAIDs can also cause ulcers in the jejunum, ileum, or colon, areas where there is little

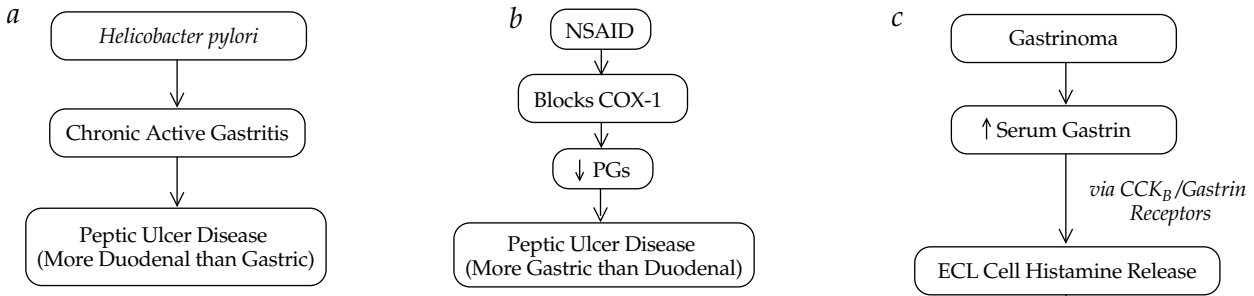

Figure 1 **Etiopathogenesis of peptic ulcers. (*a*) *Helicobacter pylori* induces a diffuse, chronic, active superficial gastritis, usually throughout the stomach. Exactly how this infectious gastritis results in peptic ulcer disease is unknown. (*b*) Nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) block cyclooxygenase-1 (COX-1) to reduce the amount of gastroduodenal prostaglandins (PGs) synthesized from their precursor, arachidonic acid. COX-2 selective NSAIDs produce a lesser reduction in prostaglandins and are associated with fewer peptic ulcers than nonselective COX-1– or COX-2–inhibiting NSAIDs. (*c*) Gastrinoma cells in the pancreas or duodenum secrete large amounts of gastrin into the circulation. Elevated serum gastrin levels promote the release of histamine by acting on receptors for cholecystokinin$_B$ (CCK_B) and for gastrin, which are located on gastric enterochromaffin-like (ECL) cells. Histamine acts on H_2 receptors on parietal and chief cells to augment hydrochloric acid (HCl) and pepsin secretion.**

or no acid-pepsin. These ulcers are not actually peptic ulcers.

Although the pathogenesis of NSAID ulcers is multifactorial, by far the most important mechanism appears to be inhibition of cyclooxygenase-1 (COX-1), the rate-limiting enzyme in GI prostaglandin synthesis [*see Figure 1b*]. Prostaglandins normally protect the GI mucosa from damage by maintaining mucosal blood flow and increasing mucosal secretion of mucus and bicarbonate. Blockade of COX-1 activity by NSAIDs reduces prostaglandin synthesis and thus lowers GI mucosal blood flow and secretion of mucus and bicarbonate. Evidence continues to accumulate that in NSAID users, *H. pylori* gastritis produces about a twofold increase in the risk of gastroduodenal ulcer formation.[7] Moreover, clinically symptomatic peptic ulcers occur much less commonly if *H. pylori* gastritis is treated before the start of long-term NSAID therapy.[8] Clinically diagnosed peptic ulcers will develop in approximately 2% to 4% of persons taking NSAIDs per year of exposure. The extent to which the damaging effects of NSAIDs on the stomach are topical rather than systemic is unclear. Many NSAIDs, such as aspirin, are acidic and thus nonionized in the acidic stomach, where they can be absorbed and initiate gastric mucosal damage. However, NSAIDs (e.g., ketorolac) given by parenteral injection and aspirin given transdermally are ulcerogenic, as are so-called NSAID prodrugs, such as sulindac and nabumetone (neither drug inhibits gastric prostaglandins until it is metabolized to its active form after GI absorption). Evidence suggests that acute mucosal damage by NSAIDs (i.e., hemorrhages and erosions, but seldom ulcers) is mainly caused by the topical damaging effects of NSAIDs. Chronic ulcer formation, often with complications such as bleeding and perforation, is mainly the result of the systemic effect of NSAIDs on prostaglandin synthesis by the GI mucosa.

Epidemiologic studies suggest that NSAIDs vary in their ability to cause ulcers,[9] but this issue is complicated by the difficulty of comparing equipotent doses of NSAIDs. All prescription or over-the-counter NSAIDs should be considered ulcerogenic, with the risk of ulcer dependent on dosages and other patient-related factors, particularly advanced age and previous ulcer history. Even low doses of aspirin used for prophylaxis of cardiovascular disease (75 to 325 mg/day) are ulcerogenic.[10] Neither buffering of aspirin nor enteric coating appears to reduce the incidence of clinically detected ulcer formation.[11] Nonacetylated salicylates such as salicylsalicylic acid (salsalate) do not block COX-1 and are not ulcerogenic. Epidemiologic studies indicate that the greatest risk of NSAID ulcers is early in the course of treatment (between day 7 and day 30 after initiation), with the risk decreasing thereafter.

Most NSAIDs, including aspirin, block both COX-1 and COX-2. Unlike COX-1, COX-2 is induced and expressed at inflammatory sites but not in the normal GI tract.[12] Selective COX-2 inhibitors (coxibs) such as celecoxib and valdecoxib

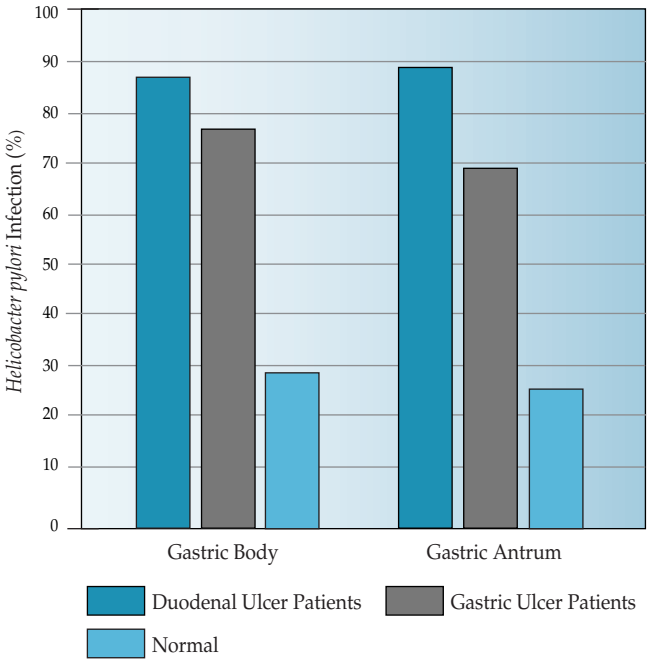

Figure 2 **Prevalence of *H. pylori* infection in either the gastric body or the gastric antrum, as assessed by endoscopic biopsy and mucosal histology. Normal control subjects were matched by age and sex to patients with duodenal ulcers and to patients with gastric ulcers. None of the ulcer patients were receiving aspirin or NSAIDs.[3]**

are analgesic and anti-inflammatory but seem to cause less GI ulcer formation than currently available cyclooxygenase inhibitors when used in recommended doses.[13,14] Whether routine use of coxibs in place of nonselective NSAIDs will be cost-effective remains to be demonstrated.

Corticosteroids, which block COX-2 but not COX-1,[12] are not ulcerogenic when used alone, although they impair healing of preexisting ulcers. When corticosteroids are used in combination with NSAIDs, the risk of ulcer formation is much greater than when NSAIDs are used alone.

ulcers in gastrinoma or other hypersecretory states

A gastrinoma is an endocrine tumor of the pancreas or duodenum (usually malignant) consisting of gastrin (G) cells. Gastrinoma causes less than 1% of all peptic ulcers. Peptic ulcers develop in 95% of patients with gastrinoma (Zollinger-Ellison syndrome); ulcers occur most commonly in the duodenal bulb but are also seen in the postbulbar duodenum, jejunum, lower esophagus, and stomach. Multiple ulcers are present in up to 25% of cases of Zollinger-Ellison syndrome.

Patients with a gastrinoma have high circulating levels of gastrin [*see Figure 1c*], which acts on receptors for cholecystokinin$_B$ (CCK_B) and gastrin located on enterochromaffin-like (ECL) cells within the mucosa of the gastric body. ECL cells then release histamine, which acts on H_2 receptors present on the membrane of neighboring parietal cells to stimulate (via an adenylate cyclase–cyclic adenosine monophosphate [cAMP]–mediated pathway) the secretion of hydrochloric acid by a unique proton pump, the H^+,K^+–ATPase pump. Of less physiologic importance, gastrin also acts directly on CCK_B/gastrin receptors on parietal cells, increasing cytosol calcium levels in the parietal cells.

Hypergastrinemia in Zollinger-Ellison syndrome results in a continuous high rate of secretion of hydrochloric acid and pepsin, even under basal (fasting) conditions. These secretions overwhelm the buffering and neutralizing capacity of food and upper digestive secretions, as well as mucosal defense factors. Peptic ulceration results, and in many cases, diarrhea (with or without malabsorption) occurs.

Approximately 20% to 30% of patients with gastrinomas have features suggesting a multiple endocrine neoplasia type I (MEN I) syndrome, such as hypercalcemia secondary to hyperparathyroidism, a pituitary adenoma, or both. MEN I is inherited as an autosomal dominant disorder.

Some patients with duodenal ulcer have marked acid hypersecretion but normal serum gastrin levels. A few of these patients have hyperhistaminemia caused by systemic mastocytosis or chronic basophilic leukemia. However, the majority of patients have no known reason for the acid hypersecretion (idiopathic basal acid hypersecretion), although some are infected with *H. pylori*. Eradication of *H. pylori* in these individuals may reduce basal acid hypersecretion.

idiopathic ulcers

In the United States, up to 20% of cases of chronic gastric and duodenal ulcers occur in patients who have no evidence of *H. pylori* infection, deny taking NSAIDs, and have normal serum gastrin concentrations. These ulcers are referred to as idiopathic peptic ulcers. Some patients with this disorder may be taking NSAIDs surreptitiously or are unaware that they are taking these drugs. In others, emotional stress, perhaps associated with gastric acid hypersecretion, may be a contributing factor.[15] Cigarette smoking is also a risk factor for peptic ulcers.

acute stress ulcers

Acute gastroduodenal erosions and ulcers are very common in patients with serious medical and surgical conditions.[16] Such conditions include severe head injury (Cushing ulcers); burn injury (Curling ulcers); major surgical procedures; and life-threatening illnesses such as septic shock, respiratory failure requiring mechanical ventilation, hepatic failure, renal failure, and multiorgan failure. Unlike peptic ulcers, stress ulcers are typically asymptomatic, rarely causing dyspepsia or epigastric pain. Approximately 10% to 25% of patients with acute stress ulcers experience painless upper GI bleeding of variable severity. Bleeding may manifest itself in the intensive care unit as a dark (so-called coffee-ground) or bloody nasogastric aspirate, as a declining hematocrit, as an increasing transfusion requirement, or as unexplained hypotension.

The pathogenesis of stress ulcers is not well understood. The common denominator seems to be tissue hypoxia and acidosis, precipitated by mucosal vasoconstriction and ischemia. Systemic hypoxia, metabolic acidosis, anemia, and reduced cardiac output often are contributing factors. Once mucosal hypoxia develops, mucosal defense factors are impaired and the cells lining the stomach and duodenum become vulnerable to damage by acid-pepsin. Acute stress ulcers have become less common because of the routine use of effective prophylactic medications in patients at high risk for this condition (see below).

cameron ulcers

Linear gastric erosions that occur in a hiatus hernia are known as Cameron ulcers.[16] The erosions are thought to be related either to traumatic injury of the stomach by the surrounding diaphragm or to mucosal ischemia at the point where the stomach herniates through the diaphragm. Like acute stress ulcers, Cameron ulcers tend to present as bleeding without dyspepsia. Both acute and chronic GI blood loss are possible outcomes of Cameron ulcers.

Diagnosis

clinical manifestations

Peptic ulcers produce a variety of symptoms but none specific for the disease. Also, symptoms of duodenal ulcer are indistinguishable from those of gastric ulcer. Patients with uncomplicated ulcers typically experience mild to moderate abdominal pain, usually in the epigastrium. However, the pain may be localized to the left or right upper quadrant of the abdomen, to the lower chest (subxiphoid or substernal), the midabdomen, or the back. The pain is often gnawing or burning. It may occur in the middle of the night; rarely, it occurs upon first awakening in the morning. Discomfort is typically relieved by food or an antacid.

Severe pain or a rapid increase in pain suggests an ulcer complication (e.g., perforation or penetration) or another diagnosis (e.g., acute pancreatitis). Associated dyspeptic symptoms include nausea, bloating, heartburn, and belching. Although vomiting may occur with uncomplicated peptic ulcers and may temporarily relieve pain, repeated vomiting suggests an ulcer complication (e.g., gastric outlet obstruction) or another diagnosis (e.g., intestinal obstruction).

Peptic ulcers are the most common cause of acute upper GI bleeding. Therefore, hematemesis, melena, or both, even in a patient with no history of ulcer and no dyspeptic symptoms, should suggest the possibility of a bleeding peptic ulcer. Patients

who develop ulcers while taking prescription or over-the-counter NSAIDs or low (cardiovascular) doses of aspirin often have no history of ulcerlike pain. Other patients with bleeding ulcers will have experienced dyspeptic symptoms for the preceding days or weeks, only to have these symptoms wane when bleeding ensues.

In addition to a review of the patient's symptoms and ulcer risk factors (particularly NSAID use and smoking), a family history should be obtained. A family history of ulcer can usually be attributed to within-family infection by *H. pylori*, to NSAID use, or to smoking. However, a family history of ulcer, hyperparathyroidism, kidney stones, or endocrine tumor should alert the physician to the possibility of gastrinoma (Zollinger-Ellison syndrome), with or without autosomal dominant MEN I syndrome.

PHYSICAL EXAMINATION FINDINGS

In uncomplicated peptic ulcer disease, the examination is generally normal. The presence of epigastric tenderness does not distinguish dyspepsia caused by peptic ulcer from other types of dyspepsia.

Patients who have complicated ulcers often have tachycardia and hypotension, which are exaggerated when the patient assumes an upright position. These findings may indicate a bleeding ulcer, a perforated ulcer with peritonitis, or an obstructing ulcer with protracted vomiting and volume depletion. Pulse and blood pressure measurements may give misleading information about the extent of volume contraction if the patient has preexisting hypertension, has cardiovascular disease, or is receiving medication that can affect these parameters (e.g., a beta-adrenergic blocker or a calcium channel blocker). Fever and tachypnea suggest ulcer perforation with peritonitis.

Special attention should be given to the patient's mental status, skin and mucous membranes, heart and lungs, and, of course, abdomen and rectum. Involuntary guarding, rigidity, rebound tenderness, and a paucity or absence of bowel sounds suggests ulcer perforation with peritonitis. These findings may be less prominent or even absent in the very young, the elderly, and patients on corticosteroids or analgesics. Abdominal distention suggests gastric outlet obstruction or ileus. In a patient who has not eaten in 6 hours, a splashing sound over the stomach when the body is shaken (succussion) suggests gastric outlet obstruction or delayed gastric emptying caused by ileus. Melena or a positive fecal occult blood test suggests ulcer bleeding. Hematochezia or maroon-colored stool may be present if bleeding is voluminous and intestinal transit is rapid. Detection of melena, hematochezia, or maroon-colored stool should prompt placement of a nasogastric tube to obtain an aspirate of gastric contents. If this aspirate is grossly bloody, the diagnosis of upper GI bleeding is confirmed and the likelihood of a bleeding ulcer is increased.

LABORATORY STUDIES

Laboratory results are normal in most patients with uncomplicated ulcer. A complete blood count should be done if blood loss or ulcer perforation is suspected; and serum electrolytes, blood urea nitrogen (BUN), and serum creatinine should be measured if the patient has poor oral intake, nausea, or vomiting. An elevated serum calcium level suggests the possibility of hyperparathyroidism and MEN I with Zollinger-Ellison syndrome, but the pretest probability of this condition is too low in patients presenting with ulcerlike symptoms to recommend routine measurement of serum calcium. If the patient has a

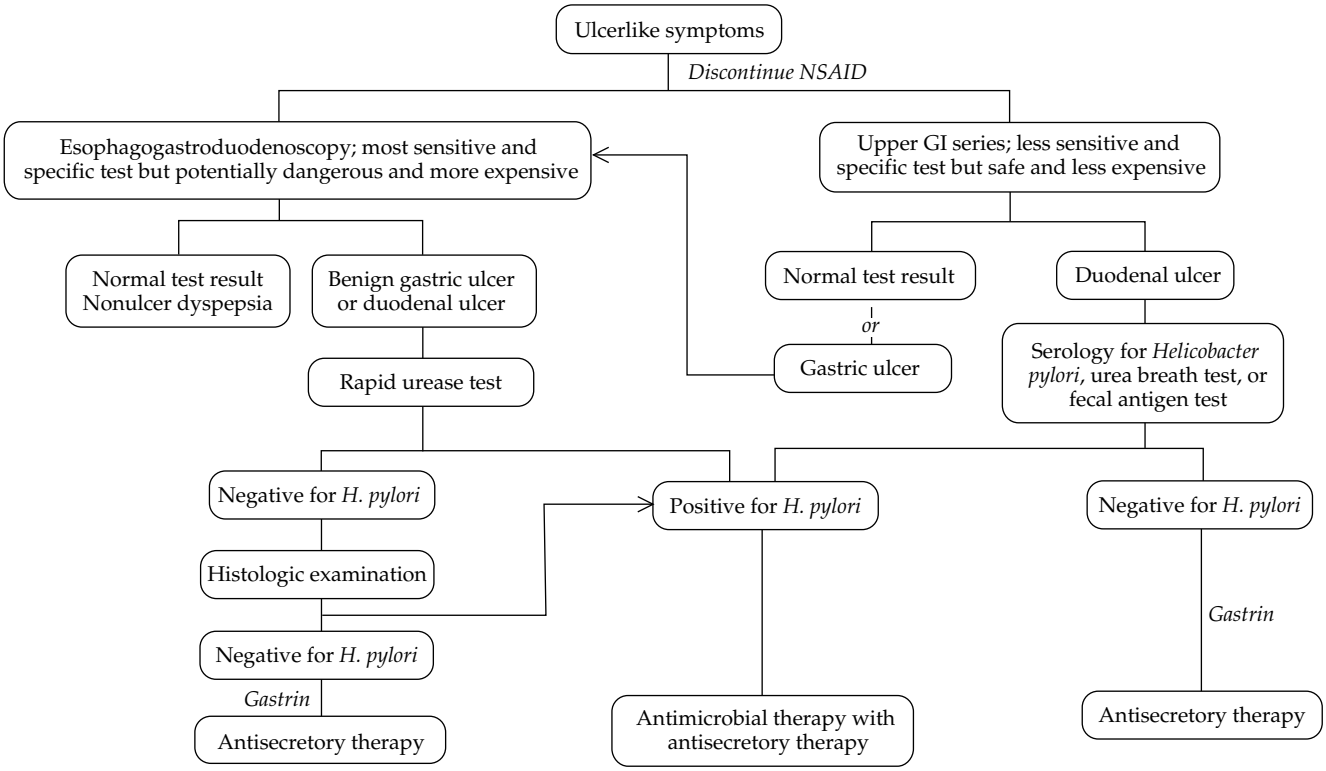

Figure 3 **Approach to a patient with new and undiagnosed ulcerlike symptoms refractory to a trial of antisecretory therapy with an H_2 receptor blocker or a proton pump inhibitor at customary doses or a patient with recurrent ulcerlike symptoms when the antisecretory therapy is stopped.**

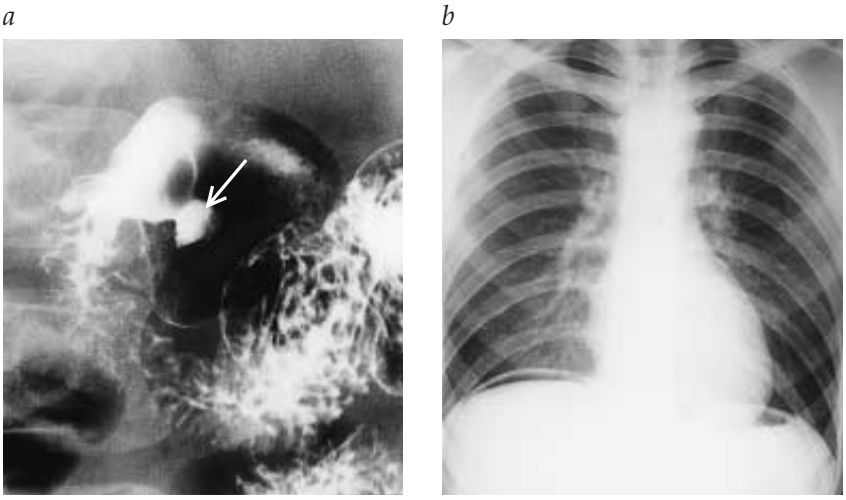

Figure 4 **(*a*) Upper GI series in which double contrast (barium and air) is used, showing rounded collection of barium in an ulcer (arrow) in the duodenal bulb of a patient presenting with dyspepsia (uncomplicated duodenal ulcer). (*b*) Upright chest x-ray showing air beneath the right hemidiaphragm (pneumoperitoneum) of a patient presenting with an acute abdomen caused by a perforated duodenal ulcer.**

strong family history of ulcer disease or of renal stones or has a personal history of renal stones, measurement of serum calcium is warranted, as is measurement of fasting serum gastrin once ulcer disease is confirmed and other causes of ulcer are excluded. If the calcium level is elevated, a serum parathyroid hormone measurement should be ordered.

Patients with complicated ulcers often have significant laboratory abnormalities, but these abnormalities are not specific for ulcer disease. Patients with bleeding ulcers have anemia and may have leukocytosis. The red cell indices (e.g., mean corpuscular volume) are typically normal. In the first several hours after an acute ulcer bleed, the hemoglobin concentration will not completely reflect the severity of the blood loss until compensatory hemodilution occurs or until intravenous fluids such as isotonic saline are administered. Thus, the pulse rate and blood pressure in the supine and upright positions are better initial indicators of extent of blood loss than are red cell counts. Patients with bleeding ulcers typically have azotemia, with ratios of BUN to serum creatinine concentrations exceeding 20:1, resulting from digestion and intestinal absorption of nitrogenous blood components in concert with reduced renal perfusion.

In patients with perforated ulcers and peritonitis, exudation of plasma into the peritoneal cavity (so-called third space) may result in an increased hemoglobin concentration from hemoconcentration. The presence of leukocytosis, elevated band forms, or leukopenia should raise suspicion of intra-abdominal sepsis. Lactic acidosis with an increased anion gap may ensue as a consequence of a sepsis syndrome or hypovolemia.

Patients with gastric outlet obstruction typically exhibit a hypokalemic, hypochloremic metabolic alkalosis. If volume loss is extreme, a coexistent metabolic lactic acidosis with an increased anion gap may be present, which may cause an elevated serum bicarbonate level to drop toward normal or even to low levels. Likewise, mild to moderate hyponatremia often develops in patients with vomiting from gastric outlet obstruction. Prerenal azotemia and a BUN–serum creatinine ratio greater than 20:1 are typical.

IMAGING STUDIES

Although ulcer disease can be suggested by history, physical examination, and laboratory studies, none of these has sufficient specificity to confirm the diagnosis. Ulcers are diagnosed endoscopically, radiologically, or surgically. Once an ulcer is diagnosed, additional studies can help in determining the cause of the ulcer (e.g., *H. pylori* infection, NSAID use, gastrinoma, or cancer masquerading as benign ulcer).

Endoscopy

Endoscopy is the most accurate way to diagnose a peptic ulcer [*see Figure 3*]. Most patients require local anesthesia of the pharynx and conscious sedation with an intravenous agent such as midazolam. The advantages of endoscopy are its nearly 100% specificity (rare false positives), greater than 90% sensitivity, portability (i.e., it can be performed in the intensive care unit, emergency department, or operating room), and ability to obtain tissue samples to help determine the etiology of the ulcer. The disadvantages of endoscopy are its cost and its potential for serious side effects. The most serious complications of endoscopy are respiratory depression and perforation of the GI tract. When a bleeding or obstructing ulcer is suspected, the stomach should be intubated and emptied with a large-bore tube before endoscopy to decrease the possibility of bronchopulmonary aspiration of gastric contents and to facilitate endoscopic visualization of mucosal lesions. Endoscopy is contraindicated in cases of suspected ulcer perforation.

Radiology

Despite having a lower sensitivity and specificity than endoscopy, an upper GI series using barium and air (double contrast) may be favored by primary care physicians and patients over referral for endoscopy for suspected uncomplicated ulcer. An upper GI series offers lower cost, wider availability, and fewer complications [*see Figure 3*]. However, for troublesome and undiagnosed dyspepsia, an upper GI series may be superfluous, because a normal result will often necessitate endoscopy (endoscopy is more sensitive than radiography) and because an upper GI series showing a gastric ulcer will also necessitate endoscopy for biopsy of the ulcer to exclude gastric malignancy. In many patients, only a finding of a duodenal bulbar ulcer on an upper GI series will preclude endoscopy [*see Figure 4*].

Plain films of the abdomen, abdominal sonography, and computed tomographic scans may be helpful in patients presenting with suspected complicated ulcers, particularly perforated or obstructing ulcers. Upright chest x-rays of a patient with a perforated ulcer may show free intraperitoneal air [*see Figure 4b*], typically beneath the right hemidiaphragm. When

plain films are negative or equivocal, pneumoperitoneum may be diagnosed by abdominal sonography or CT scan. Such studies should be performed only if the diagnosis of perforation is unclear; if physical signs of peritonitis are obvious, the patient should be referred to a surgeon. Patients with gastric outlet obstruction may have an enlarged stomach with old food debris visible on plain film of the abdomen, upper GI series, abdominal sonography, or CT scan.

SURGICAL DIAGNOSIS

Certain patients will not have ulcers diagnosed until surgery is performed. Such patients include those presenting with an acute abdomen, in whom the diagnosis of perforated ulcer is made at exploratory laparotomy; those presenting with copious upper GI bleeding, in whom it is difficult for the endoscopist to visualize and treat the ulcer; and those with an obstructing ulcer who have a pinpoint pylorus or a duodenal stricture that prevents passage of the endoscope beyond the stenosis.

Tests to Establish the Etiology of the Ulcer

ENDOSCOPIC TESTS

The endoscopist can take a biopsy sample of the stomach of an ulcer patient to determine whether *H. pylori* organisms are present [*see Figure 5*]. *H. pylori* organisms contain abundant amounts of urease, which splits urea into carbon dioxide and ammonia. If the biopsy sample is placed on a urea-containing medium that also contains a pH-sensitive dye, a change in color indicates that ammonia is being produced. This so-called rapid urease test has a high sensitivity and specificity (> 90%) for *H. pylori*. If the rapid urease test is negative, a separate biopsy specimen should be sent to a pathology laboratory in formalin for histology. *H. pylori* can be detected with routine hematoxylin and eosin stains [*see Figure 5*] or, if necessary, by special stains. Moreover, the presence of diffuse, active, chronic gastritis is highly suggestive of *H. pylori* infection, and its absence excludes *H. pylori* infection.

Another useful endoscopic procedure is to obtain multiple biopsies from the edges and the base of the ulcer to exclude malignancy. This is routinely done in cases of gastric ulcer because 2% to 4% of benign-appearing gastric ulcers are in actuality an ulcer within a malignancy, usually an adenocarcinoma. Duodenal ulcers need not be biopsied unless the ulcer is located in a mass distal to the duodenal bulb.

Endoscopy may also demonstrate a neuroendocrine tumor, compatible with a gastrinoma on special stains. Such a tumor is usually located in the proximal duodenum.

In an ulcer patient with a negative rapid urease test and no *H. pylori*–related gastritis or gastric malignancy on histology, further history regarding NSAID use should be obtained from the patient or the patient's family. Many patients with NSAID-related ulcers have erosions, subepithelial hemorrhages, or both, which clue the endoscopist to the possibility of occult or surreptitious NSAID use; these lesions may occur with or without gastric or duodenal ulcers.[7]

SEROLOGIC TESTS

A number of serum antibody tests for *H. pylori* are available that have a greater than 90% sensitivity and specificity if the patient has not yet received therapy for *H. pylori*.[17] In patients with active ulcers diagnosed by radiology or surgery in whom gastric tissue is not available, *H. pylori* serology can confirm infection with high accuracy [*see Figure 3*].

In ulcer patients with no evidence of *H. pylori* infection or NSAID use, the fasting serum gastrin concentration should be measured [*see Figure 3*] to screen for gastrinoma (Zollinger-Ellison syndrome). If the serum gastrin concentration is greater than 1,000 pg/ml in a patient with duodenal ulcer, the diagnosis of gastrinoma is confirmed. A modest elevation in fasting serum gastrin concentration (> 150 pg/ml but < 1,000 pg/ml) is suggestive of gastrinoma, but a provocative test should be performed using intravenous secretin (2 IU/kg as a bolus).[18] A rise in serum gastrin concentration of more than 200 pg/ml after secretin administration has a greater than 90% sensitivity and specificity for gastrinoma. Because achlorhydria can produce marked hypergastrinemia as a result of the loss of negative feedback of gastric acid on gastrin release, basal acid output or pH should be measured to confirm that the stomach secretes acid in ulcer patients with fasting hypergastrinemia. The combination of achlorhydria, hypergastrinemia, and duodenal ulcer is exceedingly rare, whereas the combination of achlorhydria, hypergastrinemia, and gastric ulcer is sometimes encountered and should suggest gastric adenocarcinoma or NSAID use. A fasting gastric pH measurement will almost invariably distinguish gastrinoma (pH 1 to 2) from achlorhydria (pH 6 to 8), unless the pa-

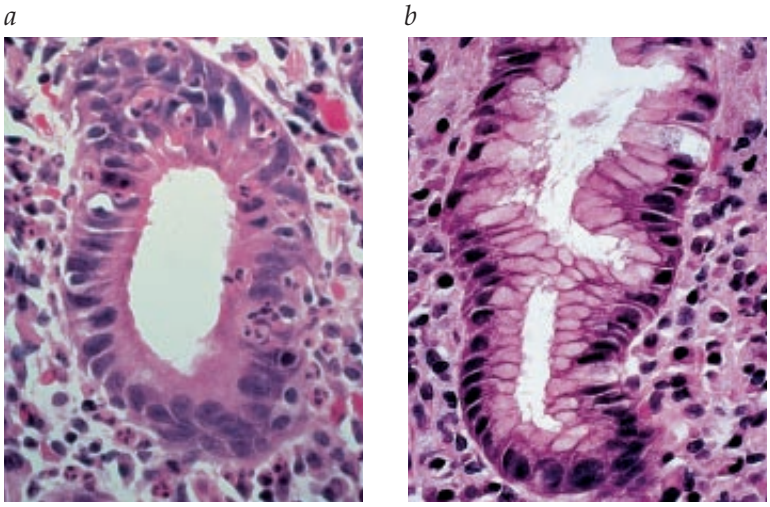

Figure 5 **Gastric biopsy samples stained with hematoxylin and eosin demonstrating (*a*) chronic active gastritis with a few *H. pylori* organisms faintly seen in the lumen of a gland and (*b*) chronic active gastritis with *H. pylori* organisms more abundant.**

Table 1 Differential Diagnosis of Peptic Ulcer Disease

Presentation	*Diagnosis*
Suspected uncomplicated ulcer	Nonulcer dyspepsia, gastroesophageal reflux, biliary colic, pancreatic disease, angina pectoris, gastric cancer
Bleeding ulcer	Varices, Mallory-Weiss tear, esophagitis, vascular lesion (arteriovenous malformation, Dieulafoy lesion, angiodysplasia)
Perforated ulcer	Appendicitis, pancreatitis, cholecystitis, spontaneous bacterial peritonitis, bowel ischemia or infarction, diverticulitis
Penetrating ulcer	Pancreatitis, muscle strain, herniated vertebral disk, ureteral stone
Fistulizing ulcer	Gallstones, GI malignancy, Crohn disease, intra-abdominal abscess

tient has received a potent acid antisecretory agent before pH measurement.

Measurement of serum thromboxane B_2 (platelet COX-1 activity) has been used in research laboratories to demonstrate occult or surreptitious NSAID use.[19] However, this assay is not widely available.

BREATH TESTS

A noninvasive method for detecting *H. pylori* in the stomach, the urea breath test, begins with oral ingestion of urea that has been labeled with carbon-13 (^{13}C) or carbon-14 (^{14}C). If *H. pylori*, with its abundant urease, is present in the stomach, the labeled urea will be rapidly converted to $^{13}CO_2$ or $^{14}CO_2$, which can be detected in breath samples collected during the first 30 to 60 minutes after urea ingestion. Sensitivity and specificity of the breath test are comparable to those of serology.[16] In a patient for whom there is no clinical indication for endoscopy, a urea breath test is an alternative to serology for documenting *H. pylori* infection [*see Figure 3*]. However, because proton pump inhibitors can suppress *H. pylori* without eradicating it, use of these drugs should be avoided for 2 weeks before the urea breath test is administered, to minimize false negative results.

Because serology is quicker, it is preferred to breath testing for initial diagnosis. Breath testing is more useful than serology in diagnosing failure of eradication of *H. pylori* or reinfection in patients who were previously treated for *H. pylori* infection, because the serology will usually remain positive for several months even after successful treatment.[20]

FECAL ANTIGEN TEST

Stool testing for *H. pylori* antigen compares favorably with urea breath tests.[21] Like breath testing, stool testing can distinguish current infection (antigen present in stool) from past infection (antigen not present in stool).

Differential Diagnosis

The most common disorder confused with uncomplicated peptic ulcer is nonulcer dyspepsia; the most serious GI disorder confused with uncomplicated peptic ulcer is gastric cancer [*see 12:VI Pancreatic, Gastric, and Other Gastrointestinal Cancers*].

Nonulcer, or functional, dyspepsia is a symptom complex similar to that experienced by patients with peptic ulcers. However, no ulcers or other lesions are visible on endoscopy. Nonulcer dyspepsia is a heterogeneous, poorly understood group of disorders. *H. pylori* gastritis probably causes dyspepsia in a few of these patients, and many physicians treat all dyspeptic patients who are infected with *H. pylori*. The cost-effectiveness of this approach has not been established, however; studies show that eradication of *H. pylori* is unlikely to relieve symptoms of nonulcer dyspepsia.[22-24] Many patients with nonulcer dyspepsia appear to suffer from a dysmotility of the upper GI tract that is akin to irritable bowel syndrome of the lower GI tract. Such individuals may complain of abdominal fullness, postprandial bloating, early satiety, and nausea, all suggestive of delayed gastric emptying. In some of these patients, gastric prokinetic agents such as domperidone or metoclopramide may help relieve symptoms.

Complicated ulcers may be confused with a variety of disorders. These include both intra-abdominal and musculoskeletal processes [*see Table 1*].

Treatment

The goals of ulcer therapy are rapid relief of symptoms; healing the ulcer; preventing ulcer recurrences; and reducing ulcer-related complications, morbidity (including the need for endoscopic therapy or surgery), and mortality. The general strategy in a patient with an ulcer should be to treat complications aggressively if present; to determine the etiology of the ulcer; to discontinue NSAID use if possible; to eradicate *H. pylori* infection if present or strongly suspected, even if other risk factors (e.g., NSAID use) are also present; and to use acid antisecretory therapy to heal the ulcer if *H. pylori* infection is not present. Smoking cessation should be encouraged. If duodenal ulcer is diagnosed by endoscopy, rapid urease testing of endoscopically obtained gastric biopsy samples, with or without histologic examination, should reliably establish the presence or absence of *H. pylori*. If duodenal ulcer is diagnosed by x-ray, then a serologic, urea breath, or fecal antigen test to diagnose *H. pylori* infection is recommended before treating the patient for *H. pylori*.

TREATMENT OF UNCOMPLICATED DUODENAL ULCERS

H. pylori–*Related Duodenal Ulcer*

Duodenal ulcer associated with *H. pylori* infection should be treated with antimicrobial therapy because successful therapy is associated with markedly reduced ulcer recurrences [*see Figure 6*][4,5] Antimicrobial therapy is usually empirical rather than based on results of culture and in vitro antimicrobial sensitivity testing. No single antimicrobial agent has an acceptably high success rate against *H. pylori*. Combinations of antimicrobial agents are required, and some regimens that have been approved by the Food and Drug Administration can be recommended [*see Table 2*].

H. pylori has adapted to the acidic stomach, and potent acid antisecretory agents facilitate eradication of *H. pylori* by antimicrobial agents. Bismuth compounds, like proton pump inhibitors, suppress the growth of *H. pylori* but usually do not by themselves eradicate it from the stomach. For this reason, they are frequently employed together with antibiotics.

Antimicrobial agents with activity against *H. pylori* include metronidazole, tetracycline, amoxicillin, and clarithromycin. Most popular are 10- to 14-day regimens, although 7-day courses

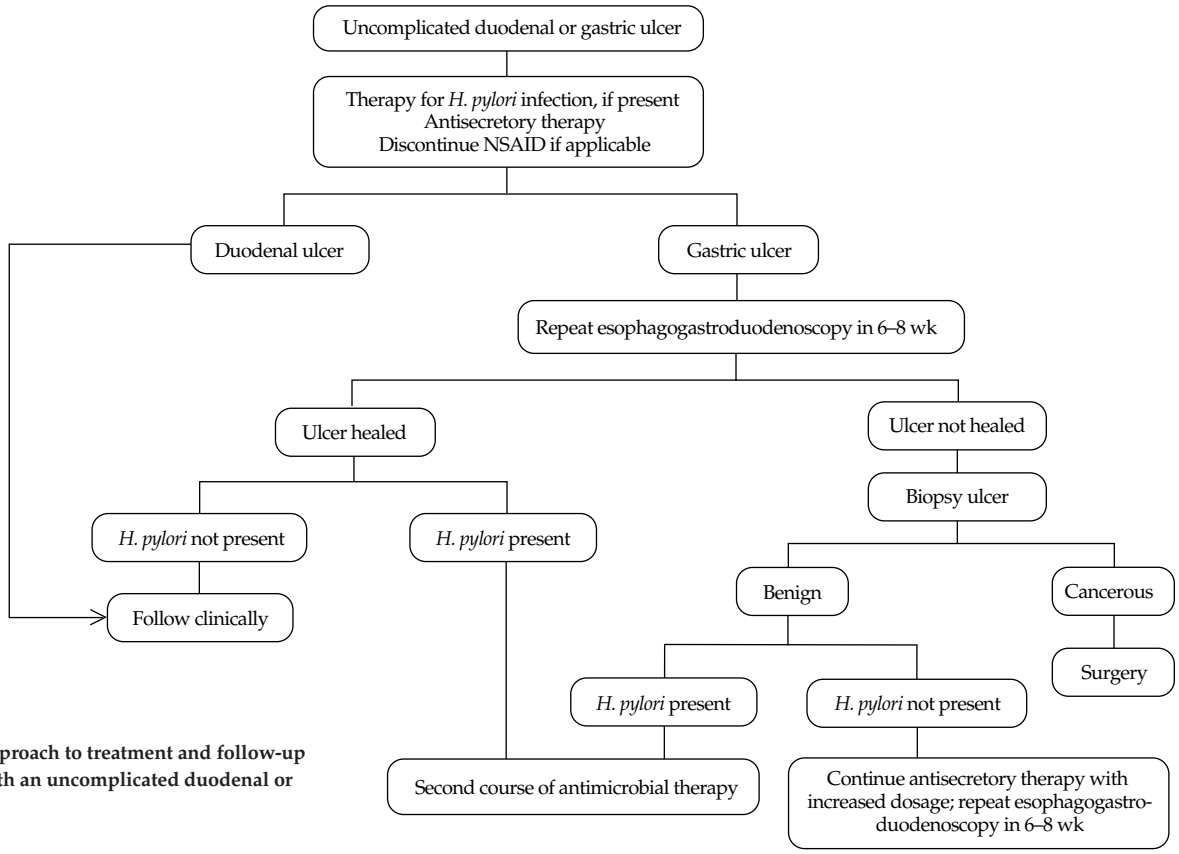

Figure 6 **Approach to treatment and follow-up of a patient with an uncomplicated duodenal or gastric ulcer.**

may be effective and are especially favored in Europe. A 2-week course of a three-drug regimen that includes a proton pump inhibitor, clarithromycin, and amoxicillin has a success rate approaching 90%. The major causes of treatment failure are poor compliance with the regimen and clarithromycin resistance; the latter occurs in around 10% of current strains and is increasing with more macrolide use in the population. Metronidazole resistance occurs in 30% to 40% of strains. However, unlike resistance to clarithromycin, which is usually absolute, resistance to metronidazole is relative and can be overcome in some patients.

If a patient carefully complies with one of the clarithromycin-based regimens yet the treatment fails, clarithromycin resistance is likely. In such cases, the retreatment regimen should not include clarithromycin. Most physicians choose a regimen consisting of metronidazole, tetracycline, bismuth (e.g., Pepto Bismol), and a proton pump inhibitor or H_2 receptor blocker. Because of the frequency of metronidazole resistance, other antimicrobials with activity against *H. pylori* are being used more often.[25-28] These agents include azithromycin, the quinolones norfloxacin and levofloxacin, and rifabutin [*see Table 3*]. In one study, a 7-day rescue treatment for persistent *H. pylori* infection using the proton pump inhibitor rabeprazole plus rifabutin and levofloxacin had a 95% success rate, as did a four-drug regimen consisting of rabeprazole, bismuth subcitrate, metronidazole, and tetracycline.[29]

It may also be possible to predict resistance to clarithromycin or to metronidazole by taking a careful history to look for prior exposure to these drugs. Such a history might help the physician choose a first-line regimen that will be more likely to be successful.

Side effects of *H. pylori*–directed therapy are not uncommon but are generally mild. Physicians should be aware of potential drug-drug interactions if the patient is receiving other medications. If the patient has an active, symptomatic ulcer, an antisecretory drug should be continued at a reduced (standard) dosage for 2 to 5 weeks after completion of antimicrobial agents.

After a patient has completed a course of ulcer therapy for an *H. pylori*–related uncomplicated duodenal ulcer, it is acceptable

Table 2 Selected Clarithromycin-Based Regimens to Eradicate *Helicobacter pylori*

Esomeprazole, amoxicillin, clarithromycin (EAC)
Esomeprazole, 40 mg b.i.d. for 10 days; then 40 mg q.d. for 18 days if an active ulcer is present
Amoxicillin, 1 g b.i.d. for 10 days
Clarithromycin, 500 mg b.i.d. or t.i.d. for 10 days
Lansoprazole, amoxicillin, clarithromycin (LAC)
Lansoprazole, 30 mg b.i.d. for 10–14 days; then 15 mg q.d. for 14–18 days if an active ulcer is present
Amoxicillin, 1 g b.i.d. for 10–14 days
Clarithromycin, 500 mg b.i.d. for 10–14 days
Omeprazole, amoxicillin, clarithromycin (OAC)
Omeprazole, 20 mg b.i.d. for 10 days; then 20 mg q.d. for 18 days if an active ulcer is present
Amoxicillin, 1 g b.i.d. for 10–14 days
Clarithromycin, 500 mg b.i.d. for 10 days
Rabeprazole, amoxicillin, clarithromycin (RAC)
Rabeprazole, 20 mg b.i.d. for 7 days; then 20 mg q.d. for 21 days if an active ulcer is present
Amoxicillin, 1 g b.i.d. for 7 days
Clarithromycin, 500 mg b.i.d. for 7 days

Table 3 Additional Antimicrobial Agents with Activity against *Helicobacter pylori*

*Agent**	*Dosage*	*Comments*
Azithromycin	500 mg q.d.	Combined with either amoxicillin or metronidazole, plus a proton pump inhibitor, for 3–7 days
Norfloxacin	400 mg b.i.d.	Combined with a proton pump inhibitor for 14 days
Levofloxacin	500 mg q.d.	Combined with either amoxicillin or metronidazole, plus a proton pump inhibitor, for 7 days
Rifabutin	300 mg q.d.	Combined with amoxicillin and a proton pump inhibitor for 7–10 days

*These agents are marketed in the United States, but they are not yet approved for *H. pylori* therapy.

to follow the patient clinically without confirming eradication, because most compliant patients will be successfully cured of their *H. pylori* infection [*see Figure 6*]. A patient with an *H. pylori*–related duodenal ulcer that does not recur symptomatically within 2 years after antimicrobial therapy is probably cured. Serology has often reverted to negative by this time.[20]

Those in whom recurrent ulcer symptoms develop during the first 2 years after therapy should be assessed either by endoscopy (for ulcer recurrence and for *H. pylori* persistence or reinfection) or by a urea breath test or fecal antigen test. The most common cause of recurrent ulceration in patients treated for *H. pylori*–related duodenal ulcer is failure to eradicate the organism. Retreatment of these patients is indicated [*see* Treatment of Intractable Duodenal Ulcers or Gastric Ulcers, *below*]. Rarer causes of duodenal ulcer recurrence include an acid hypersecretory state (e.g., Zollinger-Ellison syndrome), NSAID use, and reinfection with *H. pylori*.

H. pylori–*Negative Duodenal Ulcer*

In a duodenal ulcer patient who is *H. pylori* negative, the physician should consider NSAID use and gastrinoma (Zollinger-Ellison syndrome).[30] Patients with duodenal ulcer who are taking NSAIDs should discontinue the NSAID, if possible. At the same time, an acid antisecretory drug should be administered for 4 to 8 weeks [*see Table 4*]. The anticipated healing rate with this regimen is 85% to 95%.

Table 4 FDA-Approved Antisecretory Drugs for Active Peptic Ulcer Disease*

Class	*Drugs*	*Dosage*	*Drug Interactions*‡
H_2 receptor blockers†	Cimetidine	800 mg h.s. *or* 400 mg b.i.d.	Warfarin, theophylline, phenytoin, benzodiazepines, itraconazole, ketoconazole, atazanavir, cefpodoxime, cefditoren, gefitinib, memantine, metformin, and many others
	Ranitidine	300 mg h.s. *or* 150 mg b.i.d.	Warfarin, atazanavir, itraconazole, ketoconazole, cefpodoxime, cefditoren, enoxacin, gefitinib, memantine, metformin, tolazoline
	Nizatidine	300 mg h.s. *or* 150 mg b.i.d.	Atazanavir, itraconazole, ketoconazole, cefpodoxime, cefditoren
	Famotidine	40 mg h.s. *or* 20 mg b.i.d.	Atazanavir, itraconazole, ketoconazole, cefpodoxime, cefditoren
Proton pump inhibitors§	Omeprazole	20 mg q.d., a.c.	Benzodiazepines, ampicillin, atazanavir, digoxin, iron, itraconazole, ketoconazole, voriconazole, methotrexate, tacrolimus
	Lansoprazole	15 mg q.d., a.c.	Ampicillin, atazanavir, digoxin, iron, itraconazole, ketoconazole
	Esomeprazole	40 mg q.d., a.c.	Atazanavir, digoxin, iron, ketoconazole
	Rabeprazole	20 mg q.d., a.c.	Warfarin, ampicillin, atazanavir, digoxin, iron, itraconazole, ketoconazole
	Pantoprazole	40 mg q.d., a.c.	Ampicillin, atazanavir, iron, itraconazole, ketoconazole

*Patients with gastrinoma (Zollinger-Ellison syndrome) will usually require much higher dosages of antisecretory drugs than listed here.
†Use for 4–8 wk in the treatment of duodenal ulcer and 6–12 wk in the treatment of gastric ulcer. Duodenal ulcers that do not heal by 8 wk and gastric ulcers that do not heal by 12 wk are considered intractable. Dosage of H_2 receptor blockers should be reduced in patients with renal failure.
‡Micromedex Health Care Services. Most of these drug interactions are minor and not clinically relevant; nevertheless, caution is advised.
§Omeprazole and lansoprazole are approved for gastric ulcers; omeprazole, lansoprazole, and rabeprazole are approved for duodenal ulcers.

Table 5 Treatment and Prevention of Peptic Ulcers

Type of Ulcer	*Treatment*	*Prevention*	*Comments*
Helicobacter pylori–related ulcers	Antibiotics [*see Tables 2 and 3*] ± antisecretory agents [*see Table 4*]	None needed if *H. pylori* eradicated	Highly cost-effective; document healing in gastric ulcer; document *H. pylori* eradication in complicated duodenal or gastric ulcer and in intractable duodenal or gastric ulcer
NSAID-related ulcers	Antisecretory agents (proton pump inhibitors have greater efficacy than H_2 receptor blockers) [*see Table 4*] Discontinue NSAID use, if possible	Misoprostol (600–800 µg/day) or proton pump inhibitor (e.g., omeprazole, 20–40 mg q.d., or lansoprazole, 15–30 mg q.d.) along with an NSAID	Diarrhea may limit compliance in patients treated with misoprostol; avoid misoprostol during pregnancy (abortifacient); proton pump inhibitors are not yet approved by the FDA for prevention of NSAID-related ulcers
Ulcers associated with Zollinger-Ellison syndrome and other hypersecretory states	High-dose proton pump inhibitor	Proton pump inhibitor, adjusted to keep basal acid output < 5–10 mEq/hr	Consider exploratory laparotomy (guided by abdominal imaging studies) to remove easily resectable gastrinomas, if feasible; consider MEN I syndrome (present in 20%–30% of cases)[21]
Idiopathic ulcers	H_2 receptor blocker or proton pump inhibitor	Nocturnal H_2 receptor blocker or A.M. proton pump inhibitor	Parietal cell vagotomy for intractable duodenal ulcer and antrectomy for intractable gastric ulcer
Stress ulcers (ICU)	I.V. H_2 receptor blocker or proton pump inhibitor (e.g., pantoprazole) ?Angiography ?Surgery	I.V. H_2 receptor blocker or proton pump inhibitor; intragastric sucralfate; or intragastric antacid	Maintain pH above 4 with H_2 receptor blocker, proton pump inhibitor or antacid; continuous I.V. infusion is superior to I.V. boluses of antisecretory drug
Cameron ulcers (linear gastric erosions in a hiatal hernia)	Iron salts; packed red cell transfusions; endoscopic hemostasis ?Angiography ?Surgery	Hiatal hernia repair, laparoscopic or open	Roles of H_2 receptor blockers and proton pump inhibitors are unproved

MEN I—multiple endocrine neoplasia type I NSAID—nonsteroidal anti-inflammatory drug

Patients with duodenal ulcer as part of the Zollinger-Ellison syndrome should be managed initially with a high dose of a proton pump inhibitor, followed by a maintenance dose guided by gastric acid measurements. If there is no evidence of hepatic metastasis on abdominal CT scan, then exploratory laparotomy for gastrinoma resection, with or without parietal cell vagotomy, is warranted.[31] Radionuclide scintigraphy with octreotide, an analogue of somatostatin, is a highly sensitive and specific preoperative test for detecting and staging gastrinoma, as is endoscopic ultrasonography.

The vast majority of duodenal ulcers, regardless of cause, heal after 8 weeks of antisecretory therapy with a proton pump inhibitor or an H_2 receptor blocker. Antacids are often prescribed as needed to relieve ulcer symptoms.

In rare cases of idiopathic duodenal ulcer, it is prudent that, after the ulcer has been healed by an acid antisecretory agent, the patient be placed on a maintenance dose of an H_2 receptor blocker given at bedtime to reduce ulcer recurrences. Proton pump inhibitors are also effective in preventing duodenal ulcer recurrences. It is not necessary to confirm duodenal ulcer healing by endoscopy or x-ray before reducing the antisecretory drug dose to a maintenance level.

TREATMENT OF UNCOMPLICATED GASTRIC ULCERS

H. pylori–*Related Gastric Ulcer*

Gastric ulcer associated with *H. pylori* should be treated with antibiotics [*see Table 2*]. Because they are larger than duodenal ulcers, gastric ulcers take longer to heal. Thus, after antibiotic administration, the patient should be treated with an acid antisecretory agent [*see Tables 3 and 4*] for an additional 4 to 8 weeks. Patients with gastric ulcers should be followed endoscopically until complete healing has been achieved so that an ulcerated gastric cancer is not missed. Gastric biopsies should be obtained during follow-up endoscopy to determine whether eradication of *H. pylori* has occurred [*see Figure 6*]. Patients with a history of an uncomplicated gastric ulcer that is currently quiescent should be screened for *H. pylori* infection, and if the result is positive, they should be treated for *H. pylori* infection to prevent ulcer recurrences.

NSAID-Related Gastric Ulcer

The therapy for an active NSAID-related gastric ulcer is administration of a proton pump inhibitor [*see Tables 4 and 5*], as well as discontinuance of the NSAID. Healing rates with H_2 receptor blockers are nearly as high as with proton pump inhibitors if the NSAID can be stopped.

TREATMENT OF INTRACTABLE DUODENAL ULCERS OR GASTRIC ULCERS

Ulcers That Fail to Heal

Ulcers refractory to pharmacotherapy are rare, and in most cases, prolonging the course of the gastric antisecretory drug, increasing the dose, or taking both measures will lead to healing. The causes of nonhealing include poor compliance with medications, an acid hypersecretory state requiring higher-than-customary doses of antisecretory drugs, continued NSAID use, and persistent *H. pylori* infection. Often, combinations of these factors and others (e.g., smoking and stress) are present.

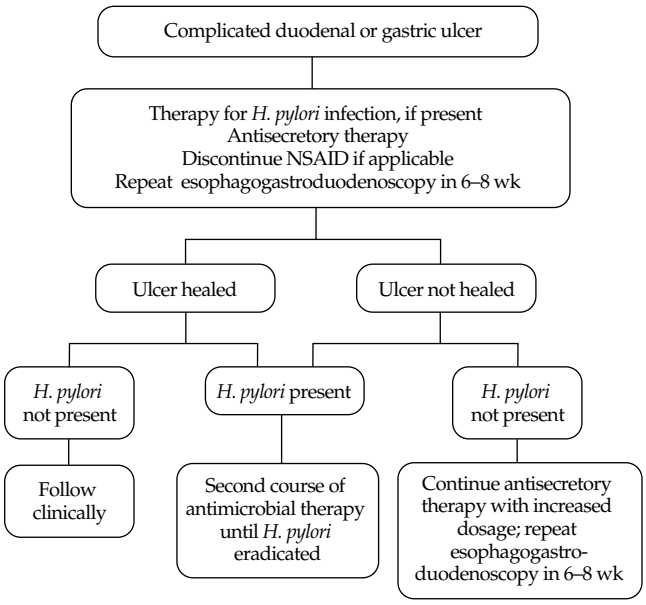

Figure 7 **Approach to treatment and follow-up of a patient with a complicated duodenal or gastric ulcer.**

Poor compliance with medications necessitates patient education and consideration of elective ulcer surgery. A fasting serum gastrin concentration can be used to screen for an acid hypersecretory state resulting from Zollinger-Ellison syndrome. Physicians should be aware that antisecretory drugs (especially proton pump inhibitors) can also raise serum gastrin levels modestly (to 150 to 600 pg/ml). Definitive documentation of an acid hypersecretory state requires quantitative gastric acid measurement (gastric analysis). NSAID use should be discontinued if at all possible. Persistent *H. pylori* infection is the result of poor compliance with medications or is caused by drug-resistant strains.[25-29] *H. pylori* has proved to be resistant to metronidazole in 30% to 40% of cases and to clarithromycin in 10% of cases; resistance to tetracycline or amoxicillin occurs in 1% of strains or less.[25] Combined resistance to macrolides (e.g., clarithromycin) and imidazoles (e.g., metronidazole) occurs in approximately 5% of patients, in whom infection may prove difficult to eradicate. Culture of gastric biopsy material for *H. pylori,* followed by antimicrobial drug-susceptibility testing when available, can guide retreatment. In the absence of this information, the patient should be retreated for 2 weeks with a proton pump inhibitor, with amoxicillin or tetracycline, and with either clarithromycin or metronidazole (whichever antimicrobial agent the patient did not receive initially). Some physicians use a bismuth preparation (e.g., colloidal bismuth subcitrate, bismuth subsalicylate, or ranitidine bismuth citrate) in place of a proton pump inhibitor [*see Table 2*]. Several other antibiotics have activity against *H. pylori* and may prove to be useful in rescue therapy for patients in whom treatments have failed; many such patients harbor antibiotic-resistant strains.[25-29] Agents that are available in the United States include the macrolide azithromycin, the quinolones norfloxacin and levofloxacin, and rifabutin [*see Table 3*].

Frequently Recurring Ulcers

Another type of intractability is frequent ulcer recurrences (at least three a year). This type of intractability occurs most often when *H. pylori* has not been eradicated (necessitating retreatment) or, less often, when NSAID use is resumed or when an acid hypersecretory state is present. Some idiopathic ulcers recur frequently and require lifelong maintenance therapy with an H_2 receptor blocker or a proton pump inhibitor. Alternatively, patients may choose ulcer surgery (parietal cell vagotomy for duodenal ulcer or antrectomy for gastric ulcer) over lifelong medication.

TREATMENT OF COMPLICATED PEPTIC ULCERS

Bleeding Ulcers

The first priority in a patient with a suspected bleeding peptic ulcer is to stabilize the vital signs with volume resuscitation, ideally in an intensive care unit. Such an approach is associated with improved patient outcomes.[32] Hemodynamic monitoring may assist in fluid and blood replacement, particularly if the patient has significant (New York Heart Association class III or IV) cardiac disease.

After the patient becomes clinically stable, diagnostic upper GI endoscopy is performed [*see Figure 7*]. If an actively bleeding ulcer or an ulcer with a visible vessel is found, the lesion is treated endoscopically, by injection of epinephrine, by thermal application with a heater probe or a bipolar electrode, or by a combination of these methods. Endoscopic therapy is successful in controlling bleeding in approximately 90% of patients; the other 10% are referred for surgery if major bleeding continues. Random gastric biopsies are obtained at the time of endoscopy to detect *H. pylori* by rapid urease testing and, if necessary, gastric histology.

Once an ulcer is demonstrated, intravenous gastric antisecretory therapy, usually with a proton pump inhibitor (e.g., pantoprazole) can be started. Oral therapy with a proton pump inhibitor is superior to no therapy in reducing early rebleeding if endoscopic therapy is not attempted[33]; proton pump inhibitors also reduce ulcer rebleeding after endoscopic therapy.[34] The combination of endoscopic therapy and an intravenous proton pump inhibitor is superior to the proton pump inhibitor alone in patients with visible vessels or with clots adherent to the ulcer.[35] However, endoscopic therapy may fail, necessitating surgery, or result in a perforation.[35] Patients who have been on intravenous therapy should be switched to oral therapy with a proton pump inhibitor as soon as they resume oral intake. If the rapid urease test or gastric histology is positive for *H. pylori*, the patient should receive at least two effective antibiotics (e.g., clarithromycin and amoxicillin) for 14 days, along with a proton pump inhibitor [*see Figure 7*]. The proton pump inhibitor is continued at the same dosage until week 6 for duodenal ulcer or week 8 for gastric ulcer. If a subsequent endoscopy shows complete ulcer healing and disappearance of *H. pylori* by both rapid urease testing and gastric histology, the risk of rebleeding is low[34,36,37] and therapy can be stopped. Future use of NSAIDs or aspirin is almost always prohibited. Although the use of coxibs instead of an NSAID is attractive, freedom from rebleeding is not guaranteed. If an NSAID or low-dose aspirin is absolutely necessary, it should be coprescribed with the prostaglandin E_1 analogue misoprostol[38] or a proton pump inhibitor.[39] If the ulcer heals but *H. pylori* organisms are still present, the patient should be treated again for *H. pylori* or left on maintenance therapy with an H_2 receptor blocker or proton pump inhibitor. If the ulcer is not healed, persistent *H. pylori* infection is likely. Under such circumstances, gastric tissue can be cultured for *H. pylori*, if available facilities exist, so that antibiotic sensitivities can be deter-

mined before retreatment. Finally, if the ulcer has not healed even though *H. pylori* has been eradicated, then NSAID use, an acid hypersecretory state, or cancer should be considered. Biopsy samples of the ulcer should be obtained, especially if the ulcer is in the stomach.

A patient with a bleeding peptic ulcer that is negative for *H. pylori* by rapid urease testing and gastric histology usually has an NSAID-related ulcer. The NSAID is stopped if possible, and a high-dose proton pump inhibitor (e.g., 40 mg of omeprazole or 30 mg of lansoprazole) is prescribed for 8 weeks for gastric ulcer or 4 to 6 weeks for duodenal ulcer. Repeat endoscopy is usually indicated to assess healing of a gastric ulcer; if the ulcer has not healed, it is biopsied. Whether to perform a repeat endoscopy to assess healing 4 to 8 weeks after an NSAID-related bleeding duodenal ulcer is controversial. If the ulcer is shown to have healed after the patient is off the NSAID, no further therapy is required unless the patient is placed back on an NSAID or aspirin, even a low dose of aspirin. In such cases, misoprostol (200 µg q.i.d.) is modestly protective against subsequent bleeding.[38] There is also evidence that maintenance therapy with a proton pump inhibitor such as lansoprazole or omeprazole is associated with a low rate of NSAID-related ulcer rebleeding. In general, however, NSAIDs should be avoided in patients with ulcers that have bled. In a study of high-risk arthritis patients with prior ulcer bleeding, use of a coxib (celecoxib) proved to be as effective as the combination of a nonselective NSAID (diclofenac) and a proton pump inhibitor (omeprazole).[40] With either therapy, however, 5% to 6% of such patients rebled over the ensuing 6 months.[40]

Patients with bleeding ulcers that are idiopathic and that heal on an antisecretory drug should receive long-term maintenance therapy with an H_2 receptor blocker or proton pump inhibitor. There is evidence that maintenance therapy with the H_2 receptor blocker ranitidine is effective in preventing rebleeding from duodenal ulcers.[41]

Perforated Ulcers

When a perforated viscus is documented or strongly suspected, the patient is started on broad-spectrum intravenous antibiotics covering gram-negative aerobic bacilli, enterococci, and anaerobes such as *Bacteroides* species and is then taken to surgery for closure of the perforation with a patch of omentum. If the surgeon does not obtain an intraoperative gastric biopsy sample, the patient should undergo postoperative testing for *H. pylori* by serology, urea breath test, or fecal antigen test, and the infection should be treated if present.[42] Many perforated ulcers are associated with NSAID use rather than with *H. pylori* infection.[43] Regardless of the patient's *H. pylori* status, antisecretory drugs should be administered for 6 to 8 weeks postoperatively. Endoscopy is then performed to assess healing, and success of eradication of *H. pylori* is ascertained by gastric biopsy with rapid urease testing and histology.

Up to 10% of perforated gastric ulcers are in fact perforated gastric cancers. If no biopsy or resection of the ulcer is done at the time of repair of the perforation, postoperative endoscopy with biopsy is imperative before the patient is discharged from the hospital or soon thereafter.

The mortality in patients with perforated peptic ulcers is 5% to 10%. Factors associated with higher mortality include delayed diagnosis and treatment of perforation; advanced age; comorbid conditions, such as cardiac, pulmonary, or liver disease; immunodeficiency; and advanced malignancy.

A small number of patients with suspected or probable perforated peptic ulcer improve rapidly before surgery is performed. Others refuse surgery or are poor surgical candidates. An alternative to surgery in these situations is nonoperative therapy consisting of nothing by mouth; intravenous fluids and electrolytes; a broad-spectrum antibiotic such as ticarcillin–clavulanic acid or piperacillin-tazobactam; and nasogastric suction. Compared with surgical therapy, nonoperative therapy is associated with more abdominal complications (e.g., abscesses), fewer pulmonary complications (e.g., atelectasis), and similar mortality.[44]

Obstructing Ulcers

The patient with an obstructing ulcer is initially placed on nasogastric suction, intravenous fluids and electrolytes, and an intravenously administered proton pump inhibitor. If the obstruction is the result of edema associated with an active ulcer, the gastric outlet may open as edema subsides and the ulcer heals, over several days to weeks. If, on the other hand, obstruction is the result of scarring from previous ulcers, it will not resolve with these measures. In some patients, it is difficult to determine whether edema or fibrosis is the primary cause of gastric outlet obstruction. Because obstruction may resolve with time, early consideration should be given to parenteral hyperalimentation. This intervention prevents or minimizes tissue catabolism during the waiting period and also induces a positive nitrogen balance, which will be beneficial if the gastric outlet fails to open up and the patient requires surgery.

A saline load test can be used to guide management. Thirty minutes after 750 ml of isotonic saline is infused into the stomach through the nasogastric tube, gastric contents (saline plus secretions) are aspirated. A return of less than 200 ml indicates normal gastric emptying of liquids and a good prognosis; 200 to 400 ml is indeterminate; and more than 400 ml is suggestive of a high-grade obstruction that will likely require intervention. Repeating the saline load test every day or two may also provide information about whether the obstruction is resolving.

If the obstruction resolves within 3 to 7 days, the nasogastric tube is removed and the patient is fed and observed clinically. An oral proton pump inhibitor or H_2 receptor blocker is started as soon as it is feasible. Gastric prokinetic agents (e.g., metoclopramide) should not be used. At least 50% of patients whose obstruction resolves with conservative medical therapy will experience another obstruction in about a year. Whether routine treatment of *H. pylori* infection will reduce this high recurrence rate is unknown. Unlike bleeding or perforation, obstruction is usually a late complication of ulcer disease. Thus, *H. pylori* eradication in ulcer patients is more likely to be effective in primary prevention of obstruction than in secondary prevention. NSAIDs may cause gastric outlet obstruction as well and should therefore be avoided. Endoscopic therapy is an option for obstruction that does not resolve with conservative therapy.[45] Using inflatable balloons placed over guide wires, the endoscopist can dilate a stenotic pylorus or duodenum under fluoroscopic guidance, although complications such as perforation may occur. Endoscopic balloon dilatation, when feasible, is a temporizing measure and rarely obviates surgery. Thus, obstruction that recurs after medical therapy or after endoscopic therapy is an indication for surgery. Pyloroplasty, gastroenterostomy, and resection plus gastroenterostomy are the most popular operations for an obstructing ulcer. Pyloroplasty and gastroenterostomy are typically combined with a vagotomy to reduce the likelihood of recurrent ulceration.

Fistulizing Ulcers

Gastric or duodenal ulcers associated with fistulas must be biopsied to exclude malignancy. Initially, benign ulcers are treated as described for an uncomplicated ulcer [*see Figure 6*]. An antisecretory agent—ideally, a proton pump inhibitor—should be prescribed, along with antibiotics, if *H. pylori* organisms are present. Ulcer healing may be associated with closure of the fistula. If the fistula persists, surgical resection of the fistula is warranted only if significant symptoms are present (e.g., troublesome diarrhea in a patient with a gastrocolonic fistula or cholangitis in a patient with a duodenocholedochal fistula).

TREATMENT OF ACUTE STRESS ULCERS

Therapy for bleeding acute stress ulcers and erosions involves blood transfusion if necessary and attempts to treat the underlying disease state. The role of intravenous H_2 receptor blockers or proton pump inhibitors is unproved. Endoscopic therapy is not usually curative, because multiple bleeding lesions are often present. In rare cases, visceral angiography with embolization of the major bleeding site is attempted. Gastrectomy for continuous bleeding or significant rebleeding is used as a last resort and is associated with a very high mortality.

Because of the dire consequences of stress ulcers and the lack of an effective therapy, high-risk patients in intensive care units should be placed on stress ulcer prophylaxis.[46] The patients at highest risk for bleeding are those with multiorgan failure and those who receive ventilatory assistance for more than 24 hours. The incidence of significant bleeding in high-risk patients is reduced from about 10% to 25% to about 1% to 5% with the use of prophylactic intragastric or oral antacids or sucralfate or with the use of intravenous H_2 receptor blockers or proton pump inhibitors given by continuous infusion. I prefer intravenous antisecretory therapy because of ease of administration, the ability to monitor gastric pH to assess effectiveness (the goal is a pH > 4), and proven efficacy in clinical trials.

TREATMENT OF CAMERON ULCERS

Although acid secretory inhibitors are often used in the treatment of linear erosions in hiatal hernias (Cameron ulcers), their value is uncertain.[16] Standard therapy consists of packed red cell transfusions for acute bleeding, oral iron replacement for chronic bleeding, and laparoscopic or open repair of the hiatal hernia when medical therapy fails. Because many of the patients with Cameron ulcers are elderly or at high risk, surgery should be undertaken only when medical therapy fails or becomes cumbersome.

The author has no commercial relationships with manufacturers of products or providers of services discussed in this chapter.

III DIARRHEAL DISEASES

LAWRENCE R. SCHILLER, M.D., F.A.C.P.

Definition and Epidemiology

The word diarrhea is derived from the Greek words for "flowing through." For most persons, diarrhea means the frequent passage of loose stools.[1] This definition includes two major components: loose-stool consistency (pourable stools) and increased stool frequency (more than two bowel movements daily). Physicians often include a third component: increased stool weight (> 200 g/24 hr), but patients are poor estimators of stool output. In addition, some patients report diarrhea when they have fecal incontinence, even if stools are solid; therefore, every patient complaining of diarrhea should be asked about incontinence.

Diarrhea is a universal human experience. Most persons have had acute infectious diarrhea at some time during their lives. The incidence of acute diarrhea is roughly 5% to 7% annually in the United States.[2] Infectious diarrhea is associated with contaminated food and water and typically is spread via fecal-oral transmission. Chronic diarrhea (i.e., lasting more than 4 weeks) is also common, with a prevalence of approximately 5% in the United States.[3] It is less likely to be caused by infection and more likely to be a symptom of other disorders, such as inflammatory bowel disease, celiac disease, or lactose intolerance.

Pathophysiology and Classification

Diarrhea results from excess water in the stool.[4] To understand the pathophysiology of diarrhea, it is necessary to briefly review how water is transported across the mucosa of the gastrointestinal tract. Water moves in response to osmotic gradients that are established by the absorption of salts (mainly sodium chloride but also potassium and bicarbonate salts) and nutrients (monosaccharides, amino acids, and fatty acids). Salts and nutrients move both passively in response to electrochemical gradients across the mucosa and actively in response to molecular pumps located in the enterocyte membranes.[5]

Each day, a typical person ingests about 2 L of fluid and produces 7 to 8 L of secretions (i.e., saliva, gastric juice, bile, pancreatic juice, and succus entericus). Thus, a total volume of 9 to 10 L enters the upper intestine daily. Most of the water is absorbed in the jejunum, along with nutrients. Absorption of residual nutrients and salts in the ileum results in a reduction of the volume of luminal contents entering the colon to only 1 to 1.5 L daily, a 90% reduction in the volume of fluid entering the intestine each day. The colonic mucosa can absorb salt against large electrochemical gradients and can reclaim 90% of the fluid passing the ileocecal valve each day, making the overall efficiency of small bowel and colonic water absorption about 99%.

Diarrhea develops if the overall efficiency of absorption declines by as little as 1%. This can occur under the following circumstances: the rate of intestinal nutrient and salt absorption decreases; net electrolyte secretion develops (an unusual circumstance except in cases of severe secretory diarrhea such as cholera, in which stool output can exceed 10 L/day); transit through the intestine speeds up, thereby limiting the time available for absorption; or poorly absorbable substances are ingested and increase intraluminal osmotic activity, causing the retention of water within the intestine.[6]

Common problems that primarily cause a reduction in the rate of intestinal nutrient and salt absorption include mucosal diseases, such as celiac disease; inflammatory diseases that disrupt the integrity of the intestinal mucosa (e.g., Crohn disease); and infections that cause diarrhea as the result of toxins that affect enterocyte function.

Isolated acceleration of intestinal transit is a poorly recognized mechanism of diarrhea, although historically, diarrhea was always attributed to it. Some patients with so-called functional diarrhea have rapid intestinal transit, which is likely to be important in the pathogenesis of their condition. Many patients with chronic idiopathic diarrhea have normal rates of fluid and electrolyte absorption when measured under perfusion conditions during which motility effects are neutralized, suggesting that motility must be playing a role in the pathogenesis of their diarrhea under ordinary circumstances.[7] Accelerated transit is also a major factor in diarrhea that is associated with some endocrine diarrheas (e.g., hyperthyroidism, carcinoid syndrome, and other peptide-secreting tumors) or with irritable bowel syndrome.

Poorly absorbed substances that can induce osmotic diarrhea include lactose in lactose-intolerant individuals. Osmotic diarrhea can also occur with ingestion of excess quantities of other poorly absorbed carbohydrates (e.g., fructose and the sugar alcohols mannitol and sorbitol) and ions such as magnesium, phosphate, and sulfate.

Mechanisms that reduce the overall efficiency of absorption may coexist in various disease states. For instance, in celiac disease, loss of intestinal villi results in reduced salt and water absorption, as well as reduced nutrient absorption. Thus, increased stool water in this condition results from both a reduced rate of electrolyte absorption and the increased intraluminal osmotic activity of poorly absorbed substances. Intestinal transit may accelerate in many diarrheal states because of stimulation of peristalsis by increased intraluminal volumes.

FECAL OSMOTIC GAP

As the rate of intestinal salt absorption decreases, the concentration of salts in stool rises to the point at which the concentration approaches plasma osmolality (290 mOsm/kg), which is defined as the osmolality that intestinal contents must maintain beyond the proximal jejunum. If the rate of salt absorption is unimpaired but either nutrients are malabsorbed or poorly absorbable substances are ingested, fecal salt concentrations decrease because most of the available osmotic space is occupied by the poorly absorbed substance. This is the basis for calculation of the fecal osmotic gap [*see Figure 1*].[8] In this calculation, the contribution of electrolytes to stool osmolality is estimated by doubling the concentration of sodium and potassium (the predominant cations in stool water) to account for unmeasured anions (mostly fatty anions, bicarbonate, or chloride). This value is then subtracted from 290 mOsm/kg (the putative osmolality of gut contents) to determine the contribution of nonelectrolytes to fecal osmolality. When electrolytes constitute most of luminal osmolality, the calculated fecal osmotic gap will be low (< 50 mOsm/kg). When poorly absorbable substances are present, the fecal osmotic gap will be large (> 100 mOsm/kg). Watery diarrhea with a low osmotic gap is classified as secretory diarrhea; diarrhea with a large fecal osmotic gap is classified as osmotic di-

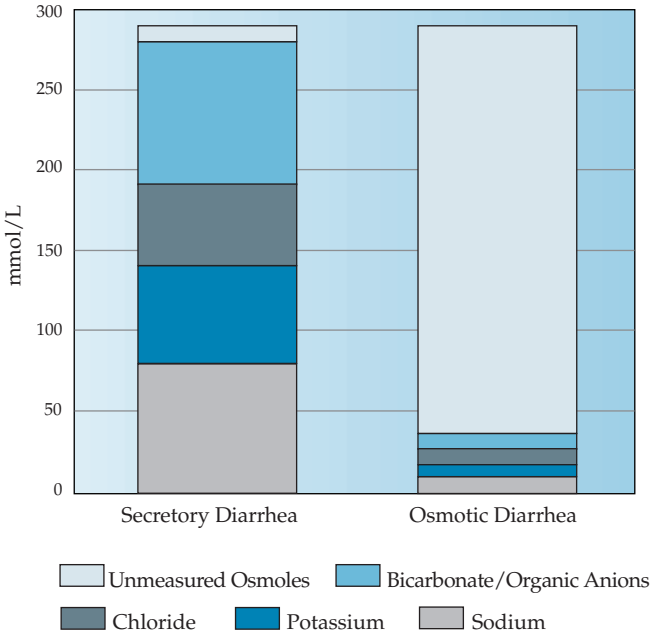

Figure 1 **Fecal electrolyte concentrations in secretory diarrhea (left column) and in osmotic diarrhea (right column). Note that most of the fecal osmolality can be attributed to fecal electrolytes in secretory diarrhea, whereas most of the osmolality in osmotic diarrhea results from the unmeasured (nonelectrolyte) osmoles. Calculation of the fecal osmotic gap allows an estimate of the contribution of unmeasured osmoles to fecal osmolality.[82]**

arrhea. These categories are most helpful in the evaluation of patients with chronic diarrhea.

CLASSIFICATION OF DIARRHEA

For clinical purposes, diarrhea can be classified as either acute (< 4 weeks' duration) or chronic (> 4 weeks' duration). Chronic diarrhea is further divided into watery, inflammatory, and fatty on the basis of stool characteristics.[3] The value of this classification is that it allows the physician to direct evaluation and management more effectively, because diarrheal diseases can be distinguished by the duration of illness and the type of stools produced.

Acute Diarrhea

ETIOLOGY

Infectious Causes of Acute Diarrhea

Most forms of acute diarrhea (i.e., those lasting less than 4 weeks) are caused by infections and are self-limiting; the majority are caused by viruses (e.g., adenovirus, Norwalk agent, rotovirus), but some are caused by bacteria (e.g., *Salmonella, Shigella,* and *Escherichia coli*) and others by protozoa (e.g., *Giardia,* amebas) [*see Table 1*].[2] The disease course of most viral and bacterial diarrheas lasts less than 1 week; therefore, infectious diarrhea lasting more than 7 days is more likely to be caused by protozoa.[9]

The epidemiology of acute infectious diarrhea depends on the circumstances of the infection and where one contracts the infection. For example, a history of recent travel, particularly to developing countries, makes a diagnosis of traveler's diarrhea likely. Previous antibiotic use and residence in an institution where antibiotic use is common (e.g., hospitals and nursing homes) are risk factors for *Clostridium difficile* infection. Children in day care facilities and their contacts, people engaging in promiscuous sexual activity, and users of illicit intravenous drugs are all at increased risk of contracting infectious diarrhea. Consumption of potentially contaminated food and drink is another risk factor for infectious diarrhea. With the globalization of commerce and mass processing of food, esoteric infections from overseas and large outbreaks of diarrhea have become more common.[10]

Pathogenic infections cause diarrhea by one of four mechanisms: (1) enterotoxins that subvert the regulatory mechanisms of enterocytes, (2) cytotoxins that destroy enterocytes, (3) adherence to the mucosa by organisms (so-called enteroadherent organisms) that alter enterocyte function as a result of physical proximity to the mucosa, and (4) invasion of the mucosa by organisms that provoke an inflammatory response by the immune system.[11] In general, patients with cytotoxin-mediated diarrhea and those with invasive organisms experience more toxicity and have more abdominal pain than patients with enterotoxin-mediated diarrhea or enteroadherent infections.

Toxic Causes of Acute Diarrhea

Another mechanism for acute diarrhea is ingestion of a preformed toxin.[12] Several species of bacteria, such as *Staphylococcus aureus*, *Clostridium perfringens,* and *Bacillus cereus*, can produce toxins that in turn cause so-called food poisoning (i.e., vomiting and diarrhea within 4 hours after ingestion). In such cases, the bacteria do not need to establish an intraluminal infection; ingestion of the toxin alone can produce the disease. Symptoms subside after the toxin is cleared, usually by the next day, and evidence of toxicity (e.g., fever) is minimal.

Other Causes of Acute Diarrhea

Other potential causes of acute diarrhea include food allergies and medication reactions. Food allergies are rarely recognized as causes of diarrhea in adults in the United States unless the diarrhea is associated with urticaria or other allergic symptoms. Medications often produce diarrhea as a side effect; this association is typically recognized by the patient because of the temporal relation between drug ingestion and diarrhea.

Finally, acute diarrhea may represent the initial stages of chronic diarrhea. However, patients with chronic diarrhea often do not seek help during the initial weeks of their illness unless the diarrhea is severe or is complicated by dehydration, symptomatic electrolyte disorders, or fever.

DIAGNOSIS

Medical History

A careful medical history is the key to the diagnosis of diarrhea. The acuity and severity of the process should be determined. Frequency of defecation is the easiest parameter for patients to relate, but frequency does not necessarily correlate with stool weight, which is a more meaningful measure of the physiologic impact of diarrhea. Manifestations of dehydration or volume depletion, such as orthostasis, thirst, decreased urine output, and weakness, suggest voluminous diarrhea. Acute weight loss can also be a guide to the severity of diarrhea; voluminous diarrhea produces substantial weight loss if rehydration efforts are suboptimal.

Stool characteristics are also quite important. The presence of blood or pus in the stool raises the issue of inflammatory diarrhea, such as that from colitis or enteroinvasive bacteria. Watery

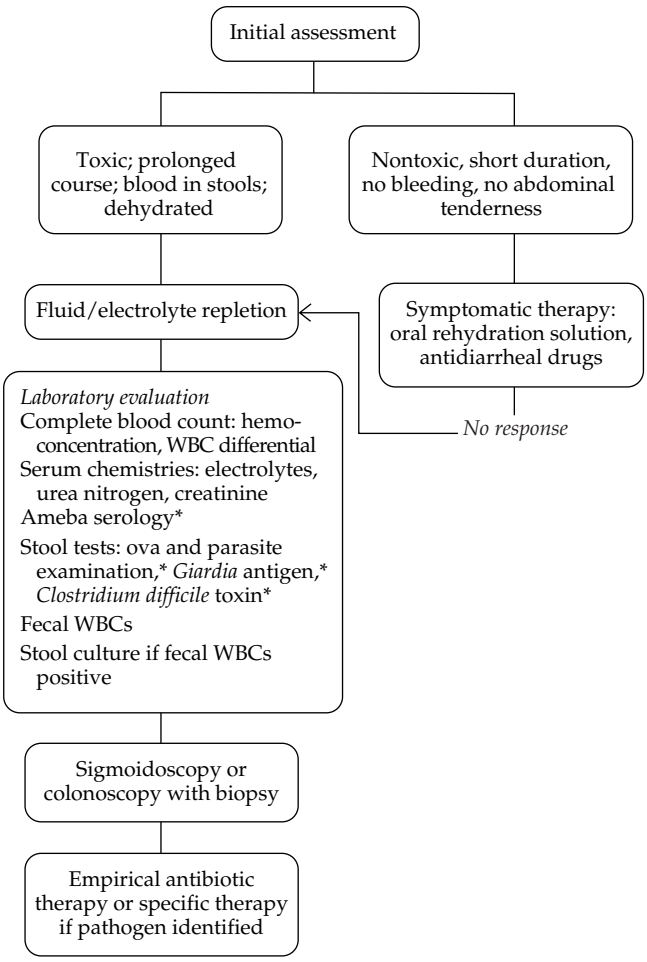
Table 1 Selected Infectious Diarrheas

Organism	*Vehicle*	*Mechanism*	*Classic Characteristics*	*Complications*
Campylobacter	Food (poultry); animal-to-person	Invasion; inflammation	Watery or bloody diarrhea; ileitis and/or colitis, ulceration	Guillain-Barré syndrome; reactive arthritis
Salmonella	Food (poultry, eggs, seafood); animal-to-person	Invasion; inflammation	Gastroenteritis, ileitis, colitis; enteric fever (*S. typhi*)	Endovascular infection; osteomyelitis; sepsis
Shigella	Food (poultry); day care centers	Cytotoxin; inflammation	Two phases: enteritis (fever, cramps, diarrhea), followed by colitis (ulcers, inflammation)	Seizures, encephalopathy; reactive arthritis
E. coli O157:H7	Food (beef); fruit juices	Cytotoxin	Hemorrhagic colitis	Hemolytic-uremic syndrome
Enteroinvasive *E. coli*	Food (various); water	Invasion; inflammation	Colitis	Fever, sepsis
Enterotoxigenic *E. coli*	Food (various); water	Enterotoxin	Watery diarrhea	Dehydration, shock
Enteropathogenic and enteroadherent *E. coli*	Food (various); water	Contact with brush border	Watery diarrhea; may be prolonged	Dehydration
Vibrio cholerae	Water, seafood	Enterotoxin	Voluminous watery diarrhea	Dehydration, shock
Clostridium difficile	Person-to-person	Cytotoxin	Nosocomial infection; antibiotic-associated diarrhea; toxicity	Toxic megacolon; protein-losing enteropathy
Aeromonas, Plesiomonas	Water	Enterotoxin	Watery diarrhea; may be prolonged	
Yersinia	Raw milk	Invasion; inflammation	Acute diarrhea or chronic ileocolitis-like Crohn disease	Reactive arthritis, extraintestinal infection, Guillain-Barré syndrome
Bacillus cereus	Fried rice	Exotoxin	Acute gastroenteritis	Fulminant liver failure
Staphylococcus	Fatty foods	Exotoxin	Acute gastroenteritis	
Clostridium perfringens	Fatty foods	Exotoxin	Acute gastroenteritis	
Viruses	Person-to-person; water	Inflammation; ?toxins	Acute gastroenteritis; watery diarrhea	
Giardia	Person-to-person; animal-to-person; water; day care	Contact	Watery diarrhea, dyspepsia	
Cryptosporidium	Water; day care; animal-to-person	Contact	Watery diarrhea, may be prolonged; epidemics	
Cyclospora	Imported fruit	Inflammation	Watery diarrhea, flatulence, pain, fatigue; may be prolonged	
Entamoeba histolytica	Person-to-person	Invasion; inflammation	Variable: asymptomatic to dysentery; may mimic irritable bowel syndrome, inflammatory bowel disease	Liver abscess
Strongyloides	Larvae invade skin	Invasion; inflammation	Abdominal pain and diarrhea	Hyperinfection in immunosuppressed hosts

stools are more in keeping with a secretory process. The relationship of defecation to meals or fasting and the occurrence of nocturnal diarrhea, fecal urgency, or incontinence are other points of potential significance. Urgency and incontinence do not necessarily indicate voluminous diarrhea; more often, they reflect independent defects in the continence mechanisms. Additional symptoms of diarrhea that should be noted are abdominal pain or cramps; flatulence; bloating or distention; fever; and weight loss. A list of all prescription, over-the-counter, and herbal medications being taken by the patient should be compiled, and previous surgeries or radiation therapy should be discussed. The patient's diet should be scrutinized, and epidemiologic features (e.g., family members or other contacts with diarrhea, recent travel, water source, occupation, sexual activity, and illicit drug use) should be investigated.

Physical Examination

The physical examination is more useful for judging the severity of diarrhea than for determining its cause. Volume status should be assessed by looking for orthostatic change in blood



*In appropriate epidemiologic circumstances.

Figure 2 **Initial evaluation of acute diarrhea.**[83]

pressure and pulse. Fever and other signs of toxicity should be recorded. A careful abdominal examination, with emphasis on bowel sounds and the presence of distention or tenderness, should be conducted.

Laboratory Testing

Blood tests Extensive laboratory testing is not necessary for most patients with acute diarrhea; it should be reserved for those with toxicity, dehydrating diarrhea, or persistence of diarrhea for longer than would be expected, given its probable cause [*see Figure 2*]. In patients requiring extensive laboratory tests, a complete blood count should be obtained to assess for hemoconcentration, anemia, or leukocytosis. Patients with viral diarrhea typically have normal white blood cell (WBC) counts and differentials, although lymphocytosis may be seen. Invasive bacterial infections typically produce leukocytosis with many immature WBCs, but salmonellosis can induce leukopenia. Serum electrolytes and renal tests can define the metabolic impact of diarrhea.

Stool tests Stool testing is of value for patients with blood in their stools, dehydrating diarrhea, prolonged diarrhea, or dysentery and for patients who present as part of an outbreak of diarrhea. Stool cultures are sensitive and specific, but they are expensive. Some experts recommend obtaining stool cultures only for patients who have leukocytes (or the leukocyte marker lactoferrin) in the stool, because the yield of pathogenic bacteria will be higher in this group.[13] Other researchers dispute this recommendation.[14] Laboratories routinely test for *Salmonella*, *Shigella*, *Campylobacter*, and *E. coli* serotype O157:H7. Special cultures for tuberculosis, *Yersinia*, *Aeromonas*, or *Plesiomonas* may need to be requested in appropriate patients. Polymerase chain reaction (PCR) testing with primers that are based on bacterial DNA is proving to be an accurate and sensitive technique for specific diagnosis.

Examination of stool for ova and parasites has variable utility, depending on the pretest probability of certain infections. For example, such testing might be very useful in a day care worker with diarrhea, but it would be of little help in a patient with hospital-acquired diarrhea. Enzyme-linked immunosorbent assay (ELISA) testing for giardiasis and serologic testing for amebiasis are more accurate tests for such specific infections in most settings. Patients who were treated with antibiotics during the 3 months before the onset of diarrhea or patients who develop diarrhea in institutional settings should have a stool sample analyzed for *C. difficile* toxin.

Imaging and Endoscopic Tests

In patients who have toxicity, blood in their stools, or persistent acute diarrhea, sigmoidoscopy or colonoscopy should be considered. In most patients without rectal bleeding, sigmoidoscopy is probably adequate as an initial evaluation, because most patients with colitis will have involvement of the left side of their colon. In patients with bleeding or those with AIDS and diarrhea, colonoscopy is preferable because some opportunistic infections and lymphomas are seen only in the right colon.[15] Mucosal biopsies should be obtained in either case, particularly if the colon is grossly inflamed, because the pathologist can readily distinguish self-limited colitis from chronic ulcerative colitis even early on in the course of the disease.[16] Patients with toxicity should undergo abdominal x-rays or computed tomography to confirm a diagnosis of colitis, to determine its extent, and to look for evidence of ileus or megacolon.

TREATMENT

Nonspecific Therapy

Because most cases of acute diarrhea are self-limited, most patients do not require specific therapy. Instead, judicious replacement of fluid and electrolyte losses is sufficient. This can be accomplished by intravenous fluids or oral rehydration solutions. Oral rehydration solutions are based on the concept that nutrient absorption accelerates sodium and fluid absorption by the jejunum.[17] Initially, rehydration formulas used glucose as the absorbable nutrient; more recently, cereal-based oral rehydration solutions have been found to be more efficient. Oral rehydration solution does not reduce fecal losses (it may actually increase stool output); instead, it increases net fluid and electrolyte absorption. These solutions cannot be used if vomiting precludes ingestion; in such situations, intravenous rehydration must be used. Sports drinks (e.g., Gatorade) are designed to offset fluid and electrolyte losses from sweating and do not contain sufficient amounts of sodium to replace fecal losses. Solutions that more closely approximate World Health Organization rehydration solution are now commercially available (e.g., Rehydralyte, Resol, Ricalyte).

Diet Most patients seek advice about altering their diets when suffering from diarrhea. Other than the provision of adequate water and salt, no specific instructions are needed. Some physicians routinely restrict dairy products in patients with diarrhea on the theory that these patients may have temporary lactase deficiency. This precaution is not necessary unless there is clinical evidence of lactose intolerance (e.g., exacerbation of diarrhea or flatus with ingestion of dairy products).

Antibiotics Empirical antibiotic therapy for acute diarrhea may be appropriate under certain circumstances (e.g., diarrhea in travelers, outbreaks of bacterial or protozoan diarrhea, patient frailty, and patient toxicity). However, experts discourage routine use of empirical antibiotic therapy because of its lack of demonstrable efficacy in many infections and because of concerns about precipitating complications, such as hemolytic-uremic syndrome in patients with *E. coli* serotype O157:H7.[18] A meta-analysis suggests that this latter point is not supported by the literature.[19] When indicated, fluoroquinolones or trimethoprim-sulfamethoxazole is commonly used as empirical therapy. Rifaximin, a nonabsorbable antibiotic with activity against most bacterial enteric pathogens, is useful in patients with infections that are limited to the lumen (e.g., traveler's diarrhea), but it may not be effective against invasive organisms.[20] In cases of persistent diarrhea in which protozoan infection is more likely, nitazoxanide, metronidazole, or tinadazole may be more appropriate.[21]

Nonspecific antidiarrheal agents, such as opiates, can reduce stool frequency and stool weight, and they may reduce associated symptoms, such as abdominal cramps.[22] Concerns about slowing the clearance of pathogens from the intestine by reducing peristalsis have largely not been borne out. Intraluminal agents, such as bismuth subsalicylate (Pepto-Bismol) and adsorbents (e.g., kaolin), are also sometimes used [*see Table 2*].

Therapy for Specific Infections and Syndromes

Campylobacter A frequent cause of acute ileocolitis in the United States,[23] *Campylobacter* is usually acquired by eating undercooked chicken; it has an incubation period of up to 1 week. Ulceration of the colonic mucosa and bloody diarrhea may occur with this infection. Antibiotics, such as erythromycin, shorten the course of the illness if given within the first few days of symptoms.

Table 2 Nonspecific Treatment of Diarrhea

Category	*Treatment*	*Typical Adult Dose*
Rehydration	Intravenous fluid	1–5 L/24 hr
	Oral rehydration solution	1–5 L/24 hr
Intraluminal agents	Adsorbents (kaolin-pectin)	15–60 ml q.i.d.
	Bismuth subsalicylate	30 ml q.i.d.
	Texture modifiers (psyllium)	18–30 g/24 hr
Drugs that inhibit transit	*Opiates*	
	Deodorized tincture of opium (10 mg morphine/ml)	5–20 drops q.i.d.
	Paregoric (0.4 mg morphine/ml)	5–10 ml q.i.d.
	Morphine sulfate (20 mg/ml)	2–10 drops q.i.d.
	Codeine phosphate or sulfate	15–60 mg q.i.d.
	Diphenoxylate with atropine	1–2 tablets q.i.d.
	Difenoxin with atropine	1–2 tablets q.i.d.
	Loperamide (2 mg)	1–2 tablets q.i.d.
	Others	
	Clonidine	0.1–0.3 mg t.i.d.
	Octreotide injection	50–200 mg t.i.d.

Salmonella enteritidis* and *S. choleraesuis *S. enteritidis* and *S. choleraesuis* are spread via contaminated food or water and cause acute gastroenteritis, ileocolitis, or colitis characterized by watery diarrhea.[24] Antibiotic therapy with a fluoroquinolone, ampicillin, or trimethoprim-sulfamethoxazole should be reserved for severely ill patients or patients with compromised immunity (e.g., infants, elderly patients, pregnant women, and AIDS patients).[25]

Salmonella typhi *S. typhi* causes typhoid fever, a form of enteric fever.[26] The propensity of *S. typhi* to produce bacteremia distinguishes it from other enteric pathogens. When the infection is limited to the intestine of an otherwise healthy individual, no specific therapy is indicated, because antibiotics may paradoxically prolong excretion of the organism and increase relapses. When the infection becomes systemic and the patient is very ill, therapy is necessary, especially if the organism produces a metastatic endovascular infection. Fluoroquinolones are most often used. The diagnosis of a carrier state is made when stool cultures are positive for over 1 year.

Shigella *Shigella* species are invasive organisms, but they also produce an enterotoxin that reduces water and electrolyte absorption.[27] Shigellosis commonly causes a watery diarrhea initially (this watery diarrhea is most likely related to the enterotoxin). Watery diarrhea is followed by bloody diarrhea, which results from colitis produced by invasion of the colonic mucosa. Because of growing resistance to the fluoroquinolones in the United States, trimethoprim-sulfamethoxazole is the recommended initial treatment for most patients with shigellosis. Shigellosis contracted overseas is initially treated with fluoroquinolones, because those strains are more likely to be resistant to trimethoprim-sulfamethoxazole.

***E. coli* serotype O157:H7** The O157:H7 organism has become a common cause of food-borne infection in the United States.[28] It produces toxins similar to those produced by *Shigella*.[29] Infection with this organism causes a hemorrhagic segmental colitis. The disease often occurs in large outbreaks from contamination of widely distributed foods, such as hamburger meat. Patients can become quite ill; hemolytic-uremic syndrome is a well-recognized complication. Antibiotics do not seem to improve the course of the illness and may cause hemolytic-uremic syndrome in children, although this theory is controversial.[18,19]

Clostridium difficile *C. difficile* has become the most common cause of nosocomial diarrhea in many institutions.[30] In nonhospitalized adults, carriage rates for this organism are low, but it is spread easily from person to person by spores. Suppression of the normal bacterial flora of the colon can result in an overgrowth of *C. difficile,* if it is present. The organisms produce toxin A and toxin B; these cytotoxins inactivate small guanosine triphosphate (GTP)–binding proteins in the enterocytes, resulting in apoptosis.[31] In institutional settings, the organism can be distributed efficiently to a large pool of susceptible persons by health care workers who do not wash their hands. The disease produced can range from a simple, self-limited diarrhea to a fulminant colitis.

Treatment for 2 weeks with metronidazole, 250 mg four times daily, or vancomycin, 125 to 500 mg four times daily, is effective against *C. difficile*. Relapses occur in up to 25% of patients, probably because of residual spores.[32] Ingestion of probiotic bacteria or the nonpathogenic yeast *Saccharomyces boulardii* may reduce relapse rates.[33] In most instances of relapse, longer periods of antibiotic therapy are indicated.

Other nosocomial diarrheas Noninfectious causes of nosocomial diarrhea include medications (particularly elixirs that contain sorbitol or mannitol as noncaloric sweeteners and cancer chemotherapeutic drugs) and enteral feeding; in addition, nosocomial paradoxical diarrhea can occur in patients with fecal impaction. Infections with organisms other than *C. difficile* also occur in institutions, particularly extended-stay facilities. An important cohort of hospital patients that may develop infectious diarrhea are those who are immunocompromised by diseases such as AIDS or by drugs that are used to treat transplant rejection or inflammatory diseases. These patients are often infected with opportunistic pathogens, including viruses (e.g., cytomegalovirus and herpesvirus), bacteria (e.g., *Mycobacterium avium* complex), and parasites (e.g., *Cryptosporidium* and *Strongyloides*).[34,35] In addition, bone marrow transplant recepients may develop acute diarrhea from graft versus host disease.

Parasites Acute diarrhea in noninstitutionalized patients can be caused by parasites.[36] The likelihood of parasitic disease as a cause of acute diarrhea is profoundly influenced by geography and epidemiologic features. Giardiasis, for example, is a common infection in some areas but not others, probably because of variability in the effectiveness of water treatment. Ingestion of as few as a dozen cysts of *G. lamblia* may establish an infection, which accounts for the frequency of person-to-person transmission of this disease. ELISA for *Giardia* antigen is superior to microscopic inspection of stool (so-called ova and parasites testing) for the detection of giardiasis. Therapy with tinidazole, metronidazole, or nitazoxanide is effective in most patients, but reinfection can occur.[37]

Amebiasis is also common in some areas. Persons with amebiasis may be asymptomatic or may be extremely ill from invasion and spread of the organism to other organs, such as the liver.[38] Diagnosis is typically made by microscopic examination of fresh stools, but ELISA shows promise in distinguishing the pathogenic species, *Entamoeba histolytica,* from nonpathogenic amebas. The colonoscopic appearance of amebiasis is often distinctive, and the organism can be identified in colonic biopsy specimens.

Cryptosporidiosis is a common but unappreciated cause of diarrhea.[39] *Cryptosporidium* is resistant to chlorination, and it can cause large outbreaks when water supplies are contaminated. Microscopic inspection of stools has poor sensitivity for this organism, and many cases go undiagnosed. Treatment with nitazoxanide reduces the duration of diarrhea in children and adults with this infection.[39]

Other parasites that may cause acute diarrhea include *Isospora*, *Cyclospora*, *Trichuris trichiura* (whipworm), and *Strongyloides*. Special tests that may be necessary to identify these parasites include concentration of stool samples and mucosal biopsy. If these organisms are suspected, consultation with the laboratory staff allows use of the proper diagnostic tests.

Chronic Diarrhea

In contrast to acute diarrhea, in which infection is the overwhelmingly likely cause of illness, chronic diarrhea has an extensive and daunting list of possible causes [*see Table 3*].[3] The simplest approach to making a diagnosis is to classify chronic diar-

Table 3 Major Causes of Chronic Diarrhea

- Osmotic diarrhea
  - Osmotic laxative abuse
    - Mg^{2+}, SO_4^{2-}, PO_4^{3-}, lactulose, mannitol, sorbitol, polyethylene glycol
  - Carbohydrate malabsorption
    - Lactose, fructose, others
- Fatty diarrhea
  - Malabsorption syndromes
    - Mucosal diseases
    - Short bowel syndrome
    - Postresection diarrhea
    - Small bowel bacterial overgrowth
    - Mesenteric ischemia
  - Maldigestion
    - Pancreatic insufficiency
    - Reduced luminal bile acid
- Inflammatory diarrhea
  - Inflammatory bowel disease
    - Ulcerative colitis
    - Crohn disease
    - Diverticulitis
    - Ulcerative jejunoileitis
- Infections
  - Invasive bacterial infection
    - *Clostridium, E. coli,* tuberculosis, others
  - Ulcerating viral infection

- Other neoplasia
  - Colon carcinoma
  - Lymphoma
  - Villous adenoma
- Idiopathic secretory diarrhea
  - Epidemic (Brainerd)
  - Sporadic

rhea by the characteristics of the stools. Three categories of chronic diarrhea are recognized: watery, inflammatory, and fatty. Watery diarrhea can be subdivided further into osmotic and secretory diarrhea on the basis of stool analysis.

WATERY DIARRHEA

Osmotic Diarrhea

Osmotic diarrhea results from ingestion of an osmotically active, poorly absorbable substance that necessitates the retention of water intraluminally to maintain isosmotic conditions.[40] In practical terms, osmotic diarrhea is caused by ingestion of osmotic laxatives (magnesium, phosphate, and sulfate salts; sugar analogues, such as lactulose; sugar alcohols, such as mannitol or sorbitol; and polyethylene glycol) and carbohydrate malabsorption. The ingestion of osmotic laxatives may be purposeful [*see* Laxative Abuse, *below*] or accidental, as when excess magnesium is ingested as part of an antacid, mineral supplement, or multivitamin tablet. Carbohydrate malabsorption is most often the result of acquired lactase deficiency (a normal development in adult mammals) or mucosal disease, such as celiac sprue, that interferes with nutrient absorption.

Secretory Diarrhea

Secretory diarrhea has a much larger list of possible causes than does osmotic diarrhea [*see Table 3*].

Congenital chloridorrhea Rarely, congenital absence of a transporter mechanism results in diarrhea. This is the case in congenital chloridorrhea, in which the chloride-bicarbonate exchanger in the ileum is not active.[41] Under such conditions, chloride becomes poorly absorbable in the distal bowel and obligates water retention intraluminally.

Chronic infections Some bacterial infections can last long enough to produce chronic secretory diarrhea.[42] These include *Aeromonas*, *Plesiomonas*, enteropathogenic *E. coli*, *C. difficile*, *M. tuberculosis*, and *Yersinia enterocolitica*. A special situation is small bowel bacterial overgrowth syndrome, in which structural problems, such as jejunal diverticulosis, or motility problems, such as those seen in scleroderma, result in proliferation of bacteria in the jejunum.[43] Although this bacterial overgrowth disrupts digestive processes and may produce fatty diarrhea, it also may reduce water and salt absorption, producing secretory diarrhea. Infection with parasites, such as *G. lamblia*, *E. histolytica*, and *Cryptosporidium*, also can produce chronic diarrhea.[44]

Inflammatory bowel disease Typically, inflammatory bowel diseases (e.g., ulcerative colitis and Crohn disease) produce inflammatory diarrhea, with blood and pus in the stool. Watery diarrhea can occur, especially when the distal colon is not involved. One form of inflammatory bowel disease that typically produces a watery diarrhea is microscopic colitis syndrome (lymphocytic colitis and collagenous colitis), in which the mucosa is inflamed but not ulcerated.[45] Colonic diverticulitis is sometimes associated with a secretory diarrhea, which is probably mediated by inflammation-linked cytokines. Vasculitis and systemic inflammatory diseases may also be associated with secretory diarrhea.

Drugs Drug therapy is a key cause of secretory diarrhea.[46] Many drugs have diarrhea as a side effect. These include antibiotics; cardiovascular agents, such as beta-adrenergic antagonists, digitalis, and quinidine; cancer chemotherapy; nonsteroidal anti-inflammatory drugs (NSAIDs); and colchicine. Thus, in taking the history of a patient with chronic diarrhea, it is critical to formulate a detailed drug list, including over-the-counter and alternative medications. A special category of drug-induced secretory diarrhea is surreptitious ingestion of stimulant laxatives.

Other causes Disordered motility or regulation can produce secretory diarrhea. Secretory diarrhea associated with disordered motility can occur in patients who have undergone vagotomy or sympathectomy, patients with autonomic neuropathy from diabetes or amyloidosis, and many patients with irritable bowel syndrome.[47,48] In the United States, irritable bowel syndrome is the most common diagnosis made in patients with chronic diarrhea. This diagnosis is often incorrect, however, and may delay accurate diagnosis and treatment.

Malabsorption of bile acid in the ileum occurs in many diarrheal diseases as a result of ileal disease or resection and may be secondary to other processes, such as vagotomy, cholecystectomy, and rapid transit past the ileum. In a relatively small group of patients, idiopathic bile acid malabsorption is the cause of diarrhea.[49]

Endocrine causes of secretory diarrhea include hyperthyroidism, Addison disease, and a group of rare tumors of the endocrine cells of the gut, including gastrinomas, carcinoid tumors, vasoactive intestinal peptide tumors (VIPomas), somatostatinomas, and medullary carcinoma of the thyroid.[50,51] These tumors produce peptides and other mediators that affect intestinal mucosal and muscle function and thereby produce diarrhea. In most cases, rapid intestinal transit seems to be the major mechanism producing diarrhea in these disorders, although this remains controversial.

Other tumors that produce secretory diarrhea include colon cancer (mechanism uncertain), villous adenoma of the rectum, lymphoma, and mastocytosis. Mastocytosis (and probably some lymphomas) produce diarrhea by release of histamine or other mediators that affect gut function. Infiltration of the mucosa also may play a role in some cases.

Secretory diarrhea can also be idiopathic.[52] Idiopathic secretory diarrhea occurs in both sporadic and epidemic forms and may be caused by an as-yet unidentified infection.

INFLAMMATORY DIARRHEA

Inflammatory diarrhea is characterized by the presence of blood and pus in the stools, which usually occurs as a result of ulceration of the mucosa. Inflammatory bowel diseases, such as Crohn disease and ulcerative colitis, are in this category [*see 4:IV Inflammatory Bowel Diseases*]. Some patients with diverticulitis and diarrhea may have blood and pus in the stool, as do patients with the rare condition ulcerative jejunoileitis. Ulcerating infectious diseases may also produce inflammatory diarrhea. Such infections include pseudomembranous colitis from *C. difficile* infection; invasive bacterial infections, such as tuberculosis and yersiniosis; ulcerating viral infections, such as those caused by cytomegalovirus or herpesvirus; and invasive parasitic infections, such as amebiasis and *Strongyloides*. Inflammatory diarrhea also may be seen with ischemic colitis and radiation colitis, as well as colon cancer and lymphoma.

FATTY DIARRHEA

Fatty diarrhea may be caused by fat malabsorption resulting from mucosal diseases, such as celiac disease or Whipple dis-

ease; short bowel syndrome secondary to extensive surgical resection of the small intestine; small bowel bacterial overgrowth syndrome; and mesenteric ischemia. Fatty diarrhea also may be the consequence of maldigestion of fat caused by pancreatic exocrine deficiency or inadequate luminal bile acid concentration [*see 4:XI Diseases Producing Malabsorption and Maldigestion*].

Diagnosis

Medical history An accurate medical history is even more important in cases of chronic diarrhea than in acute diarrhea. In addition to all the issues that should be discussed with patients who have acute diarrhea [*see* Acute Diarrhea, *above*], the history of patients with chronic diarrhea should include long-term trends in body weight, current appetite and food intake, review of previous medical problems and surgeries, potential secondary gains from illness, previous evaluations and treatments for diarrhea, and a detailed review of systems to look for clues to systemic illnesses [*see Table 4*].

A principal diagnostic distinction in chronic diarrhea is between diarrhea associated with irritable bowel syndrome and diarrhea associated with other functional or organic problems. Irritable bowel syndrome is characterized by abdominal pain associated with defecation and an altered bowel habit.[53] Variable stool consistency and intermittent constipation are common. Painless diarrhea should no longer be considered to be a type of irritable bowel syndrome; other causes of diarrhea should be sought in such cases.

Physical examination The physical examination may provide clues to the diagnosis of chronic diarrhea. Characteristic skin changes may be seen in mastocytosis, glucagonoma, Addison disease, amyloidosis, carcinoid syndrome, Degos disease, and celiac disease. Amyloidosis may produce orthostatic hypotension and hepatosplenomegaly. Thyroid nodules or findings of hyperthyroidism may suggest medullary carcinoma of the thyroid or thyroid adenoma causing hyperthyroidism. Carcinoid syndrome may produce hepatosplenomegaly, edema, and a right-sided heart murmur in addition to flushing. Arthritis may be a clue to inflammatory bowel disease, Whipple disease, and some enteric infections. Lymphadenopathy could be present in patients with AIDS or lymphoma. The absence of peripheral arterial pulses or bruits suggests the possibility of mesenteric vascular disease. Rectal examination may disclose defective functioning of the anal sphincter or pelvic floor muscle, which could produce fecal incontinence. The physical findings that reflect the severity of diarrhea should also be recorded [*see* Acute Diarrhea, *above*].

Laboratory tests As in acute diarrhea, routine laboratory testing is indicated to help determine the severity of chronic diarrhea [*see* Acute Diarrhea, *above*]. Unlike acute diarrhea, in which stool analysis is typically not used, stool analysis plays a key role in the assessment of chronic diarrhea by allowing adequate categorization of the type of diarrhea, thereby limiting the number of conditions to be considered.[3] The stool analysis can be obtained on either a random sample or a timed collection. The value of a timed collection is that it allows the physician to quantitate stool output accurately. However, stool analysis obtained on a random sample can still provide many diagnostic clues.

Table 4 Steps in the Evaluation and Classification of Chronic Diarrhea[3]

Step	*Elements*	*Findings/Considerations*
History	Onset	Congenital, abrupt, gradual
	Pattern	Continuous, intermittent
	Duration	—
	Epidemiologic features	Travel, food, water
	Stool characteristics	Watery, bloody, fatty
	Fecal incontinence	—
	Abdominal pain	Occurs in inflammatory bowel disease, irritable bowel syndrome, ischemia
	Weight loss	May be severe in malabsorption or neoplasm
	Aggravating factors	Diet, stress
	Mitigating factors	Diet, over-the-counter drugs, prescription drugs
	Previous medical evaluation	—
	Iatrogenic diarrhea	From drugs, radiation, surgery
	Factitious diarrhea	Laxatives; may be surreptitious
	Systemic disease	Diarrhea may complicate hyperthyroidism, diabetes mellitus, collagen vascular disease, tumor syndromes, AIDS, immunoglobulin deficiencies
Routine laboratory tests	CBC	Anemia, leukocytosis
	Serum chemistry	Fluid/electrolyte status, nutritional status, serum protein/globulin
Stool analysis	Weight	—
	Electrolytes	For calculating fecal osmotic gap
	pH	Acid stools suggest carbohydrate malabsorption
	Stool leukocytes	Found in inflammatory diarrhea
	Fat output	Can be assessed by Sudan stain or quantitatively
	Laxative screen	
Categorization	Watery diarrhea (secretory or osmotic)	—
	Inflammatory diarrhea	
	Fatty diarrhea	

Stool tests Stool characteristics to measure include stool sodium and potassium concentrations, osmolality, and pH. Fecal occult blood testing and examination of stool for WBCs (or a surrogate chemical test, such as fecal lactoferrin concentration) should be conducted. Stool fat output should be measured quantitatively or assessed qualitatively with a Sudan stain of a fecal smear.

Measurement of stool electrolyte concentrations allows calculation of the fecal osmotic gap [*see* Fecal Osmotic Gap, *above*]. This can be used to identify watery diarrhea as being osmotic or secretory. Measurement of actual stool osmolality is only of value in detecting samples that have been contaminated with water or dilute urine and therefore have an osmolality less than 290 mOsm/kg. Stool osmolality rises rapidly in vitro because of bacterial fermentation, so the actual measurement should not be used to calculate the fecal osmotic gap. The pH of stool water can indicate whether or not carbohydrate malabsorption is present. Carbohydrates (or sugar alcohols) that are not absorbed in the small bowel and that reach the bacterial flora of the colon are fermented into short-chain fatty acids that reduce fecal pH, usually to less than 6. Thus, acid stools suggest carbohydrate malabsorption.[8]

Fatty diarrhea can be identified by measurement of stool fat, although careful interpretation of the results is sometimes necessary [*see* Steatorrhea, *below*]. When appropriate, a laxative screen should be obtained. Measurement of laxatives by chemical or chromatographic methods can detect surreptitious laxative ingestion.

Completion of the stool analysis allows the clinician to characterize chronic diarrhea as being watery (whether secretory or osmotic diarrhea), inflammatory, or fatty. The subsequent evaluation depends on this categorization.

Evaluation of Watery Secretory Diarrhea

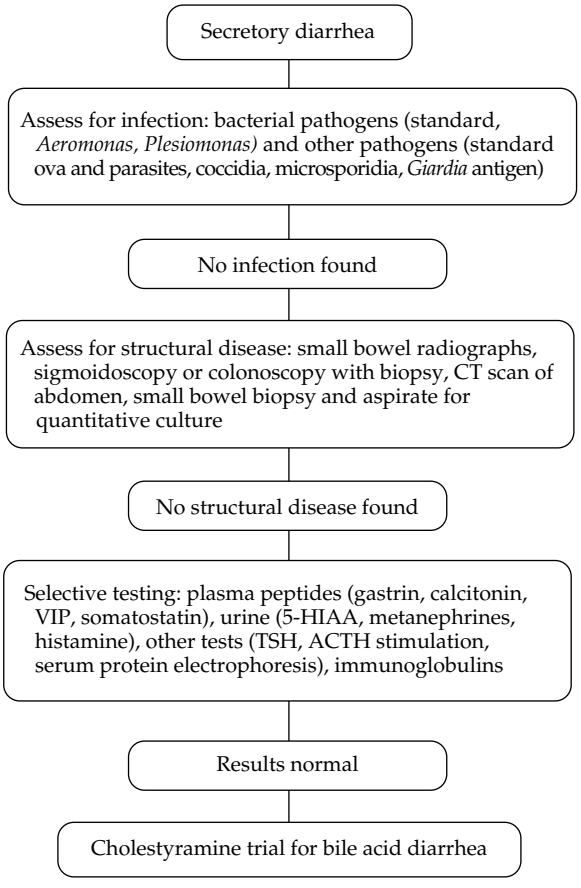
Secretory diarrhea is associated with many disorders; a thorough evaluation is therefore needed to identify the underlying cause [*see Figure 3*].

Stool tests Infection should be excluded by stool culture for bacteria, stool assay for *C. difficile* toxin, and other tests for parasites, including ELISA for giardiasis. Biopsies of the small bowel or colon may be necessary to find the pathogens, especially in patients with AIDS or other immunodeficiencies. Small bowel aspirate for quantitative culture is the best test for detecting small bowel bacterial overgrowth.

Imaging and endoscopic tests Structural diseases (e.g., short bowel syndrome or fistula, mucosal diseases, inflammatory bowel disease, and tumors) should be sought by radiographic and endoscopic testing. Small bowel radiography remains an important test in such cases. CT scans can detect small bowel and colonic disease, as well as problems extrinsic to the gut that may cause diarrhea, such as endocrine tumors. Inspection of the colonic mucosa by colonoscopy or sigmoidoscopy is essential in patients with secretory diarrhea, both to evaluate for gross changes and to obtain biopsy samples to look for evidence of microscopic colitis syndrome. Biopsies should be obtained even if the gross appearance of the colon is normal, because of the prevalence of microscopic colitis syndrome in patients with chronic watery diarrhea. A long endoscope that can reach the jejunum to obtain biopsy samples and aspirates is a valuable adjunct when other studies are unrevealing. The role of capsule endoscopy in the evaluation of patients with chronic diarrhea is under investigation; studies suggest that it may be helpful in detecting Crohn disease and, perhaps, celiac disease.[54-56] However, capsule endoscopy does not allow for biopsy of abnormalities that are visualized during the procedure, which limits its utility. Double-balloon enteroscopy offers the possibility of visualizing and obtaining biopsies from the entire small intestine; this technique may find a place in the evaluation of patients with watery secretory diarrhea.[57]

Serum peptide measurement Because diarrheagenic endocrine tumors are very rare, the measurement of serum peptides (e.g., gastrin, vasoactive intestinal polypeptide, calcitonin, and glucagons) or urinary excretion of secretagogue metabolites (e.g., 5-hydroxyindoleacetic acid or metanephrine) should be restricted to patients with symptoms consistent with tumor syndromes or those in whom a diagnosis remains elusive after initial testing.[58] More common endocrine problems, such as diabetes, hyperthyroidism, or Addison disease, should be excluded with appropriate blood tests.

Bile acid absorption measurement Ileal resection or ileal disease can result in the escape of sufficient bile acid into the colon to increase luminal bile acid concentrations above 3 to 5 mmol. At these concentrations, bile acids reduce colonic mucosal water and electrolyte absorption; alternatively, they stimulate secretion, resulting in increased stool water. In most circum-



ACTH—adrenocorticotropic hormone
TSH—thyroid-stimulating hormone
5-HIAA—5-hydroxyindole acetic acid
VIP—vasoactive intestinal peptide

Figure 3 **Evaluation of chronic secretory diarrhea.[3] Every test does not need to be done for every patient.**

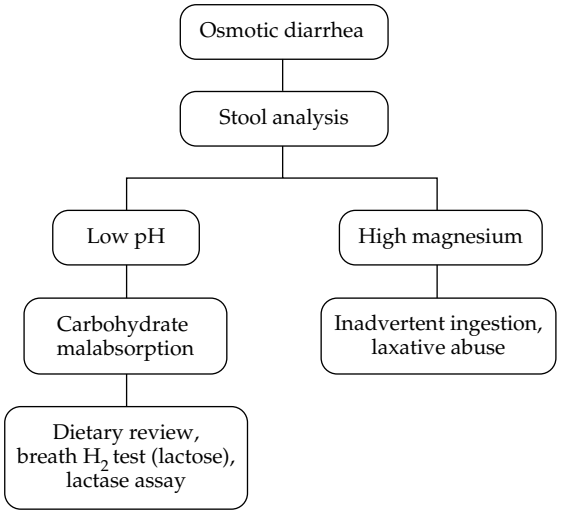


Figure 4 **Evaluation of chronic osmotic diarrhea.[3] Every test does not need to be done for every patient.**

stances, bile acid malabsorption can be inferred from a history of ileal resection or disease. More controversial is the concept that bile acid malabsorption occurring in the absence of ileal resection or obvious ileal disease is responsible for idiopathic secretory diarrhea.[59] Although bile acid malabsorption can be documented in many of these patients, administration of bile acid–binding resins does not always mitigate the diarrhea, casting doubts on bile acid malabsorption as the cause of the diarrhea.[49] Therefore, in patients with secretory diarrhea that appears to be idiopathic, it is more practical to give a therapeutic trial of bile acid–binding resins than to measure bile acid malabsorption directly.

Evaluation of Watery Osmotic Diarrhea

Because osmotic diarrhea has fewer potential causes than secretory diarrhea, the evaluation is simpler [*see Figure 4*]. If stool water has low electrolyte concentrations (and therefore a high fecal osmotic gap), some other substance is taking up the osmotic space and is holding water in the lumen. In practice, this substance is usually magnesium ingestion or carbohydrate malabsorption.

Magnesium ingestion Magnesium can be measured accurately in stool water. Excretion of more than 15 mmol (30 mEq) daily or concentrations greater than 45 mmol/L (90 mEq/L) strongly suggest magnesium-induced diarrhea.[60] This diarrhea may be intentional (surreptitious laxative ingestion) or accidental (magnesium-containing antacids or mineral supplements).

Carbohydrate malabsorption Carbohydrate malabsorption can occur from ingestion of poorly absorbable carbohydrates, such as lactose in someone with lactase deficiency, or from reduced carbohydrate absorption as a result of small bowel mucosal disease. In addition to ingestion of lactose, common causes of osmotic diarrhea include excessive ingestion of fructose (often used as a sweetener in commercial products),[61] ingestion of poorly absorbed sugar alcohols (such as mannitol and sorbitol, which are used as low-calorie sweeteners), and use of inhibitors of carbohydrate absorption, such as acarbose. Because malabsorbed carbohydrate is rapidly fermented by colonic bacteria, gas and bloating are frequent symptoms. Diagnosis is made on the basis of a finding of low stool pH (typically less than 6) and a thorough dietary history.

Evaluation of Chronic Inflammatory Diarrhea

Patients with WBCs or blood in the stool are classified as having inflammatory diarrhea. Causes may include inflammatory bowel disease, infections, ischemia, radiation enteritis, and neoplasia [*see Table 3*]. Sometimes, these conditions produce a watery, secretory diarrhea without blood or pus in the stool; therefore, they must also be considered in the evaluation of that type of diarrhea [*see* Evaluation of Watery Secretory Diarrhea, *above*].

Imaging and endoscopic tests Evaluation of patients with chronic inflammatory diarrhea should start with radiographic and endoscopic tests to look for structural problems [*see Figure 5*]. Sigmoidoscopy or colonoscopy should be considered first, because colitis is a common cause of inflammatory diarrhea. Biopsies should be performed to properly categorize colitis. CT has proved useful in many patients with inflammatory diarrhea because of the ability of CT to visualize inflammatory changes in the small bowel and colon and to identify complications of inflammation, such as abscess.

Infections that may produce chronic diarrhea, such as *C. difficile*, cytomegalovirus, amebiasis, and tuberculosis, need to be excluded by culture, biopsy, or serologic testing. It is important to realize that infection may complicate the courses of established problems, such as ulcerative colitis or Crohn disease. Patients with AIDS need an especially careful search for opportunistic infections.

Evaluation of Chronic Fatty Diarrhea

Steatorrhea Excessive fat in the stool, or steatorrhea, implies a problem with fat solubilization, digestion, or absorption in the small intestine. Steatorrhea is usually defined as stool fat output of more than 7 g over 24 hours or daily output of more than 9% of the intake of fat. These criteria may not be valid in patients with diarrhea, however, because voluminous stools per se may increase fat excretion. In one study, artificially induced diarrhea produced mild steatorrhea of up to 14 g/24 hr in 35% of normal persons.[62] Thus, in patients with diarrhea, fecal fat excretion of up to 14 g/24 hr has a low specificity for the diagnosis of defective fat absorption. The threshold for the diagnosis of steatorrhea also should be corrected for fat intake, because some patients

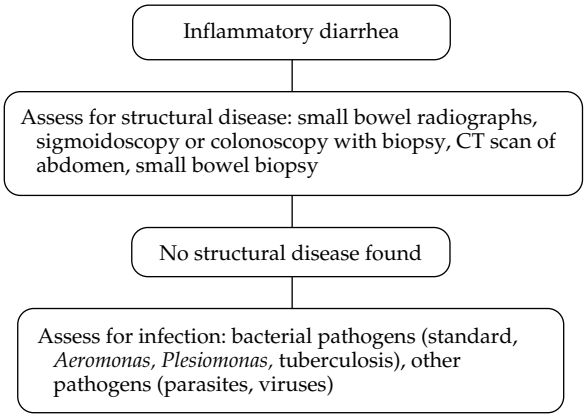

Figure 5 **Evaluation of chronic inflammatory diarrhea.[3] Every test does not need to be done for every patient.**

with diarrhea have anorexia and some patients with steatorrhea have hyperphagia. When possible, fat intake should be estimated from diet diaries that are maintained during the collection period. Finally, measurement of fat excretion can be compromised by ingestion of poorly absorbed fat substitutes, such as olestra.

Qualitative estimation of fat excretion by Sudan stain of a fecal smear can be used when a timed collection or quantitative analysis is not possible. Semiquantitative methods employing assessment of the number and size of fat globules correlate well with quantitative analysis of fat excretion.

The fecal fat concentration may provide a clue to the etiology of steatorrhea. The major causes of steatorrhea are mucosal diseases (e.g., celiac disease), pancreatic exocrine insufficiency (e.g., chronic pancreatitis), and lack of bile acids (e.g., advanced biliary cirrhosis). Mucosal diseases are often associated with reduced fluid and electrolyte absorption; as a result, fat is diluted by unabsorbed water. Furthermore, in mucosal disease, fat still can be digested to fatty acids, which can inhibit water absorption in the colon. In contrast, diseases that alter fat solubilization or digestion typically do not alter mucosal water and electrolyte absorption; as a result, unabsorbed fat is disbursed in a smaller stool volume. Fecal fat concentrations of more than 9.5 g/100 g strongly suggest pancreatic or biliary steatorrhea. Assessment of patients with chronic fatty diarrhea should therefore begin with measurement of fecal fat excretion and concentration [*see Figure 6*].

Imaging and endoscopic tests If the cause of steatorrhea is not obvious from the patient's history and the results of fecal fat assessment, the next step is evaluation of the absorptive surface of the small intestine by endoscopic, histologic, and radiographic tests. During endoscopy, small bowel biopsies should be obtained for histologic analysis, and small bowel contents should be aspirated for quantitative culture to assess for small bowel bacterial overgrowth. Indirect tests, such as measurement of antigluten (antiendomysial) antibodies or tissue transglutaminase antibodies for the diagnosis of celiac disease or breath tests for bacterial overgrowth, have not displaced endoscopic testing as the gold standard for diagnosis of these conditions. Such tests, however, may be useful in some cases. Small bowel radiography and CT are valuable adjuncts for structural assessment in patients with steatorrhea.

If the absorptive surface is normal, attention should shift to luminal problems with fat solubilization or digestion. Testing for pancreatic exocrine insufficiency is rarely done, because of unwillingness to use duodenal intubation tests. An indirect test, such as measurement of stool chymotrypsin activity, has limited sensitivity and specificity. The best test for pancreatic exocrine insufficiency may be a therapeutic trial of pancreatic enzyme supplementation. If this is done, a large dose of enzymes should be administered and objective measurement of fat excretion should be monitored to assess the response to therapy. Likewise, testing for the adequacy of bile salt solubilization of fat is rarely done. If necessary, duodenal bile salt concentration can be measured.

TREATMENT

Nonspecific Therapy

Nonspecific therapy is used in patients with chronic diarrhea in three situations: (1) as a temporizing or initial therapy before diagnostic testing, (2) after diagnostic testing has failed to result in a diagnosis, and (3) when a diagnosis has been made, but no specific treatment is available or specific treatment has failed.[22]

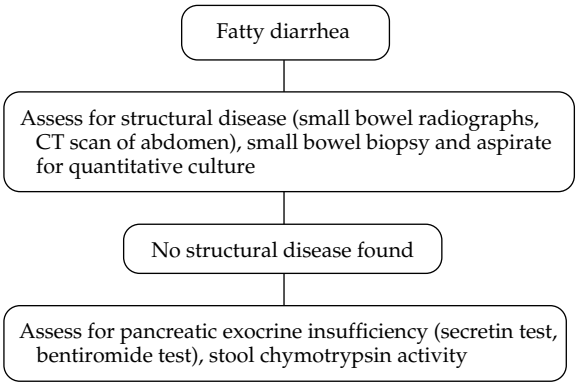

Figure 6 **Evaluation of chronic fatty diarrhea.[3] Every test does not need to be done for every patient.**

Antibiotic therapy Antibiotics are less useful in chronic diarrhea than in acute diarrhea because bacterial infection is less likely to be the cause of chronic diarrhea. Nevertheless, many clinicians try an empirical course of metronidazole or a fluoroquinolone before starting an extensive evaluation.

Symptomatic therapy with antidiarrheal drugs is often required in patients with chronic diarrhea [*see Table 2*]. Loperamide or diphenoxylate with atropine can be tried initially. In patients with chronic diarrhea, routine dosing (e.g., two tablets before each meal or at bedtime) is more effective than as-needed dosing after passing loose stools. More potent opiates, such as codeine, opium, and morphine, are underutilized in patients who do not respond to loperamide or diphenoxylate with atropine. Although these are controlled substances because of the possibility of abuse, abuse is unlikely in closely monitored patients with chronic diarrhea. Dosing should be started at a low level (e.g., codeine, 30 mg q.i.d.; deodorized tincture of opium, 3 drops q.i.d.; or morphine, 2 mg q.i.d.) and titrated up gradually to an effective dose. Stool-modifying agents, such as psyllium, can alter stool consistency but do not reduce stool weight. They may be of special help in patients with coexisting fecal incontinence.

Treatment of Specific Diseases and Syndromes

Osmotic diarrhea Osmotic diarrhea should abate with fasting or elimination of the offending agent from the diet. This response may be incomplete if other diarrhea-producing mechanisms are still active, such as short bowel syndrome or diseases of small bowel mucosa.

Irritable bowel syndrome and functional diarrhea Patients with chronic diarrhea in whom no other etiology is established are commonly diagnosed with irritable bowel syndrome or functional diarrhea. Irritable bowel syndrome is characterized chiefly by abdominal pain that is associated with altered bowel function, including constipation, diarrhea, or alternating diarrhea and constipation.[53] A diagnosis of functional diarrhea is made when patients do not have prominent abdominal pain and have no evidence of other specific causes of diarrhea. Obviously, these diagnoses are only as firm as the evaluation that is used to exclude other causes of diarrhea. For example, most cases of diarrhea from malabsorption of bile acid or carbohydrates are characterized as functional diarrhea or irritable bowel syndrome because specific testing for those malabsorption disorders is not done. Thus, careful consideration of alternative diagnoses should

precede a diagnosis of irritable bowel syndrome or functional diarrhea in patients with chronic diarrhea.

Nevertheless, there are certain clues to the diagnosis of irritable bowel syndrome or functional diarrhea that should be sought by the physician. Features that suggest a diagnosis of irritable bowel syndrome include a long history of diarrhea dating back to adolescence or young adulthood; passage of mucus; and exacerbation of symptoms with stress. Historical points that argue against irritable bowel syndrome include recent onset of diarrhea, especially in older individuals; nocturnal diarrhea; weight loss; blood in stools; voluminous stools (> 400 g/24 hr); and blood tests indicating anemia, leukocytosis, a low serum albumin concentration, or a high erythrocyte sedimentation rate.

New treatments for irritable bowel syndrome are being developed[63] in response to current theories about the pathogenesis of this disorder; pathogenetic processes that may yield new treatment strategies include dysregulation by the enteric nervous system,[64] food allergies,[65] small bowel bacterial overgrowth,[66] and changes in the colonic bacterial flora.[67]

Microscopic colitis syndrome Microscopic colitis syndrome, which subsumes the diagnoses of lymphocytic colitis and collagenous colitis, is a frequent cause of chronic diarrhea.[45,68,69] This disorder is characterized by chronic watery diarrhea and microscopic evidence of mucosal inflammation in the presence of normal gross colonoscopic findings. Histologic findings in both lymphocytic colitis and collagenous colitis include intraepithelial lymphocytic infiltration and chronic inflammation in the lamina propria without crypt destruction. Collagenous colitis and lymphocytic colitis are distinguished by the presence or absence of a thickened subepithelial collagen layer.

The cause of microscopic colitis syndrome is uncertain. It is associated with many autoimmune disorders and immunologically mediated diseases, such as celiac disease, which suggests that immune dysregulation is important. Bacterial antigens within the colonic lumen may also play a role. NSAIDs have been implicated in some reports.

Women are more likely than men to have collagenous colitis; lymphocytic colitis is equally likely in men and women. Diarrhea is of moderate severity (typically, 500 to 1,000 g/24 hr) and is characteristically secretory in nature because it results from failure of the colonic mucosa to absorb water and salt. Diagnosis is made by obtaining biopsy material from normal-appearing mucosa at the time of sigmoidoscopy or colonoscopy.

Treatment options include budesonide, bismuth subsalicylate, 5-aminosalicylate drugs, prednisone, and azathioprine.[45,68,69] Bile acid–binding drugs also have been reported to be successful in reducing diarrhea.[70] Microscopic colitis can have a remitting and relapsing course, and symptomatic therapy with opiate antidiarrheal drugs may be all that is needed. There is no evidence that microscopic colitis is a risk factor for colon carcinoma, and no surveillance program is currently recommended.

Laxative abuse Although rarely suspected, laxative abuse occurs regularly in four groups of patients: (1) those with anorexia or bulimia, (2) those who obtain a secondary gain from illness (e.g., disability payments, attention from relatives), (3) those with Munchausen syndrome, and (4) those who are dependent on others for their health care and who are poisoned by their caregivers (caregivers who do this are usually motivated by the desire to demonstrate their devotion to the patients).[71] Physicians need to consider surreptitious laxative abuse in patients who confound diagnosis and who are in one of the categories.

Detection of laxative abuse depends on having a high index of suspicion. Clues include the presence of hypokalemia in a patient who is able to eat (suggesting stimulant laxative abuse or concurrent ingestion of diuretics), melanosis coli (brownish pigmentation in the colonic mucosa caused by ingestion of anthraquinone laxatives) in a patient being evaluated for chronic diarrhea, or a large fecal osmotic gap (seen with magnesium ingestion). Most laxatives can be detected in stool water by chemical techniques. Adulteration of stool by added water or hypotonic urine can be detected by finding a low measured stool osmolality (< 280 mOsm/kg). The addition of hypertonic urine can be detected by impossibly high stool osmolality (> 600 mOsm/kg) and the presence of a negative fecal osmotic gap resulting from high urinary sodium or potassium concentrations. Negative fecal osmotic gaps may also be calculated in patients ingesting laxatives containing phosphate or sulfate.

Before patients are confronted with the diagnosis of laxative abuse, testing should be confirmed on another stool specimen, and appropriate psychiatric consultation should be available, because some of these patients become suicidal when confronted, and all of them need counseling. In cases of laxative poisoning by a caregiver, legal proceedings need to be instituted to separate the patient from the caregiver. Outcome studies in laxative-abuse patients are few. One study suggested that nearly half of the patients sought further medical attention elsewhere for chronic diarrhea.[72]

Postsurgical diarrhea Diarrhea can occur after several different kinds of operations. Peptic ulcer surgery is less common than it used to be, but new kinds of gastric operations, such as gastric bypass for obesity, produce similar complications. Dumping syndrome is the term used to describe a condition characterized by postprandial flushing, hypotension, diarrhea, and hypoglycemia.[73] This syndrome results from unregulated gastric emptying, osmotic shifts of fluid into the gut, and the rapid release of peptide hormones from the small intestine. Dumping syndrome can occur after vagotomy (intentional or accidental), pyloroplasty, gastrojejunostomy, and gastric resection. It can be treated with dietary modifications, antidiarrheal drugs [*see Table 2*], and the somatostatin analogue octreotide. Gastric surgery may also predispose patients to bacterial overgrowth in the small intestine, abnormally rapid intestinal transit, bile acid malabsorption, and pancreatic exocrine insufficiency from inadequate stimulation of the pancreas.

Bowel resection can result in loss of surface area sufficient to impair absorption of nutrients or water and salt. Lesser degrees of resection can result in diarrhea if an area of specialized function is removed.[74] For example, resection of the terminal ileum and right colon reduces bile acid absorption and the ability to absorb sodium against a large electrochemical gradient; these defects cannot be overcome by other areas of the intestine. With time, intestinal adaptation can overcome impaired electrolyte absorption, but intestinal adaptation cannot reverse loss of these specialized functions.

Ileostomy diarrhea is said to occur when stoma output exceeds 1,000 ml/24 hr. It may be caused by loss of absorptive surface area, if a substantial length of bowel has been resected; it may result from stomal stenosis, partial bowel obstruction, bacterial overgrowth, recurrent disease, medications, or intraperitoneal infection.[75] A special situation occurs in patients with ul-

cerative colitis who have had an ileoanal anastomosis with creation of an ileal reservoir pouch. These patients may develop inflammation of the pouch (so-called pouchitis) caused by bacterial overgrowth or recurrent inflammatory bowel disease.[76] Pouchitis can be treated with antibiotics such as metronidazole, anti-inflammatory drugs such as mesalamine, or ingestion of probiotic bacteria. Ordinary ileostomy diarrhea can be treated successfully with antidiarrheal opiate drugs.

Postcholecystectomy diarrhea occurs in as many as 20% of patients. It may be delayed in onset, and it is rarely severe. Diarrhea may occur as a result of ileal bile acid malabsorption at night, when the migrating motor complex may sweep bile acid past the absorptive sites in the terminal ileum, but some cases may have other causes.[77] Postcholecystectomy diarrhea is best treated with bile acid–binding agents given at bedtime. Opiate antidiarrheal drugs may be needed in refractory cases.

Diabetic diarrhea Up to 30% of patients with long-standing diabetes mellitus may experience chronic diarrhea.[78] This diarrhea has been attributed to autonomic neuropathy and dysregulation of motility, but definitive evidence of neuropathy is not always evident. If steatorrhea is present, three conditions that occur with increased prevalence in diabetics should be considered: (1) small bowel bacterial overgrowth, (2) pancreatic exocrine insufficiency, and (3) celiac disease. Other causes that need to be considered are medications, such as acarbose, and ingestion of dietetic foods containing sugar alcohols (e.g., sorbitol or mannitol).

When watery diarrhea is present, treatment with clonidine, an alpha$_2$-adrenergic agonist drug, may have special value. When clonidine cannot be tolerated because of its hypotensive effect or when it is not effective, opiate antidiarrheal drugs may be used. Fecal incontinence related to diabetic sensorimotor neuropathy may complicate diarrhea; this form of diarrhea needs to be evaluated, because therapies to mitigate incontinence, such as biofeedback training, may have a dramatic effect on quality of life.[79]

Diarrhea in patients with AIDS Diarrhea in AIDS patients is likely to result from opportunistic infections or lymphoma. A careful search for the cause of diarrhea can result in targeted therapy that may cure the diarrhea.[80] Colonoscopy is preferable to sigmoidoscopy because it allows visualization and biopsy of the right colon and ileum, which are often the sites of infection. It is possible that HIV-1 may directly produce diarrhea (so-called AIDS enteropathy), but in most cases, a specific infection can be identified.

Idiopathic secretory diarrhea The diagnosis of idiopathic secretory diarrhea can be made when an exhaustive evaluation fails to reveal a cause of chronic secretory diarrhea. This condition often begins suddenly in previously normal individuals, and it is distinguished from the acute secretory diarrhea by its persistence for more than 4 weeks. It occurs in two forms, epidemic and sporadic.

Epidemic idiopathic secretory diarrhea occurs in outbreaks that are seemingly related to contaminated food or water.[81] The initial description of this condition involved an epidemic of chronic diarrhea in Brainerd, Minnesota, and the condition has consequently become known as Brainerd diarrhea. Several outbreaks have been described in detail since the initial epidemic, and although the epidemiology suggests an infectious cause, no organism has been isolated.

Sporadic idiopathic secretory diarrhea affects individuals in an identical fashion as the epidemic form, but it does not seem to be acquired easily by family members or others.[52] Many patients describe a history of travel to local lakes or recreational sites, but they are the only members of their parties that become ill.

Both forms of idiopathic secretory diarrhea begin abruptly and reach maximum intensity shortly thereafter. Fever is unusual. Weight loss of up to 20 lb characteristically occurs in the first few months of the illness, but it does not become progressive thereafter. Empirical trials of antibiotics and bile acid–binding drugs are ineffective, but nonspecific opiate antidiarrheal drugs provide some relief. Idiopathic secretory diarrhea is self-limited and usually disappears within 2 years of onset. The offset of diarrhea is gradual, occurring over 2 to 3 months.

Diarrhea of obscure origin Diarrhea of obscure origin is said to be present when chronic diarrhea has evaded diagnosis in spite of an evaluation for structural problems. Patients are often referred commonly to centers interested in diarrheal diseases, where a specific cause for their diarrhea is often identified. Common diagnoses in these patients include fecal incontinence, drug-induced diarrhea, surreptitious laxative ingestion, microscopic colitis syndrome, bile acid–induced diarrhea, pancreatic exocrine insufficiency, carbohydrate malabsorption, sporadic chronic idiopathic secretory diarrhea, and, rarely, endocrine tumors. Most of these conditions can be recognized with a careful history, an appropriate index of suspicion, proper testing, or a well-conducted therapeutic trial. Failure to make a diagnosis is usually the result of not thinking through the differential diagnosis of chronic diarrhea and not appreciating the evidence at hand.

IV INFLAMMATORY BOWEL DISEASES

Stephen B. Hanauer, m.d., f.a.c.p.

Ulcerative colitis (UC) and Crohn disease (CD) constitute the two major idiopathic inflammatory bowel diseases (IBDs). Gastroenterologists recognize that there is a spectrum of IBDs, encompassing varying types and degrees of intestinal inflammation, and that these idiopathic disorders must be distinguished from inflammation caused by infections, drugs (particularly nonsteroidal anti-inflammatory drugs [NSAIDs]), ischemia, and radiation. UC and CD are the most common and best understood IBDs, with a well-defined epidemiology and pathogenesis; their etiologies, however, remain elusive.[1]

Epidemiology

UC and CD share most epidemiologic characteristics.[2] These diseases are relatively common in developed nations and infrequent in countries with poor sanitation. In North America and Europe, the incidence is approximately five cases per 100,000 population for each disease, with a combined prevalence of approximately 100 per 100,000 population. The diseases can affect persons of any age, but onset most commonly occurs in the second and third decades of life. Much smaller, secondary peaks in incidence occur in the sixth and seventh decades. Males and females are affected equally. Risk of disease is higher in some ethnic groups than in others. Ashkenazi Jews have a higher risk of IBD than Africans, African Americans, and Asians; the incidence of IBD increases in these lower-risk groups, however, when they emigrate to developed nations or adopt Western culture and diet.

Etiology

The cause of IBD has yet to be established. IBD probably has multiple causes, involving an interplay between genetically mediated susceptibility, environmental factors, and aberrant immune function. These disorders may well prove to be a series of syndromes with overlapping features.[1] As yet, no dietary factor has been identified, despite case-control studies suggesting a possible association with the ingestion of large amounts of refined sugar and, perhaps, fat (essentially, the Western diet).[3] Extrapolation from animal models of IBD suggests that commensal (rather than pathogenic) flora can initiate inflammation in genetically susceptible individuals,[1,4] but no specific infectious agent has been identified as causative of either UC or CD.

There are two major clues to the etiology of IBDs. The first is the familial association of IBD, which suggests a genetic predisposition.[5] Both UC and CD are more common in families with an affected relative. Once a proband has been identified, the risk of the disease occurring in a second family member is approximately 20% (40% if the proband is a child). The risk is distributed throughout families, with an estimated risk for individuals of 3% to 5% spread among first-, second-, and third-degree relatives. If both parents have IBD, the risk of disease in an offspring is nearly 50%. There is a concordance for disease type (and subtype, in the case of CD) within families, although either UC or CD may be seen.[5] Risk of disease is highest in identical twins, with a concordance of 20% for UC and 60% for CD. This degree of risk suggests a polygenic causation with higher penetrance in CD.[6] Genetic loci for IBD have been found: for example, the *NOD2/CARD15* gene on chromosome 16 (*IBD1*) increases susceptibility to CD; other potential loci are being investigated.[5]

The second etiologic clue is the relationship between cigarette smoking and UC and CD.[7] Case-control studies from around the world have demonstrated that cigarette smokers are less likely to develop UC and more likely to develop CD. In contrast, ex-smokers are more likely to develop UC. Cigarette smoking also influences the course of IBD; for example, ex-smokers with UC are more likely to have refractory disease and to require surgery than are patients who have never smoked.[8] Cigarette smoking also protects against the development of primary sclerosing cholangitis associated with UC.[9] Conversely, current cigarette smokers with CD are more likely to have disease that is refractory to medical therapies and that recurs more rapidly after surgical resection; these effects can be reversed by smoking cessation.[10] It has not been established whether nicotine is the primary factor in the associations of cigarette smoking with UC and CD. Nicotine delivered by transdermal patch appears to have a modest therapeutic potential for UC,[11] although not as much as resumption of smoking.

Pathogenesis

There are numerous animal models for IBD, including the cotton-top tamarin, a New World monkey that, in captivity, develops a so-called spontaneous colitis with many features that are similar to those of human UC. These shared features include the development of antiepithelial antibodies, response to anti-inflammatory medications, and the development of dysplasia and adenocarcinoma.

Other animal models more closely mimic CD. These include genetically engineered transgenic rats that overexpress human HLA-B27 and β_2-microglobulin molecules and knock-out mice with targeted deletions of interleukin 2 (IL-2), IL-10, T cell receptor chains, and transforming growth factor–β. The transfer of enriched populations of functional T helper type 1 (Th1) lymphocytes into severe combined immunodeficient mice induces colitis and wasting that can be prevented by transfer of unfractionated $CD4^+$ T cells.[1]

Regardless of species or immune status, animals raised in germ-free environments do not develop intestinal inflammation.[12] The significantly higher rate of autoimmune diseases in developed versus developing countries suggests that infectious agents (bacterial, viral, and parasitic) act as antigenic triggers and that exposure to numerous microorganisms early in life may protect against autoimmunity later in life; this is the so-called hygiene hypothesis.[13] The loss of immune tolerance to specific (bacterial) antigenic triggers has been demonstrated in patients with CD.[14] Hypothetically, environmental factors interact with a genetically determined, defective innate immune response. The innate immune defects may involve dendritic cells[15] and Toll-like receptors[16] [*see 6:II Innate Immunity*]; in addi-

tion, bacterial invasion of the mucosa may be facilitated by impairment of the mucosal protection mediated by mucins, trefoil peptides, or defensins.[17] Subsequently, the onset of IBD symptoms may be triggered by acute infections (e.g., traveler's diarrhea or acute gastroenteritis), antibiotic exposure, or other environmental factors in genetically susceptible hosts. Whether a trigger (specific or nonspecific) modifies the disease subtype cannot as yet be discerned.

Once intestinal inflammation begins, the primary difference between patients with IBD and unaffected persons is an impaired ability to downregulate mucosal inflammation.[1] Chronic inflammatory cells are normal in the intestinal mucosa; they comprise the gut component of the mucosa-associated lymphoid tract. The number of lymphoid elements in the mucosa is proportional to enteric exposure to bacteria. Persons raised in a sanitary environment (as is typical of developed countries) have less chronic inflammation than those raised in countries with poor sanitation. An extreme example is that of tropical sprue, in which mucosal inflammation is extensive and is associated with atrophy and ulceration of the small bowel villi.

In IBD, most immune elements (including tissue macrophages and mucosal T cells) respond to an exaggerated degree when triggered by an antigen. Activated macrophages and T cells are prominent in the recruitment of nonspecific inflammatory cells—primarily neutrophils, which are the final mediators of tissue damage.[1] The cytokine responses in UC and CD seem to differ, which may account for differences in disease phenotypes.[18] Many studies have demonstrated increases in levels of IL-1, IL-6, and tumor necrosis factor–α (TNF-α) in the mucosa of patients with UC and CD, although it is becoming apparent that the balance of cytokines may be different in the two diseases. CD is marked by a higher Th1 cytokine profile (interferon gamma, IL-2, IL-12, and TNF-α), whereas in UC, the balance is more consistent with a Th2 profile, with increased proportions of mucosal B cells, plasma cells, and antibodies.[1] In UC, increased production of both antineutrophil cytoplasmic antibodies and IgG antibodies reacting with a 40 kd tropomysin protein have been identified, although the pathogenic consequences of this interaction have not been defined.[19] Conversely, patients with CD have a greater likelihood of developing antibodies to a common brewer's yeast (*Saccharomyces cerevisiae*).[19]

A final pathway of tissue destruction is through the recruitment and activation of macrophages and neutrophils.[20] Activation of the arachidonic acid cascade leads to increased tissue levels of cyclooxygenase products (prostaglandins and thromboxanes), lipoxygenase products (primarily leukotriene B_4), and platelet activating factor. These compounds and other nonspecific mediators (e.g., nitric oxide, neutrophil tissue proteases, and reactive oxygen species) contribute to tissue destruction and can be targeted for specific and nonspecific anti-inflammatory therapy.[1,4]

Ulcerative Colitis

CLASSIFICATION

UC is marked by diffuse, superficial inflammation of the colonic mucosa, beginning in the rectum and extending proximally to involve any contiguous length of colon. The small intestine is not involved, except in the setting of extensive colitis, in which the most distal terminal ileum may exhibit similar superficial inflammation, termed backwash ileitis. Because the extent of colitis usually remains constant from the onset, the length of involved colon defines the classification of UC: proctitis (limited to the rectum), proctosigmoiditis or left-sided colitis (extending up to the splenic flexure), or pancolitis (extending into the transverse colon). Proximal extension occurs in approximately one third of patients with distal disease, and regression from pancolitis is also possible.[21,22] The extent of involvement does not necessarily imply severity but does pertain to prognosis (e.g., the risk of cancer) and to treatment selection. The symptoms and course of UC relate to both the extent and the severity of inflammation within the involved segment of colon.

DIAGNOSIS

The diagnosis of UC is made on the basis of clinical, endoscopic, and histologic findings. The presence of rectal bleeding or diarrhea should raise the suspicion of UC. Symptoms are often chronic, but they may also be intermittent or progressive. The easiest way to exclude UC is by direct examination of the rectosigmoid colon with a proctoscope or flexible sigmoidoscope. Radiography (barium enemas) has been almost completely replaced by more sensitive endoscopic examinations. Because UC always involves the rectum, inflammatory changes should be visible with a limited examination. In newly diagnosed patients, stool cultures are performed to rule out infectious diseases that may mimic or complicate UC, such as infection with *Salmonella, Shigella, Campylobacter,* hemorrhagic *Escherichia coli,* and *Clostridium difficile*.

Clinical Manifestations

The onset of UC typically is insidious rather than abrupt, although the disease occasionally presents acutely after infectious colitis or traveler's diarrhea.[23] Rectal bleeding is the most consistent feature. Bleeding may be gross or may be noted with evacuation of mucopus. Associated rectal urgency and tenesmus are related to diminished compliance of the rectum. Diarrhea, distinguished from the passage of mucopus without stool, relates to the extent of colonic involvement. Patients with proctitis often present with constipated bowel movements with interim passage of blood or mucus. Abdominal cramps preceding bowel movements are common, although abdominal pain or tenderness (related to transmural inflammation) signifies progressive, severe disease. In severe or fulminant colitis, systemic symptoms of night sweats, fever, nausea and vomiting, and weight loss accompany diarrhea. Extraintestinal manifestations can include inflammation of the eyes, skin, joints, and liver.

Ulcerative proctitis In the most common variant of UC, accounting for approximately 25% to 30% of cases and usually being the mildest, inflammation is limited to the distal 15 to 20 cm of rectum. Patients with ulcerative proctitis typically present with hematochezia, a sense of rectal urgency, and constipated bowel movements because of delayed transit of fecal material in the right colon. Systemic manifestations are uncommon, but skin or joint symptoms can occur.[24] The disease usually remains confined to the rectum but may advance proximally in as many as 30% to 40% of patients.[21]

Proctosigmoiditis Left-sided colitis is an intermediate syndrome of UC, accounting for about one third of cases. Patients present with either constipation or diarrhea accompanied by tenesmus, urgency, and rectal bleeding. Left lower quadrant

cramping abdominal pain is more common than with proctitis, as are extraintestinal symptoms. The proximal disease margin usually remains fixed throughout the course but can spread more proximally or even retract distally.

Extensive colitis (pancolitis) In pancolitis, inflammation extends into the transverse or right colon. Patients are more likely to present with diarrhea because of diminished absorptive capacity of the colon, accompanied by rectal bleeding and urgency. Abdominal cramps may be diffuse or localized, and patients are more likely to have weight loss, systemic or extraintestinal symptoms, and anemia.

Toxic megacolon Toxic megacolon refers to the most severe manifestation of UC, which occurs when the inflammation extends from the superficial mucosa into the submucosa and muscular layers of the colon.[25] Toxic megacolon occurs more commonly with extensive colitis but can also occur with severe distal colitis. The colonic wall becomes tissue-paper thin as the colon dilates and becomes hypomotile; perforation may occur. The patient often has fever, prostration, severe cramps, abdominal distention, and abdominal tenderness; the tenderness may be localized, diffuse, or rebound.

Clinical Severity

The severity of UC depends on both the length of colon involved and the severity of colonic inflammation. The set of criteria most commonly used to define the severity of disease was created by Truelove and Witts.[26-28] Although the criteria were developed to assess improvement in clinical trials, they remain useful in classifying severity in clinical practice, and they have been modified to include fulminant colitis [*see Table 1*]. Severity criteria are as follows:

Mild In mild UC, patients have less than four bowel movements daily, with minimal cramps and urgency. Usually, most of the bowel movements occur early in the day; and after the morning evacuations, the patient is able to proceed with activities of daily life.

Moderate Patients with moderate UC have four to eight bowel movements daily, more frequent rectal urgency, and postprandial cramping and bowel movements. Blood is present in most stools, and nocturnal wakening for bowel movements is common. The disease can interfere with daily work or school activities and social life.

Severe Patients with severe UC have more than eight bowel movements daily, nocturnal bowel movements, severe urgency with or without incontinence, and systemic signs that include low-grade fever, night sweats, weakness, and weight loss. Abdominal tenderness, tachycardia, anemia, leukocytosis, and hypoalbuminemia are common.

Fulminant Patients with fulminant colitis have more than 10 bowel movements a day, nocturnal bowel movements, severe abdominal pain or relentless tenesmus, and rebound tenderness or distention with tympanic bowel sounds. They also have prostration, high fever, and hypotension. Radiographic studies show evidence of mucosal edema, intramural air (pneumatosis coli), colonic dilatation (toxic megacolon), or free abdominal air (perforation).

Physical Examination

In most patients with UC, the physical examination results are normal. There may be mild abdominal tenderness to deep palpation, particularly in the left colon, but significant abdominal findings are limited to patients with moderate to severe disease, in whom tenderness is more prominent. Surprisingly, despite the frequent diarrhea, perianal manifestations are absent. Any significant perianal findings (e.g., large hemorrhoids, skin tags, fissures, abscesses, or fistulas) suggest CD rather than UC.

Table 1 Classification of Ulcerative Colitis

Feature	*Mild Disease*	*Moderate Disease*	*Severe Disease*	*Fulminant Disease*
History				
Stools	< 4/day (usually early in the day); minimal abdominal cramps and urgency	4–8/day; abdominal cramps and urgency	> 8/day; nocturnal bowel movements; severe urgency with or without incontinence	> 10/day; nocturnal bowel movements; severe urgency; tenesmus; severe abdominal pain
Blood in stool	Intermittent	Frequent	Frequent	Continuous
Physical examination				
Abdominal findings	Nontender abdomen; normal bowel sounds	Nontender or minimally tender over sigmoid	Tender abdomen; no rebound tenderness	Distended abdomen; decreased bowel sounds; rebound tenderness
Temperature	Normal	Normal	> 37.5° C (99.5° F)	> 37.5° C
Pulse	Normal	Normal	> 90	> 90
Other physical findings	Normal	Pallor	Weakness, pallor, weight loss	Prostration, hypotension
Laboratory tests				
Hemoglobin	Normal	Mild anemia	< 75% of normal	Transfusion required
Erythrocyte sedimentation rate	< 30 mm/hr	< 30 mm/hr	> 30 mm/hr	> 30 mm/hr
Radiography	Normal gas pattern	Absent stool in involved segment	Edematous colon wall, thumbprinting	Dilated colon, mucosal edema, intramural air, free abdominal air

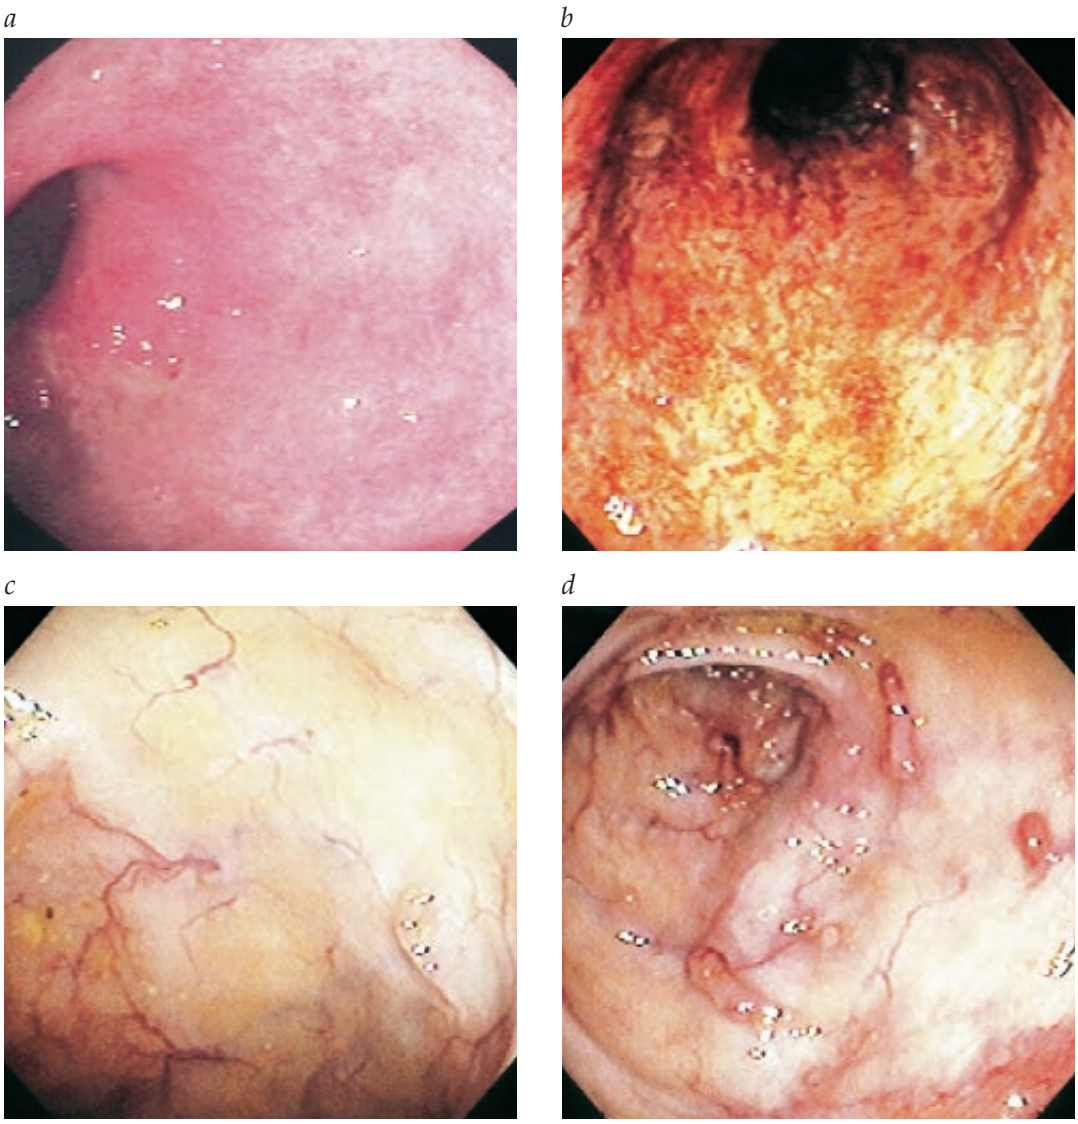

Figure 1 **The endoscopic spectrum of ulcerative colitis includes (*a*) mucosal edema, erythema, loss of vasculature; (*b*) granular mucosa with pinpoint ulceration and friability; (*c*) regenerated (i.e., healed) mucosa with distorted mucosal vasculature; and (*d*) regenerated mucosa with typical postinflammatory pseudopolyps.**

Conjunctival pallor is common because of anemia. Patients may present with ocular inflammation, erythema nodosum, pyoderma gangrenosum, or arthritis of larger joints.[29] Low back pain with diminished range of motion, or sacroiliac tenderness, is uncommon. Hepatomegaly, splenomegaly, or evidence of chronic liver disease is rare and limited to patients with end-stage primary sclerosing cholangitis.

Endoscopy

UC can almost always be diagnosed by endoscopic examination of the rectum and sigmoid colon.[30] The disease presents as diffuse and continuous inflammation beginning in the rectum, with proximal extension that varies among individual patients. In most cases, it is advisable to determine the proximal margin of disease, from the standpoints of prognosis[24] and therapy.[26,27] The initial examination should be performed without enema preparation, to avoid confusion with trauma or inflammation from administration of the enema. Patients with active colitis rarely have any fecal material in the involved lumen.

Healthy colonic mucosa is smooth and glistening, reflects light back from the scope, and demonstrates a branching mucosal vascular pattern. With inflammation, the mucosa becomes erythematous and more granular, which breaks apart the light reflection, and the vascular pattern becomes obscured by edema [*see Figure 1*]. The granularity of the mucosa may be fine or coarse. Coarse granularity represents microscopic or pinpoint ulcerations and is associated with friability (hemorrhage from the mucosa that may be spontaneous or induced by scope trauma). Exudates of mucopus are a common associated finding. Gross ulcerations represent more severe disease and, although usually shallow, can progress to a total denudation of the mucosa with exposure of the underlying circular musculature. These changes can be continuous up to a distinct margin where the mucosa appears normal, or they may extend diffusely to the cecum and, occasionally, into the distal ileum (backwash ileitis). In the setting of pancolitis, the ileocecal valve is usually wide open (patulous), allowing easy entry into the terminal ileum. Some patients with distal UC (involving the rec-

tum or sigmoid) also may have limited inflammatory changes around the appendix in the cecum (cecal red patch).[31]

As ulcerative colitis heals, the mucosal changes may become more focal.[32] The colonic mucosa regenerates from ulceration to granularity, with gradual restitution of a distorted mucosal vascular pattern with less distinct branching or irregular, pruned-appearing vessels. In areas that had been more severely inflamed, granulation tissue may protrude and become reepithelialized as so-called pseudopolyps. These postinflammatory changes can arise in a variety of sizes and shapes and are more likely to become fingerlike projections, or even mucosal bridges, in areas that had severe, undermining ulcerations [*see Figure 1*]. Pseudopolyps have no neoplastic potential but can be difficult to differentiate from adenomatous polyps. When pseudopolyps are extensive, they can totally carpet the mucosa, making it impossible to discern distinct, potentially neoplastic polyps.

Histology

Samples for histologic analysis are typically taken during endoscopy. The histologic features of UC parallel the endoscopic appearance of diffuse, continuous mucosal inflammatory changes. The principal components are disruption of glandular architecture and an inflammatory infiltrate.[33] A hallmark distinction between chronic IBDs such as UC and acute self-limited (infectious) colitis is architectural distortion [*see Figure 2*]. In UC, the normal vertical (so-called test-tube) alignment of glands is distorted; the glands are separated by expanded lamina propria lymphocytes, plasma cells, and eosinophils, as well as by neutrophils, which normally are sparse. The glands themselves become irregular in shape and, often, branched. The neutrophil infiltrate is localized to the base of the glandular crypts and invades the crypts, producing crypt abscesses. In more severe disease, the epithelial lining is destroyed, leaving ulcerations over the lamina propria. The inflammatory changes are usually superficial, limited by the muscularis mucosae. Despite severe superficial changes, deeper inflammation is uncommon, except in the setting of fulminant colitis. In fulminant colitis, the muscular layers are breached by expanding inflammatory ulceration that can leave the bowel wall tissue-paper thin and protected only by the serosa.

As the mucosa heals, the glands may become atrophied or shortened and irregularly shaped, with a thinned-out lamina propria. Inflammatory polyps are composed of vascular granulation tissue with a thin colonic epithelium. In quiescent colitis, the architectural distortion is present but acute inflammation (neutrophils and crypt abscesses) is absent [*see Figure 2*].

Both acute inflammation and regeneration of the colonic epithelium produce cellular atypia that must be distinguished from epithelial dysplasia.[34] In regenerating mucosa, the glandular epithelium can become irregularly shaped and hyperchromatic, with depletion of normal apical mucus. Stratification of nuclei and loss of polarity are manifestations of neoplastic transformation (i.e., dysplasia).

Imaging Studies

Radiography Radiographs have largely been supplanted by endoscopic examinations for the diagnosis of UC, but radiography remains a valuable adjunct to endoscopy in specified clinical situations. Plain abdominal radiographs are useful in the setting of severe colitis. These examinations outline the air-filled colon and can demonstrate the presence or absence of haustrations or dilatation of the colon (to rule out toxic megacolon) [*see Figure 3*]. Extraluminal gas under the diaphragm (free air) and evidence of an ileus pattern are additional features of severe colitis. Plain abdominal radiographs also provide a view of the sacroiliac joints and lumbosacral spine as a gross assessment of sacroiliitis or ankylosing spondylitis for patients presenting with low back pain.

Contrast barium studies, once the primary diagnostic modality, are less commonly employed because endoscopic examinations provide higher diagnostic sensitivity and specificity and

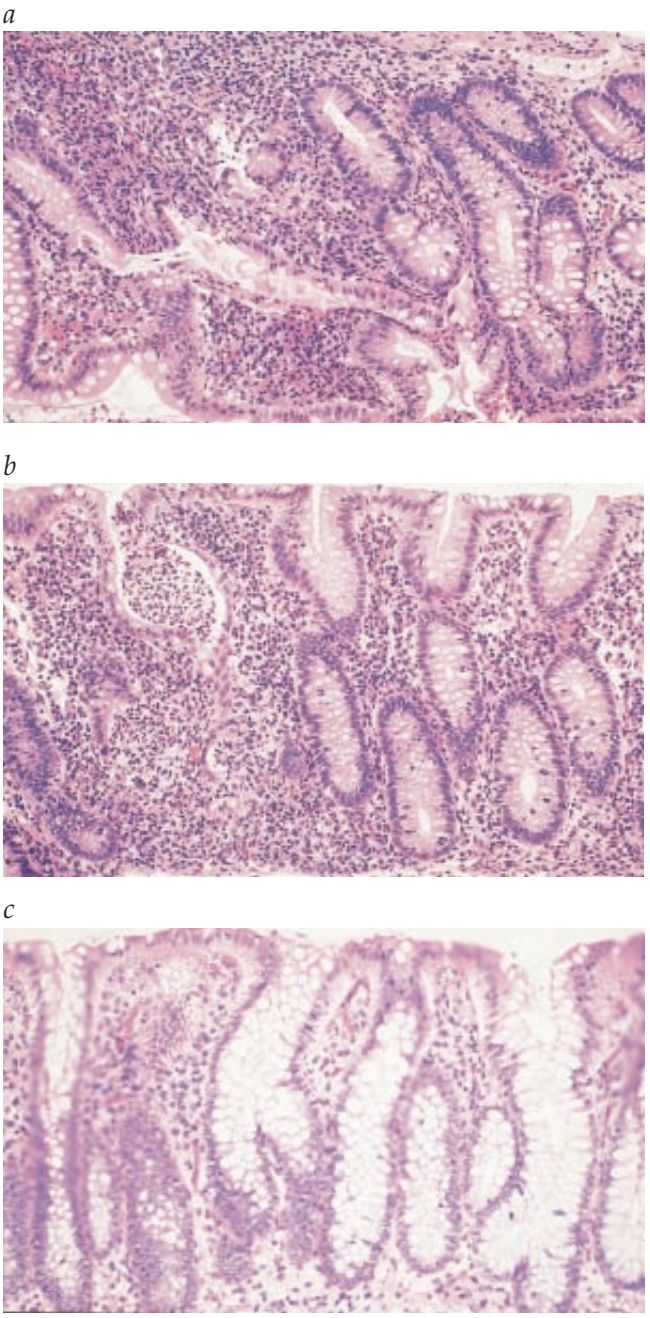

Figure 2 **Pathologic changes in ulcerative colitis include (*a*) acute superficial inflammation with distortion of the normal crypt architecture, (*b*) crypt abscesses, and (*c*) quiescent colitis without acute inflammation but with distortions of crypt architecture (abnormal branched crypts).**

Figure 3 **In this air-contrast radiograph of ulcerative colitis, the mucosal pattern is granular with loss of normal haustrations in a diffuse, continuous pattern.**

permit histologic sampling.[26] Air-contrast barium enemas demonstrate the fine or coarse mucosal granularity of microscopic ulcerations or the diffuse, continuous, and symmetrical pattern of ulceration involving the rectum to the proximal extent of disease [*see Figure 3*]. Other features of UC that may be visible on barium enemas are the loss of haustration in inflamed segments, foreshortening of the colon, and an increase in the space between the sacrum and the rectum. Barium enema examinations are contraindicated in severely ill patients because of the potential for perforation or the induction of a toxic megacolon.

Scintigraphy Scanning with indium-labeled or technetium-labeled leukocytes is occasionally indicated for severely ill adults or children when the extent of colitis is uncertain or when small bowel disease has not been excluded.[35] These studies provide relatively rapid determination of the extent, severity, and continuity of intestinal inflammation. Scintigraphy is noninvasive, is sensitive and specific for intestinal inflammation, and is occasionally helpful in discriminating UC from CD.

Crohn Disease

CD is manifested by focal, asymmetrical, and transmural inflammation of the digestive tract, at times accompanied by granuloma formation. In contrast to the inflammation of UC, which is diffuse, continuous, superficial (mucosal), and typically limited to the colon, the inflammation of CD is more patchy, may be transmural, and can involve any segment of the gastrointestinal tract from mouth to anus. Because the inflammation may be transmural, CD can lead to intestinal complications of stenoses (strictures) and fistulas. Although a hallmark of CD is the histologic finding of noncaseating granulomas, these granulomas are identified in only about 30% of patients and are not necessary to make the diagnosis.

Because CD may involve any segment of the gastrointestinal tract, the presentation is more heterogeneous than that of UC and is determined by the location, extent, severity of inflammation, and inflammatory pattern. The location and pattern tend to remain constant for each patient.[36] CD produces a spectrum of inflammatory patterns: from superficial inflammation similar to that of UC, to formation of fibrostenosing strictures, to penetration of the bowel wall and fistula formation accompanied by a mesenteric inflammatory mass or perienteric abscess. An attempt to classify CD on the basis of inflammatory patterns[37] has been compromised by the tendency of inflammatory patterns to progress to stenoses over time.[38] In contrast to UC, CD is usually not curable by surgery; intestinal resection and anastomosis are almost inevitably followed by recurrence of the disease involving the anastomotic site and proximal intestine.[39]

Table 2 Key Distinguishing Features of Ulcerative Colitis and Crohn Disease

Feature	*Ulcerative Colitis*	*Crohn Disease*
History		
Smoking status	Nonsmoker or ex-smoker	Smoker
Physical examination		
Symptoms	Rectal bleeding, cramps	Diarrhea, abdominal pain, weight loss, nausea, vomiting
Signs	Normal perianal findings, no abdominal mass	Perianal skin tags, fistulas, abscesses; abdominal mass; clubbing of digits
Laboratory tests		
Endoscopy	Rectal involvement; continuous superficial inflammation with granular, friable mucosa; terminal ileum normal or showing backwash ileitis	Rectal sparing; local ulceration with normal intervening mucosa; aphthous, linear, or stellate ulcers; terminal ileum inflamed with aphthous or linear ulcers
Radiology	Diffuse, continuous superficial ulceration; ahaustral (lead-pipe) colon; backwash ileitis	Focal, asymmetrical, transmural ulceration; strictures, inflammatory masses, fistulas; small bowel disease
Histology	Diffuse, continuous, superficial inflammation; crypt architectural deformity	Focal inflammation, aphthous ulcers, lymphoid aggregates, transmural inflammation, granulomas (15%–30% of patients)
Serology	Elevated p-ANCA (60%–80% of patients)	Elevated ASCA (~ 30% of patients)

p-ANCA—perinuclear antineutrophil cytoplasmic antibody ASCA—anti–*Saccharomyces cerevisiae* antibody

In clinical trials, the instrument most commonly used to quantify disease activity has been the CD Activity Index (CDAI).[40] However, because of its complex derivation and lack of discrimination between symptoms and inflammation, the CDAI is not used in clinical practice. Instead, patients require individualized assessments of the severity of disease according to inflammatory symptoms, obstruction, fistulization, abscess formation, systemic complications, and effect on the patient's quality of life.[41]

DIAGNOSIS

CD is diagnosed on the basis of clinical, radiographic, endoscopic, and histologic criteria. As with UC, there is no pathognomonic marker. The clinical presentation and key features of the history, physical examination, and laboratory studies determine the diagnostic workup and serve to differentiate CD from UC [*see Table 2*].

Clinical Manifestations

CD most commonly involves the terminal ileum and cecum. However, the pattern of CD can be quite varied [*see Figure 4*]. The presentation depends on the site, extent, severity, and complications of intestinal and extraintestinal disease.[42,43] Patients usually present with chronic disease, but CD can be acute, with severe abdominal pain, intestinal blockage, or hemorrhage. Abdominal pain is a more common feature of CD than of UC because the transmural extension of CD results in stimulation of pain receptors in the serosa and peritoneum. Abdominal cramping and postprandial pain are common symptoms that often are accompanied by diarrhea, rectal bleeding, nocturnal bowel movements, fevers, night sweats, and weight loss. Nausea and vomiting occur in the presence of intestinal strictures that produce partial or complete bowel obstructions. Transmural disease commonly manifests in the perianal region as skin tags or perirectal abscesses or fistulas,[44] but it also can present as an inflammatory mass in the right lower quadrant. In children and adolescents, the presentation often is more insidious, with weight loss, failure to grow or to develop secondary sex characteristics, arthritis, or fevers of undetermined origin. Skin lesions, primarily erythema nodosum, may precede intestinal symptoms.[45,46]

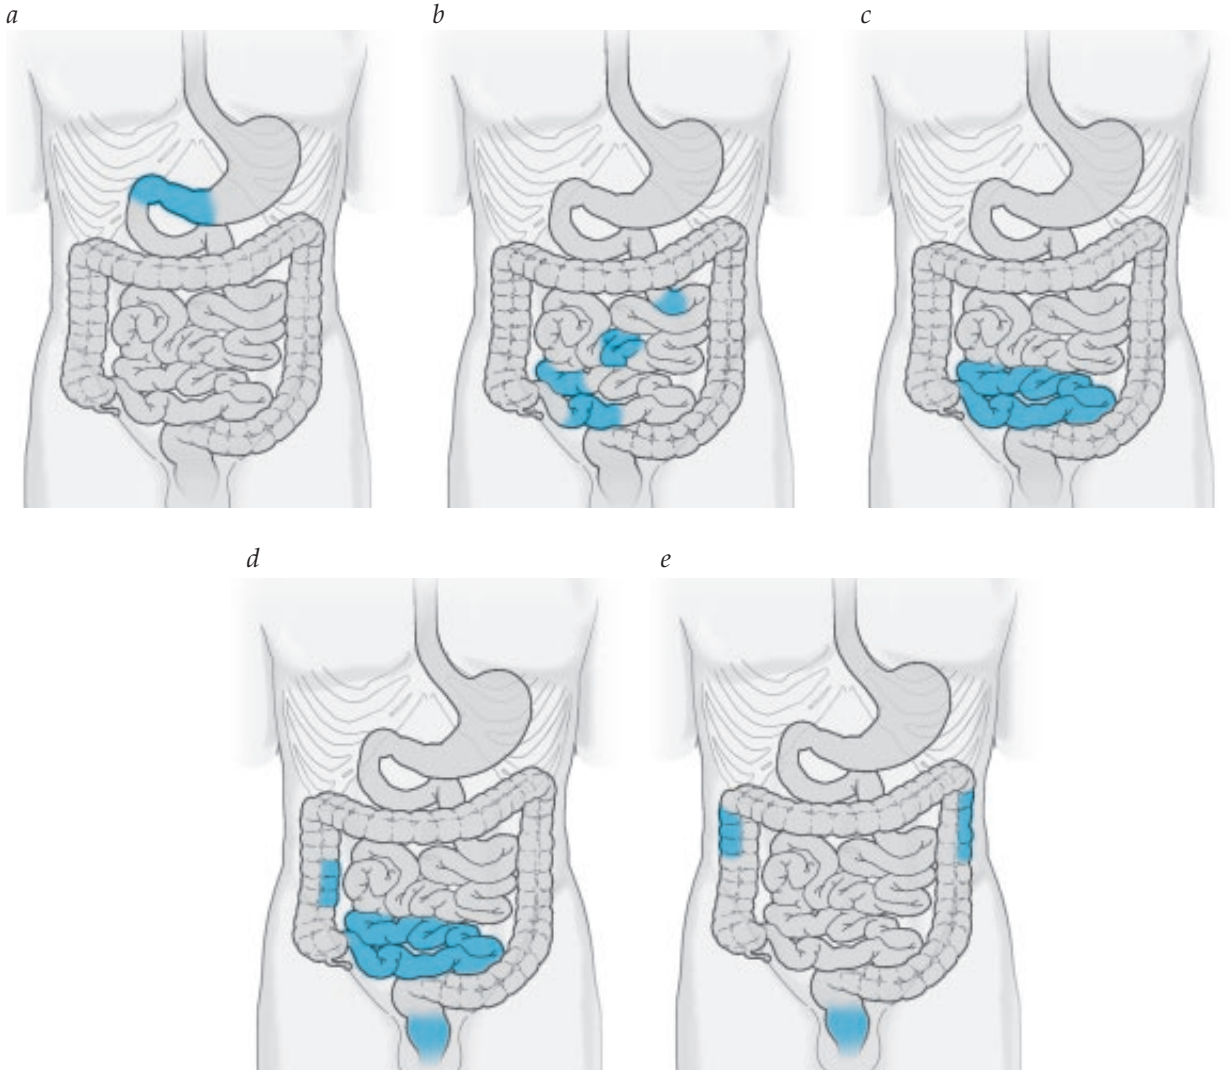

Figure 4 **The spectrum of Crohn disease presentations includes (*a*) gastroduodenitis (7% of patients), (*b*, *c*) jejunoileitis and ileitis (33% of patients), (*d*) ileocolitis (45% of patients), and (*e*) colitis (15% of patients).**

Crohn disease of the esophagus, stomach, and duodenum Infrequently, primary manifestations of CD mimic gastroesophageal reflux or peptic ulcer disease.[47,48] Heartburn, dysphagia, nausea, dyspepsia, epigastric pain, and early satiety or postprandial vomiting typically accompany other systemic inflammatory symptoms such as fever, night sweats, and rectal bleeding.

Jejunoileitis Another relatively uncommon presentation of CD, jejunoileitis most often presents with vomiting and diarrhea, cramping abdominal pain, and weight loss.[49] Patients describe borborygmi related to focal, segmental strictures compromising the passage of enteric contents. Diarrhea is multifactorial and can be secondary to malabsorption as a consequence of inflammation, protein-losing enteropathy, or stasis and small bowel bacterial overgrowth proximal to strictures.

Ileitis and ileocecal Crohn disease CD most commonly presents as right lower quadrant abdominal pain and tenderness (often accompanied by an inflammatory mass), diarrhea with or without rectal bleeding, weight loss, fevers, chills, and night sweats. An acute presentation may mimic appendicitis; occasionally, Crohn ileitis will be diagnosed at exploratory laparotomy for presumed appendicitis.

Crohn colitis Approximately 15% of CD cases are limited to the colon. Distinguishing these cases from UC can be difficult, because the clinical manifestations—diarrhea, rectal bleeding, and urgency—overlap with those of UC [*see Table 2*]. However, CD of the colon is more likely than UC to be accompanied by perianal manifestations (skin tags and perirectal abscess or fistulas), and the rectum often is spared, whereas UC always involves the rectum. In approximately 10% to 20% of patients presenting with colitis, the classification may be indeterminate in the setting of diffuse or severe inflammation or of questionable focal inflammation.[50]

Perianal Crohn disease Perianal involvement in CD most often accompanies colonic disease and begins within the anal crypts.[51] Small fistulas from the anorectal junction progress through or around the anal sphincter and present as perirectal abscesses or fistulas. Often, perianal tissue becomes hypertrophied, producing skin tags [*see Figure 5*]; these may be misdiagnosed as hemorrhoids. At times, perianal manifestations are the primary presentation, and in extreme situations, the anal sphincter and perineum can become grossly deformed.

Physical Examination

Key findings on physical examination of patients with CD include both abdominal and general systematic abnormalities. The abdominal examination may be significant for distension and abnormal bowel sounds in the presence of intestinal strictures producing partial intestinal obstruction. Tenderness in the area of involvement and the presence of an inflammatory mass are common. It is important to examine the perianal region and rectum for evidence of abscess, fistula, skin tags, or anal stricture.

Patients with CD often are chronically ill and can present with weight loss and pallor. The eye exam may demonstrate episcleritis or uveitis. Aphthous ulcerations in the mouth are common, and in extreme cases, patients may exhibit evidence of nutritional deficiencies (e.g., cheilosis or tongue atrophy). Examination of the musculoskeletal system may demonstrate swelling or redness of large joints (e.g., knees, ankles, or wrists) or clubbing of the fingers. Skin examination can reveal erythema nodosum or, rarely, pyoderma gangrenosum.

Figure 5 **The typical perianal skin tag of CD differs from the typical hemorrhoid tag.**

Laboratory Studies

Anemia is common in CD. Anemia can result from deficiencies of iron, vitamin B_{12}, or folic acid or may be the anemia of chronic disease. Serum ferritin levels correlate better than iron and iron-binding protein levels with bone marrow iron stores in IBD.[52] Leukocytosis is common, depending on the severity of inflammation and the presence of suppurative complications. Thrombocytosis also is common and is related to inflammation or iron deficiency. Elevated erythrocyte sedimentation rates and C-reactive protein levels reflect nonspecific acute-phase reactions.[53] Electrolyte disturbances depend on the severity of diarrhea and dehydration. Serum albumin levels often are reduced as a result of malnutrition and enteric protein losses. Patients with severe weight loss may have prolonged clotting times because of vitamin K deficiency. Urinalysis commonly demonstrates calcium oxalate crystals.

Quantitative stool examinations are useful in the setting of diarrhea to assess fecal leukocytes (confirming inflammatory diarrhea), stool volume, and fecal fat. Quantification of either fecal calprotectin[54] or lactoferrin[55] is a surrogate for the presence of fecal leukocytes. The presence of the serologic markers anti–*Saccharomyces cerevisiae* antibody and an antibody to the outer core membrane of *E. coli* (OmpC) have high specificity for CD.[56]

Imaging Studies

Radiography Barium contrast studies are the most commonly used diagnostic tools to assess and confirm CD of the small intestine and are useful for assessing the upper digestive tract and colon. In colonic disease, barium studies can define intestinal complications (e.g., stricture formation or fistulas) that cannot be adequately assessed by endoscopy. Features of CD that are shown with barium examinations include mucosal edema, aphthous and linear ulcerations, asymmetrical narrowing or strictures, and separation of adjacent loops of bowel caused by mesenteric thickening. Abnormalities are focal and asymmetrical, with ulcerations most often involving the antimesenteric border. Cobblestoning of the mucosa represents

networks of linear ulcerations outlining islands of residual normal mucosa. Pseudodiverticula formation or dilated loops of bowel are common proximal to strictures. There may be evidence of fistulas extending from any involved segment to an adjacent loop of bowel, the mesentery, or the urinary bladder or from the rectum to the vagina or perineum. CT scanning after direct injection of barium into the small bowel through a nasogastric tube (enteroclysis) provides excellent discrimination between intestinal and extra-intestinal disease.[57]

Other imaging studies Ultrasound examinations or CT scans are useful to assess for abscess in patients who have an inflammatory abdominal mass or who have fever, leukocytosis, or abdominal tenderness. Ultrasound or CT scan is also warranted to assess for hydronephrosis in the setting of an inflammatory mass in the right lower quadrant, because these have the potential to obstruct the right ureter. Transrectal ultrasound, CT scan, and MRI also are useful to assess the extent of perianal and sphincter involvement in patients presenting with perianal or perirectal pain.[51] Scintigraphy using leukocytes labeled with indium or technetium can be helpful to define locations of intestinal inflammation when barium studies are not possible or the results are indeterminate.[35,58]

Endoscopy Colonoscopic examinations have become a primary means of diagnosing CD that involves the colon. Endoscopy in these patients typically reveals sparing of the rectum, with focal inflammatory changes in the more proximal colon and terminal ileum. Other typical features include the presence of aphthous, linear, or irregularly shaped ulcerations with normal intervening mucosa [*see Figure 6*]. Inflammatory strictures may preclude examination of proximal segments of bowel. Inflammatory pseudopolyps may be seen, as in UC. In some patients, polypoid or masslike inflammatory changes may be difficult to differentiate from neoplastic masses; biopsy and histologic analysis may be required. Similar endoscopic

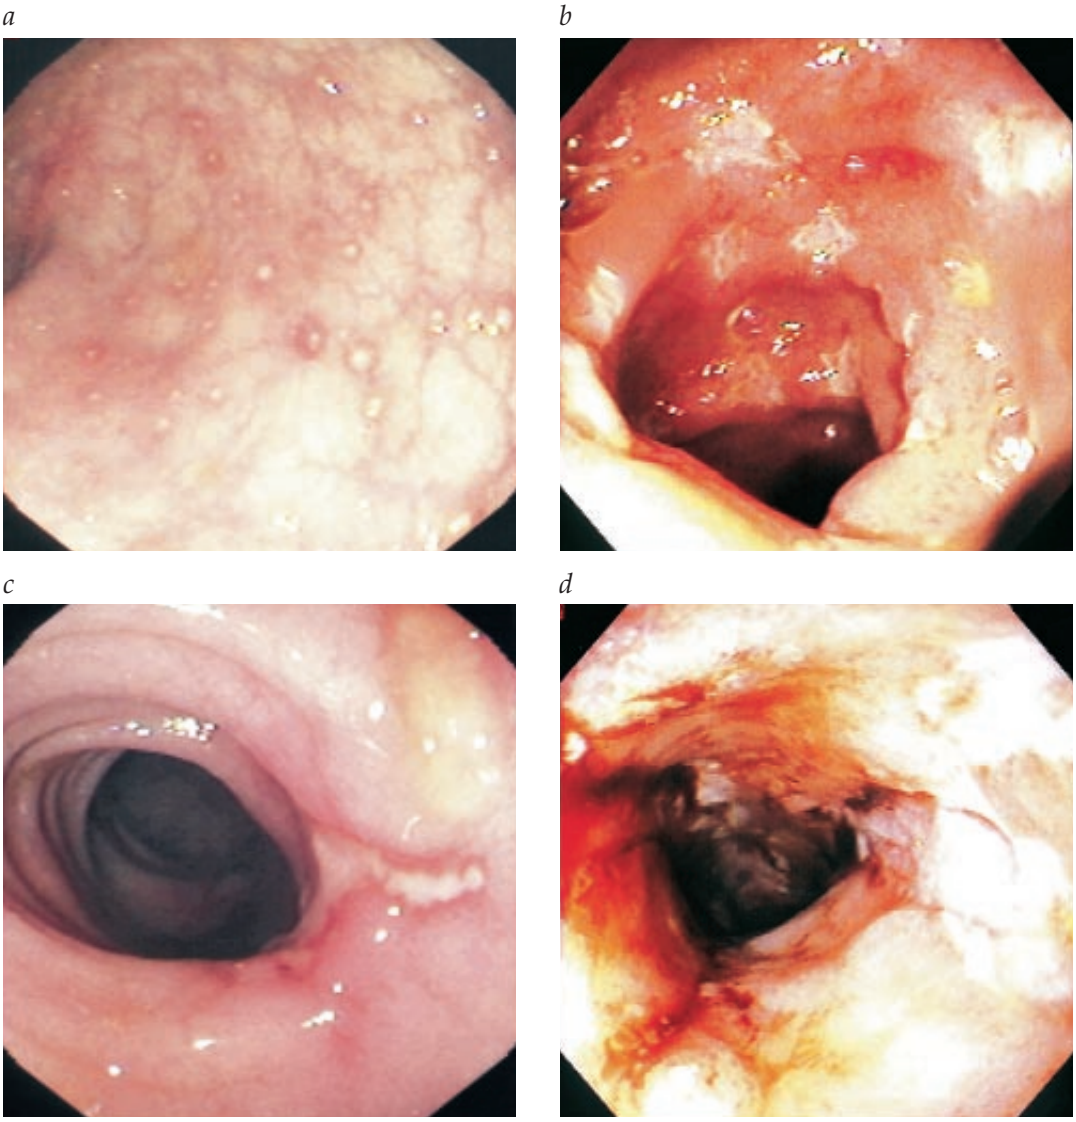

Figure 6 **Endoscopic spectrum of Crohn disease includes (*a*) aphthous ulcerations amid normal colonic mucosal vasculature; (*b*) deeper, punched-out ulcers in ileal mucosa; (*c*) a single colonic linear ulcer; and (*d*) deep colonic ulcerations forming a stricture.**

features may be present in the esophagus, stomach, or duodenum. An important aspect of endoscopic examinations is the ability to obtain samples for pathologic interpretation.

Wireless capsule endoscopy is now being used to diagnose CD. This technique offers access to parts of the small bowel that cannot be reached by standard endoscopy and may be more sensitive than conventional radiographic studies for identifying subtle lesions.[59]

Histology

Pathologic findings in CD reflect the gross pattern of focal and asymmetrical intestinal involvement.[32,33,50] The primary histologic lesion is an aphthous ulcer [*see Figure 7*]. These begin as erosions overlying lymphoid aggregates. As the minute ulceration extends, in either a linear or a transmural pattern, the microscopic and macroscopic changes that develop include a mixed acute and chronic inflammatory cell infiltrate composed of lymphocytes, plasma cells, and neutrophils. Crypt abscesses are common, and the inflammatory infiltrates often are located adjacent to normal epithelium. Noncaseating granulomas, which may be identified in mucosal biopsies or in resected specimens, are characteristic of CD; however, they are not necessary for confirming the diagnosis.

Granulomas may be found in mucosal specimens that appear grossly normal. Specimens from resected intestine demonstrate transmural inflammatory changes extending from the mucosa into the serosa (which is hyperemic, with creeping mesenteric fat). At times, there may be paradoxical involvement of the deeper layers of the bowel wall, with lymphoid aggregates overlying normal-appearing epithelium. Submucosal fibrosis, deep fissuring ulcerations, and fistulizing ulcerations communicate between loops of bowel or into the adjacent mesentery.

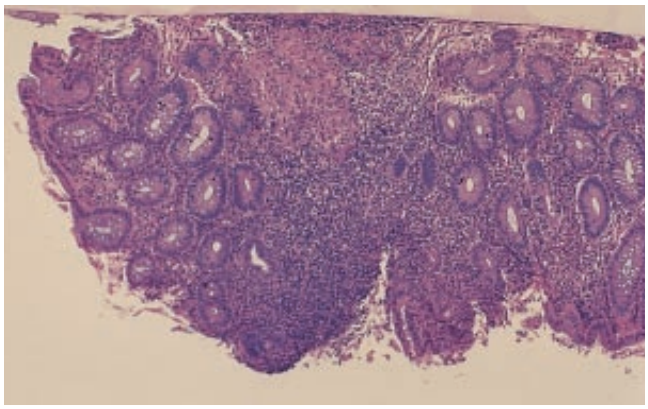

Figure 7 **Pathologic changes in Crohn disease include (*a*) ileal aphthous ulceration overlying a lymphoid aggregate and (*b*) focal colonic ulcer with noncaseating granuloma in lymphoid tissue.**

Differential Diagnosis

IBD should be considered in any patient who presents with rectal bleeding or diarrhea. Identification of fecal leukocytes is the simplest means of discerning an inflammatory process of the intestine. Other causes of rectal bleeding are either traumatic or neoplastic. Diarrhea is nonspecific and has a large differential schema [*see 4:III Diarrheal Diseases*]. The primary chronic diarrheal illness that requires differentiation from UC or CD is irritable bowel syndrome (IBS). IBS is never associated with rectal bleeding, and nocturnal symptoms are uncommon. The presence of occult blood or fecal leukocytes excludes IBS.

Patients with gross or occult blood in the stool require endoscopic evaluation. Colonic neoplasia is a prominent consideration for patients older than 50 years, whereas hemorrhoids or anal fissures are common in younger patients. NSAID-induced colitis is common and may contribute to ischemic colitis in persons in older age groups.[60] Ischemic colitis presents acutely in elderly patients after precipitating events such as dehydration or heart failure; in younger patients, the condition is associated with oral contraceptive use, vasculitis, and hypercoagulable states.[61] Endoscopic examination demonstrates focal hemorrhagic or ulcerated mucosa in the so-called watershed segments of the sigmoid colon or splenic flexure. Diverticular hemorrhage is typically profuse and painless. Some patients, however—particularly elderly persons taking NSAIDs—may present with less vigorous rectal bleeding from diverticulosis involving a segment of the sigmoid colon.[62]

Inflammatory diarrhea can be infectious or noninfectious.[63] The infectious colitides are caused by bacteria such as *Salmonella, Shigella, Campylobacter*, and hemorrhagic *E. coli*. Most of these diseases are acute and self-limited and need be considered only in patients who present with sudden onset of bloody diarrhea and fever. UC and CD develop insidiously, over weeks. *C. difficile* colitis can also mimic ulcerative colitis and may be more chronic, lasting weeks [*see 7:V Anaerobic Infections*]. In immunocompetent hosts, viral or parasitic infections rarely mimic UC. The exception is amebiasis, which may cause acute or subchronic symptoms. Amebiasis can often be distinguished from IBD by wet-mount examination of the stool for motile ameba and the more typical focal (so-called collar button) ulcerations in the colon [*see 7:XXXIV Protozoan Infections*]. Although most cases of infectious diarrhea are acute and self-limited, intercurrent infections and traveler's diarrhea can initiate flare-ups of IBD.[64] Consequently, patients presenting with new-onset IBD or acute exacerbations of IBD should be evaluated for a complicating enteric infection.

Management

The treatment of UC or CD is based on the location, extent, and severity of disease, as well as the patient's response to past therapy.[26,27] Factors that contribute to exacerbations of activity or refractoriness to therapy should be addressed. Such factors may include concomitant medications (e.g., NSAIDs or antibi-

otics), intercurrent infections (e.g., with *C. difficile*), menstruation, and dietary or lifestyle changes.

Treatment follows a sequential approach: induction of remission and, then, maintenance of remission. Clinicians can now choose from a variety of medication classes for treatment of IBD, and both medication selection and dosage may vary according to whether the therapeutic intent is induction or maintenance. Surgical treatment is indicated in selected patients to treat severe disease activity or specific complications.

ANTI-INFLAMMATORY AGENTS

Aminosalicylates

Aminosalicylates are the primary therapies for mild or moderate UC and CD.[26,27] These agents have a long history of clinical use and have been extensively studied in clinical trials for both UC and CD.[65,66] Sulfasalazine, the prototype aminosalicylate [*see Figure 8*], was developed with the intention of providing both an antibacterial agent (sulfapyridine) and an anti-inflammatory agent (5-aminosalicylic acid [5-ASA], mesalamine, or mesalazine) into the connective tissues. It was subsequently recognized that sulfasalazine remains intact through the stomach and small intestine, with minimal enteric absorption. On reaching the colon, the azo bond between sulfapyridine and 5-ASA is cleaved by colonic bacteria. Released sulfapyridine is almost completely absorbed from the colon and undergoes hepatic acetylation and subsequent renal excretion. In contrast, the 5-ASA released into the colon is poorly absorbed and is primarily eliminated in the feces.[67] Therefore, sulfasalazine primarily serves as a carrier for 5-ASA to the colon. The 5-ASA moiety accounts for the primary therapeutic benefits, whereas sulfapyridine causes the majority of side effects attributed to sulfasalazine. These attributes have led to the development of a series of sulfa-free aminosalicylates (e.g., olsalazine, balsalazide, and formulations of mesalamine) that can be targeted to specific sites along the gastrointestinal tract. A basic premise regarding the aminosalicylates is that the effects of 5-ASA are topical (mucosal), rather than systemic, and that the active moiety needs to be delivered to the site of intestinal inflammation.

Sulfasalazine and mesalamine have multiple anti-inflammatory effects, including inhibition of the arachidonic acid cascade along the cyclooxygenase, lipoxygenase, and platelet-activating factor pathways.[65,66] In addition, the aminosalicylates inhibit oxygen radical production and scavenge free radicals.[68] They inhibit lymphocyte and monocyte function and production of immunoglobulin by plasma cells. Sulfasalazine also has been shown to inhibit production of IL-1 and nuclear factor κB.[69]

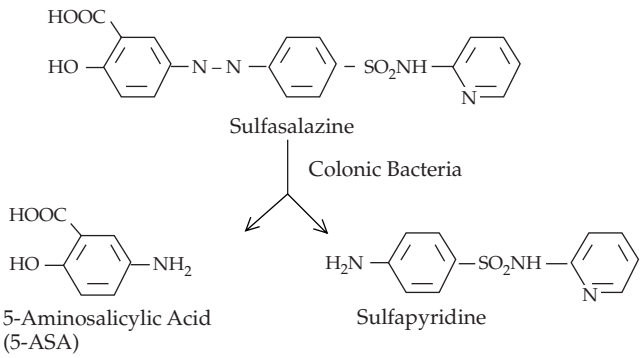

Figure 8 **Sulfasalazine is composed of sulfapyridine and 5-aminosalicylic acid (mesalamine), linked by an azo bond.**

Adverse effects of sulfasalazine are common and are primarily related to plasma sulfapyridine concentrations; these concentrations depend on the rate of hepatic acetylation of sulfapyridine, which is genetically determined.[70] Intolerance side effects (i.e., nausea, vomiting, malaise, anorexia, dyspepsia, and headaches) are dose related. In contrast, hypersensitivity reactions (i.e., rash, fever, hemolytic anemia, agranulocytosis, hepatitis, hypersensitivity pneumonitis, pancreatitis, and worsening of colitis) are independent of dose. Reversible sperm abnormalities and folate malabsorption are unique complications related to sulfasalazine.

Mesalamine has relatively few side effects, and dose-related toxicities are unusual in patients taking up to 4.8 g/day of delayed-release formulations.[70,71] Rare idiosyncratic reactions, including pancreatitis, interstitial nephritis, and worsening of colitis, have been reported. Eighty percent of patients who are unable to tolerate sulfasalazine can tolerate a nonsulfa aminosalicylate containing mesalamine. One unique complication of olsalazine is dose-related diarrhea.

Sulfasalazine and the oral aminosalicylates are equally effective for treatment of mild to moderate UC.[26,27,72] Oral aminosalicylates are effective for both proximal and distal colitis. Mesalamine suppositories and enemas effectively treat distal colitis, provided the formulation reaches the proximal extent of disease.[73] A dose-response relationship for the oral aminosalicylates is well defined for up to 4.8 g/day of mesalamine, with higher doses being more effective for moderately active disease.

Prevention of relapse and the prolongation of remission have been primary indications for all of the aminosalicylates in UC.[26,27,74] All the nonsulfa formulations provide comparable efficacy to sulfasalazine for maintenance therapy.[74] In ulcerative proctitis and distal colitis, topical mesalamine is also effective at preventing relapse and is more effective than oral treatment when continued on a long-term basis.[73]

The efficacy of aminosalicylates in CD is less definitive than that in UC and is more dependent on location of disease activity.[27,66] In CD involving the colon, the efficacy of sulfasalazine is determined by the presence of the colonic bacteria needed to cleave the azo bond and liberate 5-ASA. Aminosalicylates are commonly used as maintenance therapy for patients with quiescent CD, despite differing interpretations of the clinical trials of this indication.[27,65] The specific release characteristics [*see Table 3*] should correspond to the disease location.

Corticosteroids

Corticosteroids are the primary therapy for moderate to severe and fulminant UC and moderate to severe active CD.[27,75] They are ineffective at maintaining remissions of UC and CD, however.[76] The mechanisms of action of corticosteroids in IBD are multifactorial and are similar to their mechanisms of action in other inflammatory diseases.[77] Like aminosalicylates, corticosteroids can be targeted to specific sites within the digestive tract. Newer glucocorticoids (e.g., budesonide) both enhance potency and minimize systemic exposure.[78]

Ulcerative colitis Oral corticosteroids are the primary treatment for outpatients with moderately severe UC.[26,27,79] Prednisone, 20 to 60 mg daily, is administered once or in divided doses. In general, 40 mg is the optimal dose; the modest benefits of higher doses are offset by increasing side effects.[80]

Table 3 Aminosalicylate Preparations for Management of Ulcerative Colitis and Crohn Disease

Preparation	*Formulation*	*Delivery*	*Dosing*
Oral Agents			
Azo bond			
Sulfasalazine (Azulfidine, 500 mg)	Sulfapyridine carrier	Colon	3–6 g/day (acute) 2–4 g/day (maintenance)
Olsalazine (Dipentum, 250 mg)	5-Aminosalicylic acid dimer	Colon	1–3 g/day
Balsalazide (Colazal, 750 mg)	Aminobenzoyl-alanine carrier	Colon	6.75 g/day
Delayed Release			
Mesalamine (Asacol, 400 mg, 800 mg)	Eudragit S (pH, 7)	Distal ileum–colon	2.4–4.8 g/day (acute) 0.8–4.8 g/day (maintenance)
(Claversal,* Mesasal,* Salofalk,* 250 mg, 500 mg)	Eudragit L (pH, 6)	Ileum-colon	1.5–3.0 g/day (acute) 0.75–3.0 g/day (maintenance)
Sustained Release			
Mesalamine (Pentasa, 250 mg, 500 mg, 1,000 mg*)	Ethylcellulose granules	Stomach-colon	2–4 g/day (acute) 1.5–4.0 g/day (maintenance)
Rectal Agents			
Mesalamine suppository (Canasa, 400 mg,* 500 mg, 1,000 mg*)	—	Rectum	1.0–1.5 g/day (acute) 500–1,000 mg/day (maintenance)
Mesalamine enema (Rowasa, 1 g,* 4 g)	60 ml, 100 ml suspension	Rectum–splenic flexure	1–4 g/day (acute) 1 g q.d.–1 g t.i.w. (maintenance)

*Not available in the United States.

Rectal (i.e., topical) administration of systemically absorbed glucocorticoids (e.g., hydrocortisone) and of rapidly metabolized glucocorticoids (e.g., budesonide) is effective therapy for active distal colitis and has been incorporated into the treatment of severe colitis as an adjunct to parenteral steroids.[81]

Parenteral corticosteroids are the mainstay of therapy for hospitalized patients with severe or fulminant UC. Although controlled trial data are limited, there is consensus supporting the use of intravenous hydrocortisone, methylprednisolone, or prednisolone in dosages equivalent to 40 to 60 mg/day of prednisone; these agents may be given either in a continuous infusion or in divided doses.[26,27,79,80] There is no evidence supporting dosages higher than 60 mg of prednisone. Corticosteroids are not effective in preventing relapse of quiescent UC.[26,27,79,80]

Crohn disease Corticosteroids are the primary therapy for moderate to severe CD.[27,82] Both uncontrolled and controlled trials demonstrate a response rate of approximately 75%. Parenteral steroids have not been formally assessed in the setting of severe CD, but there is a consensus that they are as effective in severe CD as in severe UC. As a first-line therapy for mild to moderate CD, enteric-coated, delayed-release formulations of budesonide can deliver topically active steroids to targeted sites (ileum and proximal colon).[78,83] However, as with corticosteroids in UC, neither conventional nor topically active steroids have proved effective for preventing relapse in CD.[76,82]

IMMUNOMODULATORY AGENTS

Immunomodulating therapies have had an expanding role in the treatment of IBD. These agents can be used either to induce or to maintain remission in UC and CD.

Azathioprine and 6-Mercaptopurine

Although azathioprine (AZA) and 6-mercaptopurine (6-MP) have been used to treat IBD for over 30 years, their mechanisms of action and optimal use remain incompletely known. AZA is rapidly absorbed and converted to 6-MP, which is metabolized to thioinosinic acid, an inhibitor of purine ribonucleotide synthesis and cell proliferation.[84] Although AZA is considered a purine antimetabolite, its exact mechanism of action has not been defined. Presumably, AZA inhibits some function of long-lived lymphocytes, which accounts for the 3- to 6-month delay in onset of action. There is increasing evidence that these agents promote apoptosis of T cells.[85] In addition, a genetic polymorphism has been recognized in the enzyme thiopurine methyltransferase, which metabolizes the purine analogues into 6-thioguanine.[84,86] One in 300 persons lacks this enzyme, and an additional 11% of the population has depressed levels of it. Homozygotes are susceptible to increased accumulation of 6-thioguanine nucleotides and bone marrow suppression.

AZA and 6-MP usually are well tolerated.[80] Pancreatitis occurs in 3% to 15% of patients, usually within the first few weeks of therapy, and resolves completely upon withdrawal of the drug. Other potential side effects include nausea, fever, rash, and hepatitis. Bone marrow suppression, particularly leukopenia, is dose related and may be delayed, necessitating long-term monitoring of blood counts. IBD patients treated with purine analogues may experience a slight increase in relative risk of neoplasia, but the absolute risk remains extremely small.[80,87] There is a growing consensus that these agents are effective and safe for use through pregnancy and lactation.[88]

Ulcerative colitis Both controlled trials with AZA and uncontrolled series with 6-MP have supported the role of purine analogues for the long-term (maintenance) treatment of UC.[26,27,79] There have not been adequate comparative studies between AZA and 6-MP or dose-ranging trials for these agents, and to date, there are no standard guidelines for their use in UC.[26] Most authorities agree that if patients are to be started on full-dose therapy (i.e., 2.5 mg/kg/day of AZA or 1.5 mg/kg/day of 6-MP), activity of the enzyme thiopurine methyltransferase

should be measured before therapy is initiated.[80,89] However, many clinicians start therapy at lower doses and monitor the white blood cell count. Alternatively, in the event of therapeutic unresponsiveness, elevated liver enzymes, or potential noncompliance, these clinicians measure levels of the thiopurine metabolites 6-methylmercaptopurine and 6-thioguanine.

Crohn disease AZA and 6-MP can induce remission in active CD, but prolonged therapy is necessary: 56% of patients with active CD respond after 4 months of treatment with either AZA (2.0 to 2.5 mg/kg/day) or 6-MP (1.0 to 1.5 mg/kg/day).[82,90] Because of their delayed onset of action, AZA and 6-MP are most often used to maintain remission or as steroid-sparing agents.[91] They can also be used to treat CD fistulas and perianal disease.[51]

Cyclosporine

Cyclosporine is a potent inhibitor of T cells, primarily via inhibition of IL-2 production by helper T cells, and inhibits recruitment of cytotoxic T cells and production of IL-3, IL-4, interferon gamma, and TNF-α. Treatment with cyclosporine can provide dramatic results in severe IBD, particularly in UC.[79,92] Cyclosporine has a much more rapid onset of action than AZA or 6-MP; its effects are usually evident within the first week. There is controversy regarding the long-term benefits of cyclosporine, however. Cyclosporine is metabolized by a cytochrome P-450 enzyme, and interactions with a number of drugs can increase or decrease cyclosporine levels.[80]

UC trials have used intravenous cyclosporine as a continuous infusion of 2 to 4 mg/kg/day.[93] However, a dosage of 2 mg/kg/day appears to be as effective as higher doses and may reduce toxicity.[94] Correlations between response and blood levels have not been defined; similarly, the correlation between blood levels and toxicity is poor.[80]

The narrow therapeutic margin and significant potential toxicity of cyclosporine remain obstacles for its use outside of centers with transplantation expertise. Major toxicities include nephrotoxicity and opportunistic infections. Nephrotoxicity can manifest as hypertension or elevations in blood urea nitrogen and creatinine levels. Because of the increased risk of opportunistic infections, including *Pneumocystis* pneumonia, prophylaxis with trimethoprim-sulfamethoxazole has been recommended for patients receiving cyclosporine in conjunction with high-dose steroids.

The primary use of cyclosporine for IBD is in hospitalized patients with severe UC in whom therapy with oral or intravenous steroids has failed[26,27]; 50% to 80% of such patients respond to short-term treatment with intravenous cyclosporine.[79] Duration of use is limited to 3 to 6 months. The long-term prognosis after cyclosporine therapy is controversial, but approximately 40% to 50% of responders to cyclosporine may avoid eventual surgical colectomy.[93] This response improves to greater than 60% when patients are transitioned to long-term therapy with AZA or 6-MP.[95]

Cyclosporine also has been successfully used for steroid-refractory and fistulizing CD.[96] Beneficial results are primarily achieved with intravenous cyclosporine. Oral cyclosporine has not been found to be effective for maintaining remission in CD, possibly because of poor and variable absorption.

Methotrexate

Only limited evidence supports the use of methotrexate in UC. Despite early optimism from uncontrolled clinical experience, methotrexate has not been effective therapy for UC in a small number of clinical trials.[97]

In studies of steroid-dependent CD patients, approximately 40% of patients were able to achieve clinical remission while tapering steroids during a 16-week trial of methotrexate, given parenterally (intramuscularly or subcutaneously) in a weekly dose of 25 mg.[82,98] In a subsequent study, approximately two thirds of patients who achieved remission and remained on parenteral methotrexate, at a dosage of 15 mg/wk, continued in remission for 40 weeks.[99]

Methotrexate is well tolerated in IBD patients. Toxicity, which includes bone marrow suppression and hepatic fibrosis, is uncommon provided that blood counts and liver enzyme levels are monitored.[97] Hypersensitivity pneumonitis is a rare but potentially irreversible complication. Methotrexate is a known teratogen and abortifacient, precluding its use in women anticipating pregnancy.

Other Immunomodulatory Agents

Tacrolimus has been used as therapy for refractory fistulas in CD[100] and as an oral therapy for refractory UC.[101] The indications for tacrolimus are very limited, however, now that infliximab has become available for CD [*see* Biologic Therapies, *below*].

ANTIBIOTICS

Antibiotic therapy has been used selectively in both UC and CD.[102] Although a specific therapeutic role for antibiotics in UC remains unproved, most centers continue to advocate broad-spectrum antibiotics as a component of the intensive intravenous therapy used in patients with fulminant colitis and toxic megacolon.[26,27] Antibiotics are also effective in the treatment of pouchitis after ileoanal anastomoses in patients with UC.[103]

In CD, the role for antibiotic therapy as a first-line agent for mild to moderate disease continues to be debated.[104-106] In mild to moderate CD, metronidazole has proved to be comparable to sulfasalazine and superior to placebo at doses of 20 mg/kg/day.[107] Metronidazole is also effective for the treatment of perianal CD[51] and can reduce the likelihood of relapse after intestinal resection.[108] Ciprofloxacin is comparable to mesalamine for mild to moderate CD and has been used successfully in combination with metronidazole for ileal disease and perianal CD.[109-111] Combinations of antimycobacterial therapies for CD have not had consistent results in the treatment of active CD or as maintenance therapies.[112]

BIOLOGIC THERAPIES

The introduction of biologic agents has opened a new era in the treatment of IBD. Current biologic agents target cellular messengers, including cytokines, chemokines, and adhesion molecules.

The first biologic agent approved by the Food and Drug Administration for CD was infliximab, a chimeric monoclonal antibody of the IgG1 subclass that targets TNF-α. In clinical trials, infliximab has been shown to induce and maintain clinical remissions in patients with moderate to severe active luminal or fistulizing CD refractory to therapy with aminosalicylates, corticosteroids, and immunomodulators.[113-115] Infliximab is administered intravenously in a dose of 5 mg/kg. After the initial dose, repeat doses are given 2 weeks and 6 weeks later and, then, every 8 weeks on average. Infliximab is similarly effective in UC. Two large trials that enrolled patients with moderately active UC that was refractory to aminosalicylates, cortico-

steroids, and immunomodulators also demonstrated positive results.[116]

Infliximab is generally well tolerated. The primary risk with infliximab therapy is infection with intracellular organisms (e.g., tuberculosis, histoplasmosis, or cryptococcosis) in exposed or endemic populations.[117] Pretreatment skin testing with purified protein derivative and chest x-rays is recommended, but false negative results are possible because many patients with CD are anergic.[118] For that reason, clinicians must exercise clinical judgment regarding potential tuberculosis exposure. Infliximab is contraindicated in patients with active infections.

Unique adverse events with infliximab include the development of antibodies to the drug that reduce the effectiveness of the agent and are associated with infusion reactions (e.g., acute infusion reactions and serum sickness–like reactions).[119] Additionally, antinuclear antibodies and anti-DNA antibodies develop in approximately 10% of patients with CD who are receiving infliximab therapy. Drug-induced lupus reactions have been reported but are uncommon. Delayed hypersensitivity (i.e., serum sickness–like reactions) has been observed in patients retreated after a long hiatus between doses (3 months to 4 years) but not in patients who have received continuous retreatment at 8-week intervals. A small increase in the risk of lymphomas has been observed with anti-TNF therapy in IBD,[120] but it is not clear whether the increase reflects a small underlying risk in patients with CD or is the result of immune suppression.[121] Other biologic therapies under development to treat IBD include inhibitors of so-called selective adhesion molecules[122]; anti–IL-12, anti–IL-2, and anti-CD3 monoclonal antibodies[123,124]; epidermal growth factor[125]; and granulocyte-macrophage colony-stimulating factor.[126]

MISCELLANEOUS THERAPIES

The recognition that cigarette smoking can protect against the development of UC has led to trials utilizing nicotine as adjunctive therapy. Although trials have demonstrated a role for nicotine in the symptomatic management of UC, nicotine therapy has not been shown to be effective at inducing remissions.[127] Currently, nicotine is not a proven therapy for UC, but it may be a useful adjunctive measure in patients with UC that develops after smoking cessation.

Omega-3 fatty acids inhibit synthesis of leukotriene B_4 and, at high doses, have shown a modest benefit in the treatment of active UC or as maintenance therapy.[128,129] An enteric-coated fish oil preparation has proved to be effective in reducing relapse rates in CD[130] and may eventually offer an alternative therapeutic option in IBD. However, current treatment guidelines do not include these agents.

Other novel therapeutic approaches to IBD that are currently under investigation include phosphodiesterase inhibitors,[131] small molecules targeting mitogen-activated protein kinases,[132] probiotics,[133] apheresis,[134] and targeting of costimulatory molecules.[135]

NUTRITIONAL THERAPIES

Hypotheses regarding dietary intraluminal antigens as important stimuli of the mucosal immune response have led to the investigation of nutritional therapies for IBD.[3,136] Dietary manipulations have not been effective in treating UC, but patients with active CD have responded to several nutritional approaches.[136,137] Bowel rest and total parenteral nutrition (TPN) are as effective as corticosteroids at inducing short-term remissions in active CD. In contrast, enteral nutrition in the form of elemental or liquid polymeric preparations has been shown to be less effective than corticosteroids.[138] It has been suggested that elemental diets may provide the small intestine with nutrients vital to cell growth (e.g., glutamine) while avoiding complications related to TPN. However, despite their efficacy in active CD, neither enteral nor parenteral nutrition is effective at maintaining remissions.[136]

Patients with IBD are susceptible to nutritional deficits as a consequence of blood loss, protein-losing enteropathy, small bowel bacterial overgrowth, surgical resections (in CD), or inanition. IBD does not increase the risk of lactose intolerance, but ingestion of lactose can contribute to diarrhea in IBD patients with an inflamed small bowel or impaired colonic absorptive capacity. Similarly, consumption of nonabsorbable carbohydrates (e.g., sorbitol) or fats (e.g., olestra) can lead to excess flatus, bloating, or diarrhea. Occasionally, patients with proctitis present with constipation that improves with additional dietary fiber.

SUPPORTIVE THERAPIES

Many symptoms of IBD are not related to active inflammation and can therefore be treated separately from the inflammation. The management of these symptoms, which include pain and diarrhea, is as important to the patient's well-being as the treatment of mucosal inflammation. Treatment should be individualized according to symptoms and clinical disease state.

IBS is as common in IBD patients as it is in the general population.[139] A dietary history is important to identify potentially aggravating components contributing to digestive symptoms. Although the stress of day-to-day living does not impact on the inflammatory activity of IBD, many patients identify stressful aspects in life as being associated with worsening of symptoms. IBS often responds to antispasmodics, antidiarrheals, fiber supplementation, or low doses of tricyclic antidepressants [*see 4:XIV Gastrointestinal Motility Disorders*]. Antispasmodics, primarily anticholinergic agents (e.g., dicyclomine, clidinium bromide, hyoscyamine, propantheline, or belladonna alkaloids), can treat cramping abdominal discomfort or symptoms of IBS that accompany UC and CD. Similarly, antidiarrheal preparations (e.g., diphenoxylate, loperamide, or codeine) can be utilized in patients with mild or moderate IBD to reduce the frequency of bowel movements and rectal urgency. Antimotility agents should be avoided in patients with severe or fulminant IBD because of the risk of inducing toxic megacolon.

In women with IBD, flares of disease activity are often related to the menstrual cycle, occurring more often during the premenstrual and menstrual phases.[140] If menstrual cycles impact greatly on symptoms, ablation of the menstrual cycle with progesterone or leuprolide may be warranted. Pregnancy is associated with both exacerbations and remissions of IBD.[141]

There is no predisposing psychiatric personality profile in IBD, and there is no routine role for sedative, anxiolytic, antidepressant, or antipsychotic therapy. Psychopharmacologic therapies are reserved for individual patients as needed, usually after consultation with a psychiatrist.

Treatment of IBD patients with narcotic analgesia is rarely indicated. Pain in UC is related either to visceral hyperalgesia and muscle spasm or to transmural inflammation. The former condition is treated with antispasmodics and the latter with specific anti-inflammatory therapy. In CD, abdominal pain may be related to transmural inflammation or stenosis, but given the chronic nature of the disease, addictive analgesics should be avoided because of the risk of tolerance. Attempts should be made to re-

duce the inflammatory component of symptoms and to treat irritability with antispasmodics or nonaddictive analgesics.

NSAIDs (both nonspecific agents and cyclooxygenase-2 inhibitors) may exacerbate disease activity in IBD and can contribute to refractory disease.[139,142-144] Minor pain, fever, menstrual symptoms, or arthralgias should be treated with alternatives to NSAIDs. If these agents are used, it should be with great caution and continued observation for their potential to exacerbate IBD.

Approximately half of patients with IBD use complementary therapies.[145] Consequently, the history should include a careful review of nonprescription vitamins, health foods, homeopathic agents, or herbs, which may identify factors contributing to changes in bowel habits.

Patients with CD who have undergone bowel resection often have increased diarrhea, related to the length of bowel removed. Bile salt malabsorption may complicate resections of less than 100 cm; the diarrhea in these patients often responds to cholestyramine or alternative bile-salt sequestrants. Longer resections result in steatorrhea, which is managed with a low-fat diet.

MEDICAL TREATMENT OF ULCERATIVE COLITIS

Ulcerative Proctitis

Induction therapies Topical aminosalicylates are the most effective treatments for distal UC.[73] A daily dose of 1,000 to 4,000 mg is administered nightly as an enema or in divided doses as a suppository or foam. Topical corticosteroids (given via suppository, enema, or foam) are acceptable alternatives to mesalamine.[26,27] Foam preparations are easier to retain and are better tolerated, allowing maintenance of daily activities despite twice-daily administration.

Oral aminosalicylates can be used to treat mild to moderate symptoms of proctitis but are less effective than topical therapies.[146] Sulfasalazine, 2 to 6 g/day in divided doses, is the most cost-effective aminosalicylate, but sulfa intolerance, toxic reactions, or allergy can compromise therapy. Mesalamine, olsalazine, or balsalazide formulations are preferable for patients with a history of sulfa allergy or for patients who develop sulfa-related side effects.

Inductive therapy is continued until the patient is asymptomatic. Although improvement should begin within a week, a complete response may require 4 to 12 weeks. Clinicians should recognize that patients with treated UC are capable of, as well as expected to, achieve a clinical remission, which is defined by the resolution of all inflammatory symptoms and a regeneration of the colonic mucosa.

Maintenance therapies Maintenance therapy is indicated for the majority of patients with UC. In patients with proctitis, however, the limited nature of the disease permits treatment of any recurrent attacks on an as-needed basis.

Once remission has been achieved, the daily dose of mesalamine can be tapered according to the initial response; nevertheless, continuation of the inductive therapy, excluding steroids, is most effective for maintenance treatment. Mesalamine suppositories (or enemas) administered nightly, with gradual tapering to every other night and then every third night, will maintain remission in most patients. An oral aminosalicylate is added if patients continue to experience flares despite attempts to wean them from topical therapy; it may also be added after induction and then tapering of topical steroids.[133]

Left-Sided Colitis

Induction therapies Mesalamine enemas are the most effective therapy for left-sided colitis, with steroid enemas being an alternative.[73] Oral aminosalicylates also are effective, with improvement generally noted by 2 to 4 weeks.[147] The oral amnosalicylates are generally equivalent in their efficacy for distal colitis.[67,148]

Patients with moderate to severe disease and those in whom therapy with topical and oral aminosalicylates has failed are treated as outpatients with oral steroids to induce remission, in a manner similar to that for patients with extensive colitis (see below). As with extensive colitis (see below), severe left-sided colitis requires hospitalization and treatment with systemic steroids.

Maintenance therapies Inductive therapy is continued until the patient achieves clinical remission (normal bowel movements without bleeding, urgency, tenesmus, or inability to evacuate flatus). The transition to a maintenance regimen is then begun. Neither oral steroids nor topical steroids are effective at maintaining remissions. Patients who have responded to rectal mesalamine can continue with this therapy or switch to oral treatment.[26,148] The combination of oral and topical mesalamine has advantages over either therapy alone for maintenance therapy for left-sided UC.[149]

If patients who are taking an oral aminosalicylate experience relapse, the dose should be increased to up to 4.8 g of mesalamine. Maintenance of remission in such patients may require topical mesalamine. After inductive treatment with steroid enemas, patients should be transitioned to an oral aminosalicylate, with gradual tapering of the topical therapy. Those requiring systemic steroids should be maintained on an oral aminosalicylate, with or without topical mesalamine.

Extensive Colitis

Induction therapies Oral aminosalicylates are the primary therapy for outpatients with mild to moderate extensive colitis, but these agents may be supplemented with topical mesalamine or steroids.[26,27,108] The dose of the oral aminosalicylate is more important than the specific formulation.[67,72] Response rates of up to 80% can be anticipated with 4 to 6 g of sulfasalazine or 2 to 4.8 g of a mesalamine formulation given over 6 to 8 weeks. Therapy is continued as long as the patient is improving, to the point of clinical remission (i.e., normal bowel movements without blood or urgency). In the absence of a complete response, the dose of the aminosalicylate should be increased to a maximum of 4.8 g of mesalamine. An antispasmodic or antidiarrheal preparation may be added to treat abdominal cramping or mild diarrhea.

In patients who fail to improve or whose condition worsens, steroid therapy should be added in the form of prednisone, 40 to 60 mg/day.[75] Once the patient has achieved a clinical remission, which generally takes 2 to 4 weeks, steroids are tapered according to the time course to improvement. Prednisone can be tapered by approximately 5 mg every week down to 20 mg daily. Below 20 mg of prednisone, the daily dosage is reduced 2.5 to 5 mg every 1 to 2 weeks. Aminosalicylate therapy is continued as steroids are reduced.

Patients who respond to steroids but who are unable to completely taper without relapse despite optimal doses of an aminosalicylate should be started on AZA or 6-MP, which typically permits steroid withdrawal.[26,27] Achieving the therapeutic benefits of these agents requires 3 to 6 months, during which

time steroids are maintained at the lowest dose needed to prevent recurrence of symptoms. Calcium and vitamin D supplementation is indicated during steroid therapy to prevent metabolic bone disease. Reduced bone density is an indication for additional therapy with a bisphosphonate, estrogen replacement in postmenopausal women, or calcitonin.[150]

Hospitalization is indicated for patients who have significant weight loss, fever, disabling extraintestinal manifestations, frequent nocturnal bowel movements, severe anemia, or progressive symptoms despite outpatient therapy with corticosteroids.[26,27] A low-residue diet is prescribed, to minimize abdominal cramps and bowel movements; the diet should contain sufficient protein and calories to counter the catabolic influence of active inflammation and steroids. Antispasmodics or antidiarrheals should be used with caution, and patients should be monitored for worsening symptoms.

Intravenous steroids are indicated for severely ill patients with fever, orthostasis, evidence of dehydration, more than 10 to 12 stools daily, rectal bleeding necessitating transfusion, protein depletion, or abdominal tenderness or distention. Prompt correction of fluid and electrolyte imbalances is critical. In patients with active bleeding, transfusions of packed red blood cells should be given to maintain the hematocrit above 30%. Anticholinergics, antidiarrheals, and narcotic analgesics are contraindicated because they can worsen colonic dilatation and mask peritoneal signs in debilitated, steroid-treated patients.

The intensive intravenous steroid regimen consists of prednisolone (40 to 60 mg/day), methylprednisolone (32 to 48 mg/day), or hydrocortisone (300 to 400 mg/day) administered in divided doses or as a continuous infusion. Steroid enemas (e.g., with 100 mg of hydrocortisone) can be used as adjunctive treatment to reduce rectal urgency or tenesmus. Oral aminosalicylates are discontinued because their anti-inflammatory effects are minor compared with those of high-dose steroids, as well as because of the potential for intolerance and the rare instances in which 5-ASA can worsen colitis.

When vital signs normalize, the hematocrit stabilizes, and the patient is able to tolerate a full (low-residue) diet with formed bowel movements without blood or urgency, treatment can be transitioned to an oral regimen. Full-dose therapy with an aminosalicylate is resumed and intravenous steroids are replaced with oral steroids.

If the patient is not improving after 5 to 7 days of intensive intravenous steroid therapy, the likelihood of improvement is small and the patient should be considered a candidate for cyclosporine therapy or surgery. Intravenous cyclosporine has been an important advance in the therapy of severe UC, but its use should be limited to clinicians experienced in the monitoring of immune suppression. A response is anticipated within 4 to 5 days, but if there is no significant improvement within 1 week, the patient should be referred for surgery. When clinical remission is achieved with intravenous cyclosporine, the regimen is replaced with both oral cyclosporine and prednisone. The daily dose of cyclosporine is doubled and administered in two divided doses (e.g., if the patient was receiving 200 mg daily, the oral dosing is 200 mg twice daily). Because of the high relapse rate after intravenous cyclosporine therapy, AZA or 6-MP is usually added to the oral regimen.[26,151] In addition, trimethoprim-sulfamethoxazole is given three times weekly as prophylaxis against *Pneumocystis* pneumonia.[26]

Outpatient monitoring of cyclosporine levels and other laboratory measures are repeated weekly for the first month and then less often. Steroids are tapered (see above), generally over 8 to 12 weeks; cyclosporine is gradually discontinued; and maintenance therapy is begun.

Maintenance therapy Maintenance therapy for extensive UC is determined by the intensity of therapy needed to induce remission. If aminosalicylate therapy has been sufficient to induce remission, continuation of the same dosage is optimal for maintenance. Patients treated with steroids require a more individualized approach, with the rate of steroid tapering determined by the rapidity of response as maximum doses of aminosalicylate are continued. Patients receiving AZA or 6-MP also are continued on maximum aminosalicylate therapy. The optimum doses of immunomodulators, as well as the doses that will cause leukopenia, have not been clarified.[26,89] Complete blood counts should be obtained on at least a quarterly basis to detect delayed bone marrow suppression.[152]

Fulminant Colitis and Toxic Megacolon

Fulminant colitis, with or without colonic dilatation (toxic megacolon), is a medical emergency that is best managed by an experienced team of gastroenterology specialists and surgeons. Management is similar to that for severe colitis but with several modifications. Patients take nothing by mouth until they show clinical improvement. In the presence of small bowel ileus, a nasogastric tube should be inserted and maneuvers undertaken to reduce colonic distention and to allow passage of colonic gas by rectum (i.e., by rolling the patient from side to side, inserting a rectal tube, or placing the patient in the knee-elbow position).[26] Intravenous steroids are continued and broad-spectrum antibiotic coverage is added for presumed transmural extension of disease, risk of microperforation, and systemic bacteremia. Cyclosporine in this setting is controversial but has been used in selected cases.

Aggressive medical management is successful in 40% to 50% of patients with fulminant colitis or toxic megacolon. Unfortunately, many patients are destined to develop complications or resistant disease, including recurrent toxic megacolon.[25] Persisting peritoneal signs, any deterioration, or failure to improve within 24 to 72 hours is an indication for immediate colectomy.

SURGICAL TREATMENT OF ULCERATIVE COLITIS

UC is cured by proctocolectomy, and the quality of life after such surgery is generally excellent. The advantages of surgery include the elimination of the drawbacks of medical treatment, which include continued morbidity, adverse reactions to therapy, and the risk of neoplasia.[26]

Indications for Surgery

Indications for colectomy in UC are emergent, urgent, or elective. Emergent indications include exsanguinating hemorrhage, perforation, and unresponsive fulminant colitis or toxic megacolon. Urgent indications are chronic refractory colitis and significant complications of the disease or medical therapy (e.g., hemolytic anemia, pyoderma gangrenosum, and steroid-induced psychosis).

Surgical indications are often less acute and allow preparation and education of the patient and family to optimize timing and minimize physical and emotional consequences. Patients with quiescent colitis but with dysplasia diagnosed during colonoscopic surveillance are often feeling well and must adjust to the need for a major operation.

The most common indications for surgery are medically in-

tractable disease, poor quality of life, or chronic complications from colitis or medical therapy. Given the availability of a surgical cure, it is not acceptable for patients to suffer physical debility, psychosocial dysfunction, or intolerable side effects.

Surgical Procedures

Proctocolectomy Removal of the colon with an end ileostomy cures UC. This is the standard procedure with which all other treatments must be compared. Proctocolectomy and ileostomy are usually performed in a single procedure, even in the most urgent of settings. This approach has the least likelihood of complications. The primary drawback is the need for a permanent stoma. Quality of life after proctocolectomy is usually good, although many patients have difficulty adjusting to the cosmetic and functional aspects of the ileostomy. An unanticipated complication of proctocolectomy has been reduced fecundity in women.[153]

Sphincter-saving procedures Because UC is essentially limited to the colonic mucosa, alternative procedures have been developed that involve removing the proximal colon, stripping the rectal mucosa off the distal rectal musculature, and sparing the anal sphincter.[154] These so-called sphincter-saving procedures afford the opportunity of curing colitis and reestablishing continuity between the ileum and anus via an ileoanal anastomosis. Although a direct communication is technically feasible, it would result in intolerable postoperative diarrhea. Thus, these procedures include the provision of an ileal pouch to provide reservoir function. These J-, S-, or W-shaped pouches are created by folding the distal ileum and anastomosing the outlet to the anal canal.

Additional surgical modifications include the actual surgical stripping of the distal rectal mucosa or the stapling of the distal ileum to a short strip of residual rectal mucosa. In experienced surgical centers, the outcomes of stripping and stapling procedures are comparable.

Most often, sphincter-saving procedures are performed in stages: first, the surgeon removes the colon and performs an ileostomy, leaving the distal rectum as a Hartmann pouch; then, the surgeon creates the ileoanal anastomosis with a diverting ileostomy; and finally, the surgeon closes the ileostomy, which allows continuity of enteric flow through the pouch. Depending on surgeon preference and patient status, these procedures can be performed in one, two, or three stages.

Quality of life after an ileoanal anastomosis is excellent. Most patients describe full continence, with an average of six unformed (but not urgent) bowel movements daily.[155] Approximately 10% of patients develop small bowel obstructions, either between stages or after completion of the procedure. The most common complication after colectomy and ileoanal anastomosis is the development of so-called pouchitis, a superficial inflammation within the pouch that is similar to the inflammation of UC.[156] Pouchitis presents as increased urgency and evacuations that may be associated with bleeding and extraintestinal manifestations such as arthralgias, fever, and malaise. Most episodes of pouchitis respond to a course of an antibiotic, such as metronidazole or ciprofloxacin.[103] Approximately 15% of patients who develop pouchitis will have a more chronic course requiring long-term antibiotics or oral budesonide.[156] There is also evidence that high doses of the probiotic agent VSL#3 can prevent the onset of pouchitis or maintain remission of pouchitis after antibiotic therapy for recurrent or refractory pouchitis.[157-159] As with proctocolectomy, ileoanal anastomoses have been associated with reduced fecundity in women.[153]

TREATMENT OF CROHN DISEASE

Gastroduodenal Crohn Disease

Dyspepsia, epigastric burning, or nausea in CD patients with gastroduodenal involvement usually responds to acid reduction therapy with an H_2 receptor antagonist or a proton pump inhibitor.[160,161] More profound nausea or vomiting responds to corticosteroids, followed by an immunomodulator for steroid-sparing effects. Gastric outlet obstruction that does not respond to steroids or immunomodulators, or both, is an indication for surgical decompression with a gastrojejunostomy.

Jejunoileitis

In patients with isolated proximal small bowel CD, diarrhea should be evaluated from a mechanistic standpoint. Malabsorption from short bowel syndrome or resection is treated with a low-fat diet, whereas small bowel bacterial overgrowth is managed with antibiotics. Patients presenting with prominent pain or small bowel obstruction are treated with short-term corticosteroids and then usually with AZA or 6-MP. Bowel obstructions that do not respond to short-term steroid therapy require surgical resection or, more commonly, stricturoplasty.

Ileitis, Ileocolitis, and Colitis

In patients with limited ileal or ileocolonic CD, therapy should be staged to alleviate presenting symptoms, then to maintain long-term well-being, while minimizing chronic complications related to the disease or therapy.

Mild to moderate disease Outpatient therapy with anti-inflammatory agents, symptom-specific medications, and diet is utilized in patients who have abdominal pain and tenderness, diarrhea, low-grade fevers, weight loss without obstruction, painful mass, or severe malnutrition. Aminosalicylates, including sulfasalazine and mesalamine, have been effective at relatively higher doses than those that are used in UC. Sulfasalazine is effective in dosages of 3 to 6 g/day for ileocolonic and colonic CD but has not had significant benefits in limited small bowel disease.[27] In contrast, mesalamine, 4 g/day, provides modest benefits for small bowel and colonic involvement if the formulation releases the mesalamine at involved segments.[162] Benefits of sulfasalazine and mesalamine are modestly better than those achieved with placebo and less than those achieved with corticosteroids.[163] Enteric-coated, delayed-release budesonide, 9 mg daily, is an alternative first-line therapy for mild to moderate CD affecting the ileum, right colon, or both; it is more effective than mesalamine therapy.[163] Despite the limited potency of aminosalicylates, however, their potential long-term efficacy and absence of side effects make them first-line agents. As long as the patient continues to respond, the medication should be continued at the same dose used for induction. For patients with ileal or right colon disease who fail to respond within a short time (i.e., 2 to 4 weeks), budesonide therapy is a logical alternative.

Antibiotic therapy with metronidazole or ciprofloxacin, alone or in combination, is an alternative to aminosalicylates for ileocolonic and colonic CD.[27,102] Although there are no long-term data regarding antibiotic therapy for ileal or ileocolonic CD, clinical observations have suggested that maintenance therapy is

likely to be necessary. Patients receiving long-term metronidazole therapy should be monitored for peripheral neuropathy.

Dietary and nutritional therapy should focus on reduction of symptoms, prevention or correction of nutritional deficits, and avoidance of long-term complications. Elemental diets have short-term efficacy but are not practical for the majority of adult patients.[27,138] The disease location, complications, and surgical history will direct attention to potential nutritional deficiencies. Calorie and protein requisites are the primary concern. Secondary considerations include maintenance of iron stores and levels of water-soluble vitamins in the setting of proximal small bowel disease, as well as levels of vitamins B_{12}, A, D, and E with ileal disease or resection. Adequate calcium and vitamin D intake are of particular importance to avoid metabolic bone disease.

Moderate to severe disease A different therapeutic approach is required in patients who fail to respond to aminosalicylates or steroids or who present with fever, greater than 10% weight loss, and abdominal pain accompanied by tenderness (without obstruction) but who are able to maintain oral intake. Corticosteroids are required to induce a clinical remission; however, clinicians must exclude perforating complications (i.e., abscesses) before starting corticosteroids. Oral treatment with prednisone, 0.5 to 1 mg/kg, reduces symptoms in most patients.[27,75] However, the clinical response usually does not persist after steroid tapering; approximately 70% of patients will have a relapse or become steroid dependent within 1 year.[164]

Prednisone is continued at the initial dose until the patient responds completely (i.e., resolution of inflammatory symptoms). The dose is then decreased according to the time course to response. Tapering can usually proceed by 5 to 10 mg/wk, until a daily dose of 20 mg is reached, and then by 2.5 to 5 mg/wk. Calcium and vitamin D supplements reduce the risk of accelerated osteoporosis; in patients with reduced bone density, bisphosphonate or calcitonin should also be considered.[150] Clinical monitoring is continued, with attention paid to relapse of inflammatory symptoms. Persisting noninflammatory symptoms (e.g., nonbloody diarrhea or abdominal cramps) can be treated with dietary modifications, antispasmodics, and antidiarrheals without intensifying anti-inflammatory therapy.

Severe disease Infliximab may be beneficial in CD patients whose symptoms persist despite use of oral corticosteroids.[119] A single infusion of 5 mg/kg provides significant improvement and clinical remission for patients who have not responded to aminosalicylates, antibiotics, steroids, or immune suppressants. However, a three-dose induction regimen followed by maintenance infusions given every 8 weeks affords a more optimal long-term approach. Concomitant treatment with an immune suppressant minimizes the risk of developing antibodies to infliximab that are associated with loss of response and infusion reactions.[119] Before receiving infliximab, patients should be interviewed regarding exposure to tuberculosis and should undergo skin testing and chest x-rays.

Patients presenting with dehydration, high fever, cachexia, GI bleeding, obstructive symptoms, rebound tenderness, or an abscess require hospitalization and resuscitation with intravenous fluids, electrolytes, or transfusion. Acute obstructive symptoms, in the absence of chronic symptoms, mandate assessment for a mechanical cause (i.e., adhesions) rather than an inflammatory narrowing. Parenteral nutritional support is indicated as a supplement for patients unable to tolerate sufficient caloric intake and is mandatory for patients with profound malnutrition and an inability to eat.

Intravenous corticosteroids are indicated for severe manifestations of CD, once an abscess has been ruled out.[27] Prednisolone (40 to 60 mg), hydrocortisone (200 to 300 mg), or methylprednisolone (32 to 48 mg) is given in an intermittent or continuous infusion and continued until the patient is free of pain and is passing flatus and stool or until the patient no longer has diarrhea. Oral steroids are then substituted at an equivalent dose. Failure to improve with intravenous steroids should cause consideration of surgical intervention, prolonged total parenteral nutrition and bowel rest, use of intravenous cyclosporine, or use of infliximab. Broad-spectrum antibiotics are added for febrile patients and those with abdominal tenderness or an inflammatory mass. These agents are continued until defervescence unless a specific pathogen has been identified and a narrow-spectrum agent can be substituted.

Maintenance Therapy

Maintenance therapy for CD was once discounted because of poor results from early studies that evaluated low-dose sulfasalazine and corticosteroids. However, it is now apparent that other forms of maintenance therapy can reduce the possibility of clinical relapse in certain patients.[165] As with UC, steroids are not effective and should not be routinely used as maintenance agents for CD.

The aminosalicylates are useful maintenance agents when continued after inductive therapy, but they have limited value after steroid-induced remissions.[27,66] In contrast, immunomodulators have been shown to have steroid-sparing and maintenance benefits. AZA and 6-MP are effective steroid-sparing agents for patients who cannot be weaned from steroids. Initial therapy is AZA, 2 to 2.5 mg/kg, or 6-MP, 1 to 1.5 mg/kg. The dosage is adjusted at 2-week intervals according to the leukocyte count, which must be maintained above leukopenic levels. The efficacy of these agents may not be evident until after 3 to 6 months of treatment, but benefits have been demonstrated to last for at least 4 years. To avoid unanticipated bone marrow suppression, monitoring of blood counts on a quarterly basis must continue once the patient is off steroids.

Maintenance therapy to delay postsurgical relapse has been evaluated according to different end-point criteria (e.g., endoscopic evidence of relapse, clinical symptoms, or repeat surgery).[39] There is evidence that mesalamine, 3 to 4 g/day, can prevent postoperative recurrence, particularly when therapy is initiated shortly after surgery[27]; conversely, postponing therapy for more than 3 months circumvents any benefits. In addition to mesalamine, metronidazole is effective for reducing postoperative recurrence when administered at high doses (20 mg/kg) for 3 months after resection. There are no data regarding lower doses of metronidazole, prolongation of therapy beyond 3 months, or the use of other antibiotics.[27,102] Finally, 6-MP at doses of 50 mg/day may reduce postoperative relapse for at least 2 years after resection.[166] In view of the negative impact of cigarette smoking on the postoperative course of CD, however, all patients who smoke should be advised to stop.[27]

Surgical Therapy

Unlike UC, CD is not cured by surgery, except in the case of CD confined to the colon, for which proctocolectomy and ileostomy provide similar likelihoods of cure; sphincter-saving

procedures are not advocated because of the high likelihood of recurrence after anastomoses. With CD in other locations, disease recurrence at the anastomotic site is virtually inevitable. Therefore, surgery is undertaken to treat refractory disease or complications, rather than to cure the disease. Nevertheless, in view of the excellent quality of life after limited surgery and the evolving capability to reduce or delay recurrence, it is imperative that surgery not be deferred because of fear of recurrence.

Purulent complications (e.g., abscesses) require percutaneous or surgical drainage. Surgery in CD patients is also indicated for intractable hemorrhage, perforation, persisting or recurrent obstruction, or toxic megacolon. The most common indications for surgery are intractable disease, failure of medical therapy, or complications related to treatment (e.g., steroid dependence). Many of these indications are subjective, requiring experienced clinical judgment and cooperative consultation between medical and surgical specialists. Surgical resections should be limited to macroscopic disease, and in general, primary anastomoses should not be performed in the setting of uncontained purulent complications.[27]

IBD AND PREGNANCY

Fertility is usually normal in both men and women with IBD, although an increase in disease activity correlates with a decrease in libido and with menstrual irregularities.[167] Risk of early miscarriage is increased in women with active disease. When disease activity is controlled, the course and outcome of pregnancy do not differ substantially from those in the general population. Therefore, the best means of ensuring normal fetal outcome is to time conception when disease is under control, aggressively treat disease activity during pregnancy, and maintain the health of the mother.[27] Aminosalicylates, steroids, and immunomodulators are safe during pregnancy and lactation, but they should be added only when necessary to maintain maternal well-being.[88,168,169] Conversely, because of the risk of maternal worsening, neither acute nor maintenance therapy should be withdrawn during or after pregnancy. Attention to the mother's nutritional status is essential throughout pregnancy and during lactation. Neonates born to women on high doses of steroids should be monitored for adrenal suppression.

Complications

INTESTINAL COMPLICATIONS

The intestinal complications of IBD include hemorrhage, stricture, fistulas, toxic megacolon, and neoplasia. Chronic blood loss, with subsequent iron deficiency anemia, is common in both UC and CD. Profuse bleeding, however, is uncommon, particularly in UC, because the inflammation is superficial. Occasionally, patients with CD experience severe lower gastrointestinal bleeding when deep ulcerations erode into large vessels.

Strictures are more common in CD than in UC and result from transmural inflammation and fibrosis. These strictures remain fixed and lead to progressive bowel obstruction. In UC, narrowing of the lumen can occur from smooth muscle hypertrophy; the narrowing is related to disease activity and is reversible with treatment of acute inflammation. Fixed strictures in UC are almost always dysplastic or malignant. Toxic megacolon, although more common in UC, is not unique to UC and can occur in infectious colitis or CD.[170]

EXTRAINTESTINAL COMPLICATIONS

The extraintestinal complications of IBD can result from inflammation or from an HLA-related autoimmune process that underlies the intestinal disease.[171] Complications may also occur as a metabolic consequence of intestinal disease or its treatment.[29]

Mucocutaneous complications include eye changes of episcleritis or scleritis. These complications most commonly parallel colonic disease activity. Involvement of the anterior or posterior chambers with iritis or uveitis is related to HLA-B27 and follows a course that is independent of disease activity in the bowel.[172] Skin lesions of erythema nodosum and pyoderma gangrenosum usually accompany or herald the onset of colitis and respond to treatment of bowel inflammation.

Musculoskeletal lesions can either be independent of or correlate with intestinal disease activity. Peripheral arthralgias and arthritis commonly involve larger joints (e.g., the hips, knees, ankles, elbows, and wrists) in an asymmetrical pattern. The inflammation usually accompanies intestinal disease activity and is almost never deforming, progressive, or associated with rheumatoid nodules. In contrast, arthritis of the central spine, ankylosing spondylitis, and sacroiliitis are associated with HLA-B27 and progress independently of intestinal disease. Metabolic bone disease is most often a consequence of long-term steroid use and, in CD, can be accelerated by malabsorption or inadequate dietary supplementation with vitamin D or calcium.[150]

A spectrum of hepatobiliary involvement occurs in both UC and colonic CD.[173] Inflammation of the intrahepatic and extrahepatic bile ducts may take the form of a mild, periportal inflammatory infiltrate (pericholangitis or small-duct sclerosing cholangitis) that is asymptomatic, nonprogressive, and manifested only as mild elevations of γ-glutamyltransferase (GGT), alkaline phosphatase, and transaminases. At the other extreme, such inflammation may lead to full-blown sclerosing cholangitis with progressive secondary biliary cirrhosis. Of interest, cigarette smoking, which protects against UC, also protects against primary sclerosing cholangitis.[9] Hepatic steatosis commonly manifests as a mild elevation of biliary enzymes in the presence of malnutrition or steroid therapy. Patients with CD who have ileal involvement or have had ileal resections are at increased risk for gallstones because of reduced enterohepatic circulation of bile salts, which increases biliary cholesterol saturation.

Urinary tract complications are more common in CD than UC.[174] Kidney stones may reflect dehydration from diarrhea or an ileostomy.[175] In the setting of ileitis or after ileal resections, the mechanism of nephrolithiasis is hyperoxaluria caused by steatorrhea. Normally, oxalate in the diet binds to free calcium in the colonic lumen and is excreted in the feces as calcium oxalate crystals. In patients with steatorrhea, free luminal calcium preferentially binds to fatty acids, creating soaps that are similarly excreted in the feces. Lacking calcium to bind it, the free oxalate is instead absorbed by the colon and excreted by the kidneys in abnormally high amounts. In the urine, oxalate complexes with urinary calcium to form calcium oxalate crystals. Patients with CD are also more susceptible to nephrolithiasis because their kidneys excrete low amounts of citrate, which acts as a nonspecific solubilizer in the urine. Calcium oxalate stones may result from either hyperoxaluria or idiopathic hypercalciuria; the two conditions can be differentiated by measuring calcium and oxalate levels in a 24-hour urine sample. If hyperoxaluria is identified, the treatment is to reduce fat intake (to reduce steatorrhea) and increase calcium supplementation.

Hematologic complications of IBD include anemia and clotting abnormalities. Anemia is most often caused by iron loss from bleeding or, in CD, from impaired iron absorption because of proximal small bowel disease.[176] Folic acid deficiency is most often related to concurrent use of sulfasalazine, but occasionally, it is related to inadequate dietary consumption of folic acid or extensive jejunal disease. Vitamin B_{12} deficiency from extensive ileal disease or resection can lead to macrocytic anemia. Hypercoagulability is a nonspecific complication of active IBD that results from increased production of acute-phase reactants and that increases the risk of venous thrombosis.[177] Rarely, enteric losses of anticoagulant factors are a consequence of protein-losing enteropathy. In contrast, hypocoagulability may be a complication of vitamin K malabsorption or prolonged antibiotic administration.

Management of Extraintestinal Complications

Treatment of extraintestinal complications of IBD varies according to whether the manifestations are dependent or independent of intestinal (usually colonic) inflammation.[29,171] Peripheral arthritis, erythema nodosum, pyoderma gangrenosum, and episcleritis occur in the presence of active disease and require intensification of anti-inflammatory therapy.

In some patients, complications can be treated independently, along with therapy for intestinal inflammation. For example, inflamed joints can be drained or injected with steroids, and pyoderma gangrenosum can be approached with a combination of topical and systemic approaches. Infliximab therapy has been very effective for the treatment of pyoderma gangrenosum associated with CD.[178] Ocular complications should be evaluated by an ophthalmologist to prevent irreversible damage. Erythema nodosum usually responds to more aggressive therapy for colitis and should not be treated with NSAIDs. Peripheral articular manifestations of colitis can be treated with acetaminophen and increased doses of sulfasalazine; again, NSAIDs should be avoided.

Ankylosing spondylitis, sacroiliitis, and iritis (uveitis) are HLA-B27–associated manifestations that follow a course independent from colitis. The same is true of primary sclerosing cholangitis. Physical therapy is critical for patients with ankylosing spondylitis and sacroiliitis. Concurrent immunomodulatory therapy with methotrexate, hydroxychloroquine, or infliximab is indicated for inflammatory arthropathies.

NEOPLASIA

Adenocarcinoma of the intestines is a potential long-term complication of IBD, with features that are distinct from those of spontaneous adenocarcinomas in the general population.[179] The risks of colonic neoplasia are similar in UC and CD and historically have been related to the extent and duration of disease, age at onset, and stricture formation, with primary sclerosing cholangitis indicating an increased risk for cholangiocarcinoma. In addition, evidence now suggests that in UC, severity of inflammation is also a risk factor for development of neoplasia.[180] In contrast to colorectal cancer in the general population, which develops from adenomatous polyps, dysplasia is the precursor to cancer in IBD patients.[34] Dysplasia is a neoplasia and has been defined on a pathologic basis and categorized as indefinite, low grade, or high grade (carcinoma in situ).[34] Patients with dysplasia have an increased risk of cancer elsewhere in the colon if they have high-grade lesions (up to 50% of these patients have other colonic cancers) or low-grade lesions that are multifocal or in a raised plaque (dysplasia-associated lesion or mass).[181]

The ability to identify histologic dysplasia in UC makes it possible to perform surveillance colonoscopic examinations. Despite the absence of prospective data regarding colonoscopic surveillance for dysplasia in UC, most North American centers recommend that, after 8 to 10 years of UC, patients who are at increased risk for adenocarcinoma be entered into a colonoscopic surveillance program.[26,181,182] Surveillance colonoscopies are recommended every 2 to 3 years for patients with 10 to 20 years of disease and every 1 to 2 years for patients with over 20 years of disease. The confirmation of low-grade dysplasia on surveillance colonoscopy strongly predicts progression to advanced neoplasia and warrants a recommendation for colectomy.[183] Patients with indefinite dysplasia are treated aggressively to control inflammation and should undergo repeat colonoscopy after 3 to 6 months.

The risk of cancer in CD is also related to the location and chronicity of inflammation and, thus, includes a risk for small bowel adenocarcinoma in long-standing small bowel disease.[184] However, because of the varied locations and segmental involvement in CD, there are no standardized guidelines for surveillance. Although there is no means of screening for small bowel dysplasia or cancer in CD, patients with colonic CD can be followed with colonoscopic surveillance in a manner similar to that used in patients with UC. Unfortunately, stricture formation in these patients often prevents visualization of the entire colon.

In addition to being associated with adenocarcinomas, IBD is associated with a small increase in the relative risk of lymphomas.[185] This increase may be associated with immunosuppressive therapy.[186-188] However, it is difficult to tease out any small increase in the relative risk from immunomodulatory therapy from the underlying risk associated with the chronic inflammatory disease and a potential association with Epstein-Barr virus infection.[189,190]

Prognosis and Conclusion

The diagnosis and treatment of IBD challenge the physician to guide patients through chronic illness. It is important to recognize the perceptions and concerns of the patient and family members confronted with a chronic, medically incurable, socially embarrassing, and potentially disfiguring condition.[27] Despite the absence of known causes, medical therapy is usually effective, and surgical techniques have improved to the point that both longevity and quality of life can be preserved. The life expectancy of patients without fulminant disease is the same as that of the general population. Patience, optimism, and empathy are required to balance the concerns and misinformation that surround the disease, as well as the guilt associated with misconceptions that IBD is a so-called neurotic, psychosomatic, or self-induced disorder.

Patient information and support groups constitute a valuable part of management in IBD. Resources for high-quality patient information and support are available through national organizations such as the Crohn's and Colitis Foundation of America (http://www.ccfa.org).
